Le dépouillement des données de surveillance des efflorescences phytoplanctoniques du littoral ouest méditerranéen marocain de 1995 à 2002 a permis de mettre en évidence 330 espèces avec une dominance de diatomées et dinoflagellés. Quarante espèces ont fait l'objet d'une analyse ACP qui a permis de mettre en évidence l'abondance des premières espèces en hiver et printemps et des secondes en été. La richesse spécifique annuelle varie entre 43 à l'embouchure de l'oued Laou et 128 à M'diq. Le pourcentage des espèces toxiques est peu important. Cependant, des cas de contamination PSP dues à Gymnodinium catenatum ont été enregistrés; d'autres espèces toxiques ont été détectées. Des corrélations élevées ont été établies entre espèces toxiques et non toxiques.

Mots clès : Western Mediterranean, Diatoms, Dinoflagellates, Blooms, Toxins.

Une étude synthétique des données de surveillance pratiquée entre 1995 et 2002 sur la partie ouest de la cote méditerranéenne marocaine à travers un échantillonnage bimensuel au niveau de 7 localités (Fig. 1) a été réalisée. Les données, exprimées en nombre de cellules par filet, ont permis de calculer l'indice spécifique de Shannon H' et l'indice maximal H'max [1]. Un suivi de paramètres physicochimiques (T°, S psu) des eaux de surface et de fond a été effectués.

L'inventaire des espèces fait état de 330 espèces de phytoplancton dont les diatomées ( Chaetoceros, Rhizosolenia, Pseudo-nitzshia, Guinardia, Leptocylindrus) et les dinoflagellés (Ceratium, Protoperdinium, Dinophysis, Noctulica, Prorocentrum) constituent 96% de la flore totale. Quarante espèces sélectionnées selon leur fréquence d'apparition et leur abondance ont fait l'objet de traitement ACP. La majorité des diatomées est observée en période hivernale et printanière (1,3 104 Cel/l), 122 espèces réparties en 12 genres ont été inventoriées, la dominance est plus prononcée à Kabila qu'ailleurs. Les dinoflagellés prédominent en période estivale (4000 Cel/l), 189 espèces ont été recensées.

La répartition spatiale de la richesse spécifique totale montre un gradient croissant suivant le trajet fluvial à partir de l'embouchure de l'oued Laou vers le large (43 espèces) et de Martil, Kabila vers M'diq (128 espèces). L'évolution saisonnière de la diversité spécifique a permis de distinguer une période à population plurispécifique (septembre - avril) et une autre ayant une diversité minimale (mai - septembre). H' est inférieur à H'max, ce qui peut se traduire par un déséquilibre des écosystèmes.

Le pourcentage des espèces toxiques reste moins important par rapport à la flore totale (<20%). Cependant, des cas de contamination de type PSP dues à Gymnodinium catenatum ont été observés à plusieurs périodes de l'année (oued Laou - Kaâ Srass). D'autres espèces ont été identifiées : Alexandrium munitum, agent de la PSP détecté au printemps et en été, Dinophysis caudata agent de la DSP développant des blooms printaniers et Pseudo-nitzshia spp ayant une toxicité potentielle par l'ASP est rencontré à des concentrations plus élevées à Martil, M'diq et Kabila.

Des fortes corrélations entre espèces non toxiques et toxiques ont été établies (r>0,7): Lauderia spp et Prorocentrum micans avec Gymnodinium catenatum; Ceratium spp avec Dinophysis spp ; Navicula spp et Ceratium karsteni avec Alexandrium spp; Coscinodiscus spp et Leptocylindrus minimus avec Pseudo-nitzshia spp. La détection des espèces indicatrices permettrait de prédire les blooms à caractère toxique.

Dans toutes les localités, la température suit le même cycle. Des valeurs basses (13-15°C) en hiver coincident avec des densités modérées de diatomées alors que les dinoflagellés sont presque absents. Au printemps, 20°C sont atteints, la densité des diatomées augmente, celle des dinoflagellés évolue modérément. A partir de juin, les diatomées baissent au profit des dinoflagellés. La salinité a montré une stabilité permanente (35-36 psu) à l'exception des zones recevant des eaux fluviales (L3, L6 et Kabila). Les dinoflagellés sont favorisés par les salinités élevées à l'inverse des diatomées.

Ainsi, la richesse spécifique exprime bien les conditions climatiques. Mais l'efflorescence est liée aussi à d'autres paramètres (sels nutritifs, facteurs hydrodynamiques). Le bloom de Gymnodinium catenatum de l'automne pourrait être associé à l'apparition synchrone de cette espèce sur les cotes atlantiques marocaines et celles de la péninsule ibérique. Ainsi, son apparition en Atlantique après relaxation des upwellings en automne permet d'introduire cette espèce dans la région étudiée. Le tourbillon anticyclonique pourrait jouer un role primordial dans son extension en hiver et au printemps [2]. En outre, des foyers de kystes constituant un réservoir permanent pourraient exister : dès que les conditions hydroclimatiques deviennent favorables, il y a déclenchement du bloom. Dinophysis spp se caractérisant par une toxicité faible (200-500 Cel/l) suit une migration dans le sens Est-ouest suivant la dérive des courants de retour d'une partie des eaux atlantiques ayant traversé le détroit de Gibraltar. Alexandrium minutum est retrouvée depuis les cotes égyptiennes [3] et libanaises [4] jusqu'aux cotes marocaines et espagnoles. Des traces de l'acide domoique furent détectées dans Pecten maximus durant le bloom de 1997 à M'diq [5], les seuils de toxicité sont variables selon les espèces et les régions [6].

# A NEW APPROACH TO PLANKTONIC MICROBES: THE MICROBIAL HUB

Louis Legendre<sup>1</sup> \* and Richard Rivkin<sup>2</sup>

<sup>1</sup> Laboratoire d'Océanographie de Villefranche, BP 28, 06234 Villefranche-sur-Mer CEDEX, France - legendre@obs-vlfr.fr <sup>2</sup> Ocean Sciences Centre, Memorial University of Newfoundland, St. John's, Newfoundland A1C 5S7, Canada

## Abstract

When introduced in 1983, the "microbial loop" conceptual model assigned key roles to microbes in the planktonic food web. Here, we introduce the concept of "microbial hub" as an extension of the microbial loop, and develop this concept into an operational model, which provides a new, powerful tool for exploring marine pelagic community metabolism. *Keywords : Bacteria, Food Webs, Organic Matter, Plankton.* 

The conceptual model to which biological oceanographers presently refer when discussing planktonic microbes was proposed in 1983, under the name "microbial loop" [1]. In that model: dissolved organic matter released by autotrophic and heterotrophic plankton is utilised by heterotrophic bacteria; bacteria (both heterotrophic and autotrophic) are ingested primarily by heterotrophic flagellates, and these are in turn ingested by ciliates. In the microbial loop model, bacteria, flagellates and other microzooplankton have key roles, and they coexist or not with the herbivorous food web, where large phytoplankton are grazed by mesozooplankton. There is a fundamental food-web and biogeochemical difference between heterotrophic microbes, which include heterotrophic bacteria, and metazoa: microbes remineralise most of the organic carbon they ingest, whereas metazoa channel a relatively large fraction of the carbon they ingest to long-lived organisms and to sequestration. In the same vein, [2] showed that autotrophic and heterotrophic planktonic microbes, and large zooplankton are the three food-web control nodes of the main organic carbon fluxes in the upper ocean. Here, we implement the fundamental difference between heterotrophic microbes and metazoa in a model where we group all heterotrophic microbes in a "microbial hub". We propose that heterotrophic microbes represent a planktonic food-web microbial hub, into which organic carbon is channelled by various foodweb processes, and from which carbon is redirected towards both carbon dioxide (respiration) and larger heterotrophs.

Fig. 1. (a) Food-web model with 7 compartments, and (b) corresponding microbial-hub model, with 3 compartments. Symbols are defined in the text.

Figure 1 shows two versions of a food-web model, where boxes represent food-web compartments, and arrows are flows of carbon into and out of the compartments. The model in Fig. 1a has 7 compartments, many of which are simplifications of complex in situ processes. In the corresponding 3-compartment microbial-hub model (Fig. 1b), bacteria and microzoo-plankton are combined in the microbial hub, and heterotrophic organisms larger than microbes make up the metazoan compartment. The flows in Fig 1a are of various types, e.g. grazing, egestion, production, excretion, and respiration. Because the only additive property of the ecosystem is respiration (i.e. it sums up to 100% of primary production, without con-

sidering downward export and horizontal advection), the 5 flows in Fig. 1b are respiration. Heterotrophic microbes are central to the cycling of biogenic carbon within planktonic food webs for the following reasons. Bacteria (BACT) and microzooplankton (µZOO) assimilate dissolved primary production (PP) and ingest particulate PP, respectively. In addition, using the model in Fig. 1a, we calculated that the network of linkages channelled up to 35-45% of total PP (i.e., up to 45-55% of particulate PP into the dissolved organic carbon pool, assuming that 20% of total PP is dissolved), and thus towards bacteria. We also calculated that BACT and  $\mu$ ZOO remineralise most of the organic carbon they assimilate, with their combined respiration being at least 70% of total PP; the remainder of the organic carbon is transferred to mesozooplankton (MZOO) and larger animals (LARGE). The intense cycling organic carbon by the microbial hub (HUB) does not mean that MZOO do not have a significant role in carbon dynamics. Indeed, according to the food web under consideration, these organisms can consume directly most of particulate PP. In Fig. 1b, the pelagic food web is restructured around two poles: the HUB, introduced above, and a metazoan compartment (METAZ, comprising all heterotrophs larger than microbes). Structuring the pelagic food web around these two poles is consistent with the fundamental difference between heterotrophic microbes and metazoa. We applied the model in Fig. 1b to five planktonic food webs, from the extreme case where all particulate PP would be grazed directly by  $\mu$ ZOO to the other extreme where all particulate PP would be grazed directly by MZOO. We calculated that the HUB channels directly 20-100% of total PP toward community respiration. Hence, the HUB channels carbon from total PP toward community respiration even when all particulate PP is grazed by herbivores. When also found that temperature influences the partitioning of community metabolism between microbes and metazoa, i.e., as temperature increases, microbes directly respire more carbon and channel less carbon toward metazoan respiration.

Our review introduces and develops the concept of microbial hub as an extension of the microbial loop, and built this new concept into an operational model. We thus consolidated information on the functioning of the microbial heterotrophic components of the pelagic food web that had been published in the last decades. Crucial to our approach is the fundamental difference between heterotrophic microbes and metazoa, i.e., heterotrophic microbes respire a large fraction of the organic carbon they ingest, whereas metazoa move a large fraction of the carbon they ingest to long-lived organisms and to sequestration.

In conclusion, (1) the fundamental difference between heterotrophic microbes and metazoa leads to structuring the pelagic food web around two poles, i.e., the microbial hub, which comprises bacteria and microzooplankton, and metazoa, which consists of the heterotrophic organisms larger than microbes, (2) in the resulting microbial-hub model, a large fraction of the organic carbon originating from PP is channelled toward the microbial hub, from which organic carbon is redirected towards both hub respiration and metazoa, and (3) the microbial-hub model provides a new, powerful tool for exploring marine pelagic community metabolism.

# PHYTOPLANKTON PHOTOSYNTHETIC RESPONSES IN A HIGHLY DYNAMIC FRONTAL AREA (NORTHERN ADRIATIC SEA)

Olga Mangoni<sup>1</sup>\*, Monica Modigh<sup>2</sup> and Vincenzo Saggiomo<sup>2</sup> <sup>1</sup>University of Naples Federico II, Italy - olga.mangoni@unina.it

<sup>2</sup> Zoological Station Anton Dohrn, Naples, Italy

## Abstract

Photosynthetic parameters of phytoplankton assemblages in the frontal area off the Po river (Northern Adriatic Sea) were measured in different seasons. Changes in biomass concentrations and a high variability in phytoplankton photosynthetic capacity occurred on small spatial scales and were related to the notable differences in freshwater and nutrient discharge and in the complex circulation patterns of the Northern Adriatic.

Keywords : Adriatic Sea, Phytoplankton, Pigments, Primary Production.

#### Introduction

The northern Adriatic is among the most productive Mediterranean areas; the basin is one of those coastal ecosystems where seasonal and interannual variability of phytoplankton is mainly driven by the freshwater flow of major rivers(s) (e.g. [1], [2]). However, vast areas are essentially oligotrophic; phytoplankton biomass and primary production levels are relatively modest in the northern Adriatic as compared to other coastal embayments and estuaries with similar hydrological characteristics and/or nutrient inputs.

## Material and Methods

From 1996 to 1998 seven oceanographic campaigns were carried out covering all seasons in the area off the Po River delta. Data on phytoplankton physiology is lacking for the Northern Adriatic Sea and the main aim of our study was to measure photosynthetic parameters in highly variable conditions ranging from eutrophic to oligotrophic areas, including a not well-understood frontal zone between them. CTD recordings were performed and size-fractionated chlorophyll a (Chla) concentrations were measured. HPLC analyses were performed for diagnostic pigments and degradation products. PvsE experiments were conducted on samples collected over the study area and at different depths. We discuss photosynthetic parameters taking into account phytoplankton size classes and the capacity of phytoplankton assemblages to respond to physical variations on small spatial scales.

## Results and Discussion

The Po River strongly affects the thermohaline circulation in the area. Two different subsystems can be identified in a restricted area off the Po delta, separated by an ever-changing haline front. Recurrent algal blooms occur in the coastal area that is strongly influenced by the Po River, and low biomass characterizes the area outside the front. The different location of the frontal zone roughly coincided with the separation between diatom-dominated (fucoxanthin) and phytoflagellate-dominated (e.g. 19'-hexanoiloxyfucoxanthin) areas. PvsE experiments showed a clear relationship between the physiological response of phytoplankton populations and the changing hydrographic conditions caused by variations in the Po River flow.

At surface in the coastal area, directly influenced by the river plume, the photosynthetic capacity varied tenfold,  $P^B \max$  up to 20 mgC (mgChla)<sup>-1</sup>h<sup>-1</sup> was recorded, that is among the highest ever reported in marine systems, and comparable to values reported in land-locked ecosystems (e.g.  $P^B \max_{max} = 22$ , [3]). With the exception of such maximum value, the  $P^B \max_{max}$  reported here are similar to those found in temperate coastal waters. At the offshore stations,  $P^B \max_{max}$  between 2 and 9 mgC (mgChla)<sup>-1</sup>h<sup>-1</sup>, indicated that the phytoplankton assemblages of mainly small cells were well adapted to the low nutrient conditions of this area.

The variability in  $P^{B}_{max}$  was much less pronounced in the subsurface layer where environmental conditions were more stable. No correlation was found between salinity and  $P^{B}_{max}$ ; the light history is of major importance for phytoplankton photosynthetic performance.

Variations in PvsE parameters may be associated with differences in the size-structure and taxonomic composition of phytoplankton populations [4]. Our findings suggest some caution, however, as rapidly changing environmental conditions may not allow for the replacement of phytoplankton that are better adapted to the instantaneous conditions. In fact, high biomass and mainly large diatoms were occasionally associated with low photosynthetic performance suggesting accumulation at low hy-

drodynamic conditions. However, the Po delta area is characterized by discontinuous pulses of nutrient-enriched freshwater [5]. Thus any prediction of phytoplankton blooms and production in the Po delta area must be based on a physical model.

The relatively modest phytoplankton biomass reported in the eutrophic northern Adriatic may to some extent be due to the high but extremely unbalanced nutrient load being discharged into the area. Recurrent phytoplankton blooms are observed year-round in the Po river plume and accumulation of very high phytoplankton biomass occur inside the front. The phytoplankton turn-over rate may be very low due to the persistent vertical stratification of the water column and low grazing pressure as shown by the low phaeophorbid concentrations. At low Po River discharge the water circulation slows down in the plume area and nutrient limitation will occur imposing severe limits to the photosynthetic capacity of the phytoplankton.

## Abstract

In this investigation we examined the genetic diversity of several filamentous clonal cultures of cyanobacteria, from different regions of the Antarctic (*Nostoc, Leptolyngbya, Plectonema*) and Mediterranean (*Nostoc*). The genetic diversity of different genera obtained by RAPD-PCR technique was correlated to certain physiological features of the cianobacteria such as their fatty acid production. UPGMA analysis revealed two different groups *Oscillatoriales, Plectonema* and *Leptolyngbya*, and *Nostocales*, comprising two Antarctic *Nostoc* strains and one *Nostoc* Mediterranean strain. Such a study, which confirms the endemism of *Nostoc* genus in Antarctic and Mediterranean, shows phylogenetic distribution in relation to geographical position. The physiological features of the strains show a high degree of specificity with regard to their content of fatty acids. Differences were noted in production of the two groups. Such information is relevant to many questions, both basic and applied, in monitoring and assessing environmental quality in relation to the production of bioactive metabolites in response to stress.

Keywords : Cyanobacteria, Biodiversity, Physiology.

In this investigation, we examined filamentous clonal cultures of cyanobacteria, from different locations of the Antarctic and Mediterranean. Cyanobacteria (tab.1) were collected in the Antarctic region during the 2004 summer cruise and subsequently grown in axenic laboratory conditions prior to analysis at optimum laboratory conditions (Light intensity 5  $\mu$ E m<sup>2</sup>s<sup>-1</sup> PAR Photosynthetic Active Radiation; T=20 °C). Morphological and biomass analysis (Tab.1) were checked before genetic studies. DNA extraction was carried out (MagnaRack, Invitrogen SpA, Italy). Biodiversity was detected by PCR. The amplification products were separated by gel electrophoresis (agarose 1.4%) and photographed under U.V. light after ethidium bromide staining. Eight primers were used: BY11 (5'-ATCCACTGCA-3'); BY12 (5'-GGTCGCAGGC-3'); BY15 (5'-CTCACCGTCC-3'); DN4 (5'-GTCGTGCTAT-3'); DN5 (5'-CCGACGGCAA,-3'); DN6 (5'-TGGACCGGTG-3'); UB24 (5'-GGGTGAACCG-3'); UB28 (5'-GCTGGGCCGA-3'). Cluster analysis (UPGMA) of the similarity index was carried out using NT-SYS software. To analyse fatty acid, the samples were methilated. Fatty Acid Methyl Esters (FAME) were detected by gas chromatography using C19:0 as internal standard.

Tab. 1. Data on the seven populations of cyanobacteria.

## Discussion of results

UPGMA phenogram (Fig.1) revealed the pattern of genetic distance, showing two different groups comprising the order of Nostocales and Oscillatoriales. This analysis confirms the endemism of Nostoc genus in the Antarctic and Mediterranean regions, revealing its phylogenetic distribution in relation to geographical position. Data relating to the matrix of similarity [1] revealed an average similarity of 15,37 % between the six populations of cyanobacteria analized; the average value of similarity of 27,04 % appears for *Nostoc* Mediterranean and two *Nostoc* Antarctic. Matrix correlation (r) obtained by Mantel test gave a value of 0.95, revealing a good statistical result. Genomic fingerprinting, revealed by PCR technique, gave several molecular fragments of varying sizes, ranging from 0.1 to 8.0 Kb. The distribution of molecular fragments for each

species analysed indicates that the majority of the molecular fragments are in the range of 251-1000 Kb, especially in the Nostoc genus. The genetic variability we encountered was correlated to the fatty acid production of the different strains. The physiological features of the strains showed a high degree of specificity regarding their content of fatty acids. We observed that the largest percentage of fatty acid produced by all the strains was the 16:0 (palmitic) and 18: 2 n6 c (linoleic); whilst the 17:0 ante (IUPAC) was produced in large amounts by the Leptolyngbya instead of Nostoc. The 18:3 n3 (linolenic) showed an opposite trend with the highest percentage of production by Antarctic Nostoc rather than Leptolyngbya genera. Plectonema showed an intermediate concentration in percentage of production regarding this fatty acid. This analysis revealed that the amount of some fatty acids is sometimes correlated to the genus, as seen in linoleic and alpha-linolenic acids that were abundant in Nostoc species [2]. The RAPD-PCR amplification revealed that Nostoc genera produced the greatest number and weight of molecular fragments. Molecular analysis together with morphological and physiological study, is confirmed to be a valid tool in determining a first screening of the different cyanobacteria, evidencing an ample range of molecular weight between 0.1 to 8.0 Kb. These results evidence the high capacity of these organisms to consolidate their key-role. Cyanobacteria adapt physiologically to different environments, producing secondary biologically active molecules which are useful for human health [3].

## ON THE APPLICATION OF PHYTOPLANKTON BODY- SIZE STRUCTURE AS ECOLOGICAL QUALITY DESCRIPTOR OF TRANSITIONAL WATERS (VARNA LAGOON-BLACK SEA)

Snejana Moncheva \*, Veselina Alexandrova and Natalia Slabakova

Institute of Oceanology, BAS, Varna, 9000, P.O. Box.152, Bulgaria - snejm@techno-link.com

## Abstract

The present paper is an attempt to test applicability of individual body size biomass distribution spectra of phytoplankton communities as alternative quality descriptor for assessment of Varna lagoon transitional waters ecological status, analyzed against taxon-based phytoplankton quality attributes.

Keywords : Bio-indicators, Eutrophication, Lagoons, Phytoplankton.

While the WFD sets the basics of ecosystem ecological quality assessment and monitoring the identification of consistent ecological quality descriptors and metrics remains still a scientific challenge. Recently the relation among individual, population, community, ecosystem and body size was synthesized in a metabolic theory of ecology [1]. The concept employ body size to explain home range size, nutrient cycling, numerical abundance distribution, biomass production and speciation and, as a community feature, it is expected to vary with disturbance gradients, according to energetic and ecological constraints [2].

The Varna Lake - Varna Bay system is influenced by domestic and chemical industrial waste water emissions and intensive shipping, preconditioning a clearly pronounced nutrient gradient and related impacts on the biota [3].

The analysis was based on data collected during seasonal field surveys (Dec'04, May and Aug'05) at 5 station along the system: Varna bay (VB), Varna Canal (C) and Varna Lake (VL). The taxonomic composition and body size were determined under OLIMPUS-BS41 inverted microscope and a VIASystem at 200x magnification. The construction of Normalized Biomass Size Spectra (NBSS) of phytoplankton counts was according to [4]. Parallel sub-samples of chl. a fractionation ( $0.45\mu m$ ,  $20\mu m$  and  $2\mu m$ ) were measured.

The following phytoplankton attributes have been analyzed: taxonomic composition, abundance, biomass, dominant species, taxon-based indices (species richness, diversity, evenness) and NBSS descriptors - width and slope. In addition to  $T^{\circ}$ , S, O<sub>2</sub>, and nutrient measurements the Throphic State Index (TRIX) was calculated as an integrated measure of euthrophication

A steady gradient of eutrophication along the VL-VB axis persisted during all seasons - TRIX in VB maintained around 5 (moderately euthrophic), in the Canals - between 5 -7 (euthrophic/hyper-etrophic) and in VL above 7 (hyper-euthrophic). Chl. *a* was in average about 5 times higher in VL as compared to VB (25.2 -  $6.56 \mu g/l$  in spring and  $16.23 - 3.38 \mu g/l$  in summer). The nano- size fraction dominated in spring the entire system, while in the summer in the C-VL sites, overriding that in the Bay >20 fold (0.44-11.15 mg/m<sup>3</sup>).

The phytoplankton communities manifested high variability in the taxonomic spread, dominant species, abundance and biomass, species richness and diversity that in general followed the environmental gradient of nutrients. Bacillariophyceae and Dinophyceae were the dominant taxa in the abundance and biomass during winter-spring while in summer Haptophyceae took over in the abundance especially in the Canal (82.77%). Enhanced diatoms proliferation from VB to VL repsented the bulk of the biomass irrespective of the season (in % of the total in winter: 33-98-98%, spring: 33-22-81% and summer 34-69-62%) the total biomass in VL exceeding 3-5 times the biomass measured in the Bay (winter- 352-1002-2141 mg/m<sup>3</sup> and spring -1450-3930- 4068). The heterogeneity was featured also by the dominant species diversity along the gradient - Heterocapsa triquetara in VB and Rhizosolenia fragilissima in VL (winter), Cyclotella caspia (VB), Heterocapsa triquetra (C) in spring and Nitzschia delicatissima (VB), Phaeocystis pouchetii (C) and Gloeocapsa sp. (VL) in summer, related mainly to the seasonal variability of nutrients, their ratios and grazing pressure in the system. The spatial and temporal body size distribution of phytoplankton communities react to the disturbance pressure (nutrient enrichment) in a way consistent to the response of the taxon-based phytoplankton quality elements, the width decreasing along the euthrophication gradient, typical for ecosystems under stress. In contrast to the relatively high seasonal variability of most of the phytoplankton descriptors analyzed in the study, the width manifested a unimodal pattern irrespective of the season - Fig.1.

Fig. 1. Seasonal variability of phytoplankton quality descriptors: A) taxonomic structure by biomass  $[mg/m^3]$ ; B) body-size spectra width and slope.

## Abstract

The structure of the bacterial community prior and after crude oil contamination in two different marine ecosystems, a chronically exposed to petroleum pollution and a low polluted, was investigated using experimental microcosms. Seawater samples for 16S rRNA gene diversity and chemical analysis were taken at critical time points. More than 30% of the phylotypes retrieved from contaminated microcosms showed highest similarity to members of the Alteromonadaceae family. Chemical analysis revealed that biodegradation of n-alkanes and low MW unsubstituted PAHs was almost complete whereas higher MW- PAH were degraded to a much lower extent. *Keywords : Bacteria, Chemical Analysis, Petroleum*.

## Introduction

Hydrocarbonoclastic bacteria (HCBs) usually exist in very low abundance in marine environments but oil-pollution may stimulate their growth and cause changes in the bacterial community structure of the contaminated area [1]. Prior studies have shown extended oil-pollution in some coastal areas of Attiki (Saronikos Gulf) [2]. The aim of this study was to describe and compare the structure of the bacterial community prior and after oil contamination in two different marine ecosystems: the chronically exposed to petroleum pollution Elefsina Bay (Saronikos Gulf, Greece) and the low polluted Anavyssos Bay (Saronikos Gulf, Greece). Material and MethodsFour 100-1 microcosms were used. One microcosm from each site served as a control (uncontaminated) whereas a second was contaminated with a reference mixture of different crude oil. Seawater samples were taken when bacterial abundance was highest for the determination of the community structure and chemical analysis of the degrading oil. Mixed community DNA was extracted and used as template in PCR amplifications with 16S rRNA specific primers. PCR products were cloned, sequenced and the sequences were used as templates in database (Gen-Bank) searches to identify the closest relatives. Phylogenetic analysis was performed according to standard procedures.

## Results and Discussion

The majority of the sequences retrieved from both contaminated and uncontaminated samples showed a higher homology to members within the phyla of alpha- and gamma- Proteobacteria and Bacteroides/Flavobacteria. Phylotypes exhibiting higher similarity to members of the Rhodobacteraceae family and Flavobacterium genus, both positively associated with hydrocarbon degradation [3], appeared more frequently in samples originating from Elefsina Bay; the latter may reflect its chronic oil polluted state. In contrast, the uncontaminated microcosm of Anavyssos Bay contained the most abundant bacterium on the planet, Pelagibacter ubique. More than 30% of the phylotypes retrieved from contaminated microcosms showed highest similarity to members of the Alteromonadaceae family. Although this group has not been as yet strongly associated with oil degradation, members of it have been reported as "non-professional" HCBs [4]. The most significant biodegradation was observed for n-alkanes (n-C<sub>14</sub>-n-C<sub>35</sub>) and low MW unsubstituted PAHs, as these compounds were almost completely removed in both microcosms. Higher MW- PAH were degraded to a much lower extent and only in Elefsina microcosm, while in all cases significantly lower biodegradation of substituted compounds was obtained in comparison with the parent ones. This is an expected event since the substitutes obstruct bacterial attack. The rate of oil degradation in the contaminated Elefsina microcosm appeared to be greater than that of Anavyssos Bay.

The project is co-funded by European Social Fund and National Resources-EPEAEKII-ARCHIMIDIS

# MONTHLY AND REGIONAL VARIABILITY OF THE PHYTOPLANKTON ABSORPTION IN THE CILICIAN BASIN

Hasan Orek <sup>1</sup> \*, Şükrü Beşiktepe <sup>1</sup> and Dilek Ediger <sup>2</sup>

<sup>1</sup> Middle East Technical University Institute of Marine Sciences. Erdemli / Mersin. TURKEY - orek@ims.metu.edu.tr

<sup>2</sup> TUBITAK, MRC Chemistry and Environment Institute P.O.Box. 21 41470Gebze, Kocaeli /TURKEY

## Abstract

Cilician Basin is located at the North Eastern end of the Mediterranean Sea. Basin is known as oligotrophic area, however some part of the area is getting large amount of river input and relatively long shelf areas. The particle absorption measurements have done both on river plumes and offshore areas in different seasons in year 2005. Besides, monthly samples have collected from the METU-IMS time series station (36:26.463N 34:21.606E). The monthly variability and the regional variability of the phytoplankton absorption curves have extracted from the total absorption measurements (1,2,3). Results shown, that the shape of the curves and magnitude of the peaks are changing spatially and seasonally.

Keywords : Phytoplankton, Eastern Mediterranean, Pigments.

## Methodology

Particle samples have collected by filtering sea water over GF/F filters getting with 5 lt Niskin bottles. Separation of the pigmented and nonpigmented (detritus) fraction of the total particulate matter done by extracting the filters with methanol (HPLC grade). Measurements have done, Helios Single beam 2 nm resolution spectrophotometer (1,2,3).

Regional Differentiations (Offshore Mediterranean and Coastal Mediterranean

Mediterranean offshore waters and Mediterranean costal (Usually estuarine region) water samples have compared. Most of the measured phytoplankton absorption measurements are utilized among 78 samples. As a result 61 samples for offshore, and 17 samples for coastal are used. Comparison of these regions has done by averaging the all data collected from the concerned basin and normalized the averaged values to the highest absorption (at 440 nm). The comparison of these curves is showing that the chl a concentration is higher in the coastal then the offshore waters. Signature of the chl a is the absorption peak at the 675 nm (1). However, beside this well known feature, the shape of the curves are much more important. Actually both curves are similar to each other, whereas small variations are indicating the differences between the regions. Phytoplankton groups are the reason of these variations. Offshore waters of the Mediterranean are different from the coastal region by the first peak around 415 nm and nearly straight line between 550-650 nm, and a small shoulder around 490 nm. Coastal Mediterranean has clear peak at 440 nm and a shoulder occurring between 600 and 650 nm (Figure 1).

Fig. 1. Comparison of the mean normalized absorption coefficients of the regions.

## Seasonal Variability of the Phytoplankton Absorption.

The seasonal variability is not really observed. However, there are similarities within the six months periods. Between April and September, and between October to March, the absorption curves have shown similar shapes. According to these results, instead of a seasonal variability, like classical autumn, winter, spring or summer blooms, only one period should be observed. These results are also in good agreement with the HPLC chlorophyll a measurements done at the same station parallel to the particle absorption measurements (Figure 2).

Fig. 2. Monthly normalized phytoplankton absorption curves.

# BACTERIAL PRODUCTION AND RESPIRATION IN THE SEA-SURFACE MICROLAYER OF THE WESTERN MEDITERRANEAN SEA AND THE SUBTROPICAL ATLANTIC OCEAN

Thomas Reinthaler \* and Gerhard J. Herndl

Dept. of Biological Oceanography, Royal Netherlands Institute for Sea Research (NIOZ), P.O. Box 59, 1790 AB Den Burg, Texel, The Netherlands - reinthal@nioz.nl

## Abstract

We measured bacterial production and respiration along with physico-chemical parameters in the sea-surface microlayer (SML) and the underlying water (ULW) of the western Mediterranean Sea and the subtropical Atlantic gyre. Dissolved organic nitrogen and amino acids were significantly enriched in the SML as compared to the ULW, however, bacterial production was consistently low. The low bacterial production and the low bacterial growth efficiency in the SML coincided with high contributions of dissolved free amino acids to the total dissolved amino acid pool in the SML. This indicates that nitrogen rich dissolved organic matter is accumulating in the SML due to retarded DFAA availability or bacterial uptake.

Keywords : Western Mediterranean, Secondary Production.

The sea-surface microlayer is the boundary layer between the atmosphere and the oceans covering 70% of the earth's surface. Despite the longlasting interest in the physico-chemical properties of the SML, studies on microbial metabolism in the SML are scarce, particularly for open oceans. To gain more knowledge on the biological dynamics of the open ocean SML we studied a stable anti-cyclonic eddy system in the western Mediterranean Sea (WMED), and a transect from the Mauritanian upwelling into the subtropical North Atlantic gyre (SATL).

In the WMED and the SATL, the SML was significantly enriched in dissolved organic carbon (DOC), dissolved organic nitrogen (DON) and inorganic nutrients with enrichment factors (EF = SML/ULW) ranging from 1.2 up to 12. In the SML at both study sites the contribution of dissolved free amino acids (DFAA) to the total hydrolyzable amino acid pool (THAA) was remarkably high, averaging  $61 \pm 14\%$  and  $47 \pm 10\%$  in the WMED and the SATL, respectively. In contrast, the contribution of DFAA to the THAA pool was significantly lower in the ULW and 12-37%.

Bacterial production in the SML of the WMED was not significantly different from that in the ULW (Fig. 1a). Enrichment factors for bacterial production in the SML of the WMED ranged from 0.1-3 and were therefore highly variable. In the SATL, bacterial production in the SML was generally low (Fig. 1b) with enrichment factors 0.13. In the WMED, bacterial respiration was highly variable between the different stations (Fig.1c). On average, bacterial respiration in the SML and ULW was similar although considerable differences in the respiration rates between SML and ULW were detected at individual stations. Comparing average bacterial respiration rates between the two study sites for the SML and ULW separately, no significant difference was found. In the SML of the SATL, bacterial respiration was high in the upwelling region (9.5  $\pm$  0.9  $\mu$ mol O<sub>2</sub> L<sup>-1</sup> d<sup>-1</sup>) and decreasing towards the oligotrophic gyre ( 3.6  $\pm$ 2.0  $\mu$ mol O<sub>2</sub> L<sup>-1</sup> d<sup>-1</sup>; Fig. 1d). In contrast, bacterial respiration in the ULW was consistently low along the transect (0.8  $\pm$  0.8  $\mu$ mol O<sub>2</sub> L<sup>-1</sup>  $d^{-1}$ ). Thus, contrary to bacterial production, bacterial respiration was significantly higher in the SML than in the ULW over the entire transect with enrichment factors ranging from 1.6-66.

Fig. 1. Bacterial production and respiration measured in the surface microlayer (SML) and the underlying water (ULW) at the different stations in the western Mediterranean eddy (a, c) and the subtropical Atlantic (b, d).

Generally, labile DOM accumulates if the production of this DOM pool is higher than its consumption. DFAA usually cover a considerable fraction of the bacterial nitrogen demand [2]. The enrichment of DFAA in the SML suggests that bacteria in the SML are apparently inhibited in their uptake of DFAA which might also explain the low bacterial growth efficiency (BGE=BP/BR+BP) ranging from 0.2-2%. Our data on the unusually high contribution of DFAA to the THAA pool indicate a decoupling of DFAA release and uptake. Inorganic nitrogen, DON and amino acids were highly enriched in the SML and the variability of nitrogen in the SML is independent of that in the ULW, suggesting either production of DON in the SML independent from those in the ULW [3] or selective scavenging of N-rich DOM on, e.g., rising air bubbles [1].

We found that the SML in the open ocean is a highly variable environment with generally low bacterial biomass production and high respiration. Bacterial production was not related to bacterial respiration and bacterial growth efficiency was mainly determined by respiration. Despite the significant enrichments in dissolved nitrogen in the SML, with concentrations generally higher than commonly reported for oligotrophic systems, the low bacterial production in combination with high bacterial respiration suggests that the DOM pool of the SML, and particularly the amino acid pool is not readily available for bacteria inhabiting this ocean atmosphere interface.

## Abstract

In the present study, the seasonal composition and the qualitative and quantitative distributions of phytoplankton have been studied at two stations in the southern Black Sea during January-May 1999 and March 2000-October 2000. A total of 76 genera including 149 species and varieties were identified of which 46% were dinoflagellates and 34% were diatoms. The abundances of the genera *Emiliana* (in January-May 1999), *Pseudosolenia* and *Ceratium* (in March-October 2000) were higher than that of the other genera in almost every sampling period. Increased dinoflagellate to diatom ratio reflects more fertile conditions in the southern Black Sea. *Keywords : Dinoflagellates, Diatoms, Phytoplankton, Black Sea*.

#### Introduction

Phytoplankton abundance and biomass has increased in relation to a net increase in nutrient concentrations. The species composition has changed with a relative increase in species number, abundance and biomass of dinoflagellates compared to the diatoms and there has been a trend towards small-sized phytoplankton groups in the western Black Sea [1]. When the taxonomic structure (by biomass) of phytoplankton communities were compared for the years 1980's and 1990's, a decrease in the dominance of diatom species were observed [2]. However, the share of diatoms increased in winter and autumn. The taxonomic diversity was high in summer and autumn. The seasonal and the long term changes in phytoplankton community structure could be attributed to the shift of the nutrient ratios (N:P, Si:N and Si:P) [2]. Unfortunately, there is no data to compare our dinoflagelate to diatom ratios in the southern Black Sea.

## Material and Methods

The monthly samples were collected from the two stations (Fig.1) near the Sinop Peninsula in the Black Sea by the R.V. "Arastirma I" within the framework of TUBITAK (The Scientific and Technical Research Council of Turkey) project during January-May 1999 and March-October 2000. A total of 123 samples were collected in two stations from different layers of the water column (0, 10, 20, 30, 40, 50 and 75 m). A hand bucket and a Niskin Bottle were used for the sampling of surface and lower depths, respectively. Sedimentation method was used for counting and identification of the species. Samples were fixed with buffered formaldehyde to reach a final concentration of 2.5% and stored in 1 l of dark bottles for 2 or 3 weeks. Thin hoses were plunged into the bottles and the supernatant was evacuated down to a volume of 100 ml.

Fig. 1. Sampling stations.

## Results and Discussion

In January-May 1999 and March-October 2000, a total of 149 species were identified from both stations. Representatives of all phytoplankton groups were obtained during the whole study period (Tab. 1). In terms of

the species composition, dinoflagellates were the dominant group with a proportion of 50%, diatoms ranked second while silicoflagellates were the third group. In terms of the species number, diatoms were more abundant in spring (March, April) than the other periods. However, dinoflagellates were more abundant in summer (May and June) and autumn.

Tab. 1. Species composition of the total phytoplankton groups during January-May 1999 and March-October 2000.

|                   | Station A |      | Station B |      | TOTAL |      | %    |      |
|-------------------|-----------|------|-----------|------|-------|------|------|------|
| Species           | 1999      | 2000 | 1999      | 2000 | 1999  | 2000 | 1999 | 2000 |
| Dinoflagellates   | 58        | 32   | 46        | 22   | 64    | 35   | 50   | 50   |
| Diatoms           | 37        | 24   | 28        | 19   | 45    | 27   | 35   | 39   |
| Silicoflagellates | 3         | 3    | 5         | 2    | 5     | 3    | 4    | 5    |
| Euglenoids        | 1         | 2    | 1         | 2    | 1     | 2    | 1    | 3    |
| Cyanophytes       | 1         | 1    | 1         | 1    | 2     | 1    | 2    | 1    |
| Coccolithophores  | 5 7       | 1    | 5         | 1    | 6     | 1    | 5    | 1    |
| Chlorophytes      | 1         | 1    | 1         | 1    | 1     | 1    | 1    | 1    |
| Criptomonads      | 5         | ÷.   | 1         | 2    | 5     | -    | 4    |      |
| Total             |           |      |           |      | 129   | 70   | 100  | 100  |

Maximum and minimum species numbers were recorded in January 1999 (74 taxon) and October 2000 (29 taxon), respectively. The decline in diatoms was followed by an increase in dinoflagellates which began in late spring (May), reached a maximum in June and gradually decreased towards October. Dinoflagellate blooms were observed in summer. Diatoms were dominant in spring with a bloom in mid spring. The dinoflagellate to diatom ratio in terms of species number differs with season and region. In the summer and in the eutrophic regions, species number of dinoflagellates was relatively higher than in other seasons and regions. For example, while the percentage of dinoflagellates to the total species number was as low as 21 % in April 1989 [3] it increased to 51% in April 1999. Even respective ratios from summer also appeared to increase to 50 % in the year 2000, from 46 % in August 1995- July 1996 [4]. These findings indicate more fertile conditions in the Black Sea and is in accordance with the rise in fish landings.

# OCCURRENCE OF THE POTENTIALLY TOXIC DIATOM *PSEUDO-NITZSCHIA* IN BIZERTE LAGOON (WESTERN MEDITERRANEAN)

Ines Sahraoui, Asma Sakka Hlaili \* and Hassine Hadj Mabrouk

Laboratoire de Cytologie végétale et de Phytoplanctonologie, Faculté des Sciences de Bizerte, 7021 Zarzouna, Bizerte, Tunisie. -

asma\_sakka@yahoo.fr

## Abstract

Abundance of the potentially toxic diatoms *Pseudo-nitzschia*, temperature, salinity and dissolved nutrients were reported for the Bizerte Lagoon (Northern Tunisian coast, Western Mediterranean) from March 2004 to March 2005. Distribution of *Pseudo-nitzschia delicatissima* complex species showed a stronger seasonality and was more correlated with summer conditions than *Pseudo-nitzschia seriata* complex species, which in turn exhibited a narrow spatio-temporal distribution and appeared independent from major environmental constraints. *Keywords : Diatoms, Lagoons, Western Mediterranean*.

## Introduction

The first renewed ASP (Amnesic Shellfish Poisonning) event occurred in November 1987 in Canada. This deadly event led to the identification of the neurotoxin DA (domoic acid) as a harmful algal toxin. The causative species is a pennate diatom belonging to the genus *Pseudo-nitzschia* Peragallo [1]. This diatom is widely distributed and occurs well throughout the Mediterranean regions [2]. There are few data about their biology and ecology in the Tunisian coastal waters despite that occurrence of *Pseudo-nitzschia* spp. was well noted in several lagoons [3]. The aim of this study is to give information about incidence of *Pseudo-nitzschia* spp. in the Bizerte Lagoon, an important area of mussel production.

### Material and methods

Sampling was carried out monthly from March 2004 to March 2005 at four stations in the Bizerte Lagoon. Water temperature and salinity were recorded *in situ* using a microprocessor conductivity meter (LF 196). Water samples were collected at 2m depth. Subsamples were taken for nitrate, nitrite, phosphate and silicate analyses [4]. Sub-samples for identification and enumeration of phytoplankton were analysed following the Utermöhl method [5]. and *Pseudo-nitzschia* species were separated into *Pseudo-nitzschia* delicatissima or *P. seriata* groups depending on their valve width [6]. The distribution patterns of these potentially toxic species were statistically analyzed by Spearman's correlations in order to address relationships between their dynamics and the environmental variables.

Fig. 1. Annual trends of *Pseudo-nitzschia delicatissima* and *Pseudo-nitzschia seriata* groups in the four sampling stations.

## Results and discussion

Temporal distributions showed that *P. delicatissima* complex species were present during all the sampling period. Cell densities ranged between 0.034 and 3 x  $10^5$  cells  $1^{-1}$ , with the highest values in July at all the prospected stations (Fig. 1). *P. seriata* group had a narrower spatiotemporal distribution than *P. delicatissima* group. Cell densities of *P. seriata* ranged between 0.03 and 0.44 x  $10^5$  cells  $1^{-1}$ . The *P. delicatissima* group species are therefore the most frequent and abundant particularly interesting in term of their periodicity and intensity. Our results parallels those found in the Mediterranean basin, indeed the *P. delicatissima* 

group species represented a potential component of the Italian and French coasts waters [7]. Abundances of *P. delicatissima* group were positively correlated with temperature and salinity (Table 1). They were so more associated with summer water conditions. Conversely, blooms of *P. calliantha*, frequent component of the *P. delicatissima* group in the Italian coast waters, were rather associated to winter water environment [2]. A Significant positive correlation was also found between *P. delicatissima* group species number and silicate concentrations. These species tends so to be dominant in waters of non limiting concentrations of silicate. In contrast, no significant relationship was found between abundances of the *P. seriata* group and any of the environmental factors. This group appears therefore independent from major environmental constraints.

# STUDY OF THE NITRATE REDUCTASE ACTIVITY IN THE ELEFSIS GULF

Fani Sakellariadou

Lab of Oceanography and Marine Geochemistry, Dept of Maritime Studies, University of Piraeus, Greece - fsakellar@gmail.com

## Abstract

Nitrate reductase activity was measured along the water column during summer and fall by determination of nitrite produced in nitrate rich denitrifying bacteria extracts. It was found that below the thermocline, there was an oxygen depletion, and a second nitrite maximum associated with the activity of the enzyme respiratory or "anaerobic" nitrate reductase (NR). In the upper part of the water column, nitrate reductase activity was absent. The destruction of the seasonal thermocline, was followed by termination of the nitrate reductase activity. *Keywords : Anoxia, Phytoplankton, Enzymes, Models, Oxygen.* 

In marine systems, the N-cycle plays a significant role controlling the biological productivity [1]. Many microorganisms are able, via membrane transporters, to take up and assimilate dissolved inorganic nitrogen. Nitrate assimilation refers to biological conversion of nitrate to ammonium, a two step eight-electron reduction process using two enzymes. Under oxygen limiting conditions, denitrifying bacteria reduce nitrate to nitrite by assimilatory nitrate reductase and then to ammonium by assimilatory nitrite reductase [2]. Respiratory or "anaerobic" nitrate reductase (NR) is an enzyme present in various marine phytoplanktonic species that grow in nitrate rich environments while when there is either ammonium enrichment or grow on nitrite, urea or amino acid, low enzyme levels are found [3].

The measurement of nitrate reductase activity is an indicator of plankton metabolism. In the present study, nitrate reductase activity was measured during summer and autumn, at various depths along the water column of the deepest area of Elefsis gulf, a rather closed gulf in Saronicos, receiving various anthropogenic pollutants. The sampling site was selected as anoxic conditions occur seasonally near the sea-floor due to stratification. For this purpose, nitrite content, produced by nitrate rich denitrifying bacteria extracts, was determined [3-6].

It was found that during the summer, when the seasonal thermocline was well established and the water column stratified, the deeper water column was depleted in oxygen and hydrogen sulphide was present. At the same time, a secondary nitrite maximum was found, associated with nitrate depletion, showing a close relation between nitrogen species distribution and denitrification procedure. Also, nitrate reductase activity corresponded to higher values as nitrate respiration, via the enzyme NR, which is the first step of denitrification mechanism.

Nitrate reductase activity was increased in nitrate enrichment while decreased in ammonium enrichment. in the upper seawater layer, where high dissolved oxygen content was measured, nitrate reductase activity approached zero values.

## Abstract

The fate of phytoplankton production was assessed in summer 2005 in the Bizerte Lagoon. Four stations were sampled for particulate organic carbon (POC), biomass, composition, growth rate and production of phytoplankton, microzooplankton grazing and vertical sinking of organic carbon. POC concentrations and algal biomasses exhibited significant spatial and vertical heterogeneity. The phytoplankton production (511- 851 mg C m<sup>-2</sup> d<sup>-1</sup>) was mainly grazed by microzooplankton (63 - 83%) and then channelled to the higher consumers, while sinking flow corresponded to 31- 36% of the carbon produced which was exported to the benthic food web. *Keywords : Lagoons, Phytoplankton, Carbon.* 

## Introduction

Bizerte Lagoon, which supports intensive fishery activities and several aquaculture farms, is experiencing increasing anthropogenic of pollutants loading from expanding urban, agricultural and industrial development along its shores. This affected the productivity which in turn may lead to the dystrophy of planktonic and/or benthic communities. Hence, in order to assess the actual trophic status of the lagoon, it is urgent to understand and determine the carbon cycle within the lagoon. The focus of this study was to investigate the phytoplankton production and its export to the higher planktonic levels, *via* microzooplankton grazing, and to the benthic food web, through sedimentation.

## Material and Methods

The sampling was carried out in summer 2005 at four stations (MA, MB, MJ and R), which are impacted by different human activities. Each station was sampled at three depths (2, 4/5 and 7.5/8.5 m) for particulate organic carbon (POC), abundance, composition, growth rate and production of phytoplankton (<2 µm, 2-10 µm, >10 µm) and microzooplankton grazing. In the four stations, the sedimentation of organic carbon was assessed using particular interceptor traps, which were installed at 9 m depth. POC was analysed on pre-combusted GF/F (21 mm) filters with a Perkin-Elmer 2400 CHN elemental analyzer. Picophytoplankton (<2  $\mu$ m) was counted using epifluorescence microscope (x100 Fluotar objective). Identification and enumeration of 2-10  $\mu$ m and >10  $\mu$ m algae were determined under the inverted microscope (100 x objective) on 50-100 ml settled volumes. Phytoplankton abundances were converted to carbon biomass by measuring the biovolumes of species and converting them to cell carbon using conversion factors from literature. Phytoplankton production rate was estimated by the <sup>14</sup>C method. Rates of algal growth and microzooplankton grazing were determined using the dilution protocol [2]. A two-ways ANOVA analysis was performed to test spatial and vertical heterogeneity on different estimated variables.

## Results and discussion

Particular organic carbon (POC) exhibited no significant difference among stations (P>0.05) but showed vertical heterogeneity (218-400 mg C m<sup>-</sup> P<0.05). At station MA, POC concentrations increased with depth, while they decreased in the other stations. The carbon biomasses for different size fractions of phytoplankton exhibited significant spatial variations (P<0.001). The >10  $\mu$ m phytoplankton had higher biomass at station MA, with value increased from 2 m (225.6 mg C m  $^{-3})$  to 7.5 m (308 mg C m<sup>-3</sup>). In contrast, in the other stations, >10  $\mu$ m algal biomass (111.5-231 mg Cm<sup>-3</sup>) decreased with depth. The >10  $\mu$ m, which constituted the main fraction of total phytoplankton carbon, were mainly represented by diatoms. These algae were dominated by several species of Cerataulina, Chaetoceros, Navicula, Rhizosolenia and Nitzschia. The biomasses of picophytoplankton (4.5-18.9 mg C m  $^{-3})$  and 2-10  $\mu m$  phytoplankton (3.7-10.5 mg C m<sup>-3</sup>) showed vertical heterogeneity in all stations, higher concentrations being in stations MJ and MB, respectively. In most stations, total phytoplankton carbon contributed 49-80% of POC. This indicates that autotrophs were the main components of the planktonic system, since heterotrophs and detritus represent 20-50% of the POC. In stations MJ and R the production rate was maximal at 2 m and decreased with depth. Obviously, the vertical distribution of algal production is related to the vertical profile of light in the water column [3]. Algal biomasses in both stations were almost similar, but production rate was higher at station R (36-84 mg C m<sup>-3</sup> d<sup>-1</sup>) than that measured at station MJ (48-132 mg C m<sup>-3</sup> d<sup>-1</sup>). This may be due to the higher growth rate estimated at station R (0.42 d<sup>-1</sup>) than that at station MJ (0.26 d<sup>-1</sup>). The picophytoplankton contributed the main fraction (75-82%) of the production. The 2-10  $\mu$ m and >10  $\mu$ m phytoplankton represented 11-20 and 6% of produced carbon, respectively. The areal production rates, calculated by vertically integrating the values from the three sampling depths, were 511 and 851 mg C m<sup>-2</sup> d<sup>-1</sup> at stations MJ and R respectively. These rates were higher than those found in Open Ocean but similar to those measured in nearshore environments [4, 5].

Rates of microzooplankton gazing varied significantly (P<0.01) among stations, the higher rate (0.27 d<sup>-1</sup>) was at station MB and the lower (0.15 d<sup>-1</sup>) at station MJ. Grazing coefficients corresponded to consumption rates of 42-102.5 mg C m<sup>-3</sup> d<sup>-1</sup>. In station MJ and R, the levels of grazing were equivalent to daily losses of 63-83% of the phytoplankton production. The vertical flow of organic carbon exhibited spatial heterogeneity (P<0.01), higher and lower values was observed at station MA (561 mg C m<sup>-2</sup> d<sup>-1</sup>) and MJ (187 mg C m<sup>-2</sup> d<sup>-1</sup>), respectively. In station MJ and R, the sinking rates corresponded to 31-36% of the carbon produced which was exported to the benthic food wed. This stresses that the main flow of organic carbon was through microzooplankton grazing that play a key role in the carbon transfer to the higher pelagic consumers.

## SEASONAL DYNAMICS OF FRACTIONATED PHYTOPLANKTON PIGMENTS IN A COASTAL ENVIRONMENT (TYRRHENIAN SEA)

Immacolata Santarpia \* and Vincenzo Saggiomo

Zoological Station A. Dohrn, Villa Comunale 80121 Naples, Italy - santarpi@szn.it

## Abstract

The temporal variations in pigment spectra of two phytoplankton size classes ( $<5\mu$ m and  $>5\mu$ m) were investigated at a coastal site in the Tyrrhenian Sea over an annual cycle. The  $<5\mu$ m fraction accounted on average for 50% of the total phytoplankton biomass and small eukaryotes were the dominant component.

Keywords : Phytoplankton, Pigments, Coastal Waters, Tyrrhenian Sea.

#### Introduction

The cell size influences the role of phytoplankton in biogeochemical cycles and the characteristics of community structure via size-dependent interactions [1]. Signature pigments are very useful in outlining the main algal groups including the small and fragile forms, generally underestimated with classical approaches [2]. This study is focused on the seasonal dynamics of ultraphytoplankton ( $<5\mu$ m) both in terms of abundance and composition, in coastal environments. The results are discussed in relation to abiotic (e.g. nutrients) factors.

## Material and methods

The sampling site is located at 40°48.5'N and 14°15'E, in proximity of the 80m isobath. Sampling was carried out weekly between July 2004 and July 2005. CTD profiles (S, T, oxygen, fluorescence) were performed utilizing a SBE 911plus. Samples for nutrients determinations were collected along the water column. For the determination of pigment spectra (HPLC-[3]) water samples were collected at four depths (0, -10, -20 and -40m) and filtered sequentially on polycarbonate membrane (porosity of 5 $\mu$ m) and on glass-fibre filters (GF/F) for the fraction >5 and <5 $\mu$ m respectively.

## Results

Total phytoplankton biomass (average TChl  $a = 0.83 \pm 1.15 \text{ mg m}^{-3}$ ) indicated the generally mesotrophic conditions of the area, while the negative correlation between biomass and salinity highlighted the importance of land run-off for the phytoplankton blooms. TChl a peaks were mainly due to an increase in the >5 $\mu$ m fraction (slope =0.80; r = 0.98, P<0.01, n=200), while the percentage contribution of  $<5\mu$ m decreased. As to the vertical distribution, the contribution of ultraphytoplankton was higher in the 20-40m layer. The eukaryotes accounted, on average, for  $84.1 \pm 11.0\%$ of the ultraphytoplankton biomass and their contribution increased at higher nitrate concentrations. The ultraphytoplankton fraction showed a higher diversity than the  $>5\mu$ m fraction in terms of the pigment composition. Fucoxanthin and 19'hexanoiloxifucoxantin values indicated that small diatoms and prymnesiophytes were the most important groups in the  $<5\mu$ m fraction, especially during the blooms. However, the occurrence of alloxanthin highlighted the contribution of small cryptophytes during the autumnal peak (40% of the ultraphytoplankton biomass at surface). Prasinoxanthin concentrations indicated that Prasinophyceae accounted for 25% of the ultraphytoplankton TChl a during the early spring bloom (March). The prokaryotes, cyanobacteria (zeaxanthin $_{syn}$ ) and prochlorophytes (divinyl-chlorophyll a) presented an opposite distribution along the water column in summer: the prochlorophytes were almost completely absent in the surface layer, while cyanobacteria accounted for  $22.2\pm10.3\%$ of ultraphytoplankton biomass (Fig.1). In addition, prochlorophytes were never recorded at high TChl *a* concentrations (>1 mg m<sup>-3</sup>).

## Conclusions

Despite the conspicuous blooms of larger cells, the ultraphytoplankton (above all the small eukaryotes) plays a pivotal role in the phytoplankton community of coastal areas. We may hypothesize that these small eukaryotes are more competitive in exploiting the episodic arrivals of new nutrients as compared to prokaryotes. Further, the higher pigment diversity of the ultraphytoplankton may be related to a complex and stable community within the microbial loop.

Fig. 1. Contribution of the main algal groups to the ultraphytoplankton TChl a at surface (a) and at - 40m (b), during the sampling period.

# CHARACTERIZATION OF HETEROTROPHIC BACTERIA ISOLATED

S. Scarfi \*, M. De Luca , M. De Domenico , G. Ruggeri , F. Smedile , E. De Domenico Dipartimento di Biologia Animale ed Ecologia Marina - Università di Messina - Italy - sscarfi@unime.it

## Abstract

Research were carried out to evaluate the viable microbial communities structure in a two restricted areas of the Mediterranean Sea (Southern Tyrrhenian Sea and the northern side of Sicily Channel) in July 2005. Bacterial plate counts in Marine Agar medium were carried out in 202 water samples from 14 Stations of these poorly studied areas of the Mediterranean Sea and 61 bacterial strains were investigated. Isolates were tested by API 20NE system, BIOLOG GP microplates and by classical identification pathways and classified by molecular approach also.

Keywords : Bacteria, Tyrrhenian Sea, Sicilian Channel, Biodiversity.

In the framework of a multi-year investigation on distribution of the microbial communities in Mediterranean surface, intermediate and deep sea waters to compare bacteriological parameters with different water bodies [1-2] we had the opportunity to carry out researches on bacteria strains isolates from water samples taken during CIESM-SUB1 cruise (Fig. 1).

Fig. 1. Sampling area.

This multi-disciplinary oceanographic campaign, started on July 21th 2005 on board the R/V Universitatis, explored the deep waters of littleknown areas in the southern Tyrrhenian Sea and the northern Sicily Channel to analyze physical and biological changes induced by the inflow of warmer, saltier waters from the eastern sub-basin.

At each station (St. 1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 13, 15, 20 and 21) were collected sea water samples from surface down to 3596 m, according to the physical and chemical survey, by means of Niskin bottles fitted on CTD-Rosette sampling system.

Water samples were immediately sewed, by spread-plate technique, on Marine Agar plates and incubated at 20°C during 8 days; heterotrophic bacteria pure cultures on Marine Agar plates were obtained from colonies random selected, that were characterised in lab using morpho-physiological and taxonomic approaches.

The isolates were characterized using the following tests: gram staining, cell morphology, oxidase, catalase, motility, lipolytic activity on Tween 80, susceptibility to the vibriostatic O/129 ( $150\mu$ g), growth on TCBS medium via the classic methods. The biochemical characterization was carried out using API 20 NE for Gram negative bacterial strains and BI-OLOG GP microplates.

Viable colonies on Marine Agar showed highest values  $(4.9 \times 10^3 \text{ CFU/ml})$  at 800-1200m layers. From 200 isolated strains, 61 grown on replicates were analysed. From obtained results 87,3% of isolates were gramnegative, 58,1% were rod-shaped, 95,8% were oxidase positive, 63,2% were catalase positive and 64,6% motile.

For molecular analysis [3], bacterial DNA was extracted and 16S rDNA amplified for sequencing to achieve phylogenetic affiliations. Taxonomic results showed presence of 68,9% of gamma- *Proteobacteria* (42,9% *Alteromonas*, 26,2% *Halomonas*, 9,5% *Pseudoalteromonas*, 9% *sea wa*-

ter bacterium), 16,4 % of alfa-Proteobacteria (70% Erythrobacter,10% Methylarcula, 20% others), 8,2% of Firmicutes (60% Bacillus, 20% Oceanobacillus, 20% others), 4,9% of Actinobacteria (66,7% Micrococcus, 33,3% Cellulosimicrobium) and 1,6% of Bacteroidetes (100% Salegentibacter) (Fig. 2).

Fig. 2. Phylogenetic tree of isolates.

## THE EFFECT OF TWO DIFFERENT CULTURE MEDIA AND FIVE DIFFERENT SALINITIES ON GROWTH OF TETRASELMIS SUECICA

Serpil Serdar \*, Aynur Lök , Sefa Acarli and Aysun Köse

Ege University, Fisheries Faculty, Department of Aquaculture 35100, Izmir, Turkey - serpil.serdar@ege.edu.tr

## Abstract

*Tetraselmis suecica* was cultured at five different salinities, 15 psu, 20 psu, 25 psu, 30 psu and 35 psu and two culture media during one week. The highest growth (648 x  $10^4$  cell.ml<sup>-1</sup>) was determined at 25 psu and Walne medium in 6<sup>th</sup> day. However in Super medium cell density was reached 310 x  $10^4$  cell.ml<sup>-1</sup> in 20 psu in 6<sup>th</sup> day. At the end of the experiments final cell densities were significantly different between experimental groups (p<0.05).

Keywords : Phytoplankton, Growth, Aquaculture.

## Introduction

Microalgae are required for larvae nutrition during a brief period, either for direct consumption, in the case of molluscs and penaeid shrimp, or indirectly, as feed for the live prey fed to small larvae fish [1]. Microalgae types vary, but the most common are single-celled algae such as Tetraselmis, Chlorella, and Isochrysis. Tetraselmis is a marine green flagellate widely used in aquaculture facilities as feed for bivalve molluscs, penaeid shrimp larvae and rotifers [2]. *Tetraselmis suecica* has good nutritional properties [3-4]. The aim of this study was to determine optimal salinity and most suitable culture medium for successful *T. suecica* culture.

## Material and methods

*T. suecica* was obtained from algal culture collection of Fisheries Faculty, Ege University. Each experiment (1 1 flask) was designed in five different salinities (15 psu, 20 psu, 25 psu, 30 psu and 35 psu) and two culture mediums Walne [5] and Super Medium (ammonium sulphate, Super Phosphate, EDTA, Ure). Sea water was filtered and sterilized by autoclave. Initial cell densities in each flask were approximately  $30.6 \pm 1.27 \times 10^4$  cell ml<sup>-1</sup>. The cultures were kept under constant illumination and aeration at  $20\pm 2^{\circ}$ C during one week. Two replicates were set for each culture condition. Cell density was counted daily, using a Neubauer in an optic microscope. Differences between salinities and culture mediums were compared with One way ANOVA by using SPSS 11.0.

#### Result and Discussion

Figure 1 shows that the growth of *T. suecica* in Walne medium. The highest cell density was determined  $648 \times 10^4$  cell ml<sup>-1</sup> at 25 psu salinity in  $6^{th}$  day. However in Super medium maximum cell was obtained 310 x  $10^4$  cell ml<sup>-1</sup> at 20 psu salinity (Fig. 2).

Fig. 1. The growth of T. suecica in Walne culture medium.

Fig. 2. The growth of T.s uecica in Super medium.

Growth showed a decline after 6 days in two culture media and all salinities except 35 psu. Statistical analyses showed no significant differences between experimental groups at daily growth (p>0.05). But final cell densities between two culture mediums showed significantly differences (p<0.05). Similarly it has been reported that good *T. suecica* growth occurred between 25-35 psu [6]. As a result of this study, we can suggest that 25psu salinity and Walne medium is better for obtaining high cell density of *T. suecica*.

# DIEL CYCLES IN SINGLE CELL ACTIVITY OF PROKARYOTES IN THE WESTERN MEDITERRANEAN

## SEA

Eva Sintes \* and Gerhard J. Herndl

Department of Biological Oceanography, Royal Netherlands Institute of Sea Research (NIOZ), The Netherlands - esintes@nioz.nl

## Abstract

The abundance and activity parameters of prokaryotic communities were studied over four diel cycles in an anticyclonic eddy in the Western Mediterranean Sea. The prokaryotes from the different depths expressed diel variability in all the studied parameters. The prokaryotic community from the deep chlorophyll maximum (DCM) fluctuated in cell size, with larger cells appearing from the morning until noon, followed by the increase in the relative contribution and single-cell-activity of small cells. The percentage of prokaryotic cells taking up leucine showed no significant trend during the day and the single-cell uptake was higher in the early morning and around noon, however, distinct activity patterns were recorded for specific prokaryotic groups.

Keywords : Bacteria, Western Mediterranean, Open Sea.

#### Introduction

Diel cycles in prokaryotic abundance and production have been reported for several marine environments (e.g. [1]), with peaks in activity in the early morning or in the evening. These diel dynamics in prokaryotic heterotrophic activity are governed by phytoplankton production providing labile dissolved organic matter (DOM) to bacterioplankton and by ultraviolet radiation. While phytoplankton-derived DOM stimulates bacterioplankton activity, UV radiation inhibits it [2, 3].

The main objective of this study was to determine whether these diel cycles, if present, were expressed in the same way by the different prokaryotic groups at a single-cell level or whether there are interspecific differences in the activity pattern.

#### Material and Methods

An anticyclonic eddy located in the Western Mediterranean Sea was followed from 23 Sep to 6 Oct 2003 using a drifting buoy. Diel cycles of different prokaryotic parameters (abundance, production, actively respiring cells, abundance of cells with damaged membrane, MICRO-CARD-FISH) were determined by taking samples from six depths (near-surface: 5, 10, 20, 30 m), deep chlorophyll maximum (DCM, at about 50 m depth) and at the bottom of the euphotic layer at around 100 m depth approximately every 4 h over diel cycles. Using microautoradiography, the silver grain area associated with the prokaryotic cells taking up leucine has been used as an indicator of single cell activity [4, 5] at the DCM during one diel cycle.

## Results and Discussion

The abundance and phylogenetic composition of some major groups of bacteria (as determined by fluorescence in situ hybridization, FISH) was fairly stable during the diel cycles, with lowest abundance at 100 m depth (mean 2.5 x  $10^5$  cells ml<sup>-1</sup>) and highest abundance in the DCM with an average of 7.4 x  $10^5$  cells ml<sup>-1</sup> and increasing abundance from 5 m depth to 30 m depths (Table 1). The percentage of cells with a high nucleic acid content followed a similar trend (Table 1).

Although the different prokaryotic parameters varied during the day, no clear prokaryotic diel cycles were found at any of the studied depths. The percentage of cells of the prokaryotic community of the DCM taking up leucine showed no significant differences during the 4th diel cycle, while the silver grain area of the DAPI-stained cells taking up leucine were highest in the early morning and at noon. Bacteria dominated the community (48 %) followed by Euryarchaea (17 %) and Crenarchaea (7 %). The SAR11 clade and Cytophaga-Flavobacter group represented 25 % and 16 %, respectively, of the prokaryotic community, while the Roseobacter cluster represented only 4 % and SAR86 was hardly detected. Single-cell activity of Bacteria showed no clear trend during the day, but members of the Cytophaga-Flavobacter cluster exhibited high cell activities during early morning and afternoon. Archaeal groups exhibited higher cell activities in the early morning and at noon (Crenarchaea) or afternoon (Euryarchaea). The prokaryotic community size structure showed three main peaks, at size classes of 0.12-0.14, 0.16-0.18 and 0.20-0.22  $\mu \mathrm{m}$  equivalent spherical diameter (ESD) and was quite stable from early morning until noon. From the early morning towards noon, some larger cells appeared, followed by an increase in the relative abundance of the 0.12-0.14  $\mu$ m ESD size class during the afternoon, decreasing again towards the next morning. This pattern would be in accordance with an increase in cell size during the day and division during the afternoon. The dynamics of single-cell activity per size class was more variable. Higher single-cell activities were found at noon and early morning, and in the larger size classes. Excluding the larger sizes, an increase in single-cell activity was found from the smaller sizes towards the 0.26-0.28  $\mu$ m ESD during the morning, afterwards the higher cell activities were found in smaller size classes coinciding with the increase in the abundance of these small size classes.

In summary, diel dynamics of the abundance and activity of the prokaryotic community were variable in the open Mediterranean Sea. The percentage of cells inhabiting the DCM and taking up leucine was stable during the day, but the single-cell activity was higher in the early morning and noon. Different prokaryotic groups showed different diel dynamics in single-cell activity.

Tab. 1. Average ( $\pm$  SD) of prokaryotic abundance and activity over the different depths. \* The % of cells taking up leucine corresponds to one time point (6:00 am).

## Abstract

The mechanism of HAB formation and evolution in relationship to anthropogenic nutrient loading remains poorly understood despite their increasing occurrence in coastal waters around the globe. In the present study, the causes and mechanisms of the development of a HAB of the potential ASP toxin producer *Pseudonitzschia calliantha* and the confirmed PSP toxin producer *Alexandrium minutum* was studied. The event occurred in the Gulf of Kalloni in the Aegean Sea after a major rainfall event in winter. The spatial and temporal dynamics of the two HAB species were analyzed and associated to physicochemical parameters, supporting the view that a cause and effect relationship seems to exist between the HAB event and anthropogenic activities in the watershed. The indirect negative impacts of these activities on fisheries and local economy are also discussed.

Keywords : Toxic Blooms, Coastal Waters, Aegean Sea.

Nutrient inputs from terrestrial runoff have been strongly associated to the development of phytoplankton blooms as well as harmful algal blooms (HABs) in coastal waters [1]. Recurrent HAB events in the coastal zone can have serious impacts on public health and local economy. The need for meticulous monitoring of productive coastal areas is necessary in order to understand the causes and mechanisms of different HAB species development and distribution.

The Gulf of Kalloni is a semi-enclosed, highly productive, shallow water body, located at the south-western part of Lesvos Island (Greece) in the Aegean, with a surface area of 110 km<sup>2</sup>. Fish and bivalves (mussels, scallops and clams) are being harvested and exported at the national and international market. According to the EU legislation, water and shellfish quality are being monitored on a regular basis since 2001 [2]. Agricultural activity in the watershed includes olive tree, cereal and vegetable cultivation. The main contributor of nitrogen salts is runoff from the agricultural land (59%), while for phosphorous salts are domestic sewage (59%), fertilizers (19%) and residual wastes of olive press industries (19%) [3].

In order to investigate the effect of terrestrial runoff from the surrounding watershed on the phytoplankton community composition and dynamics, a network of eight stations (5-12) was set up along a gradient formed by the river plume of Tsiknias, the most important freshwater input of the area. Two of them (stations 5 and 7) along with two control stations (1 & 2) in the open sea were sampled on a monthly basis from August 2004 to July 2005, in order to collect baseline information, whereas additional samples were collected from the gradient stations (5 to 12) during the rainfall period. Physical parameters, Chl  $\alpha$  and nutrients were measured at 1 and 5 m depths. Phytoplankton species were identified, counted and measured following the Utermöhl method [4]. Phytoplankton biovolume was also calculated.

During February, a period of fertilizer application in the watershed, a major episodic rainfall event caused maximal river discharge in the gulf. At the same time nutrient (NO<sub>3</sub>, NO<sub>2</sub>, SiO<sub>2</sub>, PO<sub>4</sub>) concentrations were significantly higher than the usual background concentrations (ANOVA, P<0.05) (Fig. 1). Throughout the gulf area, the input of freshwater formed a surface layer of lower density, characterized by significantly higher nutrient concentrations and lower salinity and temperature than the bottom layer (P<0.05). This abrupt nutrient loading and the resulting stratification stimulated the development of a bloom of the potentially toxic diatom P. calliantha (max cell number of  $10.6 \times 10^6$  cells  $l^{-1}$ ) as well as the toxic dinoflagellate A. minutum (max cell number of  $1.5 \times 10^5$  cells  $1^{-1}$ ). The spatial distribution of A. minutum seemed to be related to the nutrient concentrations, since densities of this species were significantly higher in the surface layer (P<0.05) and close to the river mouth. However, the distribution of P. calliantha was more homogeneous. Both cell densities and nutrient concentrations were scarce at the outer part of the gulf. Nutrients as well as phytoplankton cell number retreated to background concentrations almost two weeks after the episodic event.

Fig. 1. Annual cycle of rainfall height and average nitrate concentrations along the river plume (stations 5-8).

The present study confirms earlier observations on the presence of the toxic dinoflagellate *Alexandrium minutum* [5] and the potentially toxic diatom *Pseudonitzschia calliantha* [6] in coastal areas with high nutrient loading. The mechanism of this recurrent bloom is attributed mainly to strong rainfall events occurring in winter (January or February), a period of fertilizer application in the watershed. The understanding of the mechanism of bloom formation not only supports the establishment of cause and effect relationships between HABs and anthropogenic activities in the coastal zone, but can additionally act as an early warning system protecting public health and local economies based on fisheries.

# Abstract

In this study, neural network analysis was used to construct prediction models of nanoplankton population change with nutrients and other environmentally important parameters. The results indicated that, with a data set of 52 weeks, it is possible to predict nanoplankton change.

Keywords : Aegean Sea, Coastal Waters, Eutrophication, Phytoplankton.

# Introduction

Coastal areas are subject to diverse anthropogenic influence including industrial development, domestic wastes, maritime transport and agricultural activities. Neural networks, a statistical tool for data analysis, can be used to extract the relations between variables depending on the predictive variables used by means of a mechanism called training or learning. After a training process, Neural Networks are able to give estimations by using the relationship developed during the learning phase. The aim of this research was to predict of temporal changes of nanoplankton variation and physico-chemical environmental parameters using Neural Networks.

# Materials and Methods

*Experimental:* In this study, physico-chemical environmental parameters, nutrients and some general biological parameters were measured weekly during an one year period. All these parameters were measured at different depths of 3 selected sampling stations which are located in middle and inner part of Izmir Bay.

*Neural networks:* Artificial Neural Networks (ANNs) are information processing algorithms that are inspired by the way biological nervous systems work, such as learning from past experience, making generalizations from similar situations and producing decisions out of incomplete knowledge of the states [1]. Neural networks are generally used in two main application areas, function approximation and pattern classification [2]. A feed-forward ANN, trained with the back-propagation algorithm, was implemented using the software package Neuroshell 2 (Ward Systems Group Inc., 2000).

*Data division and pre-processing:* 468 data was collected from selected stations, however, 18 points from PON and 18 points from nanoplankton data were missing. Missing data points replaced with the values from best matching weight vector for corresponding variable after training process using Self Organizing Map (SOM). Self Organizing Map (SOM) is an unsupervised neural network method which has properties of both vector quantization and vector projection algorithms. The obtained data were smoothened by Simple Moving Average (5 weeks) technique.

The 464 available data sets were divided into three groups, of which the 63 were used for testing, a set of 53 for evaluation and the remaining 348 data were used for training. The training set was used for adjusting the connection weights, whereas the testing set was used for the determination of network geometry and model parameters. Finally, the validation set was used for testing the optimality and generalization ability of the model developed [3]. The data were normalized between 0.0 and 1.0 before the NN analysis, corresponding to the limits of the transfer function, in order to improve training characteristics.

*Network:* The best results were obtained with a network consisting of two hidden layers, with having 14 and 4 neurons, respectively. Hyperbolic tangent transfer function used at hidden layers. Every  $4^{th}$  data for testing and evaluation set extracted from the data.

# Results and Discussion

During training, a number of different descriptive correlation values, namely the R Squared and Minimum Average Error (MAE) were observed for both training and testing sets. Using these values, monitoring of the local and the global minimum values for correlation values could be possible. Therefore, training was continued until overtraining was observed. Correlation values were calculated for evaluation data set after training.

The best network geometry was chosen according to highest correlation and lowest MAE error value of the testing/evaluation sets. Overall results are given in Table 1.

Tab. 1. Overall results. \* percent of data within specific error range.

|                   | Training |       | Testing |       | Evaluat | tion  |
|-------------------|----------|-------|---------|-------|---------|-------|

| % within 5*       | 82.76    | 25.00 | 69.84   | 12.70 | 69.81   | 22.64 |
| % within 5 to 10  | 14.37    | 19.54 | 26.98   | 20.64 | 30.19   | 20.76 |
| % within 10 to 20 | 2.87     | 22.99 | 3.18    | 19.05 | 0       | 24.53 |
| % within 20 to 30 | 0        | 15.23 | 0       | 23.81 | 0       | 15.09 |
| % over 30         | 0        | 17.24 | 0       | 23.81 | 0       | 16.98 |

The prediction models demonstrated good abilities to model the training data. The denormalized actual and simulated DO and nanoplankton values are presented in Figure 1. As seen, the actual and predicted values were in good agreement. The performance of neural networks can be seen from training and evaluation data sets. As can be seen, the proposed network exhibited a good performance overall.

Fig. 1. Comparison between actual and predicted values of the NN model.

#### Conclusions

ANNs were applied to the obtained data. These analyses were carried out so that less analyses in laboratory conditions are needed in future to see the effect of nutrients on the nanoplankton population.

# Résumé

Dans l'ensemble de nos récoltes nous avons inventorié 192 espèces réparties entre les différents groupes phytoplanctoniques suivants : Les Diatomées, Dinoflagellés, Coccolithophoridés, Cryptophycées et les silicoflagellés. La liste floristique obtenue indique que les Diatomées détiennent le premier rang avec 96 taxons, le deuxième rang revient aux Dinoflagellés avec 62 espèces. La richesse quantitative des ciliées est répartie entre deux espèces : *Strombidinium wullfi* et *Mesodinium rubrum* du phylum des Ciliophora. Les résultats obtenus par une MANOVA, montrent que la station et le mois (descripteurs qualitatifs) n'ont pas un effet significatif sur l'abondance et la richesse spécifique (descripteurs dépendants) ; L'interaction de ces deux facteurs n'est pas significative (p = 0.767). *Mots clès : Algerian Basin, Diatoms, Dinoflagellates*.

La biodiversité méditerranéenne est menacée par l'intrusion d'espèces non indigènes. Parmi les espèces introduites (par exemple par les eaux de ballast de navires), le phytoplancton occupe une place de choix ; notre laboratoire effectue un suivi mensuel du phytoplancton ainsi que des protozoaires planctoniques, dans le but d'établir un inventaire floristique et un suivi de la biodiversité côtière.

#### Matériels et méthodes

Les prélèvements ont été réalisés l'année 2004 sur deux stations localisées à Tamentfoust (Est d'Alger) : l'une située dans une zone protégée et l'autre exposée aux vents. Les récoltes d'eau destinées à l'étude microscopique du phytoplancton et des ciliés ont été faites à l'aide de bouteilles de type Van Dorn, d'une contenance de 5 litres à une profondeur de 5m. Un volume de 500ml a été fixé par du lugol. Avant sédimentation nous avons pré-concentré l'échantillon ; L'identification et le dénombrement des espèces phytoplanctoniques et des ciliés ont été effectués sous microscope inversé équipé d'une caméra HRC, selon la méthode d'Utermhöl.

#### Résultats et Discussion

Nous avons inventorié 192 espèces réparties entre les différents groupes phytoplanctoniques suivants: les Diatomées, Dinoflagellés, Coccolithophoridés, Cryptophycées et les silicoflagellés. Les Diatomées détiennent le premier rang avec 96 taxons, suivi des Dinoflagellés avec 62 espèces. Les principaux genres diatomiques sont : *Rhizosolenia, Nitzschia, Leptocylindrus, Thalassiosira Chaetoceros* et *Cerataulina.* En ce qui concerne les Dinoflagellés nous pouvons citer : *Scripsiella, Noctiluca scintillans, Ceratium furca, C.fusus, C.macroceros, Prorocentrum micans Oxytoxum scolopaxet le genre Dinophysis.* Ces genres et espèces ont déjà été signalés dans le bassin algérien [1]. En ce qui concerne les Ciliés, le nombre d'espèces répertoriées en est restreint ; nous signalons pour la première fois la présence dans les eaux côtières algériennes les espèces: *Mesodinium rubrum et Strombidinium wulfii.* 

Fig. 1. Proportion des groupes phytoplanctoniques rencontrés.

Les Diatomées dominent avec 366 692,13 ind. /litre et 428 316,78 ind. /litre (Fig.1) en juin et septembre respectivement. Durant le mois de septembre 2004 cette floraison phytoplanctonique est due principalement à un épanouissement mono spécifique de *Leptocylindrus danicus*. Ces

poussées printanière et automnale sont caractéristiques des eaux méditerranéennes. En revanche en juillet nous observons une baisse de la concentration du phytoplancton dont le maximum n'est que de  $50 \ge 10^3$  cell/l. Le phytoplancton est dominé par des Dinoflagellés notamment Scripsiella trochoida et le genre Ceratium. L'activité phytoplanctonique reprend en mars 2005 avec une concentration supérieure à 224 x10<sup>3</sup> cell/l. L'analyse microscopique montre que les densités des ciliées sont maximales en hiver, c'est à dire, lors de la régression de la production phytoplanctonique. Nos résultats montrent que la station et le mois (descripteurs qualitatifs) n'ont pas un effet significatif sur l'abondance et la richesse spécifique (descripteurs dépendants) ; ce résultat étant confirmé par l'analyse de variance multiple (MANOVA). L'interaction de ces deux facteurs n'est pas significative (p = 0.767). En revanche, le dendrogramme (Fig.2) illustre distinctement la ségrégation entre les principales espèces planctoniques (plus fréquentes et plus abondantes), et met en évidence l'effet temporel dans la structuration des peuplements phytoplanctoniques. Ces associations phytoplanctoniques ont déjà été observées dans les eaux Nord-ouest africaines. De plus notons la proximité des deux espèces de ciliées introduit dans l'analyse ce qui démontre la pertinence de ce type d'analyse multi varié.

Fig. 2. Dendrogramme des espèces les plus abondantes et les plus fréquentes.

# Abstract

Average temperature, salinity, pH, DO, TDS, TSS,  $NO_2^{-}+NO_3^{-}$ ,  $PO_4^{-3}^{-3}$ ,  $SiO_4$  and chlorophyll-a were found to be 25.0 °C, 23.3 ppt, 8.42, 9.26 mg L<sup>-1</sup>, 23.9 g L<sup>-1</sup>, 36.1 mg L<sup>-1</sup>, 1.90  $\mu$ M, 0.24  $\mu$ M, 3.61  $\mu$ M and 1.70  $\mu$ g L<sup>-1</sup>, respectively. Average N:P and S:P rates were calculated as values of 12.5 and 25.0, respectively. Total phytoplankton density and bio-volume varied between 2.86x10<sup>5</sup>-1.5x10<sup>7</sup> cell L<sup>-1</sup> and 5.98x10<sup>8</sup>-8.81x10<sup>10</sup>  $\mu$ m<sup>3</sup>L<sup>-1</sup>, respectively.

Keywords : Dardanelles, Phytoplankton, Eutrophication, Hydrography.

The Dardanelles is located between the Aegean Sea and the Sea of Marmara and has a 50 m mean depth. This study was carried out to determine the diurnal distributions of phytoplankton density, bio-volume and chlorophyll-a in relation to nutrients and CTD in surface waters of the Dardanelles (Fig. 1) in the summer period of 03 July 2002 and 04 August 2002. It was collected 99 surface (0.5m) samples for nutrient, chlorophylla and phytoplankton.

Fig. 1. Dardanelles and sampling station (D)

CTD parameters, nutrient and chlorophyll-a were measured by using YSI 556 MPS, Technicon Model Two Channel Autoanalizor and Jasco V-530 UV/VIS spectrophotometer, respectively [1]. For enumeration of the phytoplankton species, Uterhmöhl Sedimentation Chambers, Neubauer and Sedgwick-Rafter counting slides were used in combination according to the dimensions of the organisms. The phytoplankton was identified under phase-contrast microscopy to the taxonomic level of species.

Temperature, salinity, pH, DO, TDS, TSS, NO<sup>-2</sup><sub>2</sub>+NO<sup>-3</sup>, PO<sup>-3</sup><sub>4</sub>, SiO<sub>4</sub> and chlorophyll-a were varied between 22.5-26.5 (mean 25.0, SD 0.97 °C), 22.7-23.7 ppt (mean 23.3, SD 0.23 ppt), 8.31-8.49 (mean 8.42, SD 0.04), 8.46-10.1 mg L<sup>-1</sup> (mean 9.26, SD 0.48 mg L<sup>-1</sup>), 23.4-24.3 g L<sup>-1</sup> (23.9; SD 0.21 g L<sup>-1</sup>), 16.8-76.0 mg L<sup>-1</sup>(36.1; SD 10.7 mg L<sup>-1</sup>), 0.04-11.8  $\mu$ M (mean 1.90; SD 2.15  $\mu$ M), 0.02-0.97  $\mu$ M (mean 0.24; SD 0.20  $\mu$ M),0.64-8.50  $\mu$ M (mean 3.61; SD 2.15  $\mu$ M) and 0.21-5.62  $\mu$ g L<sup>-1</sup> (mean 1.70; SD 0.76  $\mu$ M), respectively. N:P and S:P rates were also varied between 0.44-142.8 (mean 12.5, SD 19.5) and mean 3.82-125.5 (25.0, SD 22.3), respectively. Diurnal variations of bio-physicochemical parameters in time interval between 08:00 and 19:00 were generally much higher than daily variations in period of 03 July and 04 August due to two counter flows system and domestic inputs of Çanakkale city.

On the other hand, the negative correlation between SiO<sub>4</sub> and diatom cell density (r=-0.295) was more significant than between SiO<sub>4</sub> and diatom bio-volume (r=-0.134). These correlations showed that utilization of SiO<sub>4</sub> by diatoms was more connected with diatom cell density than with diatom cell volume. This study showed that the relationship between chlorophyll-a and Bacillariophyceae (r=0.570) was more important than the relationship between chlorophyll-a and Dinophyceae (r=0.176) and between chlorophyll-a and other taxonomic groups (r=-0.145). These relationships between chlorophyll-a was highly controlled by Bacillariophyceae species than those of Dinophyceae and other taxonomic groups. In fact, very important relationship between Bacillariophyceae and total phytoplankton (r=0.702) also accurate important contribution of Bacillariophyceae to total phytoplankton.

Fig. 2. Daily variations in density (A) and bio-volume (B) of different phytoplankton groups in the Dardanelles in the period of 03 July 2002 and 04 August 2002

Total phytoplankton density and bio-volume varied between 2.86x10<sup>5</sup>- $1.5 \times 10^7$  cell L<sup>-1</sup> and  $5.98 \times 10^8$ -8.81×10<sup>10</sup>  $\mu$ m<sup>3</sup>L<sup>-1</sup>, respectively (Fig. 2). Due to Black Sea surface waters, rational contribution of Bacillariophyceae (66.5%) to total phytoplankton bio-volume was higher than contribution of Dinophyceae (31.0%). It has been showed that there are 8-10 population growth slopes by different species such as dinoflagellates Prorocentrum compressum (Bailey) Abé and Prorocentrum micans Ehrenberg, diatoms Pseudonitzschia pungens (Grunow ex. P.T. Cleve) Hasle, Pseudosolenia calcar-avis Schultze, Rhizosolenia fragilissima Bergon and a globally significant coccolitophore Emiliania huxlevi (Lohmann) Hay & Möller at different times and different densities in the Dardanelles. These species were also responsible for algal blooms in different times during the sampling period. In view of both cell density and bio-volume, although diatoms (Bacillariophyceae) showed some algal blooms in summer period, dinoflagellates (Dinophyceae) showed more regular and stabile fluctuations in the summer sampling period especially in bio-volume profile (Fig. 2). Phytoplankton community structure was observed to be controlled by these species in the summer period in the Dardanelles as shown like in the Black Sea ecosystems.

# PICOPLANKTON DYNAMICS IN THE LEVANTINE BASIN

Zahit Uysal \*, Yesim C. Yildiz and Suleyman Tugrul

Middle East Technical University, Institute of Marine Sciences, PB.28 33731 Erdemli, Turkey - uysal@ims.metu.edu.tr

# Abstract

Abundance and biomass of picoplankton (heterotrophic bacteria and cyanobacteria *Synechococcus*) were monitored monthly at three stations over a year in the northern Levantine Basin shelf waters. Relationships with other ambient chemical and physical parameters were also sought. An apparent decreasing trend in picoplankton content from inshore towards offshore was observed Bacterial population was found relatively low during winter. *Synechococcus* was most abundant at or near surface waters during the summer. In general, heterotrophic bacterial biomass surpassed the cyanobacterial (*Synechococcus*) biomass in the water column throughout the year. *Keywords : Cyanobacteria, Biomass, Levantine Basin.* 

Picoplankton samples for this study were collected from three stations offshore the Institute of Marine Sciences of Middle East Technical University, Turkey, located on the norteastern coast of the Mediterranean (Figure 1). Seawater samples taken from standard depths for picoplankton analysis were filtered onto 25 mm diameter, black, polycarbonate, nuclepore membrane filters with 0.2  $\mu$ m pore size. Total bacterial as well as the cyanobacterial abundance were estimated by acridine orange direct counts with epifluorescence microscopy (1). Counts were performed under a Nikon epifluorescence microscope with a filter combination of B-2A (blue excitation, dichroic mirror DM 505, excitation filter EX 450-490, barrier filter BA 520) and G-1A (green excitation, dichroic mirror DM 575, excitation filter EX 546/10, barrier filter BA 580). The main light harvesting pigment of Synechococcus is phycoerythrin which is responsible for the orange fluorescence of Synechococcus when excited with green light. Mean cell volumes were estimated using image analysis system composed of a digital camera, computer and the image analysis software. Cell volumes were determined using the volume formula for an ellipsoid (2). To calculate carbon content of bacteria and Synechococcus, 77 and 123 fg carbon per cubic micron were used, respectively (3, 4).

Fig. 1. Location of the sampling stations in the Levantine Basin.

In general shelf waters have a dynamic nature and strong mixing during winter effect greatly the concentration of nutrients as well as the distribution of suspended matter in the water column. Winter bacterial population was low in abundance and cells were distributed homogeneously in the water column. At the nearshore station surface bacterial biomass ranged from 3.05  $\mu$ gC l<sup>-1</sup> in December to a maximum of 32.27  $\mu$ gC l<sup>-1</sup> in September. The minimum and the maximum bacterial biomass ranged between 2.81 (at 100m depth in October) and 12.11  $\mu gC~l^{-1}$  (at 20m depth in September) at the middle station. At the offshore station bacterial biomass ranged from a low level of 0.99  $\mu$ gC l<sup>-1</sup> at 175 m in October to a high level of 10.7  $\mu$ gC l<sup>-1</sup> achieved at surface in September. In general, heterotrophic bacterial biomass surpassed the cyanobacterial ( Synechococcus) biomass in the water column throughout the year. Size of bacteria varied greatly with depth at all three stations. Cyanobacteria Synechococcus was found most abundant at or near surface waters during the summer. Changes in cell abundance with depth was insignificant during winter due to intense vertical mixing and remained at lowest levels compared to other seasons. At the nearshore station Synechococcus biomass ranged from 1.08  $\mu$ gC l<sup>-1</sup> (at 10 m depth in January) to a maximum of 11.59  $\mu$ gC l<sup>-1</sup> obtained at surface in July. At the middle station cyanobacterial biomass ranged between 0.04 (at 100m depth in October) and 7.55  $\mu$ gC l<sup>-1</sup> observed at 20 m depth in July. At the offshore station, to a highest value was reached in July at 20 m depth (6.31  $\mu$ gC l<sup>-1</sup>).

# DISTRIBUTION AND ACTIVITY OF BACTERIA AND ARCHAEA IN THE DEEP NORTH ATLANTIC OCEAN

Marta M Varela \*, Hendrik M Van Aken and Gerhard J Herndl

Department of Biological Oceanography, Royal Netherlands Institute for Sea Research, PO Box 59, NL-1790 AB Den Burg, The Netherlands - varela@nioz.nl

# Abstract

We determined the distribution and activity of the major prokaryotic groups (Bacteria, *Cren-* and *Euryarchaeota*) in the deep water masses of the eastern North Atlantic. The bacterial contribution to total picoplankton abundance was rather homogeneous, comprising 50% of DAPI-stainable cells. *Euryarchaeota* cells were hardly present, while the percentage of *Crenarchaeota* ranged from <5 and >20% in subsurface and deep waters, respectively. Both Archaea and Bacteria were taking up D- and L-Aspartic acid, while we did not find any evidence that *Crenarchaeota* take up inorganic carbon, suggesting that they are heterotrophs incorporating mainly D-amino acids. *Keywords : Bacteria, Carbon, Deep Waters.* 

Prokaryotic (Bacteria and Archaea) plankton are the major drivers of biogeochemical cycles in the ocean. While the importance of bacteria in the biogeochemical cycles of marine ecosystems is well established, particularly for surface waters, little is known about the distribution and metabolic activity of the prokaryotic community in the meso- and bathypelagic realm of the ocean. Recent studies found that Archaea have the potential to use both inorganic and organic carbon [1-2] as energy source in the deep ocean. However, more information is needed in order to identify the distribution of group-specific prokaryotic activity in deep water. Sampling of meso- and bathypelagic waters was carried out along a 4000-km transect covering the major deep water masses of the eastern North Atlantic. Water samples were taken from the 100m layer (subsurface), the oxygen minimum zone (O2-min), the Mediterranean Sea Outflow Water (MSOW) in the subtropical gyre, the Antarctic Intermediate Water (AAIW) in the North Equatorial Counter Current, the Northeast Atlantic Deep Water (NEADW) and the Lower Deep Water (LDW). D- and L-aspartic acid (Asp) incorporation was measured on the bulk prokaryotic community and archaeal production via the incorporation of <sup>14</sup>C-bicarbonate. We compared bulk activity measurements with that on a single cell level using catalyzed reporter deposition fluorescence in situ hybridization combined with microautoradiography(MICRO-CARD-FISH)

The bacterial contribution to total picoplankton abundance ranged from 40 to 55% of DAPI-stainable cells both in the subtropical gyre and North Equatorial Counter Current stations. Generally, the vertical distribution was rather homogeneous and lacked a clear latitudinal pattern. *Euryarchaeota* were hardly present along the transect, comprising always <5% of DAPI-stainable cells. *Crenarchaeota* exhibited a more patchy distribution throughout the transect. The percentage of total picoplankton identified as *Crenarchaeota* ranged between<5% and >20% in subsurface waters (around 100m depth) and the LDW, respectively. In general, *Crenarchaeota* were less abundant in the subtropical gyre waters(<10% of the picoplankton community) than in the North Equatorial Counter Current stations (up to 25% of total picoplankton cells) (Figure 1).

Fig. 1. Abundance of Bacteria and Archaea enumerated with CARD-FISH in the different water masses of the North Atlantic.

Mean L-Asp bulk uptake rates decreased from 8.3 pmol  $L^{-1}h^{-1}$  at 100m depth to 0.03 pmol  $L^{-1}h^{-1}$  in the NEADW, while D-Asp decreased from

0.5 pmol L<sup>-1</sup>h<sup>-1</sup> at 100 m depth to 0.005 pmol L<sup>-1</sup>h<sup>-1</sup> in the NADW. The ratio of D-/L- Asp uptake by the prokaryotic community increased from the subsurface layer (D-/L- Asp uptake ratio ~0.09) to the deeper layers reaching a ratio close to 1 at 4000 m depth (Figure 2).

Fig. 2. D-/L-Asp uptake ratio derived from the bulk prokaryotic community measurements in the different water masses of the North Atlantic.

Archaeal production generally followed the same decreasing trend with depth as the prokaryotic production, declining from 295  $\mu$ mol C m<sup>-3</sup> day<sup>-1</sup> at a depth of 100 m to 85  $\mu$ mol C m<sup>-3</sup> day<sup>-1</sup> in the oxygen minimum layer at a depth of 500 m. However, in the deep ocean we could not measure any inorganic carbon incorporation. Using MICRO-CARD-FISH, we found that both *Archaea*and Bacteria were taking up D- and L-Asp. The percentage of *Crenarchaeota* taking up D-Asp was highest in the LDW of the North Equatorial Counter Current, while we did not find any evidence that *Crenarchaeota* take up inorganic carbon. Thus, in contrast to recent findings showing that *Crenarchaeota* are chemoautotrophic in the mesopelagic waters, using inorganic carbon as a carbon source and oxidizing ammonia as an energy source [4], in bathypelagic waters, *Crenarchaeota* are likely heterotrophs using efficiently D-amino acids.

# PHYTOPLANKTON ASSEMBLAGES IN THE NORTHEASTERN SHELF OF MEDITERRANEAN SEA DETERMINED BY CHEMTAX ANALYSIS OF PIGMENT DATA

Doruk Yilmaz \*, Dilek Ediger and S. Tugrul

Middle East Technical UniversityInstitute of Marine Sciences, Mersin, Turkey - doruk@ims.metu.edu.tr

# Abstract

Relative contributions of the major phytoplankton groups to the total chlorophyll a were estimated by the CHEMTAX analyses. Chemotaxonomic results for phytoplankton characterization showed mixed phytoplankton community and reflecting major contributions of cyanobacteria at the surface of the deep station. However, diatoms and dinoflagellates were the most abundant algal classes in shallow zone water.

Keywords : Eastern Mediterranean, Phytoplankton, Pigments.

# Introduction

The eastern Mediterranean is known as one of the oligotrophic seas over the world, due to limited nutrient input to its surface waters from external and internal sources. Chlorophyll concentrations previously recorded in the Levantine basin were low, not exceeding  $1\mu g/l$  even in coastal waters [1]. However, phytoplankton composition is quite diverse (minimum 70 spp.). Microscopic analysis of phytoplankton composition is a tedious and necessitates well-trained taxonomist. Unfortunately, there are almost no studies on the pigment characterization of phytoplankton in the NE Levantine basin. The main aim of this research was to use the chemotaxonomy for great improvement in our understanding of the distribution and composition of oceanic phytoplankton populations.

#### Material and Method

In this study, the distributions of phytoplanktonic community composition in the NE Mediterranean coastal waters were described by using chemotaxonomy of photosynthetic pigments. In the field, sampling was carried out from a deep (total depth is 200 m) (36.26 N 34.22 E) and a shallow (total depth is 20 m) (36.33 N 34.15E) stations. Measurements were conducted in these stations in monthly intervals during December 2001 - December 2003 period. Pigments were analyzed by improved HPLC method [2].

#### Results and Discussion

Average chl-a concentrations was 0.13  $\mu$ g/l (range 0.01-1.19  $\mu$ g/l) at the deep and 0.71  $\mu$ g/l (range 0.03-8.0  $\mu$ g/l) at the shallow station during the entire studied period. Chlorophyll-a concentrations at the deep station was within the range of oligotrophic waters. Maximum surface CHL *a* values in shallow and deep station (8.0 and 1.2  $\mu$ g/L) were recorded during January 2002 sampling period probably due to transport of nutrients by river water in shallow station and winter mixing processes in deep station (Figure 1). Higher nutrient concentrations in shallow station (average ( $\mu$ M)  $\pm$  StDev; PO<sub>4</sub>: 0.08 $\pm$ 0.08, NO<sub>3</sub>: 0.25 $\pm$ 0.23, Si: 1.39 $\pm$ 0.56) resulted in higher algal biomass.

The output marker pigment: CHL *a* ratios calculated by CHEMTAX [3] were used in the calculation of the relative abundance of each phytoplankton group and hence their contributions to the total CHL a (Fig. 1). In surface waters of the deep station, the composition of the phytoplankton population was generally dominated by cyanobacteria, contributing 8-96% CHL a (mean=52%, SD=24%). Recent studies in the area showed that cyanobacteria abundance were generally high [4]. Marty et al. [5] reported that high contribution of cyanobacteria was observed at DYFAMED timeseries station in the western Mediterranean Sea. The specific occurrence of cyanobacteria is related to possible N2 fixation of some of the species composing this group. Algal classes, constituted the bulk of the remaining CHL a, showed mixed phytoplankton assemblages in deep station. However, in January 2002 where the highest concentrations of CHL a were recorded, surface waters of deep station were dominated by diatoms (56%), prymnesiophytes (15%) and dinoflagellates (13%). In shallow station, different composition of algal class was observed, with a general shift from surface waters dominated by prokaryotic cyanobacteria to populated predominantly by the eukaryotic diatoms (mean=41%, SD=16%) and dinoflagellates (mean=20%, SD=12%) (Figure 1). Similar to deep station, diatoms (62%) and dinoflagellates (22%) were the dominant algal groups in January 2002 (Figure 1).

Fig. 1. Contribution of various algal classes to total CHL a biomass in surface waters of deep and shallow waters determined using CHEMTAX analysis.

# THE LITTORAL AND PELAGIC DISTRIBUTION OF ASTERIONELLA FORMOSA ON THE SURFACE WATER OF SAPANCA LAKE

Neşe Yilmaz

Istanbul University, Fisheries Faculty, Laleli, Istanbul, Turkey - nyilmaz@istanbul.edu.tr

# Abstract

The littoral and pelagic phytoplankton distribution in regions on the surface of the Sapanca Lake water was studied between December 1999 and February 2001 from 4 stations on a monthly basis. During the study, the dominant type of phytoplankton was the *Asterionella formosa* of the Bacillariophyta division.

Keywords : Diatoms, Surface Waters, Pelagic.

# Introduction

Phytoplankton is one of the top living species groups that react fast to pollution in lakes. The composition of phytoplankton in designated water mass shows there is a trophic structure [1]. The aim of this study was to determine the difference in composition of the phytoplankton in the littoral and pelagic regions and to study the distrubution of the dominant phytoplankton types.

#### Materials and Methods

Four stations were designated in the west side of the lake, in both the littoral and pelagic regions (Fig. 1).

Fig. 1. The research stations at Sapanca Lake.

The samples were taken in nansen bottles and were flipped with lugol [2]. The surface water temperature of the lake and the dissolved oxygen quantity was measured with Oxi330/set make temperatures and the oxygen by meters, the pH on the other hand, was measured with the Knick make pH-meter. Seki discs were used when measuring the permeability of the light. The rations of OrtoPhosphate (PO<sub>4</sub>-P) and Nitrate Azote (NO<sub>3</sub>-N) in the water samples, was done with the help of Dr. Lange make kits at only the sample station points which were by the shore (Table 1).

# Results and Discussions

In the research period, 54 taxa was found in the seven divisions belonging to phytoplankton. Bacillariophyta, Chlorophyta and Cyanophyta were the dominant members of phytoplankton. Members of the Bacillariophyta group were found to be mostly dominant on the surface when it came to number of type and number of individual. *A. formosa* is the dominant type within the group. This species was found more in the pelagic region stations of 1., 2. and 3. than they were in the stations of the littoral regions. *A. formosa* was found more in the  $4^{th}$  station of the littoral region than in the pelagic region. The changes in the composition of species are a result of an increase in nutritional salt [1]. *A. formosa* is usually an indicator species of eutrophic structure. It has been stated that the taxa can be found in high numbers in mesotrophic and eutrophic and even in oligotrophic waters [3,4]. *A. formosa* was stated as being phytoplankton characteristic

and nutrionally rich in warm lakes in spring and when of high number has known to be the reason of the lessening in matter of dissolved Nitrate and Phosphate like nutrients in the water [5]. Nutrients seem to lessen in periods when *A. formosa* is of a higher number. In the research carried out by Numan [6] in1958, it was seen that the lake was of oligotrophic status, however in the research done by Aykulu at al. [7], it was seen that the lake was heading towards mesotrophic characteristic. In this study, it is obvious from the results that the lake is changing from oligotrophic character over to mesotrophic character.

# MOLECULAR ANALYSIS OF *GYRODINIUM INSTRIATUM* EXCYSTMENT CELL USING FTA TECHNOLOGY

Amel Zouari Bellaaj \*, Moufida Abdennadher and Asma Hamza

Institut National des Sciences et Technologies de la Mer la Goulette Tunisie - zouari\_amel@yahoo.fr

# Abstract

*Gyrodinium sp.* (BgT3C2) strain isolated from a resting cyst in sediment from Bougrara lagoon (Tunisia) was used to investigate the utility of FTA Technology for the protection and purification of nucleic acid. We have used FTA cards to obtain the sequence of the LSU rDNA D1-D2 region from very low concentrated BgT3C2 strain culture. Nucleotide sequence analysis supported and confirmed identification of BgT3C2 strain to *Gyrodinium instriatum*.

Keywords : Biotechnologies, Genetics, Phytoplankton.

# Introduction

Using molecular approaches revolutionised the identification and taxonomic of the organisms with their genetic characterization, mostly based on nuclear ribosomal DNA markers [1]. DNA-based studies usually require highly concentrated clonally cultures. However, the culturing process is not always suitable. FTA enables the collection, storage and purification of nucleic acids from a wide variety of biological sources. The aim of this study is to investigate the suitability of FTA technology to obtain specific genes sequences for molecular identification of marine dinoflagellates avoiding highly concentrated cultures. Molecular data were compared to morphological characters of BgT3C2 strain to study the reliability of FTA in the species identification.

#### Materials and methods

*Gyrodinium sp.* cyst was isolated from sediment by core sampler from Bougrara Lagoon (Tunisia). The culture was maintained in L1 medium on a multiwell plate and grown at 22°C (12:12 L:D, 50  $\mu$ Em<sup>-2</sup>s<sup>-1</sup>). A monoclonal culture of *Gyrodinoium* (BgT3C2) was subsequently established and the growth phase of the BgT3C2 strain determined every 1-2 days.

Genomic DNA was extracted using FTA technology (Transgenomic) according to the manufacturer's recommendations. 65  $\mu$ l of the BgT3C2 strain culture was applied to FTA cards. After six months of storage, punches (2 mm) were removed from the FTA cards, washed and used as PCR template for the amplification of the LSU rDNA D1-D2 domains. The amplified rDNA fragment was purified and sequenced. PCR and sequencing reactions were performed using D1R, D2R, D1C and D2C primers [2].

### Results and discussion

Two different motile cell types emerged after 11 dormancy days from cysts in artificial medium  $L_1$ . The morphology of the cyst and motile cell of BgT3C2 strain seems to be similar to those described for *Gyrodinium instriatum* [3]. The lag phase of *Gyrodinium instriatum* lasted only for one day. The exponential stage lasted 30 days and maximum abundance was 40cells/ml. This low abundance prevent the use standard molecular method to identify the strain.

Using FTA cards, the D1-D2 region of rDNA LSU was successfully amplified from low density cultures of BgT3C2 strain. The D1R/D2C PCR product was purified and sequenced with D1R, D1C, D2R and D2C primers. We obtained a new sequence of approximately 650 bp using FTA cards as the source of PCR template. The new sequence of the LSU rDNA D1-D2 region of BgT3C2 strain has been deposited in GenBank under the accession number DQ997780. The LSU rDNA sequence analysis confirmed that the identity of the *Gyrodinium instriatum* cysts, BgT3C2 strain.

### Conclusion

Using FTA cards, allow obtaining specific gene sequences from marine dinoflagellates even at low abundance.

# Résumé

Dans cette étude la composition d'une microflore bactérienne d'eau de mer polluée par les hydrocarbures a été étudiée en se basant sur l'analyse de la diversité du gène du 16S rDNA. Nos résultats ont montré une diversité importante de la microflore (MA) et une composition se répartissant sur quatre groupes bactériens (l *es Protéobactérie, les Clostridia, les Flavobactérie et les Bactéroidètes*) avec dominance du sous groupe des *Beta-protéobactérie*. Sur les 94 clones analysés 59,2% sont affilés à des représentants cultivables et 22,2% sont affilés à des représentants non cultivables alors que 18,6% sont considérés comme des nouvelles séquences ayant moins de 97% de similarité avec les plus proches.

Mots clès : Bacteria, Genetics, Biodiversity, Pollution.

#### Introduction

Les microorganismes jouent un rôle important dans la bioremédiation des milieux pollués par les hydrocarbures. La plupart des études s'intéressent à un nombre limité d'espèces bactériennes cultivables connues par leurs capacités dégradatives. Cependant, il serait plus intéressant d'étudier la composition des écosystèmes bactériens complexes pour contribuer à la compréhension des phénomènes de dégradation des hydrocarbures. L'émergence des techniques moléculaires liée au développement de la phylogénie moléculaire basé généralement sur l'ADNr 16S comme marqueur évolutif universel [1] a contribué à l'amélioration des recherches dans ce thème.

# Matériels et Méthode

Une approche moléculaire a été appliquée pour étudier la composition de la microflore bactérienne indigène adaptée à partir d'eau de mer polluée par les hydrocarbures pétroliers. La microflore adaptée (MA) a été utilisée dans des tests de dégradation in vitro d'un pétrole brut tunisien et les capacités dégradatives de cette microflore ont été déterminées. Une banque de clone a été construite après extraction d'ADN génomique, amplification par PCR du gène du 16S rDNA, clonage et séquençage. Le traitement des séquences (nettoyage et "contigage") a été effectué [2]. Les séquences chimériques sont au préalable recherchées [3]. Toutes les séquences ayant plus de 1200 nucléotides sont importées dans la base de données ARB, après avoir été comparées à la base de données GenBank grâce à une analyse de type BLAST. Lorsque le pourcentage d'homologie des séquences obtenues est supérieur ou égal à 97 %, ces séquences sont regroupées en OTUs (Unité Taxonomique Opérationnelle). La raréfaction de l'échantillon et les indices de diversités sont étudiés grâce au logiciel DOTUR.

#### Résultats et discussion

Les résultats de l'analyse de la composition de la microflore indigène acclimatée, obtenue par extraction directe des acides nucléiques totaux à partir d'eau de mer polluée par les hydrocarbures, a montré une hétérogénéité mise en évidence par la construction de la courbe de raréfaction relative aux séquences analysées. En effet l'analyse de cette courbe a montré que d'autant d'autre clone peuvent être séquencés. D'autre part, parmi les 94 clones analysés 59,2% sont affilés à des représentants cultivables et 22.2% sont affilés à des représentants non cultivables alors que 18,6ù sont considérés comme des nouvelles séquences ayant moins de 97% de similarité avec les plus proches représentant dans la base GenBank.

Quatre divisions du domaine *Bacteria* ont été représentées dans cette microflore : les *Protéobactéries* (*Alpha-, Beta- et Gamma-protéobactéries*) respectivement avec 40.8 %, 18,5%, 14,8%; les *clostridia* qui contribue avec 18,5 % ; les *Actinobacteria* (3,7%) et les *Flavobactérie* avec aussi (3,7%). L'ensemble des clones analysés sont regroupés en 27 OTUs et les pourcentages de similarité avec les plus proches parents sont comprises entre (92,12 % et 100%). La prédominance des *Protéobactérie* dans les zones contaminées par les hydrocarbures a été constatée par d'autres travaux [4].

Cette analyse phylogénétique montre des affiliations des séquences obtenues avec des phylums connus comme colonisateurs des milieux pollués par les hydrocarbures comme les *Pseudomonas*, *Marinobacter* 

*et Alcanivorax* [5]. Cependant plusieurs autres phylums sont considérés comme des nouvelles séquences qui n'ont jamais été cités dans la littérature et qui peuvent avoir un rôle non négligeable dans la dégradation des hydrocarbures.

Cette microflore a montré des hautes performances de biodégradation d'un pétrole brut de type zarzatine ; Ainsi après une dégradation de 28j les pourcentages de biodégradation sont respectivement : 92,6% pour les hydrocarbures saturés et insaturés non aromatiques (HNA) et 68,7% pour les hydrocarbures aromatiques (HCA).

#### Conclusion

Au terme de l' étude de la diversité bactérienne de la microflore indigène de l'eau de mer dans une zone polluée par les hydrocarbures pétroliers on peut conclure que l'analyse moléculaire de la diversité du gène16S rDNA, dans le domaine Bacteria, permet une meilleure compréhension de la contribution directe ou indirecte des différents groupes bactériens dans les phénomènes de biodégradation. Ainsi la connaissance de la composition réelle de la microflore du milieu pollué constitue une étape préliminaire dans la sélection des espèces à haute performance de dégradation dans une éventuelle bioremédiation des sites pollués par les hydrocarbures.

# SOFT BOTTOM SIPUNCULANS IN ILDIR AND GERENCE BAYS (AEGEAN SEA)

Sermin Acik

Ege University, Faculty of Fisheries, Dept. of Hydrobiology, Izmir, Turkey - serminacik@yahoo.com

# Abstract

Soft bottom benthic samples were collected at 11 stations in Ildir and Gerence Bays at the depths 15-60 m between the years 2003 and 2006. A total of 480 individuals belonging to 3 species were encountered; *Aspidosiphon (Aspidosiphon) muelleri, Golfingia (Golfingia) vulgaris* and *Onchnesoma steenstrupii steenstrupii.* Among the biotopes, *Posidonia oceanica* was represented by the highest number of species (3 species). The most dominant and frequent species in the area was *Onchnesoma steenstrupii steenstrupii.* The biometrical features of specimens of the species found in this study were also given.

Keywords : Zoobenthos, Biometrics, Systematics, Aegean Sea, Eastern Mediterranean.

# Introduction

Thirty-three sipunculan species are known from the Mediterranean Sea (3), but the Turkish fauna is poorly known: Demir (1) and Ergen et al. (2) reported 2 and 4 species in the Sea of Marmara and Aegean Sea, respectively. The aim of this study was to identify the soft bottom sipunculans in two neigbouring bays in the Aegean Sea, and to investigate their distributional and biometrical features.

#### Material and Methods

The benthic samples were collected by a dredge and Van Veen Grap at Ildir (5 stations) and Gerence Bays (6 stations) at depths ranging from 15 to 60 m, between 2003 and 2006 (Figure 1). The samples were sieved through a 0.5 mm mesh, fixed with 10% formalin. In the laboratory, sipunculans were identified, counted and preserved in 70% ethanol. A number of biometrical features (lengths of trunk and introvert etc.) of the smallest and largest individuals of each species were measured by using an ocular micrometer.

Fig. 1. Map of the investigated area with location of sampling sites.

# Results and discussion

Faunistic analysis of 37 benthic samples collected in 11 stations in Ildir and Gerence Bays yielded a total of 480 specimens belonging to 3 species; Aspidosiphon (Aspidosiphon) muelleri Diesing, 1851 (Aspidosiphoniidae), Golfingia (Golfingia) vulgaris (De Blainville, 1827) (Golfingiidae) and Onchnesoma steenstrupii steenstrupii Koren & Danielssen, 1875 (Phascolionidae). Phascolosomatidae was the dominant family in the area (348 specimens; 72.5% of the total), followed by Aspidosiphonidae (131 specimens, 27.3%) and Golfingiidae (1 specimens, 0.2%), respectively. Among the biotopes, Posidonia oceanica was represented by the highest number of species (3 species) and sandy mud had the highest number of individuals (45.2%) (Table 1). Golfingia (G.) vulgaris occurred only on P. oceanica at 35 m (Table 1). Only Aspidosiphon (A.) muelleri was found between 10 and 20 m depth on sand and P. oceanica. In terms of the frequency values of the species, Onchnesoma steenstrupii steenstrupii ranked first, occurring in 26 samples (70.3%), followed by Aspidosiphon (A.) muelleri (48.6%) and Golfingia (G.) vulgaris (2.7%). Onchnesoma steenstrupii steenstrupii had the highest frequency score between the depth interval 41-60 m (88%). The majority of specimens of sipunculans were determined between 41 and 60 m. In the shallow waters (10-40 m depth), P. oceanica had the highest number of specimens of the sipunculans. The

Jaccard similarity index showed that there was a weak similarity between the co-occurrence of species in samples. The highest similarity score was found between *Aspidosiphon (A.) muelleri* and *Onchnesoma steenstrupii steenstrupii (32%)*.

Tab. 1. List of sipuncula species found in Ildir and Gerence Bays with the total number of their individuals at the depth intervals and on biotopes (Po: *Posidonia oceanica*, S: Sand, Sm: Sandy mud, Ms: Muddy sand).

| Depth Interval (m)                      |    | 1  | 0-20 |    |    | 2  | 1-40 |    |    | 4   | 1-60 |    |

| Golfingia (G.) vulgaris                 | -  | -  | -    | -  | -  | -  | -    | 1  | -  | -   | -    | -  |
| Aspidosiphon (A.) muelleri              | 12 | -  | с÷   | 73 | -  | -  | -    | 19 | 15 | 4   | 8    | -  |
| Onchnesoma steenstrupii<br>steenstrupii | -  | ÷  | -    | -  | 12 | -  | ÷    | 2  | 52 | 213 | 69   | -  |

The biometrical features of the specimen (1 specimen) of *Golfingia* ( *Golfingia*) *vulgaris* in the area are; trunk 6 mm long, 1.4 mm wide; introvert 2.7 mm long, 0.7 mm wide; papillae on base of introvert 23-40  $\mu$ m height, 18-35  $\mu$ m in diameter; papillae on caudal end of trunk 38-45  $\mu$ m in length, 25-33  $\mu$ m in diameter; hooks 53-105  $\mu$ m in height. This species is distributed in the Atlantic, Pacific and Indian Oceans and, Mediterranean Sea at depths ranging from 0 to 6000 m depths (see 4).

The biometrical features of specimens (131 specimens) of Aspidosiphon (Aspidosiphon) muelleri in the area are; trunk 2.9-5.6 mm long, 1.2-1.6 mm wide; introvert 3-6.8 mm long, 0.4-0.5 mm wide; introvert longer than trunk length; introvert with 30-50 rings; bidentate hooks 13-30  $\mu$ m tall, 15-30  $\mu$ m wide; unidentate hooks 15-25  $\mu$ m long, 15-28  $\mu$ m wide; longitudinal grooves on anal shield numbering 13-20; radial grooves on caudal shield numbering 18-24. This species was previously reported from the northeast Atlantic, Mediterranean, Red Sea, and Indian and Pacific Oceans at the depth interval 0-1470 m (see 4).

The biometrical features of the specimens (348 specimens) of *Onchnesoma steenstrupii steenstrupii* in the are; the spherical trunk, 0.7-1.2 mm long, 0.5-0.8 mm wide; introvert partly everted, 0.5-5 mm long, 0.2-0.4 mm wide; small wart-like papillae on surface of trunk 13-18  $\mu$ m long, 15-25  $\mu$ m in diameter; trunk has 20-24 keel-like structures; some specimens with elliptical eggs; longer axis 110-145  $\mu$ m in diameter, smaller axis 90-120  $\mu$ m in diameter. This species is distributed in the North Atlantic, south eastern Atlantic, western Pacific and south western Indian Ocean, Mediterranean Sea between 0 and 3362 m depths (see 4).

The future studies to be undertaken in the region will shed more light on the real biodiversity of sipunculan species and their functional roles in benthic communities.

# Abstract

We have reviewed estimates of large-scale trends in the distributions and status of Euro-Mediterranean coastal habitats. Conspicuous declines of coastal wetlands, seagrasses, biogenic reefs, and complex macroalgae have been observed in several countries. In some regions, most valuable habitats were already severely degraded or driven to virtual extinction well before 1900. Nowadays less than 15% of the coastline is considered in "good" condition. Those fragments of native habitats that remain are under threat, and their management is not informed by adequate knowledge of their distribution and status

Keywords : Biodiversity, Coastal Management, Ocean History.

In terrestrial environments, understanding and abating the effects of habitat loss and fragmentation are a huge focus in science, conservation and management [1]. Habitat loss is also well recognized as an important threat in the marine environment [2] but has not been as much a focus of science and conservation as in terrestrial environments.

We have compiled and reviewed estimates of large-scale trends in the distribution and status of coastal habitats along European coastlines [3], which has included the Mediterranean and Black Sea. Over the centuries, land reclamation, coastal development, overfishing and pollution have nearly eliminated coastal wetlands, seagrass meadows, shellfish beds, biogenic reefs and other productive and diverse coastal habitats. It is estimated that every day between 1960 and 1995, a kilometre of coastline was developed, with the greatest urban developments occurring along the Euro-Mediterranean coasts. More than 50 % of the Mediterranean coasts are dominated by concrete with >1500 km of artificial coasts, of which about 1250 km are developed for harbours and ports [4]. Most countries for which documentation is available have estimated losses of coastal wetlands exceeding 60% of original area, with peaks above 80 % for countries such as Italy and France [3]. Documentation of seagrass loss is more limited, but there are suggestions that there may have been historical losses of Posidonia oceanica ranging from 40 to 80%. Conspicuous declines, sometimes to virtual local disappearance of fucoids and other complex macroalgae have been observed along the coasts of the Mediterranean and Black Sea.

A few dominant threats have led to these losses over time [3]. The greatest impacts to wetlands have consistently been land claim and coastal development. The greatest impacts to seagrasses and macroalgae are presently associated with degraded water quality while in the past there have been more effects from destructive fishing and diseases. Coastal development remains an important threat to seagrasses. For biogenic habitats, some of the greatest impacts have been from destructive fishing and over- exploitation with additional impacts of disease, particularly to native oysters. Coastal development and defence have had the greatest known impacts on soft sediment habitats with a high likelihood that trawling has affected vast areas. The concept of 'shifting baselines', which has been applied mostly to the inadequate historical perspective of fishery losses, is extremely relevant for habitat loss more generally. Most habitat loss estimates refer to a relatively short time span primarily within the last century. However, in some regions, most estuarine and nearshore coastal habitats were already severely degraded or driven to virtual extinction well before 1900. Native oyster reefs were ecologically extinct by the 1950s along many coastlines and in many bays well before that. These shellfish reefs are one of the most endangered coastal habitats, but some of the least protection is being directed at them. Nowadays less than 15 % of the European coastline is considered in 'good' condition [5], with the Mediterranean coastlines among the most severely depleted. Those fragments of native habitats that remain are under continued threat, and their management is not generally informed by adequate knowledge of their distribution and status.

There are many policies and directives aimed at reducing and reversing these losses but their overall positive benefits have been low. Further neglecting this long history of habitat loss and transformation may ultimately compromise the successful management and future sustainability of those few fragments of native and semi-native coastal habitats that remain in the Mediterranean and Black Sea.

# ABUNDANCE OF SCOMBRID LARVAE IN MERSIN BAY (NE MEDITERRANEAN)

Yesim Ak Orek<sup>1</sup>\*, Zahit Uysal<sup>1</sup> and Belgin Hossucu<sup>2</sup>

<sup>1</sup> Middle East Technical University, Institute of Marine Sciences, P.O. Box. 28, 33731 Erdemli, Mersin, Turkey - yeso35@yahoo.com <sup>2</sup> Ege University, Faculy of Fisheries, 35100, Bornova, Izmir, Turkey

# Abstract

Distribution and abundance of Scombrid larvae were determined for the period January 1998-2001, at three stations in Mersin Bay (NE Mediterranean). Scombrid larvae were composed of a total of 10 taxa (6 species, 2 genera and 2 families). Among the most abundant scombrid species were the bluefin tuna Thunnus thynnus, observed during June-August at offshore station, the albacore Thunnus alalunga, found during June-September at the second station, and Atlantic mackerel Scomber scombrus, observed at the offshore station during January-April. These species together contributed 48% of the total scombrid larvae catch. Keywords : Ichthyoplankton, Larvae, Eastern Mediterranean.

# Introduction

Scombrid species are of high commercial value to fisheries, world-wide [1]. This family contains 15 genera and 51 species all around the world [1] of which only 10 genera, including 12 species, live in the Mediterranean [2]. The already published data on the ichthyoplankton of the northeastern Mediterranean Turkish waters is limited [3]. The distribution and abundance of Thunnus thynnus, Auxis rochei and Euthynnus alletteratus larvae have been reported only for a short period (in June) for this region [4]. This work aims to study the abundance, distribution and spawning period of all species present over a period of three years.

# Material and methods

Sampling was performed in Mersin Bay (NE Mediterranean) at three stations (34° 16'E, 36° 33'50 N; 34° 18' E, 36° 32'N; 34° 22' E, 36° 30'N) which are located within about 10 km from the coast. Samplings were made from January 1998 to June1999 weekly all stations (20, 80, 100 m depth) and from July 1999 to January 2001 biweekly at two stations (20, 100 m depth). Vertical net tows were carried out from bottom to surface with Nansen net (112  $\mu$ m mesh size). The collected ichthyoplankton material was then preserved in 5% neutralized formalin. Scombrid larvae were separated from zooplankton under a stereoscopic microscope in the laboratory.

#### Results and discussion

10 different scombrid larvae were identified from the region throughout the study period. A total of 68 scombrid larvae were collected at three stations (Table 1).

Tab. 1. Abundance of Scombrid larvae during 1998-2000 in Mersin Bay (NE Mediterranean).

| Total                               | 13    | 37   | 1    | -     | 4    | 5    | 7     | 1    | 68    |

Scombrid larvae were more abundant at the second station during sampling except from July 1999 to January 2001 (Fig. 1). Since the larvae were found at low number at the coastal station, it is concluded that they prefer offshore waters. Contribution of the bluefin tuna T. thynnus larvae to the total was 21% of all scombrid larvae collected, followed by albacore Thunnus alalunga (14.5%) and Atlantic mackerel Scomber scombrus (12.7%). Larvae of bluefin tuna were abundant during June-August with peaks during June at the first station (offshore). Albacore larvae were abundant from June to September at the second station in 1998. Previous works have also reported similar high values for this species during this period for different areas of the Mediterranean [5]. During 1998-1999, larvae of Atlantic mackerel were only found between January-April, being most abundant at the offshore station. Larval abundance of chub mackerel Scomber japonicus peaked during March at the second station in 1998. Little tunny E. alletteratus at the second station in July and skipjack tuna Katsuwonus pelamis at the offshore station in June were found in relatively low numbers only during 1998. In general, Scombrid larvae were more abundant at the second station in 1998. Tuna larval survey conducted earlier in the Levantine basin has revealed three species (bluefin tuna, bullet tuna and little tunny) of scombrid larvae for June 2004.

Fig. 1. Weekly changes in abundance of Scombrid larvae at stations 1, 2 and 3 during 1998-2001.

# ALIEN AND INVASIVE SEAWEEDS DISTRIBUTION ALONG THE TURKISH COAST OF THE AEGEAN SEA

Bariş Akçali<sup>1</sup> \* and Şükran Cirik<sup>2</sup>

<sup>1</sup> Dokuz Eylul University, Institute of Marine Sciences and Technology, Inciralti 35340 Izmir, Turkey - baris.akcali@deu.edu.tr <sup>2</sup> Faculty of Fisheries, Çanakkale Onsekiz Mart University, Çanakkale, Turkey

# Abstract

The distribution of alien invasive species, *Caulerpa racemosa var. cylindracea*, *Stypopodium schimperi* and *Halophila stipulacea*, was observed along the Aegean coastline. The distribution areas of these species were also mapped. *Keywords : Aegean Sea, Algae, Migration.* 

### Introduction

Mediterranean and Aegean coastline has a very rich biodiversity however it is threatened and affected from intensive coastal settlement, transportation, tourism, industrial fisheries, aquaculture activities and alien invasive species which enters the Mediterranean from channels (Suez and Gibraltar). At the beginning of this century the number of lessepsien migrated species was at level of tens but nowadays this number comes to hundreds and it is thought to reach to thousands at 2020 [1-2].

*Caulerpa racemosa var. cylindracea* was observed to be distributed intensely among the other alien and invasive species along the southern half of the Aegean Sea. In this study, special emphasis was given to *Caulerpa racemosa var. cylindracea* because of the problems this species creates with regard to biodiversity. The distribution of these species at the base stations were mapped with the aid of GPS. The spreading charasteristics of these three species were compared.

# Materials and Methods

In this study, the alien invasive seaweeds distribution areas were observed, mapped, sampled and water quality parameters were measured. *Caulerpa racemosa var. cylindracea* is the species which affects the biodiversity and distributes more than other observed species, so three base stations where this species shows an intense distribution in the northern, central and southern Aegean Sea were determined. Sampling were taken place seasonally to indicate these species life cycles and effects to the ecosystem by scuba diving. The diving equipments, underwater cameras, fishermen observations and trawl materials were used for the investigation. The deep sea observations were made by ROV, so the deepest points of distribution were determined. GPS was used to map the distribution of the species at the sampling sites.

#### Results and Discussion

It is observed that, alien invasive species have negative effect on biodiversity and ecosystem[1-3]. Besides that, the new distribution areas of *Caulerpa racemosa var. cylindracea*, *Stypopodium schimperi* and *Halophila stipulacea* are determined as an addition to previous studies[4-6].

As a result, among alien invasive species Caulerpa racemosa var. cylindracea observed intensely along Aegean Sea coasts especially at the southern half of the coastline. While because of its tropical origin Stypopodium schimperi's northernmost distribution range was Cesme coasts, subtropical Halophila stipulacea showed more northernly range until Dikili coasts. When the spreading characteristics of these three species were compared, Caulerpa racemosa var. cylindracea was determined to be the fastest spreading weed, Stypopodium schimperi was markedly faster, and Halophila stipulacea was reasonably faster. While first two species affects the biota and biodiversity of the site that they occur greatly, Halophia stipulacea was found to be spreading without affecting the surrounding biota. When the spreading kinetics were taken into account, Caulerpa racemosa var. cylindrecea has the capacity to influence the whole Turkish Mediterranean coasts. Furthermore, with such kind of distribution and spreading mechanism, the eradication of the species has not been foreseen. Under the light of the present information, the distribution of this algea should be monitored with a big scale programme.

# GILL HISTOLOGY OF PATELLA LINNEAUS, 1758 (MOLLUSCA: GASTROPODA)

Deniz Aksit and Beria Falakali Mutaf \*

Akdeniz University, Faculty of Aquatic Sciences and Fisheries, 07059 in Antalya/Turkey - fmberia@akdeniz.edu.tr

# Abstract

The gill structure was studied in representative species of genus *Patella*, using histology. Secondary gill consisted a single layer of wavy lamellae covered with cuboidal end interspersed columnar epithelium. Hemocytes and nefrocytes were commonly observed. This normal morphological characteristics are to be a reference point for further research in natural and aquacultured specimens of this genus. *Keywords : Mollusca, Gastropods, Rocky Shores.* 

Introduction - Genus *Patella*, known as limpet, is a widespread gastropod on the rocky shores and is characterized by a cone-shaped shell. These organisms become more important as serving an alternative food with increasing human populations in the world. The respiration in gastropods is generally achieved by gills located within the mantle cavity and regarded as a pallial organ [1]. In the *Patellidae*, however, the respiratory organ have lost ctenidial structure and become monobranchiate body [2-3]. The respiratory current is created by a complete ring of single layer of secondary pallial gills [1]. The external effects, before progressing into the visceral body, are first initiated on the gills as they are the first contact point with water except the thick shells and the foot of the animal. The main purpose of this study is to define the normal structure of the

*Patella* gills and to provide a basis to interpret more efficient results in further research on natural or cultured populations of these organisms.

Materials and Methods - Specimens of *Patella caerulea* and *P. rustica* were collected from Antalya Bay (between  $36^{\circ}53'04.26 \text{ N}-36^{\circ}36'25.22 \text{ N}$  and  $31^{\circ}46'31.30 \text{ E}-30^{\circ}42'03.62 \text{ E}$ ) on Southwestern coast of Turkey. Gills were dissected and fixed in Bouin's solution. Samples were taken through graded alcohol, cleared in xylene and embedded in wax. Sections were stained by Ehrlich's hematoxyline [4], examined by light microscopy and photographed at 3X digital zoom.

Results - The monobranchial structure extends along the pallial groove. The gill has long slender tubules which are are anchored to the body surface by the mantle border and shows no ramification. Two gill folds face each other along the sagittal plane.

Fig. 1. Light micrograph showing general organization of pallial gills of *Patella*.

The tubules afferent openings are clearly seen in oblique sections (Fig 1). The lamellae have wavy borders. The epithelium covering the external face of the gill folds is made made up by a single layer of large, cuboidal cells, but some columnar cell groups are scatterred among them with a puff-like appearance forming bursicles (Fig. 2a). Epithelial cells, with very thin cuticle layer, are mostly equipped with cilia. None chitonous support for the filaments has been observed. But thin muscle stripes are attached to each lamella separately. Vascular channels are divided into hemocoelic spaces by trabecula. Large number of hemocytes and some nephrocytes, cells of vascular system, are commonly observed within the vascular spaces of the gill folds (Fig. 2b).

Discussion - Pallial structures have been evolved into secondary gills in limpets [5], although ctenidium is well developed in other Patellogastropods [6]. The wavy border of each gill filament have increased the contact surface with sea water. The free movement was achieved by muscle fibres under control of pallial nerves as no skeletal rod exist in Patellacea [2]. Hemocytes are the best characterized cells in hemocoelic areas of the *Patella* gills. They have been described to play mediating role in immune function in mollusks [7-9].

Fig. 2. Histological micrograph of gill lamellae of *Patella*; a) Puffs of columnar epithelia. b) Hemocytes (thick arrow) and nephrocytes (long arrow) within vascular spaces covered by cuboidal epithelia (\*).

Histological observations of the respiratory organ is means to asses the adequacy of the environment. The increase in the industrialization and world population presents antropologic effect on natural populations. Once the anatomic and physiological characteristics of normality is known, they establish a reference point for further research to challenge with unnatural effects as well as to achieve a good management for development of aquaculture of alternative organisms.

# ENVIRONMENTAL EFFECTS OF THE THREE FISH FARMS IN IZMIR BAY (AEGEAN SEA-TURKEY) ON WATER COLUMN AND SEDIMENT

Mehmet Aksu \* and Ahmet Kocataş

Ege University, Faculty of Fisheries, Dept. of Hydrobiology, Izmir-Turkey - mehmet.aksu@ege.edu.tr

# Abstract

In order to detect environmental impacts of three fish farms; water and sediment samplings were carried out on a monthly basis between June 2001 and May 2002. Physico-chemical variables, chlorophyll -*a*, particulate organic carbon values of water samples, organic carbon values of sediment samples were investigated. We found that each of the fish farms affected the marine environment adversely, but the effects of the fish farm situated in a less protected cove compared to the other two were more apparent due to wrong feeding strategies and its shallow depth.

Keywords : Aegean Sea, Aquaculture, Monitoring, Pollution.

# Introduction

Turkish efforts in aquaculture started in 1970's and developed rapidly with the contribution of marine aquaculture in 1980's. Uncontrolled expansion of fish farms have led to environmental problems [1]. Uneaten feeds and feces adversely effected water column and sediment especially in closed and semi-enclosed coves. Our aim was to determine environmental effects of the three fish farms located in the Izmir Bay.

#### Materials and Methods

Samplings were carried out at three fish farms in Izmir Bay (Aegean Sea-Turkey) between June 2001 and May 2002 on a monthly basis (Fig. 1). All farms produced sea bream (*Sparus aurata*) and sea bass (*Dicentrarcus labrax*); 60, 240 and 160 tons/year and depths in the farms were 8, 20 and 10 m. respectively (Farm 1, 2 and 3). Two stations were chosen for sampling in each farm, one at the cage unit and a control station 200 meters away. Water samples were collected by Nansen Sampling Bottle, sediment samples were obtained using an Van-Veen grab. Visibility was measured by Secchi disc. Temperature and dissolved oxygen (Winkler titration) measurements were carried out *in situ*, pH, salinity (Mohr-Knudsen) analyses were done at the laboratory. Nutrients, chlorophyll-a and Particulate organic carbon (POC) concentrations were obtained according to standard methods [2]. Organic carbon values of sediment were determined as described [3]. In order to detect statistical difference between samples at the cage and the control stations, T-test was performed.

Fig. 1. Map showing the location of the studied fish farms.

# Results and Discussion

Results of analyses of the three fish farm stations (cage and control) are given in table 1. Temperature, salinity and pH values fluctuated throughout the sampling period in relation to seasonal changes. DO concentrations were low in the summer months at all stations due to increased temperature and there were no significant differences between cage and control stations. Secchi disc readings were higher at all control stations. Nitrate+nitrite values were higher at cage stations than control stations in summer samplings in all fish farms. But these differences were not important statistically.

Tab. 1. Range of variables troughout the sampling period in the fish farms.

| Ammonium (µM)        | Nd-11,40    | Nd-3,13     | Nd-5,76     | Nd-4,01     | 0,24-2,25   | Nd-1,80     |
| Phosphate (µM)       | Nd-0,87     | Nd-0,62     | Nd-0,87     | Nd-0,46     | 0,07-0,85   | Nd-1,20     |
| Silicate (µM)        | Nd-7,47     | Nd-5,66     | Nd-9,56     | Nd-11,10    | Nd-5,45     | 0,06-5,83   |
| Chl-a (µg/L)         | Nd-2,56     | Nd-2,56     | Nd-3,36     | Nd-2,56     | Nd-4,17     | Nd-4,59     |
| POC (mg/L)           | 0,174-1,094 | 0,226-1,096 | 0,236-1,044 | 0,132-1,012 | 0,264-1,000 | 0,219-0,953 |
| Org. carbon (%)      | 2,42-10,54  | 0,21-1,40   | 0,66-3,67   | 0,80-2,04   | 2,50-3,50   | 0,48-1,35   |

Significant increases in concentrations of ammonium were detected at cage stations over control stations in the first and the third farms. Phosphate concentrations were significantly higher at cage station only in the first farm. However, no significant differences were found between cage and control stations for chlorophyll-a and POC. This lack of POC and chl-a respond to nutrients is consistent with other studies in the Mediterranean [4,5]. In the first and third fish farms, organic carbon concentrations at cage stations were very significantly higher than control stations. Similar increased nutrient and organic material concentrations at cage stations have been also reported in the Mediterranean [4, 5, 6]. We found that the fish farms examined, impacted adversely the marine environment, and although the first fish farm was situated in a less protected cove compared to the other two farms, its effects were more apparent due to overfeeding and shallow depth of the area.

# CROISSANCE ET REPRODUCTION D' ARTEMIA SP. DE LA SEBKHA EZ-ZEMOUL (ALGERIE NORD-EST) DANS LES CONDITIONS D'ELEVAGE

Mounia Amarouayache , Farid Derbal \* and M. Hichem Kara

\* Laboratoire bioressources marines, Université Badji-Mokhtar, Annaba, Algérie - mfderbal@yahoo.fr

# Résumé

La population d'élevage d'*Artemia* de la Sebkha Ez-Zemoul  $(34^{\circ}03'N - 06^{\circ}20'E)$  est caractérisée du point de vue de sa croissance et de sa reproduction. Le taux de croissance est de 0,33 mm/jour. Les femelles, plus grandes que les mâles, atteignent leur première maturité sexuelle à une longueur de 6,54 mm (âge = 22 jours) et produisent en moyenne 13 cystes/portée. La population, composée essentiellement d'individus mâles (SR = 1,86), est bisexuelle et ovipare.

Mots clès : Aquaculture, Crustacea, Growth, Reproduction.

# Introduction

Le genre *Artemia* est un complexe d'espèces bisexuelles et parthénogénétiques qui vivent dans les milieux hyperhalins, situés généralement dans des régions arides et semi-arides. Au sein de la même espèce, les populations de différentes origines ont des réponses physiologiques différentes en fonction des conditions du milieu qu'elles fréquentent, se traduisant par des phénotypes différents [1]. Les nauplii de ce crustacé sont très utilisés en larviculture de poissons marins. En Algérie, les travaux effectués sur ce crustacé sont relativement rares et assez récents [2, 3, 4, 5]. Dans le présent travail, la croissance et la reproduction de la population d'élevage d'*Artemia* de la Sebkha Ez-Zemoul sont abordées.

# Matériel et méthodes

Des cystes (0,2 g) originaires de la Sebkha Ez-Zemoul ( $34^{\circ}03$ 'N -  $06^{\circ}20$ 'E) sont incubés dans une eau marine (salinité = 37 psu, température =  $25^{\circ}$ C) durant 30 h. Les nauplii récupérés dés l'éclosion sont mis en élevage dans les mêmes conditions, à raison de 1500 ind/l. Ils sont nourris de levure de bière (85%) et d'un complexe vitaminé [6]. Tous les trois jours, les individus sont mesurés de la tête à l'anus après anesthésie au chloroforme. Le taux de croissance est mesuré par le gain moyen de taille linéaire (en mm) par jour.

Le sex-ratio est exprimé par le rapport du nombre de mâles sur le nombre de femelles. La taille à la première maturité sexuelle est déterminée lorsque 50% des femelles présentent des signes de reproduction. Le mode de reproduction est défini en fonction de la dominance des cystes (oviparité) ou des nauplii (ovoviviparité). Les sacs ovigères sont disséqués sous une loupe binoculaire et le nombre moyen de cystes ou de nauplii par femelle est compté et représente la fécondité.

#### Résultats

Le taux de croissance est de 0,33  $\pm$  0,3 mm/j. Le stade juvénile est le plus long (10 jours) où les métanauplii passent d'une longueur totale de 1,73 mm à 5,11 mm pour devenir des pré-adultes. Le sexe se différencie à partir de 22 jours.

Les femelles sont plus grandes que les mâles (7,98 mm contre 6,78 mm; t<sub>obs</sub>= 2,72; P  $\leq$  0,05). Le sex-ratio est de 1,86. La taille à la première maturité sexuelle est de 6,54 mm et correspond à un âge de 24 jours. Le mode de reproduction est l'oviparité (100 %). La fécondité est de 13,5  $\pm$ 5,12 cystes/portée. Elle est significativement corrélée à la longueur totale des individus (r = 0,897; P  $\leq$  0,05).

#### Discussion

Le taux de croissance chez la population d'élevage d' *Artemia* de la Sebkha Ez-Zemoul est plus élevé que celui des populations mexicaines et celles de San Francisco Bay appartenant à l'espèce *A. franciscana* (0,159 et 0,183 mm/j) [7]. Les femelles sont plus grandes que les mâles ce qui est commun chez le genre *Artemia* [1]. Les adultes d'élevage de la Sebkha Ez-Zemoul sont plus petits de taille que les sauvages [5] et sont parmi les plus grands en comparaison avec les autres populations méditerranéennes [3, 6, 8, 9].

Le sex-ratio est en faveur des mâles comme chez la majorité des populations bisexuelles d' *Artemia* [1]. Les femelles sauvages de la Sebkha Ez-Zemoul deviennent matures à une taille (8 mm) plus importante que celle de la population d'élevage [5]. Elles sont plus fertiles (13-105 zygotes/portée) et se reproduisent jusqu'à 10% par ovoviviparité [5]. Les femelles d'élevage de la saline d'Arzew (Nord-Ouest algérien) [2] et celles d'Egypte [6] sont également plus fertiles (40 et entre 29 et 40 zygotes/portée respectivement). Selon [9], les conditions du milieu, en particulier la salinité, ont une influence directe sur la morphométrie et la reproduction du genre *Artemia*. Son augmentation entraîne une réduction de la longueur totale de la fécondité et une maturité précoce [9].

# Abstract

Morphometric relationships of *C. agassizi* (B.1848) from the Ionian Sea are presented for the first time and may be a useful reference for future studies. Analysis of Variance indicates significant relationships for several parameters (p<0.01). *Keywords : Eastern Mediterranean, Deep Sea Ecology, Fisheries.* 

C. agassizi is the dominant species in the uppermost layer of Ionian Sea. Although it undoubtedly plays an important role in the eastern Mediterranean deep-fish assemblages [1, 2], information is still scarce regarding its population status, biology and habitat needs. In the Ionian Sea it has been studied monthly over the course of a year recording biometry, growth, reproduction and dietary requirements [3]. Morphologic variation between populations is used in stock identification. Community structure, stock identification, and productivity are important factors in the development of management strategies as well as for experimental design of sampling programs [4]. The objective of this paper is to present morphometric relationships of the species from the Ionian Sea. Specimens were collected monthly from December 1996 to November 1997 by a commercial bottom trawler using a net with a cod end mesh size of 14 mm from knot to knot. Sampling was carried out at 92 stations between 300 and 800 m depths, covering an area of about 1500  $\mathrm{km}^2.$  As the species is synchronously hermaphroditic, data collection did not record gender. In all, 2309 specimens were measured. All morphometric relationships between parameters were calculated using linear regression. To test for isometry, the allometric index values obtained were compared with the expected values using a student t- test. Morphometric ranges for various parameters were: TL (total length): 48-201 mm (SD=  $\pm 30.6$ ); the FL (fork length): 45-181 mm (SD=  $\pm 27.3$ ); SL (standard length): 41-169 mm (SD=  $\pm 25.4$ ); HL (head length): 11-52 mm (SD=  $\pm 7.7$ ); BH (body height): 4-35 mm (SD=  $\pm 4.9$ ); DFL (length of dorsal fin): 3-19 mm (SD=  $\pm$ 3.9); D\_AL (distance from the end of the dorsal fin till the origin of the adipose fin): 13-144 mm (SD=  $\pm 8.2$ ). All morphometric relationships are summarized in Table 1.

Tab. 1. Relationships and allometry of *C. agassizi* measured characters. N=number of individuals, SD=standard deviation of the slope b, t=values of the student's t-test for the type of allometry (Ho:b=1 for all the occasions). In each relationship P<0.01.

| Relationship | Equation                   | N    | Allometry | $r^2$ | SD(b) | t        |
|--------------|----------------------------|------|-----------|-------|-------|----------|
| TL-SL        | SL= -0,6785 + 0,9989 * TL  | 2304 | Isometry  | 0,998 | 0,046 | -1,15    |
| TL-FL        | FL = -0,2002 + 0,8942 * TL | 2283 | Isometry  | 0,998 | 0,045 | 0,21     |
| FL-SL        | FL = 0,0312 + 1,0002 * SL  | 2282 | Isometry  | 0,998 | 0,038 | 0,27     |
| HL-TL        | HL= -0,7073 + 0,2395 * TL  | 2223 | Negative  | 0,931 | 0,065 | -551,61  |
| HL-FL        | HL= -0,5801 +0,2673 * FL   | 2202 | Negative  | 0,93  | 0,073 | -469,68  |
| HL-SL        | HL= -0,5678 + 0,2876 * SL  | 2213 | Negative  | 0,932 | 0,077 | -453,22  |
| BH- TL       | BH= -2,9822 +0,1407 * TL   | 2224 | Negative  | 0,809 | 0,068 | -596,81  |
| BH- FL       | BH= -2,9385 +0,1574 * FL   | 2199 | Negative  | 0,811 | 0,076 | -520,6   |
| BH-SL        | BH= -2,9459 + 0,1692 * SL  | 2222 | Negative  | 0,81  | 0,082 | -478,86  |
| DFL-TL       | DFL=-0,6498 + 0,0958 * TL  | 2232 | Negative  | 0,918 | 0,029 | -1493,66 |
| DFL-FL       | DFL=-0,6013 + 0,1069 * FL  | 2209 | Negative  | 0,918 | 0,032 | -1311,72 |
| DFL-SL       | DFL=-0,6021 + 0,1150 * SL  | 2231 | Negative  | 0,915 | 0,035 | -1194,32 |
| D_AL-TL      | D-AL=1,4620 + 0,2599 * TL  | 2214 | Negative  | 0,962 | 0,051 | -682,84  |
| D_AL-FL      | D-AL=1,6038 + 0,2899 * FL  | 2196 | Negative  | 0,961 | 0,058 | -573,74  |
| D_AL-SL      | D-AL=1,5086 + 0,3127 * SL  | 2221 | Negative  | 0,963 | 0,061 | -530,96  |

Three relationships (TL- FL; TL- SL; FL-SL) indicated an isometric growth while all the others indicated negative allometric growth. In figure 1 the relationships between HL- TL, BH-TL, DFL- TL and D\_AL-TL are presented. The relationships between the different lengths of the species (TL, FL, SL) showed  $r^2$  =0.998. Statistically significant relationships were observed in all cases. Unfortunately, there is no any other morphometric information for this species, except some data available at www.fishbase.org where the relationship TL-FL: b=1.113 and TL-SL:

b=1.151 but the measurements were based on only two individuals. Future studies on stock identification need to be conducted over a larger study area as population structure is considered a basic element of conservation biology and finally for fisheries management. Poor understanding of the biology of fishes in a fishery management could lead to dramatic changes in the biological attitudes and productivity of species [4].

Fig. 1. Relationships of head length (HL), body height (BH), dorsal fin length (DFL) and distance dorsal-adipose fin with the total length of C. *agassizi* (TL).

# THE ASCIDIA STYELA PLICATA AS A NATURAL EUTROPHICATION CONTROL. PRELIMINARY RESULTS OF AN EXPERIMENTAL APPROACH

Chryssanthi Antoniadou<sup>1</sup>\*, Yannis Krestenitis<sup>2</sup>, Magdalini Panagiotou<sup>1</sup> and Chariton Chintiroglou<sup>1</sup>

<sup>1</sup> Department of Zoology, School of Biology, Aristotle University, Thessaloniki, Greece. - chintigl@bio.auth.gr

<sup>2</sup> Department of Hydraulics and Environmental Engineering, School of Civil Engineering, Aristotle University, Thessaloniki, Greece.

# Abstract

The potential of the solitary ascidia *Styela plicata* as a natural eutrophication control was investigated at the inner Thermaikos Gulf. Experimental work was carried out in the laboratory to estimate filtration efficiency, and in the field to study the colonization potential. *S. plicata* specimens halved the original concentration of particulate organic matter in about 2 hours, and successfully colonized a variety of artificial substrates within 3 months. These results support the abilities of this species as biological filter. *Keywords : Aegean Sea, Tunicata, Eutrophication, Diet, Recruitment.* 

# Introduction

Suspension feeders dominate benthic communities in eutrophic environments [1]. In Thermaikos Gulf the species *Styela plicata* (Lesueur, 1823) is among the dominant biota, both in terms of population density and expansion [2]. The purpose of this work was to investigate the abilities of *S. plicata* as a natural eutrophication control, by estimating the filtration efficiency, *i.e.* the amount of retained particulate organic matter (POM), and the colonization success on various artificial substrates.

# Materials and Methods

Thirty specimens of *Styela plicata* were collected with SCUBA diving from the inner Thermaikos Gulf, weighted and transferred to three experimental aquariums (10 each) with continuous airflow. After three days of acclimatization, 15g of phytoplankton were added in two aquariums (the third one served as control). Three water samples (100 ml each) were collected from each aquarium at 30-min intervals, for the estimation of POM [3]. To study the colonization of *S. plicata*, ropes (2 x 10 m, each), wooden and plastic plates (3 replicates of 30 x 30 cm each) were deployed (40° 30'49" N 22°54'25" E) at 10 m depth in March 2005 (Figure 1), and visually sampled every 15 days for 6 consecutive months.

Fig. 1. Map of the study area and location of experimental artificial sub-strates.

# Results and Discussion

The filtration efficiency of *Styela plicata* was equal at both experimental aquariums (Krüskal-Wallis statistic 6.48, p>0.05). Mean concentration of particulate organic matter (POM) dropped within the first two hours of the experiment to 50% of its original level, showing that *S. plicata* can assimilate half of the input food (15g POM) in about two hours. Thereafter POM started to increase again and stabilized to a lower concentration than the original input (around 9g POM), as the specimens started to produce faeces [4] and the experimental aquariums were closed circuits, so the seawater was not renewed. The colonization process started within the first 15 days with the development of the biological film. Thereafter, and within the first month, organic matter started to accumulate as well as the eggs of squids and cuttlefishes. Next, a dense population of the amphipod *Corophium sextonae* appeared, followed by *Mytilus galloprovincialis* recruits. Finally, after about 2 cm) were recorded. These results, although

preliminary, support the use of *Styela plicata* as a biological filter to reduce particulate organic matter. Considering the importance of the species as human food (Japan) and fishing bait (Europe), the produced biomass can be exploited respectively [5].

# Abstract

Population structure of the edible sea urchin, *Paracentrotus lividus*, was studied over a three-year period in a South Aegean island. Spatial variations in population density and dispersion patterns were estimated. Sampling was carried out with a non-destructive method, the randomly placed frames technique, combined with *in-situ* registration of data. Mean population density was  $13 \pm 3.86$  individuals/m<sup>2</sup>, while the pattern of dispersion was random. The population genetic structure was also determined, using RAPD fingerprinting. *P. lividus* populations in Hellenic waters appeared to be panmictic and should be considered as a mixture stock over a large geographic scale. *Keywords : Aegean Sea, Echinodermata, Density, Population Dynamics, Genetics.* 

#### Introduction

Sea urchins are among the most important elements of the hard bottom benthos. In the Mediterranean Sea *Paracentrotus lividus* is one of the most abundant and widely distributed echinoderms. This edible and commercial sea unchin presents low mobility in adult stages. Therefore, its populations may exhibit high gene flow only when strong ecological or biogeographical barriers to dispersal are absent [1]. *P. lividus* is a well studied species, especially in the Western Mediterranean, where the depletion of its natural populations have lead to intense research effort for the management of its stocks [2], [3]. Contrarily, very few studies have been conducted in the Eastern Mediterranean, and even fewer in the South Aegean, where *P. lividus* has been traditionally harvested. The present work contribute to the study of *P. lividus* population structure in the Aegean Sea.

#### Materials and Methods

Sampling was carried out with SCUBA diving at three sites (A, B, C) along the coastline of Astypalea Island, at depths ranging from 2 to 10 m, in August 2003, November 2003, March 2004, October 2004, December 2004, June 2005, September 2005 and June 2006. The method of randomly placed frames, permitting in-situ counting, was applied to estimate population density and spatial dispersion (20 frames of 50 x 50 cm each) [4]. Morisita's index (I) was calculated to assess spatial dispersion and a chi-square test was used to determine the significance of deviation from random distribution [4]. Adult specimens from Astypalea (n=40), Amvrakikos Gulf (n=53, Ionian Sea), Pagasitikos Gulf (n=75, Central Aegean) and Chalkidiki (n=40, North Aegean) were used to determine the genetic structure of P. lividus populations in Hellenic waters. Genomic DNA was extracted from the gonads of each specimen using a modified Levitan's protocol [5]. Seven RAPD primer markers and eight loci were used for distance computation between and within populations. Analysis of Molecular Variance (AMOVA) was performed among and within populations. Total population differentiation value (Fst) was estimated, as well as its overall and pairwise gene flow (Nm) values. A UPGMA tree of genetic distance [6] was produced.

# Results and Discussion

Mean population density of P. lividus, over all sites and sampling periods, was  $13 \pm 3.86$  individuals/m<sup>2</sup>. At each site a decrease in population density was evident at least twice during the study period. Two-way ANOVA showed significant spatial differences on mean population density (F=9.37 p<0.05), as well as temporal ones (F=19.98 p<0.05). The spatial differences were restricted to the reduced density of P. lividus at station A. Temporally, the abundance of sea urchins increased, gained maximum values in November 2003 and remained at high levels till March 2004; thereafter it declined, started to upturn in September 2005 and reached a second peak in June 2006. P. lividus individuals were randomly dispersed in most cases (I ranged from 1.05 to 1.32). These results indicate that P. lividus stocks undergo temporal fluctuations, probably linked to its reproductive output. The population seems to sustain the pressure of the local fisheries, since it retains overall high density, with no significant reduction on the mean test diameter (unpublished data). AMOVA permutation showed significant differences either among or within studied populations (Fst=0.077 p < 0.001). Pairwise Fst values were statistically significant for all populations at all loci. These data, along with the high value of migrants per generation (Nm=13.95), imply near panmixis among populations. Cluster analysis showed low values of genetic distance even between the Aegean and Ionian populations (Figure 1). Echinoderm species dispersal may occurs over long distances [8]. *P. lividus* populations in the Atlantic Ocean and the Mediterranean Sea appear to be panmictic within each, as gene flow occurs over large distances with no evidence of isolation by distance, indicating formidable plasticity to environmental or other pressures [1]. *P. lividus* populations, due to their panmictic nature in Hellenic waters should be considered as a mixture stock over a large geographic scale.

Fig. 1. UPGMA cluster analysis using Slatkin's genetic distance between the studied populations of *P. lividus*.

# Abstract

In the present work we used three molecular techniques (allozymes, RAPDs and mtDNA RFLPs) in order to study the genetic structure of four marine species (*Mullus surmuletus, Mullus barbatus, Merluccius merluccius* and *Pagellus erythrinus*). Each species was sampled from three regions of the Gulf of Pagasitikos as well from two neighbour regions outside the Gulf (Trikeri and Allonissos). Values of genetic heterozygosity and genetic diversity found for all populations studied were above the mean values observed in marine fishes. None of the three methods used reveal diagnostic patterns which could allow the identification of individuals to one of the populations. The results revealed that the three populations within Pagasitikos were homogenous representing thus a panmictic stock. However, there were evidences of genetic population subdivision between localities from inside and outside of the Pagasitikos Gulf. *Keywords : Aegean Sea, Fishes, Genetics.* 

#### Introduction

Gene flow through larval exchange is assumed to be the major mechanism in homogenizing spatially discrete marine populations. However, several studies of marine species have illustrated examples where apparently panmictic or neighbor populations demonstrate surprisingly high levels of genetic structuring. Genetic structuring in marine populations might be caused by several factors such as by differences in local selection pressures, or by local hydrographic conditions 1. The Gulf of Pagasitikos (west central Aegean Sea) presents particular interests and advantages for such kind of analyses due to local topographical and managerial peculiarities of the area i.e. it is a shallow, semi-enclosed basin where trawling is by low prohibited. The work presented here is part of a larger research project aiming on understanding the structure, function and dynamics of the Pagasitikos Gulf ecosystem, with a final target to achieve its sustainable management. It is well established that for a proper fishery management knowledge of the genetic population structure is important [2]. In the present study we examined both nuclear (allozymes and RAPDs) and mitochondrial DNA (mtDNA) variation in collections of four commercial marine species made in five different regions within and outside the Gulf of Pagasitikos with the goal of describing their genetic population structure.

### Materials and Methods

The four studied species were red mullet ( Mullus barbatus L.) striped red mullet ( Mullus surmuletus L), European hake ( Merluccius merluccius) and common pandora (Pagellus erythrinus). An average of 200 individuals of each species were collected at five locations (average 40 individuals per location), three from the Pagasitikos Gulf and two from neighbour areas that is from Trikeri and Allonissos. Samples of white muscle, liver and eye were taken from each individual and stored at  $\ensuremath{-}40^0 C$  until further treatment. Allozyme analysis was carried out employing standard horizontal starch-gel electrophoresis. Fourteen enzymic systems coding for a total of 20 (16 in *P. erythrinus*) putative loci were analysed for each species except for hake where 12 loci were analysed. The electrophoretic data were analyzed using BIOSYS-1 [3]. For the purposes of DNA analyses, DNA was extracted from muscle tissue following protocols reported in Mamouris et al [4]. RAPD analyses were performed using initially 40 decamer primers, 5-10 of which were used for intraspecific analyses. Experimental conditions as well as data analyses for the RAPD method are documented in Mamuris et al [4]. Finally, mitochondrial DNA variation was analysed by restriction fragment length polymorphisms (RFLPs) performed on four PCR-amplified mtDNA regions: control region (D-loop), COI, 12S-16S rRNA and cytochrome b. The amplified segments from each specimen were subsequently screened for polymorphism with 15 restriction endonucleases. The restriction site pattern data was analysed using the REAP [5] computer packages.  $N_{ST}$  [6] was used to estimate the degree of population subdivision at the nucleotide level within each species.

# Results and Discussion

Mean heterozygosity is considered the most important way of measuring genetic variation. The results of the present study revealed that the values of heterozygosities and nucleotide diversities found from allozyme/RAPD

and mtDNA analyses, respectively, were above the average values found for other marine teleosts using the same methods. For example the values of the observed heterozygosity found from allozyme analyses range from 0.062 to 0.137 while the average for all marine teleosts has been estimated as 0.064 [7]. The large values of heterozygosities imply that the populations studied have had a long unbroken history in the area without population bottlenecks.

None of the three methods used for each of the four species studied succeed to yield any diagnostic marker that could lead to unambiguous identification of the various geographical populations. Regardless of the method used, genetic population subdivision was not evident for any species within the Pagasitikos Gulf, suggesting homogeneity within the Gulf. On the other hand, there was some evidence of genetic population subdivision between localities from within and outside of the Pagasitikos Gulf. The estimated values (through allozyme and RAPD analyses) of effective migration rates (Nem) for the populations sampled range from 6.2 to 9.7 depending of the method used. These values were much smaller than the mean value for marine fishes (Nem=22.76) but they were close to those estimated for other marine species in the Mediterranean Sea [1]. These values of effective migration rates were small enough to allow significant divergence of gene frequencies among samples, although large enough to counteract the effect of genetic drift if one assumes an infinite island model.

# THE BRYOZOA FAUNA OF BOZCAADA ISLAND (NE-AEGEAN SEA)

Herdem Aslan Cihangir

Canakkale Onsekiz Mart University, Faculty of Fisheries, Canakkale, Turkey - asherdem@comu.edu.tr

# Abstract

The Bryozoa of Bozcaada Island (NE Aegean Sea) were studied at 11 stations during 2000-2001. Bottom depths of the stations ranged from 0.5-40 m. The samples were collected by means of dredging, drift netting, bottom trawl and scoop netting. Sixteen species, belonging to 12 families, were identified, in total, 46 species are known from Bozcaada Island.

Keywords : Bryozoa, Aegean Sea, Dardanelles.

# Introduction

Bryozoans have an abundant fossil record stretching back over 400 million years. In aquatic habitats, bryozoans may be found on all types of hard substrates: sand grains, rocks, shells, wood, and blades of kelp and other algae may be heavily encrusted with bryozoans. While some species have been found at depths of 8200 meters, most bryozoans inhabit much shallower water.Most bryzoans are sessile and immobile, but a few colonies are able to creep about, and a few species of non-colonial bryozoans live and move about in the spaces between sand grains. Bryozoans feed on small microorganisms, including diatoms and other unicellular algae. These are trapped by the protrusible ciliated feeding tentacles, or lophophore. In turn, bryozoans are preyed on by grazing organisms such as sea urchins and fish, and are also subject to competition and overgrowth from sponges, algae, and tunicates [1].

The Aegean Sea is one of the four major basins of the Eastern Mediterranean. In the north it is connected to the Black Sea through the Strait of Dardanelles, the Sea of Marmara and the Strait of Bosphorus, and in the south to the Ionian Sea and the Levantine Sea, which are two of the other major basins of the Eastern Mediterranean.

Bozcaada Island which is located of the Aegean Sea  $(39^{\circ} 47' 30" - 39^{\circ} 50' 90"N)$ , and  $25^{\circ} 57' 80" - 26^{\circ} 05' 00" E)$  has an area of 42 km<sup>2</sup> and is situated nearly 5 km off the coast of the mainland, between the Strait of Dardanelles and Bababurnu (Figure 1).

Unsal, 1975 [2] studied Bryozoa species and reported 112 species from all of the Turkish coast and 35 species of them were from Bozcaada Island.

# Materials and Methods

The samples were obtained during 2000 and 2001 from 11 stations (Fig. 1) at the depths of 0.5-40 m by dredging, drift netting, bottom trawling and scoop netting.

Fig. 1. The maps of the Agean Sea and Bozcaada Island.

Samples were sieved with 0.5 mm mesh size. The residuals on the mesh were fixed in 3% formalin solution. In the laboratory Bryozoa were then sorted under magnification, preserved in 70% alcohol and identified to species level.

#### Results

A result of this study, totally 16 Bryozoa species belonging to 12 families were determined from Bozcaada Island. These species were as follows: *Crisia eburnea* (Linnaeus, 1758), *Idmonea bidenkapi*Kluge, 1955, *Aetea truncata* (Landsborough, 1852), *Electra crustulenta*(Pallas, 1766), *Electra monostachys* (Busk, 1854), *Caberea boryi* (Audouin, 1826), *Adeona vio-*

lacea (Johnston, 1847), Fenestrulina malusii Audouin, 1826, Cryptosula pallasiana (Moll, 1803), Calpensia nobilis (Esper, 1796), Reteporella couchii (Hincks, 1878), Reteporela beaniana (King, 1846), Hippaliosina depressa (Busk, 1854), Alcyonidium mamilatum Alder, 1857, Alcyonidium polyoum (Hassal, 1841), Mimosella gracilis Hincks, 1851.

#### Discussion

Eight species were newly recorded for Bozcaada Island. Unsal [2] reported 35 species from Bozcaada Island, so in total 43 species are now known from Bozcaada Island.

Ünsal [2] reported 130 Bryozoa species from the Turkish Seas. On the other hand, 255 species are known from the Ionian Sea, the Aegean Sea, the Black Sea and the Levantine Seas [3]. While Italian Seas bryozoans where 305 species have been recorded [4], the total number of recorded species is 222 from the Eastern Adriatic [5]. Since around 400 species have been recorded in the Mediterrenean so far, future research is expected to yield more species in the Eastern of Mediterranean Sea.

# ÉTUDE DESCRIPTIVE DE L'INFESTATION DE LA PALOURDE (*RUDITAPES DECUSSATUS*) À *PERKINSUS OLSENI* DANS LE LAC DE BIZERTE EN TUNISIE

Hédia Attia El Hili \*, Chefik Ben Salah , Wassila Ayari and Naima Ben Amor Unité de Pathologie des Animaux Aquatiques, INSTM, 2025-Salammbô-Tunisie - hedia.attia@instm.rnrt.tn

# Résumé

Un suivi de l'infestation parasitaire de la palourde *Ruditapes decussatus* à *Perkinsus olseni* (protozoaire, *Apicomplexa*) au lac de Bizerte a été effectué pendant deux ans (2004-2006). Les prélèvements ont été réalisés au niveau de deux sites de production naturelle : Faroua et Menzel Jemil. La méthode d'analyse utilisée est l'histologie. Les résultats ont montré que la prévalence de cette parasitose varie notablement aussi bien dans le temps que dans l'espace. Cette variation est indépendante de la taille, du sexe et du stade de maturité sexuelle de la palourde, ce qui suggère l'influence d'autres paramètres du milieu. *Mots clès : Bivalves, Lagoons, Parasitism.* 

# Introduction

La palourde (*Ruditapes decussatus*) est présente dans le lac de Bizerte (nord de la Tunisie) surtout dans les secteurs nord est (Menzel Jemil) et nord ouest (Faroua). Sur le plan économique, elle est considérée l'espèce de mollusque bivalve la plus importante pour le pays. Elle fait par conséquent l'objet d'une surveillance zoo sanitaire pour la recherche d'une maladie à déclaration obligatoire: La Perkinsiose dont l'agent pathogène est *Perkinsus olseni* (protozoaire, *Apicomplexa*). Le présent travail n'est qu'une analyse rétrospective des résultats obtenus après deux années de surveillance. Il a consisté à suivre l'évolution spatio-temporelle de cette parasitose et à étudier les paramètres qui en sont influents. Ainsi, nous avons cherché des éventuelles associations entre les prévalences de l'infestation parasitaire et certains paramètres biologiques de la palourde comme la taille, le sexe et le stade de maturité sexuelle.

#### Matériel et méthodes

Le suivi a été réalisé pendant une période qui s'est étalée de janvier 2004 à janvier 2006. Les prélèvements ont été effectués dans le lac de Bizerte au niveau de deux sites (Menzel Jemil et Faroua). Les échantillons, composés chacun d'une cinquantaine d'individus, ont été prélevés tous les six mois (hiver et été). Pour chaque palourde, nous avons déterminé la taille et fixé les organes dans une solution de Davidson pour une étude histologique. L'examen microscopique de chaque coupe nous a révélé le sexe, le stade de maturité sexuelle ainsi que la présence éventuelle du parasite. En fonction de l'état de maturité des gamètes, nous avons fixé trois stades de maturité sexuelle à savoir le stade A: sexe indéterminé (absence de gamètes), le stade B: gamètes non mâtures et le stade C: gamètes mâtures.

Fig. 1. Variation de la prévalence de la perkinsiose et de la moyenne des tailles des échantillons de palourde *Ruditapes decussatus* au niveau Menzel Jemil (MJ) et Faroua (F).

# Résultats et discussion

Les prévalences de l'infestation parasitaire au site Menzel Jemil sont plus importantes que celles du site Faroua (figure 1). Cette différence est significative uniquement pendant les trois premières campagnes (p<0,001). Ces résultats signifient que la différence de prévalence entre le site Faroua et le site Menzel Jemil ne serait pas liée à la période de prélèvement (hiver, été). Par ailleurs, la comparaison annuelle et saisonnière des prévalences de l'infestation parasitaire au niveau de chaque site ne montre une différence significative qu'en juin 2005 pour les palourdes du site Menzel Jemil et

qu'en janvier 2006 pour les palourdes du site Faroua (p <0,001). Ceci indique que le facteur saison ou année ne serait pas associé aux prévalences de l'infestation à Perkinsus olseni. Certes, ces résultats concordent avec certains travaux [1,2] mais, d'autres études [3,4] ont enregistré une variation saisonnière significative des prévalences de l'infestation à Perkinsus. Les données biologiques relatives au sexe et aux stades de maturité sexuelle ont montré qu'en période estivale la majorité des individus sont mâtures. Cependant, leurs variations ne sont pas liées aux prévalences de l'infestation parasitaire. De même, la figure 1 montre l'absence de corrélation entre les moyennes des tailles des échantillons et les prévalences de l'infestation parasitaire. Ces résultats nous incitent, par conséquent, à considérer d'autres facteurs tels que les fortes densités des palourdes qui accroîtraient le taux de transmission des parasites et les paramètres physico - chimiques de l'eau qui moduleraient le cycle de vie parasitaire. Il serait ainsi intéressant de vérifier ces deux hypothèses, sachant que des travaux récents [5] ont indiqué que les deux sites de prélèvement, étant très influencés par les eaux de ruissellement, sont différents sur le plan physico-chimie. De plus, le site Faroua, de part sa situation géographique, est dominé par les entrées d'eau salée du canal qui relie la lagune à la mer.

#### Conclusion

La variation des prévalences de la perkinsiose dans le temps et dans l'espace ne serait liée ni à la taille ni au sexe ni au stade de maturité sexuelle de la palourde. Les caractéristiques physico-chimiques de l'eau qui sont *a priori* différentes au niveau des deux sites de prélèvement ainsi que les densités de la population hôte pourraient influer les prévalences et expliquer la variation spatio-temporelle de cette parasitose.

# VARIATION SAISONNIÈRE DU RYTHME LOCOMOTEUR DE *TALORCHESTIA DESHAYESII*, ISSU DE LA PLAGE DE BIZERTE (TUNISIE)

Amel Ayari \* and Karima Nasri-Ammar

Unité de recherche "Biologie Animale et Systématique Evolutive ", Faculté des Sciences de Tunis, Campus Universitaire de Tunis El Manar I 2092, Tunis, Tunisie. - ayari\_amel13@yahoo.fr

# Résumé

Le rythme de l'activité locomotrice de *Talorchestia deshayesii* (Amphipode, supralittoral) a été enregistré au niveau de la population de Bizerte (Nord de la Tunisie). L'étude de la variation saisonnière des caractéristiques du rythme locomoteur a montré une période circadienne plus longue au printemps et un temps d'activité plus étendu en automne. Par ailleurs, l'étude du rythme de l'activité locomotrice des animaux expérimentés a révélé l'existence d'une composante circatidale dont la période est proche de12 heures. *Mots clès : Behaviour, Crustacea, Supralittoral.* 

# Introduction

*Talorchestia deshayesii* est un Amphipode nocturne [1] qui vit dans l'étage supralittoral le long des côtes sableuses de la Méditerranée et de l'Atlantique orientale. Ce talitre occupe la même niche spatiale qu'un autre talitridé, *Talitrus saltator* [2]. Le but de ce travail est d'évaluer la persistance et la précision du rythme endogène de cette éspèce face aux fluctuations saisonnières.

# Matériel et Méthodes

L'activité locomotrice de cette espèce a été enregistrée chez une population issue de la plage de Bizerte (Nord de la Tunisie), au mois de septembre (photophase naturelle = 12h16) et au mois de mai (photophase naturelle = 14h14). Les individus adultes, ont été collectés à main nue et ont été transférés, au laboratoire, individuellement dans des actographes. Ces derniers sont placés dans une enceinte climatique qui permet de contrôler aussi bien la température que la photopériode.

Les individus de *Talorchestia deshayesii* ont été maintenus sous une température constante de  $18\pm0.5^{\circ}$ C. Ces spécimens ont été d'abord, soumis à la photopériode naturelle (sous le cycle nLD) du jour de la collecte puis ils ont été maintenus en libre cours (obscurité continue).

#### Résultats et discussion

L'analyse des actogrammes en double plot, ainsi que les courbes d'activité locomotrice moyenne par heure et par jour ont permis de mettre en évidence une sensibilité plus importante des individus testés vis-à-vis de l'aube expérimentale et ceci quelque soit la saison considérée (Fig.1).

Fig. 1. (a) Actogramme en double plot et (b) courbe d'activité moyenne/h/j ; la barre noire représente la nuit expérimentale.

L'étude des caractéristiques du rythme de l'activité locomotrice (période circadienne sous cycle nLD ; période circadienne en libre cours; stabilité du rythme (SNR) ; pourcentage de rythmicité, rapport temps d'activité/temps de repos et déphasage), a montré que quelque soit la saison (automne ou printemps), le taux de rythmicité circadienne de *Talorchestia deshayesii* est sensiblement le même aussi bien en obscurité continue (DD) qu'en conditions d'entraînement (alternance lumière/obscurité) ; il est supérieur ou égal à 87%. Par contre l'analyse statistique (test non paramétrique de Wilcoxon) a révélé que le temps d'activité et la période circadienne du rythme locomoteur sont significativement plus courts en automne qu'au printemps, et ceci quelque soit le régime photopériodique imposé (Tableau1). De même, la stabilité du rythme de cette espèce (calculée à l'aide du rapport SNR= Signal Noise to Ratio) la plus élevée, est observée au printemps (Tableau1). Par ailleurs, les individus présentent une avance et un retard de phases respectivement en automne et au printemps. La différence entre les déphasages moyens des deux saisons est hautement significatve.

Tab. 1. Variabilité saisonnière des caractéristiques du rythme locomoteur de *Talorchestia deshayesii*. LD : alternance lumière/obscurité ; DD : Obscurité continue ; SNR : Signal Noise to Ratio.

|             |     | Automne               | Printemps             | Test Wilcoxon |
|-------------|-----|-----------------------|-----------------------|---------------|
| Période     | LD  | $\tau = 23h20\pm1h01$ | $\tau = 23h52\pm0h40$ | p< 0.01       |
| circadienne | DD  | $\tau = 23h54\pm0h28$ | $\tau = 24h30\pm0h19$ | p≺ 0.05       |
| SNR         | LD  | 0.262±0.079           | 0.415±0.190           | p≺ 0.05       |
| Temps       | LD  | 932±135               | 608±176               | p< 0.01       |
| ďactivité   | DD  | 786±208               | 565±117               | p≺ 0.05       |
| Déphasage   | Į , | 169±118               | -135±124              | p< 0.01       |

L'allongement de la période circadienne et le raccourcissement du temps d'activité peuvent être expliqués par l'augmentation de la photophase naturelle durant le printemps ; la scotophase devenant de plus en plus courte, les individus ajustent leur activité locomotrice nocturne en fonction de ces variations.

<sup>3</sup> ICRAM, Central Institute for Marine Research, Rome, Italy

# Abstract

This paper summarizes some observations on gonad development and fecundity of the Lessepsian migrant Siganus luridus (Osteichthyes: Siganidae), recently settled in the islands of Malta and Linosa (Sicily strait, Mediterranean sea). The analysis of ovarian and testicular development showed that these early colonizers attain final gonad maturation and have the potential for successful reproduction. Keywords : Sicilian Channel, Fishes, Water Convection.

# Introduction

Siganus luridus (Osteichthyes: Siganidae) is an Indo-pacific species which entered into the Mediterranean through the Suez Canal [1], becoming one of the most successful exotic fishes in this sea [2]. Recently, the finding of new settled populations in the Sicily strait [3] offered a valuable opportunity for studying a Lessepsian migrant during the early phases of colonization [4]. As far as we know, these individuals, together with Tunisian siganids [5] represent the westernmost propagules of the species in the Mediterranean.

# Materials and Methods

The study is based on a sample of 49 individuals (13.5-24.6 cm total length) captured in Linosa (N=43) and Malta (N=6) in July-August 2003 and October 2006, respectively. These specimens represented the first siganids to be recorded in these two islands. Gonads were processed trough routine histological analyses; oocyte dynamics were reconstructed by oocyte size frequency histograms and fecundity estimates were made on (N=11) ripe ovaries, according to the gravimetric method. Gonads were staged on the basis of macroscopic [2] and microscopic [4] criteria and follicular atresia was estimated by counting the number of atretic follicles included in 10 sectors of 0.39 mm<sup>2</sup> randomly selected in the histological sections.

# Results and Discussion

Both males and females had reached final stages of gonad maturation and reproductive behaviors were observed. In August at Linosa, mature individuals were represented by a number of 8 ripe (13.8-17.0 cm TL) and 4 spawning (16.5-21.8 cm TL) females plus N=20 running males (13.5-24.5 cm TL); in October at Malta, a number of 3 ripe females (23.8-24.6 cm TL) plus 2 running males (23.0-24.0 cm TL) were found.

Fig. 1. Size frequency distribution of secondary growth oocytes in (N=6) ripe S. luridus captured in August at Linosa (a) and in October at Malta (b). N=500 oocyte/ovary were measured.

Absolute fecundity ranged from 115,739 to 740,433 oocytes per female and relative fecundity ranged from 1,239 to 3,162 oocytes  $g^{-1}$ . Fecundity of Linosa and Maltese individuals were within the range of values found in a Lebanese population [2]. The atresia rates in these new colonizers appeared moderate and analogous to what is known for other teleost species during the pre-reproductive stage [6]. In developing and ripe females, the percentage of secondary growth phase oocytes (SGP) in atresia was

always below 15%, with the exception of a female which presented the 46.7% of attetic SGP. Attetic oocytes were not detected in immature nor in spawning females.

As emerged by oocyte size distribution analyses, females at advanced maturity stage presented a bimodal size frequency distribution of SGP oocytes (Fig.1). This finding was validated by histological observations and indicated an ovarian development of the group-synchronous type. The comparison with Lebanese individuals [2] showed relevant differences in the distribution of maturity stages and suggests that the reproductive season of S. luridus in the Sicily strait could be delayed with respect to the eastern Mediterranean. To conclude, our results showed that S. luridus has the potential for successful reproduction in the newly colonized areas and indicated the potential of this species to spread across new sectors in the central and possibly western Mediterranean. It is clear that extensive temporal and spatial samplings would allow to a proper description of their reproductive cycle, but up to date, their small abundances both in Linosa [4] and Malta (Azzurro unpublished data) rendered this task impracticable.

# Abstract

This paper presents the preliminary results of the effects of sewage pollution on a shallow fish community along the NW coasts of Malta (Sicily strait, Mediterranean sea). Clear differences in the abundance, structure and composition of fish assemblages were highlighted by means of univariate and multivariate analyses. At the sewage outfalls, the decline in species richness testified the severity of the impact, moreover the great increase of two benthic fishes gave evidence of enduring alteration in the fish community. *Keywords : Fishes, Sewage Pollution, Sicilian Channel.* 

#### Introduction

Sewage discharges are known to have profound effects on diversity, abundance and structure of Mediterranean coastal fish communities [1,2]. To assess these effects, "BACI" designs (Before-after control-impact) are the ideal tools but often the "before impact" data are missing and "after" study are the only way to detect some aspects of disturbance. Our purposes were to assess the effects of two sewage outfalls on the rocky-reef fish community along the NW coast of Malta.

# Materials and Methods

Underwater visual censuses were performed, between 5 and 8m of depth, at fixed point of a standard surface of  $25m^2$ [2]. This technique was chosen among the available visual methods as the most appropriate in highly heterogeneous substrata. Surveys were carried out at four locations on the NW Maltese coasts: two putatively disturbed locations (where the outfalls directly discharge waste waters on the coastline) and two controls. At each location, four sites were randomly selected and four repeated censuses were performed. Abundance data were analyzed by means of univariate (one-way ANOVA) and multivariate (nMDS, PERMANOVA and SIMPER) procedures. Based on the null-hypothesis that there are no differences between disturbed and control areas, a PERMANOVA design was created on two factors (Disturb, fixed with two levels and Site, random nested in Disturb with four levels).

#### Results

Overall 41 fish taxa were identified. The nMDS plot (Fig. 1) showed a good separation (Stress = 0.18) between fish counts at disturbed (D) and control (C) sites. A symmetrical PERMANOVA (Table 1) provided evidences for significant differences both for factor Disturb and for Location.

Fig. 1. Non-metric Multidimensional Scaling (nMDS) ordination plot comparing fish assemblages from sewage-disturbed locations (D1 and D2) and control (C1 and C2) locations. Centroids of single sites are represented.

According to SIMPER procedure, the average dissimilarity between the two groups was 78%. *Gobius bucchichi* and *Parablennious rouxi* were the most typifying species in disturbed locations, whilst *Oblada melanura* and *Symphodus roissali* contributed mostly to the similarity of the controls. One-way ANOVA detected significant differences in species richness and total abundance between the two groups. Total abundance resulted higher in D than at C whilst species richness showed the opposite pattern. Significant differences also occurred among single locations.

Tab. 1. PERMANOVA based on the Bray-Curtis dissimilarities of log (x+1) transformed data (41 taxa).

#### Discussion

The present study provided evidence that the two sewage outfalls affect assemblage structure and fish abundances. According to the few studies which dealt with the sewage impact on Mediterranean fish communities [1,2], these changes may be mostly ascribable to the increase of nutrients and particulate organic matter due to the outfalls. At moderate levels, this enrichment can influence the fish assemblage by attracting gregarious and planktivorous fishes and our results showed a small but significant increase of the abundances of these species (e.g. *Chromis chromis* and *O. melanura*). However, the most striking differences were related to the decline in species richness which usually reflects a severe impact on fish community [1]. Fishes such as the labrids *Simphodus spp, Thalassoma pavo* and the sexard *Sparisoma cretense* resulted to be particularly affected by the sewage. Some ecological requirements of these species were probably not satisfied in the polluted areas, e.g. food availability and nesting grounds.

At the disturbed locations, the high abundance of *G. bucchichi* and *P. rouxi* resulted to be remarkable. In fact, the mobility of these benthic fishes is minimal and they are reliably indicators of the effect of different levels of sewage impact [1]. To conclude our results highlighted profound alterations to the marine environment caused by the sewage outfalls. Given the reasonable inconceivability of these sources of pollutions with the need of environmental protection and tourist activities, appropriate measures should be taken, in accordance with the current guidelines.

# DIET OF THE LESSEPSIAN *FISTULARIA COMMERSONII* (TELEOSTEI, FISTULARIIDAE) OFF THE COAST OF LEBANON: PRELIMINARY RESULTS

Michel Bariche

Department of Biology, FAS, American University of Beirut, Lebanon - michel.bariche@aub.edu.lb

# Abstract

Stomach content analysis showed that *F. commersonii* preys exclusively upon fish, mainly Atherinidae, Sparidae, Centracanthidae and Blenniidae. The seasonal variation showed a preference for anchovies in summer, blennies in autumn and silversides in both winter and spring. *F. commersonii* seems to feed mostly on native Mediterranean fish regardless of the habitat type in which it lives in. *Keywords : Diet, Teleostei, Species Introduction, Levantine Basin, Eastern Mediterranean.* 

# Introduction

The opening of the Suez Canal (1869) removed a natural biogeographic barrier which separated the temperate Atlantico-Mediterranean biota from the Indo-Pacific organisms of the Red Sea. This connection resulted in a massive introduction of marine organisms (Lessepsian migration) into the eastern Mediterranean [1, 2]. *Fistularia commersonii* Rüppell, 1838 is a Lessepsian fish that has established large populations in the eastern basin and has been spreading towards the western Mediterranean Sea [3, 4]. The purpose of this study was to examine the stomach contents of the invasive predator as a first step towards assessing its feeding ecology in the new environment.

# Material and methods

Sampling took place from May 2003 to April 2004 in different localities off the coast of Lebanon. Measurements included total fish length (T<sub>L</sub>) and gutted fish weight (W<sub>G</sub>), and all prey items were identified to the lowest taxon possible. Percentage frequency of occurrence (%F), percentage composition by number (%Cn), percentage composition by weight (%Cw), and the index of relative importance (IRI) were calculated [5]. Prey items were separated into "bottom" *vs.* "water column" species according to the environment in which they live.

Results and discussion

A total of 156 *F. commersonii* specimens were collected. Size varied between 36.2 and 112.1 cm T<sub>L</sub> (79.60  $\pm$  14.79 cm TL) with 80-90 cm T<sub>L</sub> being the most frequent size-class. W<sub>G</sub> varied between 22.3 and 1033.2 g (371.85  $\pm$  198.63 g).

Sixteen families, represented by 21 species of fish prey, were identified from the stomach contents. Atherinidae represented 16.6% of the total number of prey ( $(N_{TP})$  ingested; Blenniidae (14.1%) and Engraulidae (10.1%). Sparidae, Centracanthidae and Labridae were found at 8.2, 8.1 and 4.6% respectively (Table 1). The majority of the identified food items were fishes native to the Mediterranean Sea; Lessepsian prey were *Atherinomorus lacunosus, Callionymus filamentosus, Siganus luridus* and *S. rivulatus* and accounted for only 3.3% of fish prey. This showed that the earlier presence of Lessepsian prey in the Mediterranean was not one

of the reasons for the success of *F. commersonii* in its new environment. Atherinidae and Sparidae showed the highest %F, with respectively 14.7% and 11.5%. They were followed by Centracanthidae and Blenniidae. In contrast, Labridae, Engraulidae and Gobiidae had a lower %F, despite their relative high presence in the examined stomachs (Table 1). Similarly %Cn, %Cw and %IRI showed that Atherinidae, Sparidae, Centracanthidae and Blenniidae were the most represented families by number and in terms of biomass.

Seasonal fluctuation of ingested prey showed a clear temporal pattern where one species *E. encrasicolus* (Engraulidae, 38.7%) was favoured in summer and *A. lacunocus* in winter (Atherinidae, 38.5%) and spring (Atherinidae, 56.9%). Blenniidae (34.5%) was the most represented prey in autumn. Centracanthidae seemed to be an important forage fish in the diet during most of the year (summer to winter) (Fig. 1).

Fig. 1. Seasonal variation of F. commersonii diet based on % F values.

"Water-column" species represented 59.1% of the consumed prey, mainly Atherinidae (22.7%), Engraulidae (13.8%), Centracanthidae (11.1%) and Sparidae (7.1%). "Bottom" species represented 40.9% with Blenniidae (19.1%), Labridae (6.2%) and Gobiidae (4.5%) being the most important ones. No significant differences (Wilcoxon test, P>0.05) existed between the two habitat groups. This implies that *F. commersonii* does not feed selectively in any of the two habitats considered, which might be one of the reasons for its success in the Mediterranean.

# Abstract

Food composition of common guitarfish (*Rhinobatos rhinobatos*) was studied in the Iskenderun Bay (northeastern Mediterranean). A total of 115 common guitarfish were caught and examined. Fish ranged in total length (TL) from 39 to146 cm and in weight between 121 and 13042 g. Males ranged from 39 to 124 cm TL, while females ranged between 42 and 147 cm TL. Of the fish examined, 49 individuals (43%) were males and 66 (57%) females. Out of 115 stomachs examined, 18 (15.7%) were empty, and 97 (84.3%) contained prey. A total of 392 prey items, belonging to 14 prey taxa, were counted. The main prey items found in the stomachs were unidentified shrimps (IRI%=35.89), unidentified teleosts (IRI%=34.51), unidentified crabs (IRI%=16.91), *Squilla mantis* (IRI%=5.11), and *Crangon crangon (IRI*%=4.69). Overall, the food of *R. rhinobatos* in the study area was mainly consisted of crustaceans (IRI%=72.04). *Keywords : Diet, Elasmobranchii, Eastern Mediterranean*.

# Introduction

Elasmobranchs are among the top predators in the marine environment, thus affecting the populations of both fish and invertebrates at the lower trophic levels [1]. Information on feeding habits of species contributes to a better understanding of the trophic dynamics and food webs, which is essential for fisheries management [2]. The common guitarfish (*Rhinobatos rhinobatos*) is a shallow water bottom-living elasmobranch found in the Eastern Atlantic, including the Mediterranean. The purpose of this study was to examine the feeding habits of common guitarfish caught in the Iskenderun Bay (Northeastern Mediterranean).

# Material and Methods

Specimens were caught with longlines and otter trawl at depths 20 -120 m in all seasons in the Iskenderun Bay (36°33' N - 35°34' E, 36°18' N -35°46' E, 36°54' N - 36°00' E, 36°35' N - 36°11' E) from April 2004 to May 2005. Stomachs with contents were placed in plastic bags and frozen for subsequent analysis. The gross stomach contents were noted and whenever possible, the fish remains were identified to species level. Account was taken of the fullness of the stomach. Prey groups were weighed to the nearest 1 g. Stomach content was analyzed using the percentage frequency of occurrence (O%), numerical percentage (N%), percentage by weight (W%), the index of relative importance (IRI), and percent of IRI (IRI%) for each prey type [3, 4]. The weights of the digested prey were estimated with two ways (1) length-weight relationships from the literature (e.g., www.fishbase.org) were used for calculating the weight of species having measurable parts (carapace width, vertebrae length or cephalothorax length) in the stomachs, and (2) the mean weight of the species found in the stomachs as a whole were used for estimating the weight of some digested species [5].

#### Results

A total of 115 common guitarfish were caught and examined. Fish ranged in size from 39 to 146 cm (TL) and in weight between 121 and 13042 g. Males ranged from 39 to 124 cm TL, while females ranged between 42 and 147 cm TL. Of the fish examined, 49 individuals (43%) were males and 66 (57%) females. Out of 115 stomachs examined, 18 (15.7%) were empty, and 97 (84.3%) contained prey. A total of 392 prey items, belonging to 14 prey taxa, were counted. The main prey items found in the stomachs were unidentified shrimps (IRI%=35.89), unidentified teleosts (IRI%=34.51), unidentified crabs (IRI%=16.91), *Squilla mantis* (IRI%=5.11), *Crangon crangon* (IRI%=4.69) and other species (IRI%=2.90).

# Discussion

Generally, skates and rays are benthic feeders, eating organisms such as small fish, mollusks, crustaceans and worms [1, 6]. Beretovski [6] concluds that skates could not feed in the water column because of their morphology and suggests that pelagic fishes traumatized by trawls in the fishing grounds were subsequently preyed upon by skates. However, some researchers state that rays are active predators and able to feed semipelagically [7, 8]. According to Parin [8], the ability of skates to hunt in the water column, even reaching the sea surface, is well known.

In the current study, pelagic species were also found in the stomachs. The total IRI% of the identified pelagic species was 1.57. Differences in diet

composition of species reflect the faunal composition of the region [9]. Consequently, it may be concluded that common guitarfish do prey upon bony fishes and crustaceans, and is an indiscriminate predator preying upon those species that are most abundant and available in the area and season.

# DIET COMPOSITION OF THE CHUB MACKEREL, *SCOMBER JAPONICUS* (PISCES: SCOMBRIDAE), IN CANDARLI BAY (AEGEAN SEA, TURKEY)

Bahar Bayhan \*, Tuncay Murat Sever and Murat Kaya

Ege University, Faculty of Fisheries Department of Hydrobiology, 35100 Bornova, Izmir-Turkiye - bahar.bayhan@ege.edu.tr

# Abstract

Stomach contents of 223 *Scomber japonicus* specimens collected from Candarli Bay, Aegean Sea (Turkey) have been analyzed. Overall, crustaceans (copepoda and amphipoda) were the most significant prey in terms of IRI%, followed by teleosts and thaliaceans. *Keywords : Aegean Sea, Fishes, Diet.* 

# Introduction

The chub mackerel, *Scomber japonicus* Houttuyn, 1782, is a cosmopolitan species inhabiting the warm and temperate transition waters of the Atlantic, Indian and Pacific oceans, as well as in their adjacent seas [1]. Chub mackerel is a commercially important pelagic species of the Turkey seas.

Because of the worldwide importance of the chub mackerel fishery, several studies have been carried out mainly related to its biology and feeding regime [2, 3, 4, 5]. Quantitative studies on its feeding ecology are scarce in Turkish coast. The biology of *S. japonicus* inhabiting the Sea of Marmara has been studied in [6, 7] and [8] studied the diet composition of juvenile chub mackerel in Izmir Bay (Aegean Sea).

The purpose of the present study is to examine the diet of chub mackerel on the Candarli Bay (Aegean Sea coast of Turkey), with a quantitative determination of the food based on the seasonal analysis of stomach contents.

### Material and Method

Scomber japonicus specimens, with total lengths ranging from 13.20 to 25.40 cm, were sampled seasonally during 2005 from commercial purseseine boats operating in Candarli Bay. Candarli Bay, located between the coordinates  $38^{\circ}$  43.8' N -  $39^{\circ}$  01.8' N and  $26^{\circ}$  32.0' E -  $27^{\circ}$  07.2' E (Fig.1), is one of the most important fishing ground in the Aegean Sea. Stomachs were removed immediately from all of the fish after capture and preserved in 4% formalin for later analysis. A stomach was considered empty when the food items in the stomach weighed <0.01 g. Quantitative description of the diet followed [9]. Besides, IRI% was calculated in order to determine ratios of food groups in the stomach to overall food groups.

#### Results

The overall diet composition revealed that the chub mackerel fed mainly on crustaceans during all seasons except summer (Table 1).

Tab. 1. Diet composition of chub mackerel from the Aegean Sea during all seasons. (N%: percentage numerical; F%: frequency of occurrence; W%: percentage weight; IRI%: index of relative importance expressed as percentage).

# Abstract

Experimental fishing trials were carried out to compare the size selectivity of the 40 mm stretched diamond mesh size cod-end, commonly used in the Italian waters, and the 60 mm stretched diamond mesh size cod-end. In total, 24 tows were carried out in summer 2003 and spring 2004 between 20 and 350 m depth. Selection curves were estimated through the covered cod-end method. The experimental net was more selective for most of the commercial species, showing a reduction of the percentage of retained fraction and a consistent increase of the  $L_{50}$  retention length.

Keywords : Demersal, Fisheries, Tyrrhenian Sea.

#### Introduction

Mediterranean trawling is typically multi-species. In addition to the target species, an important contribution to the commercial value of the catch is provided by the accessory species; most of the marketed species are of small size, as many cephalopods and crustaceans. This implies the use of gears with reduced selectivity, especially in the case of trawling. A previous study in the same area showed the high multi-specificity of the commercial landing and the importance of discards in trawl activity [1]. In the context of the reform of the EU Common Fisheries Policy, in 2003 the Commission proposed a regulation concerning management measures for the sustainable exploitation of fishery resources in the Mediterranean Sea based on the Community action plan for the conservation and sustainable exploitation of fishery resources in the Mediterranean Sea (COM(2002) 535 final of 9 October 2002). The proposal introduces technical measures to improve the selectivity of the current 40 mm mesh size for towed nets by increasing the minimum mesh size to 60 mm. The aim of the present study was to compare the selectivity parameters of the 40 mm commercial diamond mesh cod-end and of an experimental 60 mm mesh cod-end.

# Materials and methods

The study was performed in the northern Tyrrhenian Sea (western Mediterranean). Two trawl nets were used: a commercial net, provided with nominal 40 mm diamond mesh cod-end, and an experimental net, provided with a 60 mm diamond mesh cod-end.

Experimental trials have been carried out onboard of a demersal fishing vessel in summer 2003 and spring 2004, at depths ranging from 20 to 350 m. The nets were enclosed in an enveloping small mesh cover to trap the escaping fish. In order to maintain a good flow of water and to avoid the masking effect, the cover was held from the cod-end by means of two hoops placed outside the cover.

For each net, six 1-hour experimental hauls were carried out every season for a total of 12 hauls. The selection curve for each net, commercial and experimental, was estimated through the covered cod-end method [4]. The selectivity of the net was estimated by comparing the catches at length in the cod-end with those in the cover. Estimation of the 50% retention length ( $L_{50}$ ), of the selection factor (SF) and of the selection range (SR) were done by fitting the experimental data to a logistic curve using the SELECT statistical package (Trawl function package for R) [2, 3]. Due to the small number of specimens collected in most individual hauls, it was necessary to merge the survey data. The retained fraction R in the cod-end was estimated by the following equation:

 $R = [(N_{cod-end})/N_{total}] x 100, where N_{cod-end} was the number of specimens in the cod-end and N_{total} the total number of specimens caught (cod-end plus cover cod-end).$ 

#### Results and discussion

The species richness of the catches was not affected by the use of a larger mesh size in the cod-end. During the experimental trials, 142 species were caught, belonging to four major taxa: teleosts (88), crustaceans (28), cephalopods (20) and elasmobranchs (6). Table 1 shows the number of species caught in each survey, according to the major taxa.

The experimental net showed higher selectivity for most of the commercial species (Tab. 2), with a consistent decrease of the percentage of retained fraction. For almost all species, the  $L_{50}$  estimated from the 60 mm cod-end mesh size was higher than the  $L_{50}$  obtained from the 40 mm cod-end mesh size; in addition, the  $L_{50}$  from the 60 mm mesh was higher than the minimum landing size established by the EU regulation for the Mediterranean.

These results encourage further investigations on alternative methods, such as selection grids, square mesh panels, separator trawls, etc., to increase the escape of small sized fish.

The study was partially supported by the Italian Ministero Politiche Agricole e Forestali (contract number 6-B-2).

# ÉTUDE DES MACROINVERTÉBRÉS ASSOCIÉS ET ACCOMPAGNATEURS DE L'HERBIER DE POSIDONIE À *POSIDONIA OCEANICA* DANS LA RÉGION DE RAS JEBEL (NORD EST DE LATUNISIE)

Walid Belgacem and Oum Kalthoum Ben Hassine \*

Unité de Recherche de Biologie, Ecologie et Parasitologie des Organismes Aquatiques, Département de Biologie - Faculté des Sciences de Tunis, Tunisia - kalthoum.benhassine@fst.rnu.tn

# Résumé

Dans le présent travail, nous avons procédé à l'étude des macro invertébrés de l'herbier de posidonie, *Posidonia oceanica*, au niveau du site de Ras Jebel, localisé dans le Nord Est de la Tunisie, afin d'apprécier la richesse spécifique et l'état de ce dernier. Un échantillonnage saisonnier a été effectué durant la période allant de septembre 2004 à Août 2005. Au cours de ce suivil, nous avons identifié 152 espèces appartenant à 10 phylums.

Mots clès : Biodiversity, Phanerogams, Posidonia.

Les herbiers à *Posidonia oceanica* (L.) Delile sont largement répandus sur les côtes méditerranéennes [1]. Ils constituent des habitats permanents ainsi qu'une source trophique pour plus que 400 espèces végétales et plusieurs milliers d'espèces animales [2]. Cette importance écologique nous a incité à connaître la macrofaune benthique associée et accompagnatrice de cet herbier.

Les prélèvements ont été effectués au niveau de trois transects parallèles allant de la plage vers le large. Au total, 9 stations, localisées au niveau des trois transects, ont été prospectées. Elles sont réparties sur une profondeur qui varie de 1.5 à 5 m. Au niveau de ces stations, le prélèvement de la macrofaune a été réalisé au moyen d'un quadrat de 20 cm de côté [3]. Les prélèvements sont réalisés en scaphandre autonome. Une fois prélevés, les échantillons sont amenés au laboratoire, triés par ordre zoologique et identifiés. Par la suite, nous avons pris en compte divers indices écologiques pour caractériser l'état de l'habitat et du peuplement. Ainsi, nous avons calculé la richesse spécifique (nombre d'espèces), l'indice de Simpson (Is), l'indice de Shannon - Weaver (H') et l'indice d'équitabilité.

Ainsi, nous avons rencontré au total 152 espèces réparties comme suit : 1 Spongiaire, 2 Cnidaires, 62 Mollusques, 1 Bryozoaire, 1 Némertien, 3 Tuniciers, 9 Echinodermes, 4 Sipunculidés, 21 Annélides et 48 Crustacés. La richesse spécifique varie en fonction des saisons avec un maximum de 81 espèces pendant l'hiver et un minimum de 45 espèces durant l'automne. Au cours du printemps et de l'été, la richesse spécifique n'a pas beaucoup fluctué.

Le suivi saisonnier de l'indice de Simpson (Is) montre une variation de sa valeur entre un minimum de 23,54 bits, enregistré en été et un maximum de 27.51 bits observé en hiver. Ces résultats indiquent que 24 à 28 espèces ont les mêmes abondances durant toutes les saisons. L'importante valeur de l'indice de Simpson durant l'hiver est expliquée par le fait que les espèces sont représentées par un nombre élevé d'individus.

Le suivi des fluctuations de l'indice de Shannon - Weaver (H') en fonction des saisons (Tab. 1) révèle une valeur moyenne maximale égale à 5.39 bits en hiver, ce qui témoigne du nombre important d'espèces rencontrées pendant cette saison. La valeur moyenne minimale de cet indice, enregistrée durant toute la période d'étude, est égale à 4.92 bits. Cette valeur classe le site d'étude comme étant un secteur à peuplement normal [4].

Les valeurs moyennes de l'indice d'équitabilité, calculées en fonction des saisons, montrent un maximum automnal (0.89) et un minimum hivernal (0.84). Ces valeurs révèlent que la totalité des effectifs recensés se répartissent sur 84 à 89 % des espèces collectées.

En outre, nous avons remarqué que la valeur de l'indice d'équitabilité est toujours supérieur à 0.8 au niveau des différentes stations prospectées, ce qui indique que les différentes populations sont bien équilibrées dans les différentes profondeurs prospectées et durant toute la période d'échantillonnage.

Sur les côtes tunisiennes, plusieurs travaux se sont intéressés aux macro invertébrés associés à l'herbier de posidonie. Ces travaux ont été réalisés pendant l'année 2004 au niveau du grand golfe de Tunis. Sur les côtes de Port aux Princes, Ben Ismail [5] à identifié 87 espèces alors qu'au niveau du récif barrière de Sidi Rais, Telahigue [6] a récolté 84 espèces. Au niveau de la baie de Gammarth, le travail de Chabbi [7] a permis de révéler 66 espèces.

Comparé à ces travaux, nous constatons que le site étudié est caractérisé par une richesse spécifique très importante et par des indices écologiques qui témoignent des populations bien équilibrées. Ces résultats s'expliqueraient par les faibles activités anthropiques exercées sur les côtes de cette région. De ce fait, cette zone devrait faire l'objet d'un programme de protection contre toutes les activités anthropiques vu son importance écologique comme frayère sous marine.

Tab. 1. Variations saisonnières des indices écologiques dans la région de Ras Jebel durant la période d'échantillonnage.

# Résumé

Une analyse des paramètres synthétiques descriptifs des peuplements malacologiques da la lagune de Bizerte a été effectuée afin d'identifier les différentes associations faunistiques dans la lagune. La répartition spatiale de la richesse indique la présence de 93 taxons. L'analyse des divers indices écologiques révèle l'importance de la zone Ouest à Nord-Ouest sous influence marine caractérisée par des eaux plus fraîches, qui est la plus peuplée et qui présente une forte diversité malacologique. Mots clès : Biodiversity, Lagoons.

La lagune de Bizerte qui est la plus vaste étendue lagunaire du nord de la Tunisie, constitue un site d'un grand intérêt économique vu la présence de diverses activités (pêche, conchyliculture, agriculture, industrie, activités portuaires et militaires). Toutes ces activités engendrent nécessairement des nuisances par le déversement de différents produits chimiques et organiques dans les eaux de la lagune. Le benthos constitue un véritable piège à polluants d'où l'importance de son étude pour la biosurveillance des systèmes aquatiques.

L'échantillonnage de la macrofaune benthique a été effectué à travers une centaine de stations réparties selon un maillage régulier couvrant toute la lagune. Les échantillons ont été récoltés à l'aide d'une benne Van Veen pour les stations lagunaires et à l'aide d'un quadrat métallique (de 0,25  $m^2$ ) de surface pour les stations. Les échantillons recueillis sont tamisés, triés et enfin identifiés en se basant sur les manuels typiques de la macrofaune méditerranéenne [1,2, 3]. La diversité spécifique a été étudiée à trois niveaux : la recherche du nombre d'espèces d'une communauté ; la détermination de la densité totale (D) de ces différentes espèces et le calcul des indices de biodiversité : indice de Shannon (H') et Indice d'équitabilité (E).

L'inventaire spécifique de la faune malacologique de la lagune de Bizerte révèle la présence de 93 espèces réparties sur 3 classes et 41 familles. La richesse spécifique globale varie de 4 à 28 espèces par station avec des densités spécifiques allant de 0 à 15872 individus par mètre carré ; cette densité numérique est favorisée par les espèces de petite taille. L'indice de Shannon a varié entre 0 et 3.48 avec une tendance élevée au niveau du chenal ainsi que dans la partie Sud-Ouest de la lagune (Figure 1). Celui d'équitabilité reflète la même répartition (Figure 2)

Fig. 1. Répartition spatiale de l'indice de diversité de Shannon (bits)

Fig. 2. Répartition spatiale de l'Equitabilité dans la lagune de Bizerte

Nous avons distingué 2 principales zones:

- Des zones montrant des valeurs d'indice de Shannon et d'équitabilité maximales (H'>3bits et 0,8<E<1). Les peuplements appartenant à ces stations sont en état d'équilibre et présentent une très forte compétition interspécifique.

- Des zones où les valeurs de diversité de Shannon et d'Equitabilité sont très faibles (o<H'<1bits et 0<E<0.4), reflètent le caractère de stagnation d'eau et l'influence anthropique par la pollution. De telles conditions entraînent impérativement un très fort déséquilibre au niveau des peuplements expliquant ainsi les valeurs quasi nulles de l'équitabilité.

# TOWARDS A CENSUS OF TORRE GUACETO MARINE RESERVE MALACODIVERSITY THROUGH NO-IMPACT METHODS

Giambattista Bello \* and Alessandro Ciccolella

Area Marina Protetta Torre Guaceto, Via Sant'Anna 6, 72012 Carovigno (Br), Italy - giabello@libero.it

# Abstract

Methods with no impact on biocoenoses are being used in the Torre Guaceto Marine Reserve (Italy; south-western Adriatic Sea) to describe the biodiversity of its malacofauna. The results of a previous survey on death assemblages of stranded mollusc shells were complemented by data gathered by collection of washed ashore shells, underwater collection of empty shells, and underwater visual census. In this way 30 additional species (10 gastropods, 19 bivalves and 1 cephalopod) were recorded. The overall list of shelled molluscs presently includes 144 species: 96 gastropods, 46 bivalves, 1 scaphopod, and 1 cephalopod.

Keywords : Adriatic Sea, Biodiversity, Marine Parks, Mollusca.

Marine Reserves (MR) play an important role in the conservation of marine biodiversity. In order to observe possible changes in biodiversity it is necessary to monitor it through periodical surveys. Standard methods may be harmful to living organisms, hence methods have been developed to study marine biocoenoses that avoid harming biota, such as visual and photographic censuses [1]. In order to investigate the diversity of the malacofauna, one of the main components of the Mediterranean diversity [2], a no-impact method - examination of thanatomalacocoenoses - was tested in the Torre Guaceto MR (Italy, Brindisi province, SW Adriatic Sea). Such a method is based on fidelity, i.e. the manifold verified correspondence between the qualitative compositions of thanatocoenoses and nearby living malacocoenoses [3, 4]. The examination of mollusc shells found in death assemblages of a Torre Guaceto MR beach showed the presence of 114 different species: 86 gastropods, 27 bivalves, and 1 scaphopod [5]. Advantages and disadvantages of such a method have also been dealt with [6, 7]. Indeed, in the case of Torre Guaceto MR, some drawbacks of this technique to document the overall diversity of molluscs were apparent. An implied deficiency was the exclusion from the survey of all shell-less molluscs, which however are just a numerical minority (but photographic surveys of nudibranchs are underway.) An unforeseen and somewhat surprising weakness was the absence in the examined death assemblage

samples of many shelled molluscs common in the MR, mainly mediumand large-sized species (from a few to many cm). But also certain micromolluscs were absent, e.g. all members of the Caecidae (Gastropoda: Neotaenioglossa). In fact, most shells belonged to small size species (<1 cm) and only a small fraction was from juveniles of larger species; overall mean size = 5.1 mm [5].

Tab. 1. List of additional shelled molluscs recorded in the Torre Guaceto Marine Reserve. S: shells collected from the beach or the sea floor; A: alive individuals observed underwater.

In order to improve the checklist of Torre Guaceto shelled molluscs with-

out breaching the no-impact guiding principle, additional data were gathered through the following actions: A) collection of washed-ashore shells during beach-combing; B) hand collection of empty shells on the sea floor during underwater surveys; C) underwater visual census.

In all, 30 species - 10 gastropods, 19 bivalves and 1 cephalopod - were recorded in addition to those already found during the death assemblage survey [5]. They are listed in Table 1.

The checklist of shelled molluscs recorded in the Torre Guaceto MR presently contains 144 species: 96 gastropods, 46 bivalves, 1 scaphopod, and 1cephalopod. The species recorded correspond to about 22 and 58% respectively of the shelled gastropods and bivalves reported in the southwestern Adriatic Sea in the Checklist of the Italian marine fauna [8, 9]. However, one should note that the latter checklist includes many deepwater species, whereas the Torre Guaceto list comprises only infralittoral molluscs.

# BIODIVERSITY OF HARDBOTTOM COMMUNITIES GROWN ON ARTIFICIAL SUBSTRATA IN THE SARONIKOS GULF (AEGEAN SEA) - A PILOT STUDY

N. Bellou<sup>1</sup>, J. Canning-Clode<sup>2</sup>, K. Tsiamis<sup>1</sup>, M.-A. Pancucci-Papadopoulou<sup>1</sup>, P. Panayiotidis<sup>1 \*</sup>, M. Salomidi<sup>1</sup>, M.

Lenz<sup>2</sup>, M. Wahl<sup>2</sup>

<sup>1</sup> Hellenic Center for Marine Research, Institute of Oceanography, Athens, Greece <sup>2</sup> IFM-GEOMAR, Experimental Ecology, Kiel, Germany - ppanag@ath.hcmr.gr

# Abstract

In this pilot study, we monitored for the first time the biodiversity of hardbottom communities grown on artificial substrata in two shallow water habitats of the Saronikos Gulf, Greece. Here we report preliminary results from the analysis of assemblages that established at a disturbed and an undisturbed study site as well as a list of macrofouler species. This research was performed within the framework of the German-Greek collaboration for the advancement of knowledge exchange among young scientists (IKYDA, 2006). Keywords : Aegean Sea, Monitoring, Biodiversity, Artificial Reefs, Fouling.

Intertidal and shallow water subtidal coastal ecosystems are more impacted by human activities than any other marine habitat. Therefore, they can be a useful tool to measure human-induced changes in the marine environment [1]. One promising approach to detect and quantify these changes is to compare the composition and stability of hardbottom communities from impacted and non-impacted areas. The aim of this pilot study was to describe and analyse the structure of assemblages grown on artificial substrata that were deployed at a disturbed and an undisturbed site in the Saronikos Gulf.

#### Study sites

Settlement panels were exposed to natural fouling at two study sites in the Saronikos Gulf: Agios Kosmas (AGK) and Mavro Lithari (ML) (Figure 1). The Inner Saronikos Gulf is one of the most heavily polluted regions of the Greek coast, mainly due to domestic and industrial effluents [2]. Mavro Lithari lies in the Outer Saronikos Gulf far from these effluents, while Agios Kosmas is located only a few kilometres SE of Piraeus Port and has lately been heavily disturbed by the construction of the Sailing Center for the Olympic Games 2004 [3].

Fig. 1. Study sites in the Saronikos Gulf: Agios Kosmas (AGK) and Mavro Lithari (ML).

# Methods

At each study site 6 PVC carrier rings (each with 10 PVC settlement panels, 15 x 15 cm in size) were deployed in March 2006. The communities that established on these 60 settlement panels were sampled randomly every two to four weeks. All macrofouler species larger than 1 mm were identified and their abundances were estimated as percent cover.

In order to compare community structure between study sites, species number (N), the Shannon index (H', loge), and Evenness (J') were calculated for each sampling event. We tested for differences in mean community parameters with the t-test. Additionally, significant differences in community composition between sites were identified using Analysis of Similarity (ANOSIM) conducted on the base of the abundance data.

# Results and Discussion

Until the 10<sup>th</sup> week the assemblages at both sites consisted only of

biofilms. Macroufoulers were then observed from the 12<sup>th</sup> monitoring week on. A total of 29 macrofouling species were identified until the  $26^{t\tilde{h}}$ week (Table 1). Hydrozoa and the red alga Polysiphonia sp. were the first settlers and became dominant taxa in ML, while in AGK Serpulidae settled first and dominated the communities up to the 20<sup>th</sup> week.

Tab. 1. Species monitored on artificial settlement panels.

| Commo              | on to both sites        | May 10 Lithari         | Agios Kosmas              |
|--------------------|-------------------------|------------------------|---------------------------|
| Schizoporella sp.  | Cladophora sp.          | Hydrozoa               | Colpomenia sinuosa.       |
| Miriapora          | Laurencia sp.           | Serpulidae sp. B       | Ectocarpus sp.            |
| Dictyota dichotoma | Champia parvula         | Bivalve sp. A          | Bivalve sp 2              |
| Ceramium sp.       | Wrangelia pericillata   | Sycon sp.,             | Leuconia sp.              |
| Chondria sp.       | Acetabularia acetabulum | Mytilus sp.,           | Acanthophora nayadiformis |
| Chaetomorpha sp.   | Balanus (amphitrite)    | Gastropoda             |                           |
| Polysiphonia sp.   | Serpulidae sp. A        | Diplosoma listerianium |                           |
| Jania sp.          | Corallinales            | Botryllis (schlosseri) |                           |

Between sampling sites we found a significant difference (p <0.05) in species number (N) and Shannon index (H', loge) for each sampling event, while the communities differed in their evenness (J', p <0.001) from the 6<sup>th</sup> month on. Significant differences in the composition of hardbottom communities from the two study sites were also observed for all sampling events ( $R \ge 0.77$ ,  $p \le 0.001$ ).

Since communities from the impacted site were always less diverse than the assemblages from the non-impacted habitat, we assume that the composition and structure of the hardbottom communities reflect the ecological conditions at the two study sites. Differences between assemblages from Agios Kosmas and Mavro Lithari should therefore not only be due to different colonizer pools. This assumption will be tested in the future course of this study in order to establish hardbottom communities grown on artificial substrata as a tool in the ecological monitoring of Mediterranean coastal waters.

## Résumé

Nous signalons, pour la première fois, la présence de l'espèce Cribrilina punctata (Hassall, 1841) dans les eaux tunisiennes à Sidi Raies, dans le Golfe deTunis (Famille Cribrilinidae, Sous-Ordre Ascophorina, Ordre Neocheilostomina). Mots clès : Bryozoa, Posidonia.

Onze espèces de la famille des Cribrilindae (Hincks, 1879) ont été signalées en Tunisie [1]. Une seule d'entre elles appartient au genre Collarina (C. balzaci), quatre au genre Cribrilaria, une au genre Figularia ( Figularia figularis) tandis que le genre Puellina est représenté par cinq espèces. Nos recherches sur les Bryozoaires des eaux tunisiennes nous ont permis d'ajouter à cette liste une nouvelle espèce : Cribrilina punctata (Hassall, 1841). Nous en avons collecté un unique échantillon, en août 2005, lors d'une plongée en scaphandre autonome, à une profondeur de 3m dans la zone de Sidi Raies située à 39°46'09 Nord et 10°32'49 Est. La colonie était fixée sur une petite portion de rhizome de Posidonie. Le zoarium est circulaire, aplati et encroûtant, de couleur blanc-jaûnatre, mesure  $600\mu$  x  $450\mu$  ; il s'agit d'une très jeune colonie, seulement constituée par 5 autozooécies cribrimorphes. La face supérieure est calcifiée ; elle présente des pores de forme arrondie et de taille variable apparemment disposés de manière irrégulière, les côtes frontales étant très peu distinctes chez cette espèce. Les zooïdes mesurent  $230\mu$  long et  $140\mu$ de large ; leurs orifices semi-circulaires portent 4 à 5 épines distales. Un petit aviculaire, pointu à bec orienté distalement vers l'extérieur, est situé à coté de l'orifice. Nous n'avons pas observé de zoécie ovicellée, ce qui est logique compte tenu du très jeune âge de la colonie (probablement quelques semaines), et étant donné par ailleurs qu'elle a été récoltée (et s'est développée) en dehors de la période de reproduction de l'espèce (trouvée ovicellée en Méditerranée durant les mois d'avril et d'octobre par Gautier [2]. Les caractères observés concordent avec les descriptions de cette espèce données par Hincks [3], Prenant et Bobin [4], Bishop [5] ainsi qu'Hayward et Ryland [6], et l'exactitude de l'identification a été confirmée par comparaison avec des spécimens de référence conservés dans les collections du Muséum National d'Histoire Naturelle de Paris. Les auteurs précédents indiquent toutefois des dimensions autozoéciales supérieures aux nôtres (0,40-0,54 mm x 0,26-0,45 mm) ; la très petite taille de loges observées dans le cas présent s'explique par le fait qu'il s'agit des premières jeunes autozoécies péri-ancestrulaires du zoarium. Cribrilina punctata est une espèce boréo-atlantique qui se retrouve depuis l'Arctique jusqu'à l'Atlantique tempéré chaud, et qui serait plus rare en Méditerranée. Gautier [2], qui l'a récoltée à Marseille, a récapitulé les localités méditerranéennes des auteurs antérieurs (Corse, Capri et Naples) ; nous renvoyons à son travail pour les références bibliographiques correspondantes.L'espèce n'avait pas encore été mentionnée, ni de Tunisie ni plus largement des côtes du Maghreb ; l'échantillon que nous avons récolté correspond donc au premier signalement de cette espèce sur les côtes tunisiennes et sur le littoral sud de la Méditerranée. Le fait qu'elle n'ait encore jamais été récoltée sur les côtes d'Afrique du Nord peut impliquer, soit qu'elle y soit peu fréquente et/ou localisée, soit qu'elle y ait été introduite, et peut-être à une date assez récente. Lors de sa révision du genre Cribrilina, Bishop [5] précise curieusement qu'il n'a pas eu la possibilité de consulter de spécimens de C.punctata provenant de Méditerranée (alors que les échantillons de Gautier existent pourtant dans les collections du Muséum National d'Histoire Naturelle de Paris), et émet par ailleurs l'hypothèse qu'il pourrait s'y rencontrer une espèce nouvelle du genre Collarina susceptible d'être confondue avec elle. D'après Hayward et Ryland [6], cette espèce vit dans toute la zone littorale, aussi bien sur les algues, que sur les pierres, que sur les coquilles de Mollusques. Selon Gautier [2], qui l'a recueillie sur des fragments de coquilles et d'oursins, elle se rencontre jusqu'à 50m de profondeur.

## Abstract

A database on Lessepsian fish species occurrences from 1869 until 2006 was built and the colonization rate of each species was estimated. Data about geographic distribution and ecological traits were gathered from the literature. Classical test of hypothesis were used to investigate the relationships between fish ecological attributes and establishment success. Among the ecological variables studied, the climate match and the propagule characteristics are significantly related to the establishment success of Lessepsian species: the subtropical species and the species with pelagic propagules may have an advantage in the colonization process of the Mediterranean Sea. *Keywords : Species Introduction, Red Sea, Suez Canal.* 

#### Introduction

The completion of the Suez Canal in 1869 has led to spectacular biotic exchanges between the Mediterranean and Red seas which are both hotspots of endemism. Despite the importance of the phenomenon, determinants of establishment success for Lessepsian fishes in the Mediterranean Sea have been poorly investigated. In this study we reconstructed the spatiotemporal dynamic of all the Lessepsian fish species and we analysed the relationship between ecological variables and invasion rate.

#### Methods

By compiling the existing bibliography, we reconstructed the chronological history of fish species invasions since their first Mediterranean record in 1896 until 2006. Each record was plotted on a map using a Geographical Information System (GIS) software (Arcview). Through this GIS application, we measured the distance covered by each fish species during a period of time and then we estimated the invasion rate.

All the species were classified into three categories according to their ability to spread over the Mediterranean Sea: (1) absence of colonization; (2) limitation to the Levantine basin; (3) widespread colonization. A database containing some predictor variables for each species was elaborated from the literature and from FishBase [1]. Then, we formulated some hypotheses:

- Climate matching: the establishment success of some exotic species was positively related to the match between their native and their colonized environment [2,3]. Based on this prediction, the subtropical species are more likely to colonize the Mediterranean Sea than the tropical species because they are more tolerant to cooler waters.

- Location in the water column: our prediction suggests that pelagic species have higher colonization ability than benthic species owing to their swimming performance and their hydrodynamic body shape.

- Maximum length: fishes with rapid growth, high reproduction rate and early sexual maturity would be better colonizers because invaders have to breed quickly to avoid extinction [4]. We may expect that small species, with earlier sexual maturity, are more likely to colonize the Mediterranean Sea than larger species.

- Propagules: species whose propagules have wider dispersal ability are expected to reach larger geographic range sizes [5,6]. Our hypothesis posits that fishes with pelagic egg would expand more widely their geographic range size than fishes with benthic egg.

- Confamilial resistances: it has been demonstrated that exotic taxa less related to native species are more invasive [7]. In our case confamilial resistance predicts that invading species with no or few confamilial counterparts in the Mediterranean Sea would be more likely to successfully colonize than species that encounter close relatives.

The non parametrical test of Kruskal-Wallis was used to test the hypothesis including quantitative variables and the Khi2 was used to test hypothesis involving qualitative variables.

#### Results

When species are split between the benthic and pelagic categories no significant relation with the invasion success was observed, the null hypothesis is not rejected. Neither species size nor confamilial resistance have an effect on the establishment success in the Mediterranean Sea or influence species colonization.

The Khi2 test revealed a significant dependence (P=0.024) between the latitudes of species and their invasion success in the Mediterranean Sea.

Tropical species spread less than expected by chance while the spread of subtropical species was greater than expected, colonising areas outside the Levantine basin. This result confirms that establishment success depends on the suitability of the abiotic environment for the exotic species at the introduction site: the Mediterranean Sea water temperature seems more appropriate for the subtropical species than for the tropical ones.

When we test the effect of propagule on the colonization, it appears that species with pelagic propagules tend to colonize more the northern side of the Mediterranean Sea than the benthic propagules species can do. Pelagic propagules are more exposed to the general circulation of sea waters than benthic propagules. It may explain why fishes with pelagic propagules are more likely to colonize the north side while fishes with benthic propagules colonize more proportionally both south and north sides of the Mediterranean Sea. Thus, the counterclockwise circulation in the Levantine basin appears to be one the main forcing factors in the Lessepsian species propagation.

Conclusion

Overall 28% of the Lessepsian species succeeded in colonizing the Mediterranean Sea. The northern side is more rapidly invaded than the southern one because of the counterclockwise oceanic circulation in the Levantine basin. In conclusion, crossing the Suez Canal does not guarantee the establishment and the widespread colonization for fish populations. Instead, it appears that some life-history and functional traits are key determinants for invasion (climate matching, propagules). Some Lessepsian fishes, favoured by warmer temperatures and selected according to their ecological attributes, may establish to the detriment of the Mediterranean species. This phenomenon may accelerate with the global warming occurring nowadays.

## Résumé

Des observations récentes faites au cours de campagnes de prélèvements d'organismes benthiques dans la zone infralittorale du golfe de Gabès (petite Syrte) et de la grande Syrte (Libye) nous ont permis de mettre en évidence l'installation d'espèces d'origine lessepsienne, à savoir 3 gastéropodes: le *Cypraea annulus, Strombus persicus, Erosaria turdus* et un ophiuride *Ophiactis savigny. Mots clès : Species Introduction, Eastern Mediterranean.* 

Des échantillonnages benthiques faits dans les eaux kerkeniennes (Tunisie) et tripolitaines (Libye) nous ont permis de récolter plusieurs spécimens d'un Cypreidae que nous avons pu identifier en tant que *Cypraea annulus* Linnaeus, 1758. Cette petite porcelaine littorale, réputée comme typique des eaux tropicales de l'Océan Indien, a été trouvée, au cours du printemps 2006, en plusieurs points de l'horizon infralittoral supérieur de la partie nord de l'archipel des Kerkena et au large de la ville de Tripoli. Les exemplaires récoltés (3 à Kerkena, 1 à Tripoli mesurent entre 14 mm et 22 mm).

Fig. 1. Cypraea annulus - Kerkena ( $i \pounds_i$  droite et  $i \pounds_i$  gauche) et Tripoli (au centre).

Cette espèce, comme le soulignent les auteurs de l'Atlas des espèces exotiques en Méditerranée [1], serait à bannir de la liste des "envahisseurs" car elle serait à ranger dans le groupe des objets "égarés" en mer dans les temps anciens! Ces coquilles seraient, en conséquence, les témoignages des civilisations ayant eu ce gastéropode comme monnaie d'échange ou comme ornement. Ceci est possible, mais il existe des arguments permettant de contredire cette assertion. Le premier est que nous avons récolté cette espèce vivante dans une fourchette bathymétrique et un contexte biocénotique voisins de ceux de son milieu originel. Le second argument, nous permet de situer cette acclimatation à partir d'une date très récente, car nous disposons de nombreuses listes malacologiques concernant la zone littorale kerkenienne. A ce titre, une étude [2] que l'on peut considérer comme quasi exhaustive a été faite en 1979 sur plus de 300 prélèvements répartis sur l'ensemble du pourtour de l'archipel des Kerkena. Les résultats de ces observations ont permis de mettre en évidence la présence de 96 espèces de gastéropodes parmi lesquels l'auteur n'a pas rencontré notre porcelaine. Il faut, par ailleurs, souligner que l'acclimatation de cette espèce suit celle de l'espèce allochtone voisine Erosaria turdus qui, en moins de 10 ans, est devenu fréquente et abondante dans les eaux de la strate infralittorale inférieure du golfe de Gabès [3, 4] et d'Italie du sud [5]. A cette répartition nous devons ajouter sa présence dans la grande Syrte. On assisterait donc, à l'heure actuelle, à une prise de relais progressif, aussi bien dans l'infralittoral supérieur avec Cypraea annulus qu'inférieur avec Erosaria turdus des espèces indigènes Luria lurida et Zonaria pyrum. Un spécimen du strombe Strombus persicus Swainson, 1821 (l'exemplaire mesure 45 mm de hauteur) a, quant à lui, été récolté dans les seules eaux infralittorales tripolitaines (Libye). Cette espèce originaire du golfe Persique a été signalée à partir de 1983 depuis les côtes méditerranéennes du Moyen Orient jusqu'à la Grèce avec une petite incursion en Adriatique [1].

Des prélèvements du benthos de substrat dur faits sur le littoral nord est de l'île de Jerba nous ont permis de récolter l'ophiure *Ophiactis savigny* (Müller & Troschel, 1842). Cette minuscule ophiure à 6 bras et de 3 mm de diamètre de disque a été trouvée à 3 m de profondeur dans une zone de blocs rocheux (elle a été déterminée par Mme Sabine Sthör du muséum d'Histoire Naturelle de Stockholm que nous remercions ici). Cette espèce indo-pacifique qui a déjà été récoltée en Méditerranée orientale et, plus bizarrement, à Banyuls [6] est donc signalée, ici, pour la première fois, en Méditerranée méridionale.

Au vu de ces récentes découvertes, il est certain que la liste des espèces invasives originaires de l'Océan Indien et de la mer Rouge s'allonge de manière continue dans le sud de la Méditerranée. On peut évoquer, pour cela, non seulement, le rôle, de plus en plus important, des transits pétroliers dans les grande et petite Syrtes, via les ports de Tripoli, Gabès ou la Skhira, mais aussi, l'influence croissante d'un courant oriental le long des côtes de la Méditerranée méridionale.

## Abstract

Seasonal distribution, biomass and abundance values of gelatinous macrozooplankton (*Aurelia aurita, Pleurobrachia pileus, Mnemiopsis leidyi, Beroe ovata*) in the central southern Black Sea were studied during January 2002 - December 2003. The highest values of gelatinous macrozooplankton abundance were obtained from vertical tows in February and July of 2002, and in June and July of 2003, respectively. The maximum biomass of gelatinous macrozooplankton was recorded in March and July of 2003. *Keywords : Black Sea, Biomass, Cnidaria, Ctenophora.* 

Gelatinous macrozooplankton is one of the key components of the Black Sea ecosystem. In particular, the invasive ctenophore, *M. leidyi* is the agent responsible for the decrease of mesozooplankton and anchovy fishery in the Black Sea [1], most notably at the end of the 1980s, but also in mid 1990s. However, there are signs that the ecosystem of the Black Sea began to improve substantially due to sharp decreases in *M. leidyi* population as a result of appearance of its predator *Beroe ovata* in the late 1990s. The present study was carried out to determine gelatinous macrozooplankton structure in the pelagic ecosystem of the southern Black Sea. Seasonal distribution, biomass and abundance values of average gelatinous macrozooplankton in the Sinop peninsula of the central southern Black Sea were studied.

Fig. 1. Seasonal distribution of total gelatinous macrozooplankton (A) and species composition (B) of Sinop, in 2002 - 2003

The maximum abundance and biomass of total gelatinous macrozooplankton was obtained from vertical tows was 42,5 n.m<sup>-2</sup> and 224.4 g.m<sup>-2</sup> in September and July 2002. In June and July 2003, highest abundance values were 80.8 n.m<sup>-2</sup> and 91.3 n.m<sup>-2</sup> respectively. Maximum average biomass of gelatinous macrozooplankton were determined in March (1073.5 g.m<sup>-2</sup>), April (365 g.m<sup>-2</sup>) and July (397 g.m<sup>-2</sup>) 2003 (fig. 1,A). Minimum abundance and biomass values were found in winter periods in both years.

In terms of annual abundance, *A. aurita* was the dominant species in 2002 and 2003. The highest abundance value of *A. aurita* was found in 2003 (55%). Abundance of *A. aurita* was 50 n.m<sup>-2</sup>and 53,3 n.m<sup>-2</sup>in 2002 and 2003, these walues were higher than in 2000. In terms of abundance the contribution of *P. pileus* was 21 % in 2002 and 23 % in 2003. In 2000, *P. pileus* was the most abundant species with approximately 80%,

abundance value was 360 n.m<sup>-2</sup> [2], whereas total percent of *P. pileus* decreased compared with the study of Unal (2002) for 1999 (49.5%) and its abundance was 734 n.m<sup>-2</sup> [3]. In 2002 and 2003, abundance of *P. pileus* decreased to 29,1 n.m<sup>-2</sup> and 253,5 n.m<sup>-2</sup>. Maximum abundance of *P. pileus* was observed June 2003 (74,17 n.m<sup>-2</sup>) (fig. 1,B).

Our samples show that the abundance of *M. leidyi* was  $42.5 \text{ n.m}^{-2}$  and  $115 \text{ n.m}^{-2}$  in 2002 and 2003. *M. leidyi* decreased compared to 1999 (546,5 n.m<sup>-2</sup>) [3], and its abundance low in 2000 (30 n.m<sup>-2</sup>) [2]. Maximum abundance of *M. leidyi* was determined in july 2003 (86,25 n.m<sup>-2</sup>) (fig. 1,B). Abundance and biomass of *M. leidyi* showed oscillations until 1998, when its values declined [1]. In our study the percentage of *B. ovata* was significantly higher the 2002 ( $22,5 \text{ n.m}^{-2}$ ) than the 2003 (7,91 n.m<sup>-2</sup>). In 2000, *B. ovata* was found to constitute 2% of total gelatinous species [2], and its abundance 10 n.m<sup>-2</sup>. In the northern Black Sea in 1999-2001, development of *B. ovata* and *M. leidyi*. *M. leidyi* was more abundant from mid-spring to autumn. Its autumnal decline closely coincided with the appearance of *B. ovata*. This pattern was repeated in 2002-2003.

This study was supported by T.C. Basbakanlik DPT (T.R. Prime Minister State Planning Organization), Project Number 2002 KI20500 (TAP-S013) and Ondokuz Mayıs University, Research Fund Project Number S.090.

## Abstract

Some Red sea alien species and thermophilic species have successfully colonized the coast of the Levantine basin and formed a particular facies in the infralittoral biocenosis. With regard to this, the Lebanon coast represents an excellent natural laboratory to check those important biotic and climatic changes.

Keywords : Eastern Mediterranean, Phytobenthos, Zoobenthos, Species Introduction.

#### Introduction

Pérès and Picard [1] pointed out the high frequency of thermophilic species in the Levantine basin, but did not mention Red Sea alien species (RA). Possibly, the role of those species in structuring the Mediterranean biocenosis was still insignificant 40 years ago. The coast of Lebanon represents an interesting area to study the biotic changes related to the RA [2] and the 'tropicalisation' of the Mediterranean [3], since the study of the lebanese biota has progressively increased [4-9]. Actually, RA have outcompeted or replaced native species locally in the inshore benthic communities (0-40m depth).

The biota of the supralittoral-midlittoral rocks and the littoral fringe (0-2m depth) are similar to the rest of the Mediterranean coast [1], with the addition of the corallinacea facies *Lithophyllum trochanter*, *Tenarea undulosa* and *Neogoniolithon brassica-florida* with the vermetid *Dendropoma petraeum*. However, the Red Sea bivalve *Brachidontes pharaonis* is particularly dominant on eutrophic sectors; and, together with *Balanus* perforatus and *B. trigonus*, forms a facies on exposed shallow zones (0-2m depth).

Biocenosis of small boulders and pebbles (0-1m depth): This interesting habitat (in sheltered sites) presents some frequent RA, as Cerithium scabricum and Ergalatax obscura (gastropods) and Pyura momus, Rhodosoma turcicum and Phallusia nigra (ascidians) . Biocenosis of the infralittoral algae (0-35m depth): The RA macroalgae Codium taylori and Cladophoropsis patentiramea (chlorophytes) and Stypopodium schimperi (phaeophyte) dominate that biocenosis in late summer. Among the sessile fauna, some RA are abundant: Lytocarpus philippinus (hydrozoan), Malvufundus regulus, Spondylus spinosus and Chama pacifica; (bivalves) and P. nigra (ascidian). In exposed shallow zones (1-5m depth), S. spinosus and Ch. pacifica cover completely the rock, and forming a particular facies. Among the more frequent RA and/or warm benthic mobile fauna: Hermodice carunculata (polychaete), Strombus persicus (gastropod), Charybdis helleri (decapod), Synaptula reciprocans (holothurian) and the fishes, Siganus luridus, S. rivulatus, Sparisoma cretense and Sargocentrum rubrum. Fouling community (0-20m depth): B. perforatus and B. trigonus, and B. pharaonis have been the dominant species at the shallower zone (0-5m depth). Deeper (5-20m depth), ascidians dominane, with the cosmopolitan Styela plicata, S. partita and Microcosmus exasperatus, and the RA P. momus, P. nigra and Symplegna brakenhielmi. Other RA are frequent: Spirobranchus tetraceros (polychaete), and the bivalves S. spinosus, M. regulus and Pinctada radiata.

Biocenosis of the coralligenous (35-40m depth): Although impoverished with regards to the other Mediterranean sectors, it present the typical components of the Mediterranean: macroalgae ( Lithophyllum, Mesohyllum, Peyssonnelia, Osmundaria, Palmophyllum spp.). The poriferans are dominant (Axinella, Agelas, Dysidea, Petrosia, Phorbas, Spirastrella spp.); with the madreporarians ( Phyllangia and Madracis spp.) and bryozoans (Sertella, Margaretta spp.). Although the influence of the RA species does not appear significant, some of them are frequent: S. persicus, S. spinosus, Ch. pacifica, S. reciprocans and S. rubrum. Biocenosis of the semi-dark and dark caves (0-10m): The poriferans (Sycon, Axinella, Chondrosia, Cliona, Crambe, Ircinia, Petrosia, Phorbas, Pleraplysilla, Microscleroderma, Gastrophanella spp.) and the madreporarians (Polycyathus, Phyllangia, Oculina, Madracis spp.) are dominant. Some RA species are present in that biocoenosis: the serpulid Pomatoleios kraussii; the molluscs Hypselodoris infucata, Petaloconchus glomeratus, S. spinosus and Ch. pacifica; the ascidians H. momus and Ph. nigra; and the fish Pempheris vanicolensis. Biocenosis of sandy mud (25-40m depth) is represented by the association *Halophila stipulacea* and *Caulerpa scapel-liformis* with the RA gastropod *Rhinoclavis kochi*.

#### Discussion

Some important changes occur in the Levatine basin, due to the RA and the 'tropicalization' of the Mediterranean (1,2), particularly in the infralittoral zone (0-35m depth), and to a lesser degree in the circalittoral. The marked seasonal changes in the macroalgae cover are noteworthy: in spring and early summer, the phaeophytes dominate the upper strata ( Cystoseira spp., Dictyota fasciola, Dictyopteris polypodioides, Halopteris scoparia, Padina pavonica, Sargassum vulgare, Taonia atomaria); in late summer and autumn, that phaeophyte canopy disappears (also due to the herbivorous pressure?), and the permanent turf of corallinacea ( Amphiroa, Corallina, Jania, Lithophyllum, Neogoniolithon spp.) dominates the photophilic surfaces. Some rocky infralittoral sectors (exposed zones, sheltered boulders, photophilic and sciaphilic surfaces, fouling communities) can be dominated by RA: macroalgae ( C. taylori, C. patentiramea, L. lallemandii, S. schimperi), Cnidaria (L. philippinus), Polychaeta (S. tetraceros, P. kraussii), molluscs (S. persicus, C. scabricum, E. obscura, R. kochi, B. pharaonis, S. spinosus, Ch. pacifica, P. radiata, M. regulus), crustaceans ( Ch. helleri), echinoderms ( S. reciprocans), ascidians ( P. momus, P. nigra, R. turcicum, S. brakenhielmi).

# SEASONAL VARIABILITY IN ABUNDANCE AND BIOMASS OF TINTINNIDS IN THE KAŠTELA BAY (MIDDLE ADRIATIC SEA)

Natalia Bojanić

Institute of Oceanography and Fisheries, Šetalište I. Meštrovića 63, 21000 Split, Croatia - bojanic@izor.hr

## Abstract

Temporal variability in tintinnid abundance and biomass were investigated in the central part of the Kaštela Bay, Croatia. The highest abundance (755 ind.1<sup>-1</sup>) and biomass (3.230  $\mu$ gC 1<sup>-1</sup>) were recorded in February 1998 at the surface, and in September 1998 at 25 m depth, respectively. *Helicostomella subulata, Codonellopsis schabi, Stenosemella nivalis* and *Salpingella rotundata* represented 68% of the total tintinnid number and may have an exceptional importance in the microbial food web of the investigated coastal ecosystem. *Keywords : Adriatic Sea, Biomass, Density, Zooplankton.* 

Ciliated protozoa participate in the transfer of energy and carbon from bacterioplankton and phytoplankton to higher trophic levels through the microbial food web [1, 2]. Also, they can act as a link between classic herbivorous food chain and microbial food web [3]. One approach to studying trophic relations and their role in the cycling of organic matter is to analyse the temporal variability of planktonic components [4]. Therefore, the present study focuses on seasonal changes in abundance and biomass of tintinnids as one important part of ciliated protozoa community [3]. These are the first results for this part of the Bay as well as the first biomass data, which are one of very few available for the whole Adriatic Sea.

Samples were collected at a station located in the middle of Kaštela Bay  $(43^{\circ}31.2^{\circ} \text{ N}; 16^{\circ}22.9^{\circ} \text{ E})$  in the central Adriatic Sea. Sampling was performed on a monthly basis from January 1998 until November 1999, at 5 m depth intervals between the surface and bottom (35 m) with 5 l Niskin bottles. The plankton material was preserved and prepared for microscopic analysis as described in reference [3]. The carbon biomass value of tintinnids was estimated by measuring linear dimensions of the lorica, which were afterwards inserted in appropriate formula [5].

Tintinnids were represented with 45 species, which is about half of the known tintinnid species from the Adriatic Sea. It is commonly known that tintinnid biodiversity is affected by the nearness of land as well as the open sea influence. The influence of both factors at investigated station was almost equal. The highest biodiversity was recorded in October 1999 (17 neritic-estuarine species and 14 open sea species) which points at very intensive exchange of water masses between the Kaštela Bay and the surrounding area.

Temporal variability in abundance of tintinnids was characterised by spring and autumn peaks, with average values of  $132 \pm 169$  ind. $1^{-1}$  in April 1999 and 205  $\pm 77$  ind. $1^{-1}$  in September 1998. The high mean value in winter ( $192 \pm 246$  ind. $1^{-1}$ ) was recorded only in February 1998, with the highest value of 755 ind. $1^{-1}$  at the surface (figure 1). Similar abundances were noticed in the bays of the south Adriatic [6, 7]. Very low abundances during summer could be explained by encystment of tintinnids in unfavourable living conditions, such as high sea temperature and increased light intensity [8].

Fig. 1. Temporal variability in abundance and biomass of tintinnids in the Kaštela Bay

In spite of isothermal conditions in winter, tintinnids were most abundant in the surface layer. In September, they concentrated in the deeper layers. For better understanding of seasonal and vertical distribution of tintinnids it is important to know the taxonomical structure. Quantitatively the most important tintinnids of the Kaštela Bay were *Helicostomella subulata*, *Codonellopsis schabi*, *Stenosemella nivalis* and *Salpingella rotundata*. These species represented 68% of the total tintinnid number and may have an exceptional importance in the microbial food web during the period of their highest abundance. *H. subulata* was most abundant from the end of winter to spring. Favourable environmental conditions and probably the trophic state of the investigated area may be relevant. *C. schabi*, *S. nivalis* and *S. rotundata* are typical autumn-winter species. Very high abundances of *H. subulata* were recorded in the surface layers, while three other species preferred the deeper layers.

Seasonal and vertical distribution of tintinnid biomass was quite similar to oscillations of their abundances (r=0.86, p<0.0001, N=17). The average biomass values ranged between 0.088 ±0.048 and 2.081 ±0.788 µgC l<sup>-1</sup>, recorded in July and September 1998, respectively (figure 1). The highest biomass of 3.230 µgC l<sup>-1</sup> was found in September 1998 at 25 m depth. Similar values were found in the Gulf of Trieste [9]. Differences in the succesion of tintinnid biomass affect the energy flow in the marine food web. Therefore, changes in the abundance or biomass of tintinnid species are important indicators of changes in the microzooplankton community, as a consequence of the changed trophic state of an area.

# IMPORTANCE OF THE COPEPODITE STAGES IN THE TOTAL NUMBER OF CALANOID COPEPODS IN THE MIDDLE ADRIATIC SEA

Dubravka Bojanić

Institute for Marine and Coastal Research, University of Dubrovnik, Damjana Jude 12, 20000 Dubrovnik, Croatia -

dubravka.bojanic@unidu.hr

## Abstract

Samples were collected at six stations along Palagruža transect in the Middle Adriatic Sea during four cruises in 2002 and five in 2003. Contribution of juvenile developmental stages of calanoids was pointed out. Their percentages in the total number of calanoids were 41-92%. The highest values were in April, on the station CJ007 from maximal 1333 ind./m<sup>3</sup>, 1117 ind./m<sup>3</sup> copepodites. *Keywords : Adriatic Sea, Copepoda, Zooplankton.* 

## Introduction

The duration of life cycle from egg to adult in calanoid copepods is governed primarily by temperature and food availability. In the past investigations of the calanoid copepods of Adriatic Sea, copepodite stages were insufficiently represented. Because of the method of sampling, big mesh size nets (>200  $\mu$ m) were used, majority of calanoid developmental stages flew through. Many authors counted them with corresponding species.

#### Materials and methods

Planktonic material was investigated along Palagruža transect in the Middle Adriatic Sea during four cruises in 2002 (May, June, August and September) and five in 2003 (April, June, August, October and December). Samples were collected at six stations (CJ007-CJ012) using Nansen net with mesh size 200  $\mu$ m, mouth opening 57 cm and length 255 cm in one or two vertical hauls depending on stations' depth. Organisms were preserved in 2.5% of formaldehyde neutralized with CaCO<sub>3</sub> and later in the laboratory, counted by the means of stereomicroscope Carl Zeiss. All results are presented as the number of individuals per cubic meter (ind/m<sup>3</sup>). Differentiating the last copepodite stage from adults is rather difficult in some groups so they are oftenly counted in adults.

#### Results and discussion

Papers in which the authors refer to copepodite developmental stages as a special quantitative and qualitative category are very scarce. Hure and Scotto di Carlo (1969) investigated open waters of northern Adriatic with 333  $\mu$ m mesh size net (No.3). According to authors, winter samples include minimum copepodites and their number grows up to 40.2% in the total number at the end of the year. Although they noticed quantitative importance they couldn't tell about their real representation in the calanoid populations.

In this investigation contribution of postnaupliar developmental stages in the total number of individuals of calanoids was 41-92% with a median value of 81%. Examining each cruise, percentage of the copepodites ranged from 72 to 85%, except in September 2002 (48%) when the adults prevailed. Some of the calanoid families (e.g. Calanidae, Centropagidae, and Augaptilidae) recorded maximal number of copepodites in late spring and summer, but most of the others were equally presented and durinated during all cruises. Figure 1. shows abundance of the adult and copepodite stages of calanoid copepods in biannual cycle. Although the copepodite values are five times higher that the adult ones, their cycles are nearly equal with the same exception of September 2002.

Lučić i Kršinić (1998) investigated zooplankton in Mali Ston Bay with the Adriatic net equipped with different mesh gauze cylinders, 125 and 250  $\mu$ m. Statistically significant difference (p<0.001) in calanoid copepodite abundance was determined. 250  $\mu$ m mesh sized net kept only 27.7% calanoids i.e. 2.2-8.4% of their copepodite stages comparing to 125  $\mu$ m mesh sized net.

Pronouncedly high concentrations of copepodite stages in the total number of calanoid copepods verify their quantitative importance not only in the Middle Adriatic, but also in general. It would be advisable to perform detailed investigations of the Adriatic Sea and to apply appropriate sampling methods in order to obtain the complete picture about populations of calanoid copepods, their adult individuals but also their copepodites.

Fig. 1. Abundance of the adult and copepodite stages of calanoid copepods in biannual cycle.

### Abstract

In the Balearic Islands, the *Caulerpa racemosa* is an actual problem because colonize all kind of bottoms between 0-40 meters. The colonization of the dead rhizomes of *P. oceanica* seagrass by the green algae *Caulerpa racemosa* change the molluscan community previously associated with *P. oceanica*. This change is reflected in an increase of molluscan abundances and diversity, higher in *C. racemosa*.

Keywords : Algae, Balear Islands, Mollusca, Coastal Systems.

#### Introduction

*P. oceanica* meadows are characterized by a high molluscan diversity, especially gastropoda species [3]. The substitution of the seagrass *P. oceanica* by *Caulerpa racemosa* macroalgae changes abundances and diversity of molluscan species [1,2]. *C. racemosa* is expanding its presence in the Mediterranean and has been reported in 11 Mediterranean countries [4]. In Balearic Islands *C. racemosa* is frequent growing over dead *P. oceanica* rhizomes near the edge of the meadow.

The aim of this study is to analyze changes in species composition, diversity and abundance in the molluscan fauna associated to *Posidonia oceanica* after the substitution of the seagrass beds by *Caulerpa racemosa* macroalgae.

#### Material and methods

During 2004, bimonthly samples of molluscan fauna were collected in Portals Vells (Balearic Islands) at 5-8 m depth among *Posidonia oceanica* rhizomes colonized by *Caulerpa racemosa*. The control sampling station (*P.* oceanica) without Caulerpa was located in Cala d'Or. Molluscan individuals were collected using a 20x20 cm frame set by scuba-diving in the rhizome bed inserted 5 centimeters into the sediment; both sediment and rhizomes inside the frame were removed, placed in a net-bag of 200  $\mu$ m mesh size and sorted in laboratory.

SIMPER routine (PRIMER 5.0) was used to evaluate main species in each meadow and a CLUSTER (based in Bray- Curtis similarity algorithm) was performed to analyse the grouping of the samples.

#### Results and discussion

A total of 17 gastropoda species and 20 bivalve species were identified in the C. racemosa macroalgae. In C. racemosa samples there was a low similarity value (average similarity 37%, SIMPER). Main species in C. racemosa were Glans trapezia, Ctena decussata, Bittium reticulatum, Limaria hians, Paphia aurea, Rissoina bruguieri, Alvania cimex, Nassarius incrassatus and Arca noae. At seagrass P. oceanica samples a total of 12 gastropoda species and 16 bivalvia were identified. The main contribution to the similarity percentage (average similarity 24%, SIMPER) was due to the bivalves Glans trapezia, Loripes lacteus, Pinna nobilis and Arca noae. The dissimilarity percentage between meadows Caulerpa vs Posidonia was high (average dissimilarity 80,22%) attributed to the differences between the species and abundances between meadows. The cluster analysis clumped all samples from C. racemosa apart from that of P. oceanica showing a clear seasonal pattern in the molluscan species at C. racemosa. In the C. racemosa Margalef diversity maximum values (d= 2,13) and Shannon-Wiever maximum data (H'=2,12) were found in October, and maximum abundance (308 ind/m<sup>2</sup>) was quantified in February. The values at Caulerpa mats were higher than those obtained in the P. oceanica seagrass, where maximum diversity values (d=1,42 and H'=1,9) corresponded to June, and maximum abundance (67 ind/m<sup>2</sup>) to April and June. The substitution of P. oceanica by C. racemosa seems to produce a change in the dominant and most frequent molluscan species of P. oceanica, reflected in an increase in diversity values and abundances quantified at C. racemosa mats.

Fig. 1. CLUSTER representation of the collected samples from *P. oceanica* and *C. racemosa*. PO means *Posidonia oceanica* and CR means *Caulerpa racemosa*.

## Abstract

Planktonic ostracod abundance was investigated in the South Adriatic Sea in the vertical layers at the station 1000 m deep in March 1998 and October 2001. Fifteen species were found, and the dominant ones were *Porroecia spinirostris* and *Archiconchoecia striata*. Maximal abundance of 1084 ind.100 m<sup>-3</sup> was found in 200-300 m layer in March 1998. *Keywords : Adriatic Sea, Biodiversity, Density, Pelagic, Zooplankton*.

Planktonic ostracods are widely distributed in the world seas. Some of dominant species must be amongst the most abundant invertebrates in the world and they still remain almost totally unknown, even amongst oceanic biologists [1]. Nevertheless, little is known about their population structure, reproduction and life-cycle [2]. The investigations in the Adriatic Sea [3, 4] and wider in the Mediterranean [5] are rare. The present investigation shows the species composition and abundance of ostracods in the deep South Adriatic.

Planktonic samples were collected at the 1000 m deep station in the South Adriatic ( $42^{\circ}21.2$ 'N,  $17^{\circ}41.7$ 'E) by r/v Bios in March 1998 and October 2001. Samples were taken by Nansen type net, mesh 200  $\mu$ m, mouth 1/4 m<sup>2</sup>, and 255 cm long, equipped with the closing mechanism. Samplings were performed in the layers of 0-50, 50-100, 100-200, 200-300, 300-400, 400-600 and 600-1000 m. Catch was fixed by 2.5% neutralized formalin and analyzed in laboratory under the stereoscope. The abundance of ostracods was reported as number of individuals per one hundred cubic meters (n ind.100 m<sup>-3</sup>).

Fifteen species of planktonic ostracods from family Halocyprididae were found: *Porroecia spinirostris, Porroecia porrecta, Porroecia porrecta adriatica, Conchoecia magna, Mikroconchoecia curta, Mikroconchoecia echinulata, Proceroecia procera, Proceroecia macroprocera, Proceroecia microprocera, Discoconchoecia elegans, Paraconchoecia spinifera, Paramollicia rhynchena, Loricoecia loricata, Metaconchoecia rotundata and Archiconchoecia striata.* In March 1998 (fig. 1) the abundance increased by the depth down to 200-300 m layer, where the maximum of 1084 ind.100 m<sup>-3</sup>(178 adult ind.100 m<sup>-3</sup>) was recorded.

Fig. 1. Total ostracod abundance in March 1998.

Going deeper the abundance decreased, and in the deepest layer it was slightly higher in comparison to the surface layer. The proportion between juveniles and adults in the surface layer was 2:1, and in the layer of 100-200 m the proportion was 7.6:1.

In October 2001 (fig. 2) the highest total abundance was 50% lower, 544 ind.100 m<sup>-3</sup> (180 adult ind.100 m<sup>-3</sup>), in 100-200 m layer. In the deepest layer the ostracods were less abundant in comparison to the surface abundance.

The dominant species were *Porroecia spinirostris* and *Archiconchoecia striata*. *P. spinirostris* in March 1998 had the highest abundance in the layer of 100-200 m. Above 100 m only females, and beneath 200 m only juveniles were found. In October 2001 the highest abundance was found

in layer 0-200 m. In layer 200-300 m only juveniles were found and deeper in layer 400-600 m only a few females were found.

Fig. 2. Total ostracod abundance in October 2001.

A. striata was noted in both investigations at the depths of 50-300 m, and the highest abundance was recorded in the layer 100-200 m. The results of investigation of planktonic ostracods in the South Adriatic co-incided with former investigations, which also confirmed the ostracods appearance from the surface to 1000 m depth [3, 4]. Angel notes that at temperate latitudes, ostracods are often missing from the surface to 100 m, but otherwise they are usually the second-most abundant group only to the copepods [1].

# BIODIVERSITY CHANGES OF THE WATER COLUMN LARGE PELAGIC SPECIES IN THE ALBORAN SEA

Juan Antonio Camiñas<sup>1</sup>\*, José Carlos Báez<sup>2</sup>, Carlos García-Soto<sup>2</sup> and Raimundo Real<sup>3</sup> <sup>1</sup> Instituto Español de Oceanografía, Centro Oceanográfico de Málaga, Spain - jacaminas@ma.ieo.es

<sup>2</sup> Instituto Español de Oceanografía, Centro Oceanográfico de Santander, Spain

## Abstract

The large pelagic species biodiversity variation of the Alboran Sea (Western Mediterranean) was analysed using data from on board observations in the Spanish longline fisheries. A relationship was found between the estimated H-value (Shannon-Weaver index) and lunar phases, which can be explained by the existence of vertical migrations within the water column in relation to lunar phases. *Keywords : Alboran Sea, Biodiversity, Fisheries, Pelagic.* 

The Alboran Sea (the Western Mediterranean zone connecting with the Atlantic Ocean through the Gibraltar Strait) is an outstanding area for marine biodiversity and constitutes an important corridor for many marine migratory species in the North Atlantic-Mediterranean region [1]. We studied the Spanish surface longline fleet fishing in the north Alboran Sea. This fleet, based in Mediterranean ports, targets Swordfish (*Xiphias gladius*), Bluefin tuna (*Thunnus thynnus*) and Albacore (*T. alalunga*), the latter two species mainly in summer. Surface longline gears targeting large pelagic species are considered the main threat for protected marine vertebrates (mainly marine mammals and turtles) because they are unspecific [2].

Fig. 1. Study area (Alboran Sea).

We assumed homogeneity in the configuration and components of each observed longline set and also that the probability of capture during each fishing operation was the same. Catches should deplete the abundance of vertebrates hooked (target and by-catch species) within the gear deployed area (the water column), particularly for species that have low rates of movement [3]. In this line of reason, if the gears are set in the same fishing area and depths (30 to 40 m), the biodiversity for each set's capture should be a reflection of the large pelagic species abundance/presence within the water column. This paper analysed the large pelagic species biodiversity associated with the surface longline targeted species in the Alboran Sea during the summer of 2004 and its relation with environmental and technical parameters. Environmental parameters included wind intensity and moon phase, satellite measurements of phytoplankton concentration (SeaWiFS), sea surface temperature (AVHRR), and sea surface velocity (altimeter), whereas the technical parameters included bait combination and boat strata. The study area extended from  $36^{\circ}$ -  $37^{\circ}$  N and  $2^{\circ}$ - $5^{\circ}$  W (Figure 1). The Spanish fishery is artisanal and fishes close to the coast, in an area where larger vessels do not operate because of the maritime traffic. During an EU LIFE02NAT Project (E/8610) we observed (onboard) 23 longline sets from 3 boats (15.34 m length and 20.75, register gross tonnage average).

Nine different species were caught during the observed period (27/06/04 to 27/09/04): Blue Shark, *Prionace glauca*, Bluefin tuna, *Thunnus thynnus*, Common dolphinfish, *Coryphaena hippurus*, Common stingray, *Dasyatis pastinaca*, Loggerhead *Caretta caretta*, Ocean sunfish, *Mola mola*, Shortfin mako, *Isurus oxyrinchus*, Swordfish, *Xiphias glaudius*, Thresher shark, *Alopias vulpinus*, and Tope shark, *Galeorhinus galeus*. We calculated the H-value [4] (biodiversity index of Shannon-Weaver) per fishing

#### operation.

Linear multiple forward regressions, Generalized Linear Models, and second-degree polynomial regressions were applied to the captures by species using several technical or ecogeographical numerical factors as predictors, but no significant relationship was found. However when we selected four categorical factors (lunar phases, bait combination, boat strata, and wind) an H-value model was found in relation with Lunar phases (Figure 2). We tested the average of H-value between different moon phases using the Mann-Whitney test, and found significant differences between the H-value from longline set operating during waning Moon and the other longline sets (U= 32; P= 0.036). The higher H-value was obtained during waning Moon and the lower H-value during the New Moon phase. These results could be explained by vertical migrations of species within the water column according to lunar phases.

Fig. 2. The H-values per lunar phase. For each box the average H-value and its confidence interval are shown (individual square point: anomalous point). Key: 1, Full Moon; 2, waning Moon; 3, New Moon; 4, crescent Moon.

The by-catch in pelagic longlines represents an important conservation problem. If these results could be extended all over the Mediterranean Sea, effective management measures could be implemented to preserve threatened pelagic species.

# WEIGHT-CARAPACE WIDTH RELATIONSHIP OF THE MEDITERRANEAN GREEN CRAB ( CARCINUS AESTUARII, NARDO 1847) IN ÇAKALBURNU LAGOON, IZMIR BAY

Elif Can \*, Eyup Mumtaz Tirasin , Bulent Cihangir and Uysal Yilmaz

Dokuz Eylul University, Institute of Marine Sciences and Technology, Inciralti 35340, Izmir, Turkiye - elif.can@deu.edu.tr

## Abstract

The weight-carapace width relationship of *Carcinus aestuarii* Nardo,1847 (Crustacea, Decapoda, Brachyura, Portunidae) of Çakalburnu Lagoon is given for a sample of 795 specimens. Crabs were collected during 2001-2002. Carapace width, weight and sex of specimens were determined.

Keywords : Crustacea, Decapoda, Lagoons, Aegean Sea.

#### Introduction

Growth is defined as the increase in length, the weight or volume [1]. The Mediterranean green crab, *Carcinus aestuarii* Nardo inhabits in the Mediterranean estuarine and lagoon waters [2], the Black Sea and the Sea of Asov [3]. The aim of this study is to give some information on the seasonal weight- carapace width relationship of the crab population in Çakalburnu Lagoon, Izmir Bay, the Aegean Sea.

#### Material and Methods

The study area, Çakalburnu Lagoon, is a shallow, coastal lagoon, which spreads over 150 h area [4] and is located on the southern coast of the Izmir Bay (Fig.1). The water depth in the lagoon ranges between 0.5-1 m. A total of 795 *C* . *aestuarii* specimens were sampled between 2001 and 2002, using a beam trawl. All sampled crabs were sexed, weighed (wet weight) and measured carapace width (CW, nearest mm). The common allometric equation  $Y = aX^{b}$  has been used to estimate the weight-carapace width relationship, where Y is the wet weight (g), X is the carapace width (mm), respectively. Allometric growth equations that can be linearized by logarithmic transformation, such as log  $Y = \log a + \log X$  [5]. A Student's t-test ( $\alpha$ =0.05) was used to check whether b=3 for the weight-carapace width relationship.

Fig. 1. (A)-(B) Geographical location of Izmir Bay and Çakalburnu Lagoon.

#### Results and Discussion

Data on 384 (48.3%) males and 411 (51.7%) females were analyzed for the relationship between weight-carapace width. The carapace width of the female crabs ranged from 9.06-38.74 mm with a mean value of  $26.54\pm5.37$ mm and males from 5.06-48.41 mm with a mean of  $31.39\pm10.45$ mm. The weight-carapace width relationships are presented seasonally in Table 1.

The males and females of *C. aestuarii* showed negative allometric growth in all seasons, except for the females in spring; their growth was isometric. When the growth of the crabs show positive allometry, this indicates that the weight of the animal increases as it matures [5]. Here, the results denoting negative allometry indicated that the weight of *C.aestuarii* in Çakalburnu lagoon decreased as it matured. The coefficients of determination were high except in summer period. The reason of this difference may be explained by the increased range in the carapace widths of the specimens in this season. Generally, the values of b range between 2.5-3.5 in the weight-length relationship. In this study, the values of b ranged

2.66-2.81 in females and 2.30-2.92 in males. In a study on another portunid crab *Callinectes sapidus*, the estimated b values varied in a similar range (2.19-2.93) just as in this study [6].

## DEVELOPMENT OF HIGH-RESOLUTION MOLECULAR TECHNOLOGIES TO INVESTIGATE ECOSYSTEM CHANGES IN THE SOUTHERN EUROPEAN SEAS: THE PROTOTYPING OF DNA CHIPS TO IDENTIFY INVERTEBRATE PREY SPECIES IN MARINE FOOD WEBS OF ADRIATIC SEA

## Abstract

A invertebrate DNA microarray targeting ten species common in the Mediterranean was developed within the framework of the FP6 STREP FISH& CHIPS. Based on sequence variation of the 16S rDNA gene, we designed species-specific probes that were used to construct a DNA chip prototype for the identification of invertebrate (i.e. molluscans and crustaceans) preys of demersal fishes in the Adriatic Sea. The constructed invertebrate DNA chip represents a technological advance towards the wide use of rapid and high-resolution molecular tools to assess structure and changes of marine ecosystems such as the monitoring of invasive species and of re-emerging pathogens in ballast waters.

Keywords : Biotechnologies, Adriatic Sea, Food Webs, Species Introduction, Zoobenthos.

The understanding of trophic interactions among organisms and in the marine ecosystem is crucial for sustainable management of fishery resources and for conservation of marine biotas [1, 2]. Unfortunately, the analysis of gut contents carried out using the traditional analytical approach of morphological identification is time-consuming and requires highly-specific taxonomic expertise. Here, within the framework of the FP6-STREP FISH& CHIPS, we aim to develop a prototype DNA chip targeting invertebrate species (INVCHIP) that are common preys of demersal fish species in the Mediterranean Sea [3].

Ten invertebrate species belonging to molluscans and crustaceans widely distributed in the entire Mediterranean have been sampled in the Adriatic Sea. A 500 bp PCR-amplified 16S rDNA fragment of at least three individuals per species was sequenced using universal or taxon-specific primers. The capture probe design was performed through multiple alignments of DNA sequences using the programmes WinProbe and GeneDoc. Sequences of phylogenetically related species were retrieved from the NCBI nucleotide data bases and used for probe design. Chip configuration, probe immobilisation and hybridisation experiments have been done according to available protocols. Positive and negative controls were added to each microarray.

An INVCHIP-1 was realised including 6 target species (Mollusca: Illex coindetti, Eledone cirrhosa, Crustacea: Meganychtiphanes norvegica, P achigrapsus marmoratus, Liocarcinus depurator, Liocarcinus vernalis). 14 probes were designed and tested with subsequent hybridisation experiments. Capture probes gave different results: four oligonucleotide probes were specific for their target DNA (one for each I. coindetti, E. cirrhosa, P. marmoratus, L. vernalis); one probe hybridised the target species L. depurator but also the closely related species L. vernalis; nine probes did not bind the target DNA., Preliminary experiments carried out under different experimental conditions (i.e. decreased Tm and increased hybridisation time) allowed increasing of specificity and sensitivity for some probes and target species. The realisation of a INVCHIP-2 (including Mollusca: Lentidium mediterraneum, Chamalea gallina; Crustacea: Alpheus glaber, Goneplax rhomboides) is now in progress through probe design and chip configuration steps. Hybridisation experiments are scheduled for the end of 2006.

The developed INVCHIP represents a relevant technological advance towards the wide use of rapid and high-resolution molecular tools to assess structure and changes of marine ecosystems. Beside the investigation of marine food webs, DNA microchips coupled with a metagenomic analytical approach can effectively contribute to the monitoring of invasive species (either as eggs or larval stages) and re-emerging pathogens in ballast waters which are reversed daily in the Southern European Seas [4-6].

## ABUNDANCE AND SIZE FLUCTUATIONS IN THE DEEP-WATER SHRIMPS ARISTAEOMORPHA FOLIACEA (RISSO, 1827) AND ARISTEUS ANTENNATUS (RISSO, 1819) IN THE NORTH-WESTERN IONIAN SEA (MEDITERRANEAN SEA)

R. Carlucci \*, G. D'Onghia , P. Maiorano , L. Sion , F. Capezzuto , A. Matarrese , A. Tursi Department of zoology University of bari, 70125 bari - Italy - r.carlucci@biologia.uniba.it

## Abstract

Fluctuations in abundance and size in *Aristaeomorpha foliacea* and *Aristeus antennatus* were recorded in the North-western Ionian Sea during 1995-2005. Significant increases in both the biomass and density indexes were shown in *A. foliacea* while the abundance changes observed in *A. antennatus* did not show any significant trend. A significant increasing trend in the median value of carapace length was detected for both shrimps. Changes in the abundance of the two shrimps recorded during 2002-2004 seem to be due to delayed transient phenomenon effects.

Keywords : Crustacea, Decapoda, Demersal, Fisheries, Ionian Sea.

The abundance and size of the deep-water shrimps *Aristaeomorpha foliacea* (Risso, 1827) and *Aristeus antennatus* (Risso, 1816) were investigated within the framework of national [1] and international [2] trawl surveys carried out in the North-western Ionian Sea (Mediterranean Sea), from 1995 to 2005, with the aim of assessing the most important economic demersal resources.

Throughout the study period, 21 trawl surveys were carried out, during each spring and autumn, at depths between 300 and 800 m using a commercial vessel with standard equipment for trawling. The percentage of the positive hauls per survey ranged from about 30 to 84% for *A. foliacea* and from about 41 to 82% for *A. antennatus*.

The giant red shrimp *A. foliacea* showed highly variable abundance indexes, both in terms of biomass (BI in kg/km<sup>2</sup>) and density (DI in N/km<sup>2</sup>). The BI values were between 0.62 and 31.09 kg/km<sup>2</sup> and the DI values fluctuated from 46 to 2496 N/km<sup>2</sup>, both showing significant increasing trends evaluated with both parametric and non parametric correlations (p<0.05). In *A. antennatus* the BI values ranged from 4.22 to 25.74 kg/km<sup>2</sup> and the DI values varied between 214 and 1911 N/km<sup>2</sup>. However, the abundance changes observed in this shrimp did not show any significant trend.

During the period 2002-2004 an uncommon increase in abundance of *A. foliacea* together with a decrease in *A. antennatus* were recorded. Moreover, the decrease in *A. foliacea* during the last surveys (2005) coincided with a new increase in *A. antennatus* (Fig. 1).

Fig. 1. Trend of biomass index (kg/km<sup>2</sup>) in *A. foliacea* and *A. antennatus* during 1995-2005 in the North-western Ionian Sea.

For both species, the carapace length (CL in mm) of the specimens varied largely throughout the study period. In fact, the calculated median values varied between 23 and 34 mm CL for *A. foliacea* and between 26 and 42 mm CL in *A. antennatus*. The observed increasing trends were significant in both shrimps (Fig. 2).

The significant increase in *A. foliacea* after 2000 seems to be due both to success in recruitment and to the stability of the fishing effort in the study area. The inverted abundance of the two red shrimps during 2002-2004 could be related to the change in hydrological conditions in the Ionian Sea

derived from the "transient" phenomenon [3]. Such conditions (warm water with high salinity) are considered favourable for *A. foliacea* but not for *A. antennatus* [4, 5]. In relation to the conclusion of the transient effects, *A. antennatus* was again found to be more abundant than *A. foliacea*.

Fig. 2. Trend of median carapace length (CL mm) in *A. foliacea* and *A. antennatus* during 1995-2005 in the North-western Ionian Sea.

# SURVIVAL OF THE *POSIDONIA OCEANICA* CUTTINGS TRANSPLANTED INTO THE NORTHEASTERN LEVANT SEA

B. Celebi \*, A.C. Gucu , M. Ok , S. Serdar , E. Akoglu

Institute of Marine Sciences, Middle East Technical University, Mersin 33731, Turkey - billur@ims.metu.edu.tr

## Abstract

In the present study *Posidonia oceanica* shoots collected near from Bozyazı- Mersin are transplanted to 3 different sites along the south eastern coasts of Turkey, at 2 of which *Posidonia oceanica* meadows are not present naturally. The survival of transplants was followed from 2004 until recently. The success of the transplantation at the most eastern station, though the high seawater temperature, suggests that there may be combination of environmental reasons for the absence of *Posidonia oceanica* meadows in that area. *Keywords : Posidonia, Levantine Basin, Temperature.* 

## Introduction

The distribution of endemic sea grass species *Posidonia oceanica* L. Delile is limited to the littoral zones of the Mediterranean and Marmara Seas [1]. Nevertheless along the eastern Mediterranean coasts of Turkey there are no *P. oceanica* meadows present and the northeastern boundary of meadows end in the Levant Sea, at  $36^{\circ}$  09' N  $33^{\circ}$  26' E [2]. The possible reason of this absence has been attributed to physical parameters of the seawater in that area such as high temperature [3]. The present study investigated the reason of absence of *P. oceanica* meadows along the northeastern Levant Sea by an experimental transplantation method, which is also being used for acceleration of recovery in damaged *P. oceanica* beds in western Mediterranean Sea.

#### Materials and Methods

*P. oceanica* shoots were collected either by SCUBA or free diving. Additionally some shoots from the by-catch of trawl surveys were used as cuttings to avoid serious impacts on donor *P.oceanica* meadows. Collection was made from 2 stations at various depths: at Turgutlar, where the most eastern boundary of meadows along the southern coasts of Turkey is present; and at Bozyazı, which is located near to the Kizilliman Marine Protected Area with healthy meadows. Afterwards cuttings were attached with nylon cable ties to the iron frames with grids made of nylon rope. Totally 21 frames with different coverage areas ranging from 0,49 to 2,25 m<sup>2</sup> were placed at 3 different stations in winter of 2004, in spring and autumn of 2005 and in spring of 2006. One of the stations was chosen only for control purpose at Bozyazuwhere the shoots were collected. The other two eastern stations, Erdemli and Samandag, were located outside the boundary where the *P. oceanica* meadows are naturally absent [Figure 1.].

Fig. 1. Study area: Site number 1 is the only collection site, the all 3 sites are the transplantation sites.

#### Results

A few weeks after the first transplantation in 2004 at Samandag two frames were found broken on a commercial trawling boat. The cuttings of the next 2 frames transplanted at Erdemli in May 2005 were found dead after two months whereas the leaves of the cuttings on the third frame were alive but overgrazed. The secchi disc measurements at this station during these months ranged from 4 to 10 meters at 20 meter bottom depth. The sixth frame transplanted in August 2005 to the harbour of the Institute for visual observation of potential grazers was also overgrazed. The other 3 frames transplanted parallelly in autumn of 2005 to Bozyazıfor control purpose, Erdemli and Samandag were still alive in May 2006, January 2006 and October 2006, respectively. But leaves of transplanted to Samandag were shortened due to grazing. Last 11 frames, transplanted to Samandag in

May 2006 for increasing the coverage area of the last frame against the reduction by erosion of sediment, were still alive in October 2006.

#### Discussion

The study area is a unique site for P. oceanica transplantation experiments due its geographical position. The eastern Levant Sea is dominated by Levantine surface water mass whose most important features are high salinity and high temperature [4]. The area is also under the effect of pollution due to urbanization and high pressure of fishing by trawlers and purseiners. All of these parameters and activities have negative influence on the health of sea grass ecosystems. Destruction of first 2 grids by trawlers may indicate the significance of heavy trawling pressure on the sea bottom. As was repeatedly observed during visual inspections, grazing by herbivorous organisms seems to be an important factor in the absence of P. oceanica in the region. In addition to the only true herbivorous fish species of the Mediterranean fish fauna Lessepsian Siganids may pose a significant threat to the sea grass. Beside invasive fishes, some herbivorous exotic gastropod species e.g. Conomurex persicus, whose grazing activity may also have potential impacts on native ecosystem [5], have been observed in high concentrations around the frames. The water temperature over the shoots transplanted in Samandag exceeded the upper critical seawater temperature for P. oceanica growth suggested by Celebi et.al. (2006). On the other hand, despite relatively lower temperatures, the first 2 frames transplanted at Erdemli on May 2005 did not survive. The light penetration depth seems to be shallower in Erdemli compared to Samandag. However, the natural meadow in Turgutlar survives under even lower light condition than Erdemli. These three examples may indicate the combined effect of light penetration and temperature that may play synergistic role in the balance between respiration and photosynthesis of the P.oceanica. The long term effects of physical properties of the sea water on growth and production of P. oceanica shoots still need to be observed in following years by lepidochronological analysis of the transplants. Acknowledgements - This study was carried out within the framework of 2 projects CAYDAG 105Y023 and YDABAG 104Y028 by the Turkish Scientific and Technical Research Council. We are indebted to SAT-EKOG of METU and to the crew of R/V Lamas for their efforts during the surveys.

## Résumé

L'espèce *Nerophis ophidion* (Linnaeus, 1758) est pêchée, pour la première fois, au nord de la Tunisie dans la lagune de Tunis. Les caractères méristiques et morphométriques relevés sur 75 spécimens collectés ont permis de vérifier qu'ils présentent les mêmes caractéristiques que ceux déjà décrits en Méditerranée.

Mots clès : Biodiversity, Fishes, Western Mediterranean.

En Méditerranée, le genre *Nerophis* est représenté par deux espèces, *N. maculatus* et *N. ophidion* [1, 2]. Cette dernière espèce est commune en Méditerranée [1] mais aucun auteur ne rapporte sa capture dans les eaux tunisiennes [3-5].

Des prospections, récemment réalisées dans le Golfe de Tunis, nous ont permis de collecter, pour la première fois, des spécimens de ce syngnathe dans la lagune de Tunis. En effet, les pêches que nous avons effectuées dans la lagune de Tunis au moyen d'engins de pêche spécifiques durant la période allant de Novembre 2004 à Octobre 2005, nous ont permis de capturer un échantillon de 75 spécimens de Nerophis ophidion composé de 40 femelles et de 35 mâles dont la longueur totale est comprise entre 95 et 222 mm. Sur chaque individu, nous avons prélevé le poids total, cinq caractères méristiques (Nombre total des anneaux osseux "NT", nombre des anneaux osseux au niveau du tronc "NTr", nombre des anneaux osseux au niveau de la queue "NQ", nombre des anneaux osseux sous la nageoire dorsale "NSd" et nombre des rayons de la nageoire dorsale "D") et dix neuf caractères morphométriques (longueur totale "LT", largeur maximale du corps "L", hauteur maximale du corps "H", longueur de la nageoire dorsale "Ld", hauteur de la nageoire dorsale "Hd", longueur de la tête "lt", distance anté-dorsale "Da", distance post-dorsale "Dp", distance préanale "Aa", distance post-anale "Ap", largeur de la tête "Lt", hauteur occipitale de la tête "Hoc", hauteur oculaire de la tête "Hcl", longueur du museau "Lm", hauteur du museau "Hm", largeur de la bouche "Lb", distance inter orbitaire "Io", diamètre de l' oeil "O" et distance post-orbitaire "Po").

Les spécimens de *Nerophis ophidion* capturés dans la région de Tunis présentent 81 à 110 anneaux osseux le long du corps, 28 à 31 au niveau du tronc, 59 à 78 au niveau de la queue et 9 à 12 sous la nageoire dorsale. Les rayons de la nageoire dorsale varient entre 33 et 36. Les intervalles de variation de ces caractères sont en concordance avec ceux cités par Dawson [1] et Tortonese [6]. Les données morphométriques des poissons examinés sont consignées dans le tableau 1.

La relation taille-poids observée chez les mâles, les femelles ainsi que chez les deux sexes confondus traduit une allométrie minorante. En grandissant, le poisson devient plus élancé.

Dawson [1] a mentionné la présence de *Nerophis ophidion* sur le littoral méditerranéen. Dans les eaux tunisiennes, aucune capture de cette espèce n'a été rapportée dans la littérature [3-5]. Par conséquent, le présent travail mentionne, pour la première fois, la présence de *N. ophidion* sur les côtes nord de la Tunisie. L'absence de ce syngnathe dans les inventaires ichtyiques précédents serait probablement due à son absence dans les apports de la pêche professionnelle. En effet, en raison de sa petite taille, sa collecte n'est possible qu'avec des engins spécifiques munis de filets à petites mailles.

Notre travail apporte de nouvelles informations sur la distribution et sur la caractérisation morphologique de *N. ophidion*, poisson syngnathidé, en Méditerranée.

Tab. 1. Caractères morphométriques (exprimés en mm) de *Nerophis ophidion* dans la lagune de Tunis. min: minimum; max: maximum; m: moyenne;  $\delta$ : écart type; N: effectif; F: femelles; M: mâles.

# GENETIC STRUCTURE OF THE POLYTYPIC SPECIES IDOTEA BALTHICA (ISOPODA VALVIFERA)

Faouzia Charfi-Cheikhrouha

Unité de recherche de Biologie Animale et Systématique Evolutive, Faculté des Sciences de Tunis, Campus Universitaire, 2092 Manar II, Tunisie. - f.charfi@fst.rnu.tn

## Abstract

Allozyme variation among 15 populations belonging to the 4 subspecies, *I .b. basteri*, *I. b. stagnea*, *I b. tricuspidata* and *I. b. balthica* of the polytypic *I. balthica* and collected from the Mediterranean to the Baltic Sea were analysed using polyacrylamide gel electrophoresis. Genetic structural analysis was performed assaying four polymorphic loci. Nei's genetic distance (D) varied from 0 to 0.567 showing low divergence within populations of the same subspecies, except for *I. b. basteri*, while the highest distance was recorded between the Nordic and the Mediterranean groups. Fst and gene flow were estimated and revealed a gene flow restriction between the geographical groups. *Keywords : Crustacea, Enzymes.* 

#### Introduction

The sublittoral Isopod *Idotea balthica*, occurred in the Baltic Sea, on the Atlantic coast, on the and on the Mediterranean coasts and lagoons, is relatively widely distributed. Based on the interbreeding tests and the morphological features in parents and hybrids, [1] considered this species as a polytypic species composed of four subspecies: *Idotea b. balthica* from the Baltic Sea, *Idotea b. tricuspidata* from the European Atlantic coasts, *Idotea b. basteri* from the Mediterranean Sea and *Idotea b. stagnea* from some Mediterranean French lagoons.

In the present paper, we report the allozyme variation analysis based only on the polymorphic loci of natural populations of the polytypic species *Idotea balthica*: 1) to analyse the genetic variability within populations, 2) to estimate the gene flow between these populations 3) to calculate the genetic distance and the level of genetic divergence among populations and subspecies, 4) to reconstruct the evolutionary history of this species.

The analysis was conducted on 15 populations of the polytypic species *Idotea balthica* from different geographical areas: *I. b. balthica* from Baltic Sea, *I. b. tricuspidata* from the European Atlantic coasts, *I. b. basteri* from the Western Mediterranean basin and Adriatic Sea and *I. b. stagnea*, from some Mediterranean French lagoons.

#### Materials and Methods

The enzymatic polymorphism was performed on polyacrylamide gels. More than 30 enzyme assays were tried; ten yielded scorable results and only the four polymorphic loci (Amy-2, Est-2, Ldh-1 and Pgi-1) were considered.

For each population, mean sample size per locus, average number of alleles per locus, mean heterozygosity observed and mean heterozygosity expected under Hardy-Weinberg equilibrium were calculated using Biosys-1 program of [2]. The genetic structure within and among populations was evaluated using F-statistics (Fit, Fis and Fst).

#### Results and Discussion

The mean number of alleles ranged from  $1.7\pm0.2$  to  $3.2\pm0.7$ . Mean direct count heterozygosity gene (Ho) varied from  $0.071\pm0.059$  to  $0.201\pm0.090$  and the expected average heterozygosity from  $0.081\pm0.052$  to  $0.286\pm0.125$ . Considering the subspecies, the highest level of genetic variability was observed in *I. b. stagnea* (Ho=0.171), followed by *I. b. tricuspidata* (Ho=0.144), *I. b. basteri* (Ho=0.131), whereas the lowest belonged to *I. b. balthica* (Ho=0.088). The Fis values ranged from 0.0140 for Ldh to 0.898 for Pgi. The average value was high (0.280) showing that the populations were not in Hardy-Weinberg equilibrium.

Fst varied from 0.045 to 0.861 with an average of 0.433 and the amylase-3 locus exhibited most gene flow restriction. Among the fixation indices, Fit shows the highest value (0.590) indicating a high differentiation between populations.

Genetic distance values were low 0 < D < 0.024 within populations of the same subspecies except from *I. b. basteri* populations where D rose to 0.217. D ranged from 0.084 to 0.164 between *I. b. balthica* and *I. b. tricuspidata* with the average value  $D_m=0.120$ , and from 0.010 to 0.118 between *I. b. basteri* and *I. b. stagnea* ( $D_m=0.063$ ). The average genetic distance values among *I. balthica* subspecies showed a higher mean value among Nordic subspecies than Mediterranean ones. However, an average high value ( $D_m=0.137$ ) within *I. b. basteri* was observed when comparing Adriatic and western Mediterranean populations and a lower value between *I. b. stagnea* and *I. b. basteri* ( $D_m=0.063$ ).

The clustering pattern using the UPGMA and the NJ methods, respec-

tively requiring or not requiring, equal rates of evolution, showed two main groups, the Nordic and the Mediterranean ones. In the first group, the two subspecies can be clearly separated confirming morphological features. In contrast, within the Mediterranean group more than two subspecies could be distinguished; the Adriatic populations seem to be genetically different.

# SURROGATE MEASURES OF BIODIVERSITY IN MACROBENTHIC COMMUNITIES IN THERMAIKOS GULF, GREECE

Chariton-Charles Chintiroglou, Chryssanthi Antoniadou, Panagiotis Damianidis \* and Evdokia Kourelea Dept. of Zoology, School of Biology, Aristotle University of Thessaloniki, P.O. Box 134, GR-541 24, Thessaloniki, Greece damianidis@yahoo.com

## Abstract

The use of higher-taxon richness as surrogate for species was investigated in a study of macrobenthic communities in Thermaikos Gulf, north Greece. The correlation of genera and families to species richness showed that they can both be effective surrogates of biodiversity, while the use of an indicator group (Polychaeta) was sufficient, but it should be applied with caution and when the group is dominant in the area.

Keywords : Aegean Sea, Biodiversity, Zoobenthos.

#### Introduction

Most analyses of macrobenthic communities are based on the identification of species [1]. However, the use of higher-taxon richness as surrogate for species can also produce a reliable distribution pattern of macrobenthic fauna [1-3]. Other surrogates can be the abundance of species of certain indicator groups [4-5]. Analyses based on higher-taxon richness is often more convenient than the time-consuming and costly species identification [4-6]. The present study considered the genera and families of organisms and of polychaeta as indicator group, as regards their suitability as surrogates for species in investigations of macrobenthic fauna in Thermaikos Gulf, north Greece.

#### Materials and methods

The sampling period lasted three years (2003-2006). Three vertical transects along the NE coasts of Thermaikos Gulf were selected in the area around the construction site of the new air lane of Thessaloniki Airport. Six stations - two at each transect - were established for benthic macrofauna sampling with corer samplers at depths between 3 and 10 m (ST1-ST6). In total, 16,650 species were collected, classified in 181 species. Polychaeta were the dominant group in terms of presence and abundance in most of the stations. The Spearman rank correlation coefficient was employed to determine whether there was a statistically significant correlation (r values) between the species richness and the genera (Sp-Gen) and families (Sp-Fam) richness. The same was applied for Polychaeta (Sp-Pol.Sp. and Sp-Pol.Gen.), in order to investigate the suitability of an indicator group as surrogate.

### Results and Discussion

Figures 1 and 2 show that genera and families richness (r=0.98 and r=0.89, respectively) is a truly effective surrogate and the use of species and genera richness of Polychaeta also provides sufficient surrogacy (r=0.75 each).

There were a couple of exceptions in the latter pattern, namely St1 and St4 where Sp-Pol.Sp  $\kappa\alpha\iota$  Sp-Pol.Gen. correlations are not significant (Figure 2).In a number of studies in areas with severe organic pollution [1, 3, 7] the use of families or species and families of polychaetes are often in accordance with the biocoenotic patterns that originate from the nor-

mal use of species richness. Natural selection premises that each higher taxon contains species that can only cope with small scale environmental changes. Therefore, in areas where anthropogenic impact is large, higher taxa are represented by a small number of species and their use as surrogate for species is more reliable there than in non-disturbed areas [6]. In polluted areas, more specifically, the Polychaeta can be of great advantage as a surrogate group. Their great variety of feeding guilds and reproductive strategies enable them to be abundant in a large number of habitats, disturbed or not. Our study, however, showed that the surrogacy should be applied with caution, because there are cases like St.1 and St.2, neighbouring sites with similar substrate structure, where the same surrogate (number of species of polychaetes) was not similarly distributed and, thus, not equally effective.

Fig. 2. Correlation between the number of species and the number of genera, families, polychaeta species and polychaets genera at each sampling station.

# ICHTHYOPLANKTON DISTRIBUTION OF IZMIR INNER BAY BETWEEN 2000 AND 2005

Bulent Cihangir<sup>1</sup>\*, Tulin Coker<sup>2</sup> and Savas Mater<sup>2</sup>

<sup>1</sup> Dokuz Eylul University, Institute of Marine Sciences and Technology, Izmir-Turkiye - bulent.cihangir@deu.edu.tr

<sup>2</sup> Ege University, Faculty of Fisheries, Izmir-Turkiye

## Abstract

The Izmir Bay, which is located on the western coast of Turkey, became one of the conspicuous areas in the Mediterranean Sea with its high domestic and industrial pollution level by the end of 1990s. However, starting from 2000, as a result of terminating the pollution sources and beginning of water treatment system, positive changes have been observed in the habitat. This is reflected in all living groups in the marine ecosystem. By evaluation of the seasonal surface plankton sampling between the years of 2000 and 2005, it was determined that spawning fish populations in the Izmir Inner Bay consisted of *Engraulis encrasicholus, Arnoglossus* spp , *Buglossidium luteum, Callionymus pusillus, Solea* spp. These species are considered as resistant to the pollution. *Engraulis encrasicholus* forms 98% of eggs and 60% of larvae. Other important larval species are *Gobius niger* (14%) , *Parablennius gattorugine* (10%) and *Salaria pavo* (8%) in the Inner Bay.

Keywords : Ichthyoplankton, Pollution.

#### Introduction

The pollution process in the Izmir Inner Bay had accelerated due to domestic and industrial effects from 1960. Because of this, after 1970s the priority in scientific studies was especially given to observation of pollution effects. The pollution had reached the highest level in the Inner Bay in 2000, when the water treatment system began to work. Pollution sources of the Inner Bay were reported as; hydrocarbon, heavy metal, pathogenic organisms caused from domestic and industrial waters (organic materials) (50%), precipitations (15%), brooks and streams (10%), agricultural sources (10%), sea transportation-harbour (4%) and other sources (11%)[1]. After caving Rag ip Paşa Lagoon's walls, which is located in the Inner Bay, deep and surface flows have become more effective, and significant improvement has been observed in the Bay by completing the Great Channel Project. Eutrophication has regressed largely in the Inner Bay and light transmission has increased. The pollution effects in last 30 years as; beginning of pollution, the most polluted and termination period of pollution sources, have importantly affected certain species composition in the marine ecosystem of the Inner Bay. Related to recovery of the Bay, positive effects have been observed on the organism groups (phytoplankton, zooplankton, macrobentic organism, fish) [2]. Ichthyoplankton organisms are the most importantly affected group among the mentioned organism groups. In this study, changings in distribution of ichthyoplankton in the pelagic region during recovery period of the Bay were discussed.

Tab. 1. Fish species of which eggs and larvae were determined in the Inner Bay between 2000 and 2005.

| Fish species                               | Eggs | Larvae |
|--------------------------------------------|------|--------|
| Sardina pilchardus (European Pikhard)      |      | +      |
| Engraulis encrasichalus (European Anchovy) | +    | +      |
| Brisopterus luscus capelanus (Poor Cod)    |      | +      |
| Diplodus annularis (Annular Sea Bream)     | +    |        |
| Godius niger (Black goby)                  |      | +      |
| Pomato schistus microps (Common goby)      |      | +      |
| Zosterizessor ophiocephalus (Grass goby)   |      | +      |
| Califonymus lyra (Dragonet)                |      | +      |
| Calionymus pusillus (Dragon)               | +    | +      |
| Blennius ocellaris (Butterf ly blenny)     |      | +      |
| Salaria pavo (Pescock blenny)              |      | +      |
| Parablernius gattorugine (Tombot blenny)   |      | +      |
| Parablennius sanguinolentus (Blenny)       |      | +      |
| Parablennius tentacularis (Blenny)         |      | +      |
| Blennius spp.                              |      | +      |
| Amoglossus spp.                            | +    | +      |
| Solea spp.                                 | +    |        |
| Buglossidium luteum (Solenette)            |      | +      |

Material and Method

Sampling studies were carried out with R/V K. Piri Reis between 2000 and 2005, by horizontal (25 times) hauling with 250 m mesh size WP-2 type plankton net lasting in 10 minutes. Hauling was achieved in 5 stations located in the Izmir Inner Bay; inshore, central part (around) and exit way

to the Middle Bay. Depth in the region is maximally around 23 m. Hauling include seasonal periods as 2000 (January), 2001 (January, April, August, December), 2002 (August), 2004 (March, August, November) and 2005 (April, February). Samples were preserved in 4% formaldehyde solution and examined in laboratory with SZ-60 type 10x6 binocular microscope.

#### Result

In the study fish eggs (Clupeidae, Engraulidae, Gadidae, Callionymidae, Bothidae and Soleidae families) and larvae (Engraulidae Sparidae, Gobiidae, Callionymidae, Blenniidae and Soleidae families) were determined to belong to 18 species from 9 family. Species diversity of ichthyoplankton was observed to increase through east-west direction of the Middle Bay, except in south and south-east inshore parts of the Inner Bay.

Anchovy eggs composed 98% of the total eggs in the Inner Bay and dominated the egg composition during 2000-2005. Other species consisting of 2 % are; Callionymus pusillus, Arnoglossus spp., Solea spp., Sardina pilchardus, Buglossidium luteum and dead eggs. European anchovy (60 %) composed the highest level in larval distribution in the Inner Bay. Black goby (14 %) was in the second place. Two species from Blennidae family , Tombot blenny (10 %), Peacock blenny (8 %) were the important species. Other Blennidae and Gobiidae species distributed in 1-2 % levels. In 1 % part; Annular Sea Bream, Solenette, Common goby species had equal distribution values. According to distribution percentage of species in stations at the Inner Bay, the highest distribution rates belong to; European anchovy (64 %) and Black goby (45-47 %) species. B. ocellaris (Butterfly blenny), P. sanguinolentus (Blenny) species found in 18-27% values in central part of Inner Bay. Common goby, Dragon , P. tentacularis (Blenny), Blennius spp., and Solenette larvae were represented with the lowest levels (1-9 %) in some stations. No larvae was found around the port. In study area it was observed that egg percentage distributed irregular and larva distribution increased through out of the Inner Bay. In spite of the improvement in water quality, dominancy of anchovy known as resistant to pollution is in point issue. The Inner Bay composes one of the most important areas for anchovy to spawn in all around the Bay. On the other hand larvae of goby species (G.niger) were obtained dominantly in Inner Bay as done in past periods. Dominancy of mentioned species eggs- larvae evaluated as the indicator that the environment has not been recovered completely.

# MODELLING MARINE FOOD WEBS FOR AN ECOSYSTEM APPROACH IN THE MEDITERRANEAN SEA

Marta Coll<sup>1</sup> \* and Simone Libralato<sup>2</sup>

<sup>1</sup> Institute of Marine Science (ICM-CSIC), Barcelona, Spain - mcoll@icm.csic.es

## Abstract

This contribution aims at reviewing main applications of mass-balance and trophodynamic models for representing marine food webs in the Mediterranean Sea. This review allows evidencing the potential of these tools for an ecosystem approach to several human impacts and provides insights on future directions of research.

Keywords : Food Webs, Macroelements.

Mass-balance and trophodynamic models are used worldwide for describing marine food webs and studying ecosystem structure and functioning. In particular, Ecopath with Ecosim (EwE) enables to integrate large body of data and information in a coherent description of marine food webs and allows the study of direct and indirect anthopogenic impacts on ecosystems [1]. Therefore, although developed for understanding impacts of fishing activities, EwE represents a valuable tool for the theoretical analysis of food webs and for applying an ecosystem approach to different anthropogenic impacts [2]. Accordingly, several EwE applications have been developed in the Mediterranean Sea.

Mass-balance Ecopath models have been largely used to explore the trophic structure and apply network analysis at different scale on coastal and shelf areas. In the Venice Lagoon (Italy), Ecopath models were used to describe the trophic structure [3], to compare food webs of two habitats thus providing evidence of the high maturity of seagrass meadows [4] and to compare the same system through time evidencing the stress induced by a new fishery [5]. In the Orbetello Lagoon (Italy), the key role of cormorants and the decrease of eutrophication level were assessed by comparing mass-balance models for two different years [6]. Food web models for the Adriatic Sea [7] and the South Catalan Sea [8] allowed to evidence ecosystem effects induced by fishing through analysis of synthetic indices and cross-system comparison of standardized models enabled to examine differences between ecosystems [9-10] and ecosystem effects of protection [10]. An EwE model was also developed for the Gulf of Calvi [11] to place fishing within the ecosystem context and examine indirect effects of fishing and, analogously, a dynamic application to the Black Sea allowed exploring trophic cascade driven by fishing [12]. A mass balance model explored the energy flow controls of the Miramare Marine Protected Area [13] and a spatial one assessed the effectiveness of MPAs of different sizes in the North Adriatic Sea [14].

Few cases explore the effects of environmental forcings on ecosystem dynamics [8, 11, 14, 15] because of the general lack of time series of biological data long enough for the validation of time-dynamic simulations. Nevertheless, mass-balance Ecopath models proved to be a good basis for linking structure to dynamics and for identifying keystone species within food webs [16]. These models also gave basis for defining a new measure of ecosystem effects of fishing that has been applied extensively to landings data and models output in the Mediterranean Sea [17-18]. Moreover, trophic flows estimated by Ecopath permitted the direct coupling with ecotoxicological information thus providing a realistic representation of the bioaccumulation of organic pollutants in the food web, as in the Venice Lagoon case study [19].

Future research would benefit from the generalization of this methodology to the Mediterranean basin, through the development of new case studies (especially in the eastern part) and the standardized comparison of existing models. Moreover, fitting models to time series of data for their validation should be a priority, as well as the application of spatio-temporal dynamics for capturing ecosystem features and patterns. Finally, the assessment of uncertainty of model inputs and propagation of errors to results should be considered of overwhelming importance.

## Abstract

The present study aims at giving the first results of the composition of invertebrate fauna discarded by trawls in Thermaikos Gulf, north Aegean Sea. Sampling followed conditions of commercial fishery and resulted in collecting 64 discarded invertebrate species. The most abundant of them was the crab *Liocarcinus depurator*, while crustaceans were prominent in all samples. *Keywords : Aegean Sea, Trawl Surveys.* 

#### Introduction

The study of discards of trawl fisheries is of great interest since they consist almost a quarter (27%) of the global catch [1]. The present study is the first to focus on the invertebrates that are discarded by trawls in the Thermaikos Gulf, north Aegean Sea, during a fishing season. The aim is to present preliminary results on the composition of the discarded invertebrate fauna.

#### Methods and Material

Sampling took place in Thermaikos Gulf between October 2005 and April 2006, which is the period of allowed trawl activity in the Gulf. A total of 21 hauls, corresponding to 21 stations, took place in real conditions of commercial fishery. The duration of each haul ranged from 2 to 6 hours and their depth varied from 32 to 96 m. The average speed of the trawlers was 3.3 knots. The mesh size of the net was 40 mm in the cod-end. The average volume of each catch was 0.226 m<sup>3</sup> and samples of 0.08 m<sup>3</sup> were collected at random. Specimens were transferred to the laboratory, identified to species level and preserved in formalin solution.

#### Results

The total number of collected invertebrates was 3,789, classified to 64 species. Table 1 shows the species whose frequency in the samples exceeds 50%. The most widely represented class was Malacostraca, which constituted 87% of the total abundance of the taxa. The species with presence in every station were the anthozoan *Alcyonium palmatum*, the cephalopod *Sepia elegans* and the crustaceans *Parapenaeus longirostris, Liocarcinus depurator, Medorippe lanata, Goneplax rhomboides* and *Squilla mantis.* In terms of abundance, it is obvious that the crab *L. depurator* was the most abundant species in all surveys, making up 47.16% of the invertebrate discards, followed by *P. longirostris* and *S. mantis* (Figure 1). In general, the results show that the composition of discarded invertebrates in the Thermaikos Gulf is similar to that of other Mediterrenean regions, like Spain or the Ligurian Sea [2, 3].

## Abstract

Seasonal closures in trawling grounds are generally considered a useful management tool, but there is a lack of knowledge on their benefits for benthic communities. Two trawling grounds located in the Catalan and Adriatic seas, which are regulated by a two-month fishing closure, were surveyed to monitor changes in the benthos during the trawling cessation. Results suggest that closures are too short to detect a response of benthic communities.

Keywords : Adriatic Sea, Biodiversity, Fisheries, Western Mediterranean.

#### Introduction

The establishment of temporal closures in trawling grounds is one of the most effective measures to reduce fishing effort. Several authors have evidenced an increase in commercial catches after the closure [1]; however, the effects on benthic communities have been poorly investigated. Numerous studies have demonstrated that commercial trawling chronically modifies benthic communities [2]. Consequently, it is necessary to implement adequate management actions to improve the effectiveness of marine ecosystems protection.

#### Methods

Two trawling grounds located in the Catalan and Adriatic Seas, and regulated by a two-month seasonal closure, were selected to study the response of benthic communities to this management measure. Two study sites were delimited within each fishing ground: a fished site, regularly exploited by the local trawling fleet, and an un-fished site as a reference. In order to analyse changes in the community structure, epifaunal and infaunal samples were collected at both sites during six experimental cruises performed before, during and after the fishing closure. Total abundance, biomass and diversity, based on Shannon index, were recorded, and a two-way ANOVA was developed to identify any effects of site or cruise on these variables. Multivariate analyses, based on the Bray-Curtis similarity index and subsequent MDS ordination plot, were conducted to study changes in the community structure.

Fig. 2. MDS plot of epifaunal abundance from the Adriatic Sea. Triangles: fished site, circles:reference site. B: before closure; C1: at the beginning, and C2: at the end of the closure; A1: one month after, and A2: two months after the closure.

#### Results

An overall of 96 epifaunal species and 153 infaunal taxa were collected in the Catalan Sea study area, and 68 epifaunal species and 217 infaunal taxa in the Adriatic Sea sites. Variations in total abundance and biomass of infauna and epifauna did not reflect a closure effect. Epifaunal diversity significantly decreased immediately after the closure at the fished site from the Catalan Sea, when the fishing effort in the area is high (Fig 1). This pattern was not observed in the Adriatic Sea, where the fishing effort after the closure is low. Multivariate analysis of epifaunal data detected changes in the community structure during the closure in both study areas. Although this analysis differentiated samples from fished and reference sites, similarity between sites was slightly higher during the closure (Adriatic: 67% and Catalan: 66% similarity) (Fig. 2). Differences emerged when comparing the infaunal community from fished and reference sites, however no response to the closure was highlighted.

#### Discussion

Overall these results suggest that a two-month closure is too short to benefit benthic communities. Nevertheless, despise the brevity of this period, the epifaunal community showed a positive response suggested by the increase of similarity between the fished and un-disturbed communities during the closure. Moreover, the reduction of epifaunal diversity in the Catalan Sea fished area after the closure highlights that a high level of fishing activity has an immediate negative effect on the community.

# SMALL-SCALE FISHERIES IN THE NORTHERN ADRIATIC SEA

M. De Mauro \*, G. Fabi , F. Grati , P. Polidori , G. Scarcella

CNR - Istituto di Scienze Marine (ISMAR) - Sede di Ancona - 60125 Ancona (Italy) - m.demauro@ismar.cnr.it

## Abstract

Sampling of small-scale fishery landings at four harbours of the northern Adriatic Sea was carried out from 1999 to 2005 to study fishing capacity, fishing effort and quali-quantitative composition of retained catches. Landing data evidenced a strong seasonality of five fishing gears (sole gillnet, gillnet, trammel net, basket trap for gastropods and trap for cuttlefish) used on the basis of the target species' ecoethology. The landings of both types of traps included only few species and were dominated by the target one in biomass. In contrast, the retained catches of set nets consisted of a wide pool of species, but the highest yields were obtained only for the target species and a few kept by-catch ones.

Keywords : Adriatic Sea, Coastal Management, Fisheries.

#### Introduction

In Italy set gear fisheries play an important role at the social level, although they do not compete with trawling in economical terms. The small-scale fishery uses many different gears on the basis of the area, period of the year and target species, and vessels are usually spread out in several small mooring places, so making difficult to draw a complete picture of the actual situation in terms of catch composition, fishing effort and fishing activity. In order to increase the knowledge on this fishing sector, data on technical features of gears, fishing areas, landings, fishing effort, fishing yields and qualitative composition of landings were collected over 7 years at four harbours of the northern Adriatic Sea.

#### Materials and Methods

During 1999-2005 the small-scale fleets of Senigallia, Ancona, Portonovo and Numana harbours consited of 77 operating vessels having the following features: 0.57-8.57 GRT, 5.44-298 HP and 3.88-13.01 m Loa. The daily landings of randomly chosen vessels were analysed for a total of 587 sampling days and 1,494 census. At each time the following parameters were recorded: technical parameters of the employed vessels and gears, fishing areas, fishing time, and quali-quantitative composition of landings.

#### Results and Discussion

During the study period the number of active vessels fluctuated seasonally from 35 (winter 2003) to 73 (spring 2002), usually reaching the highest values in spring (Fig. 1). Five types of set gear were observed: basket trap for gastropods, sole gillnet, gillnet targeting grey mullets and sparids, trap for cuttlefish and trammel net (Fig. 1) [1]. Basket traps were used to catch Nassarius mutabilis from fall to spring on the coastal sandy and muddy bottoms. From 200 to 500 traps per vessel were lowered at sea at the beginning of the fishing season and hauled at 1-2 day intervals to collect the catch. At each time the traps were baited with dead fish. Landings mainly consisted of the target species accounting for 99% in biomass, while kept by-catch included only 4 species. Sole gillnet was employed all year-round on the coastal soft bottoms within 3 nm offshore following a seasonal trend with the highest values in summer and the lowest ones in winter. This net was characterised by a low height (1.6-2.5 m) and buoyancy of floats allowing it to lay partially on the seabed thus favouring the capture of benthic fish. The most commonly used mesh sizes were 64 and 68 mm (stretched) [2]. Landings included 59 taxa, but were dominated by Solea solea, Squilla mantis and Chelidonichthys lucernus, which made up 37%, 38% and 11% of the total biomass, respectively. The gillnet used for nekto-benthic and pelagic fish had a larger mesh size (80-100 mm stretched) and a higher net panel (3-5 m) with respect to the sole gillnet. This gear was mainly employed in fall and winter on the rocky bottoms close to the shore. Landings included 48 species, but Liza ramado (63%) and Lithognathus mormyrus (18%) were the most important ones in terms of biomass. Traps for cuttlefish were represented by fyke nets and pots baited with laurel branches acting as spawning substrate for Sepia officinalis. This fishing activity was carried out mainly in spring in correspondence with the reproductive season of the target species on the sandy and muddy bottoms of the coastal zone. Each vessel set 200-500 traps in late winter and collected the catch at 2-3 day intervals. Only 8 species were observed in landings and cuttlefish made up 99% of the total catch. Trammel nets were characterised by a wide variety of technical parameters: panel colour (transparent, white, brown, red, black), line type (poliamide monofilament, twisted poliamide) and diameter, height and mesh sizes of inner and outer panels. They were generally used to catch cuttlefish (60% in weight) in spring on the coastal rocky bottoms close to the shore and *L. mormyrus* (9% in weight) in winter inside the coastal area. The most important by-catch species was *S. mantis*, accounting for 11% of the total catch. A total of 41 species were observed in the landings but, beyond the three above-mentioned species, only *L. ramado* gave an appreciable contribution to the total landed biomass (8%).

The study evidenced the great dynamism of the investigated small-scale fisheries, due to their capacity of changing gear according to the target species' eco-ethology. The used gears were characterised by a high species selectivity, although sometimes kept by-catch made up a discrete portion in biomass contributing to the fishermen' overall income. The information gathered from this study may used for the management of the fishing activities in the coastal area.

Fig. 1. Seasonal number of vessels belonging to the Senigallia, Ancona, Portonovo and Numana small-scale fisheries subdivided into fishing activities. BT = basket trap; SG = sole gillnet; GI = gillnet; TR = traps; TN = trammel net; 1 = winter; 2 = spring; 3 = summer; 4 = fall.

## CETACEAN OBSERVATIONS IN THE MARMARA AND AEGEAN SEA IN SPRING SEASON 2005

Ayhan Dede \* and Bayram Öztürk

Istanbul University, Faculty of Fisheries, Ordu Cad. No:200, Laleli - aydede@istanbul.edu.tr

### Abstract

In the Aegean Sea, according to standard distance sampling procedure, 1800 km (972 nm) and 139 hrs effort of observation carried out during 20.04-20.05.2005 for determining the size and distribution of dolphin population. During the study, totally 19 sightings of three species (*Delphinus delphis, Tursiops truncatus* and *Stenella coeruleoalba*) were recorded. The sighting data were analysed by the Distance 5.0

Keywords : Cetacea, Aegean Sea, Sea Of Marmara.

#### Introduction

In the Aegean Sea, nine cetacean species are known to occur [1,2,3]. These are; D. delphis, T. truncatus, S. coeruleoalba, Globicephala melas, Grampus griseus, Pseudorca crassidens, Ziphius cavirostris, Physeter macrocephalus and Balaenoptera physalus. The situation of Phocoena phocoena that are widely distributed in the North Atlantic coasts and Black Sea and rare in the Marmara Sea is not certain in the Aegean and Mediterranean Sea [4]. Therefore it is important to understand dolphin movements between the Black Sea and Aegean Sea via the Marmara Sea and Straits. A few studies have been conducted on cetacean fauna in the Turkish Aegean coasts. Researches on determining species composition, population and distribution of Cetacea are urgently needed. Such studies conducted in the Aegean Sea, especially in the northern part are very important due to its close position to the Turkish Straits System (TSS) which is known as a migration route for dolphins [5]. Studies conducted in the Turkish coasts of the Aegean Sea and Mediterranean Sea carried out by sampling of strandings or by caught species in fishing gears. Between 1990-1997, in the Turkish coasts of the Aegean Sea and Mediterranean Sea, totally 23 cetacean; 9 T. truncatus, 7 S. coeruleoalba, 3 Z. cavirostris, 2 D. delphis, 1 P. macrocephalus, 1 P. crassidens were found as stranded animals [6]. Besides, between 1999-2000 in the Turkish coasts of the Aegean Sea during swordfish fishery, (7 S. coeruleoalba, 2 T. truncatus, 1 G. griseus) in year 1999 and (6 S. coeruleoalba, 2 T. truncatus, 1 G. griseus) in year 2000 totally; 19 cetacean bycatches were recorded by [7].

Fig. 1. Survey trackline and sighting locations.

#### Material and Method

Cetacean sighting data were collected on a research cruise carried out in spring season (20.04-20.05.2005) in the TSS and the Aegean Sea coasts of Turkey between Istanbul and Marmaris vice versa (Figure 1). This research cruise was conducted with a 16 m. sailing boat NAUTICA and followed standard line transect protocols. During the cruise, three experienced observers were placed in helm, port and starboard side. with 7x50 binoculars and naked eye, port and starboard observers, scan areas covering 0-90 and 90-180 degree and helm observer scan entire 180 degree in the front of the vessel. Dolphin species identified with lowest taxonomic level and group size estimates were recorded by observers. Estimation of dolphin density, group size and encounter rate (n/L) where (n) is the number of observed animals and (L) is the total length of transect line was

based on distance sampling [9]. Thus, Distance 5.0 beta was used for the analyses of sighting data and resolution of estimates given at global level. Average speed of the sailing vessel was 7 nautical miles/h.

#### Results and Discussion

During the survey, totally 1800 km was covered and 139 hour of effort was made. Totally 97 dolphins which belong to three species of family Delphinidae were recorded in 19 sightings; these are 56 T. truncatus in 13, 37 D. delphis in five and three S. coeruleoalba in one observation. Consequently, T. truncatus observed most frequently, although the D. delphis has a bigger group size. Besides, P. Phocoena was not observed and S. coeruleoalba observed only one point near Aegean-Mediterranean border suggest that need more effort to increase the level of encounter or these species are not common in the Aegean Sea. Distance results show hat the density of dolphins 0.27 (SE: 0.68, 95%CI; 0.17-0.45), encounter rate (n/L) 0.11 (SE: 0.01, 95%CI: 0.83- 0.14) and average cluster size 5.2 (SE: 0.5, 95%CI: 4.1-6.6). These cetacean species are under the protection by national and international (eg. Barcelona and Bern Conventions) laws. Besides, the Mediterranean common dolphins status has been declared as "endangered" [8]. Studies on cetacean species in the Aegean coasts provide an important contribution to diversty and determining conservation strategies for protection of biological richness. This is the preliminary study for understanding dolphin populations in the Turkish coasts. Therefore, more detailed studies are necessary for this purpose.

# BANQUETTE FAUNAL ASSEMBLAGES FROM GROOMED AND UNGROOMED BEACHES ON THE MALTESE ISLANDS

Alan Deidun \*, Stephen Saliba and Patrick J. Schembri

Department of Biology, University of Malta, Msida MSD06, Malta - alpra1@mail.global.net.mt

## Abstract

The macrofauna associated with beached seagrass wrack on three regularly cleaned (groomed) Maltese beaches and three that are not cleaned (ungroomed) was sampled over a two year period by taking cores and by using pitfall traps. Overall, 40 species were collected from both types of beaches. Coleoptera had the highest species richness (20 species) but the most abundant individual species were the gastropod *Truncatella subcylindrica* and the amphipod *Orchestia stephenseni*. Species richness and individual abundance were highest in the winter months for all beaches. The ungroomed beaches had more species (34) than the groomed ones (9) as well as a higher Shannon-Wiener diversity index, Pielou's evenness, and individual abundance for all species collectively. Thick and long-standing wrack accumulations support higher species richness and abundance and a more taxonomically and trophically diverse biota than thin, freshly deposited layers of wrack.

Keywords : Beach, Biodiversity, Coastal Systems, Posidonia.

#### Introduction

Extensive meadows of *Posidonia oceanica* together with some *Cymodocea nodosa* occur adjacent to the gently sloping north-eastern coastline of the Maltese Islands [1,2]. Most beaches along this coast receive substantial annual inputs of seagrass debris during the autumn and winter months [3]. However, this wrack is regularly cleared away in the summer months from beaches of importance to the tourism industry and it is only on a few relatively inaccessible beaches that this debris is left undisturbed. On such beaches, 'banquettes' [4] of beached dried seagrass (wrack), as high as 2m, can accumulate over a number of years.

### Material and Methods

The beaches at Salina, Xatt l-Ahmar and Selmun (ungroomed beaches), and those at White Tower Bay, Fomm ir-Rih, and Qarraba Bay (groomed beaches) were sampled in winter and summer of 2002 and 2003 by collecting wrack from a 20cm x 20cm quadrat until a 1 litre container was filled (in effect collecting a 0.001m<sup>3</sup> core sample), and repeating the procedure at 10cm depth intervals until the bottom of the wrack accumulation was reached. The material was then washed over a 1mm-mesh and sorted for macrofauna. Nocturnally active motile macrofauna were sampled with pitfall traps laid in the wrack at the surface and left overnight using a standardised protocol for all beaches.

#### Results and Discussion

On the ungroomed beaches, the volume of wrack on the beaches ranged from 120m<sup>3</sup> (Xatt 1-Ahmar, winter) to 15m<sup>3</sup> (Selmun, summer), whislt on the groomed beaches, the volume of wrack ranged from 273m<sup>3</sup> (White Tower Bay, winter) to 6m<sup>3</sup> (White Tower Bay, summer). On all the beaches, the longest decomposing Posidonia leaves were at the surface of the banquette, and leaf length became progressively shorter deeper down in the accumulation suggesting more trituration of leaf material in the thicker and more aged banquettes relative to freshly deposited ones. Considering all beaches collectively, 36 species were recorded from the quadrats and 29 species from the pitfall traps; 14 and 6 species were collected exclusively from the quadrats and pitfall traps respectively, therefore, the total species richness for both collecting techniques together was 40 species. A total of 15 species from quadrats and 8 species from pitfall traps were collected on the ungroomed beaches only, whilst a total of 9 species from quadrats and 3 species from pitfall traps were collected on the groomed beaches only. For the pitfall trap collections, Arachnida was the most species-rich taxon (6 species), whilst for quadrats, Isopoda and Arachnida were the most species-rich (3 species each). As estimated from the quadrat samples, Gastropoda had the highest individual abundance (73,646 individuals/m<sup>3</sup>), whilst the most abundant individual species were the gastropod Truncatella subcylindrica and the amphipod Orchestia stephenseni, which reached maximum densities of 68,070 individuals/m<sup>3</sup> at Salini and 708 individuals/m<sup>3</sup> at Selmun (winter 2003 for both species), respectively. Interestingly, whilst in the quadrat samples a mean density of 6,384 individuals/m<sup>3</sup> was recorded for *T. subcylindrica* from the three ungroomed beaches, no individuals of this gastropod were recorded from the quadrat samples from the three groomed beaches. Considering the quadrat samples only, for all the beaches sampled, the 0-10cm wrack layer was the most species-rich, whilst the lowermost layers (30-40cm and 40-50cm, where the wrack accumulated to these thicknesses) had the least number of species. Species richness (quadrat and pitfall samples together) and individual abundance (quadrat samples only) were highest in the winter months for all beaches, including the ungroomed ones. Multivariate classification (group average linkage hierarchical cluster analysis and nonmetric multidimensional scaling ordination) of the species-abundance data for the quadrat samples only (absolute densities cannot be estimated from pitfall trap data and fauna collected by pitfall traps is not necessarily resident in the wrack) showed the assemblages from Xatt l-Ahmar and Salini as distinct from those of the other beaches. This may be related to Xatt l-Ahmar being the most isolated beach of those studied and Salini to being the only one with a muddy substratum beneath the beached wrack. SIM-PER analysis showed Truncatella subcylindrica and the endemic isopod Spelaeoniscus vallettai to account for 71.6% of the observed dissimilarity between the ungroomed beach at Xatt l-Ahmar (to which both species were exclusive) and the groomed beach at White Tower Bay. Overall, the wrack assemblages from the different beaches were relatively distinct, suggesting compartmentalisation of the fauna. Considering both sampling techniques together, a higher macrofaunal species diversity (34 species compared to just 9 species from groomed beaches) was recorded from the ungroomed beaches. Considering the quadrat data alone, a higher individual abundance (a total of 317,200 individuals/m<sup>3</sup> from ungroomed beaches compared to 84,400 individuals/m<sup>3</sup> from the groomed beaches, all species considered together), the highest Shannon-Wiener diversity index value (1.475 in 2002 and 2.100 in 2003, from Selmun in both cases) and the highest Pielou's evenness value (0.823 in 2002 and 0.818 in 2003, from Selmun in both cases) were recorded for the ungroomed beaches. In addition, Arachnida and Staphylinidae were only recorded from aged wrack from the ungroomed beaches of Xatt l-Ahmar, Selmun and Salina. Thick and long-standing wrack accumulations support higher individual abundances, higher species richness, and a more taxonomically and trophically diverse biota than thin, freshly deposited layers of wrack, while breakdown of seagrass litter is more complete in the former than in the latter. These results suggest that ungroomed beaches with thick banquettes contribute more to beach biodiversity and to carbon cycling that groomed beaches.

# EFFECTS OF A TWO-MONTH CLOSURE ON TWO TRAWL FISHING GROUNDS IN THE NW MEDITERRANEAN

Montserrat Demestre \*, Laura Recasens, Pilar Sanchez and Silvia De Juan Psg. Maritim de la Barceloneta, 37-49 08003 Barcelona, Spain - montse@icm.csic.es

## Abstract

Changes in the commercial catches in two trawling grounds located in Sant Carles de la Ràpita (Catalan Coast, NW Mediterranean), were monitored in order to analyse the effects of a two-month seasonal closure. Catch data per unit effort (CPUE) of the three most representative commercial species in each of the two fishing grounds were selected for the study. Results conclude that in both trawling grounds the CPUE increases after the fishing closure.

Keywords : Fisheries, Demersal, Western Mediterranean.

### Introduction

The trawling fleet of Sant Carles de la Ràpita (SCR) corresponds to 50% of the total fleet, and is the largest (16.81%) of the Catalan Coast (NW Mediterranean). The fishing fleet activity is developed from Monday to Friday on a daily basis, operating at the two selected trawling grounds: inshore (<70m) and offshore (>70m). The trawling fleet is regulated by a two months fishing closure every year: July and August (1).

#### Material and Methods

Daily landings by vessel, indicating the specific composition, were obtained from January 2002 to June 2004 from the SCR Fisherman's Association. The fishing effort in each fishing ground was estimated as hours per month and vessel (2).

The three most representative exploited species from each fishing ground were selected to analyse the effects of the seasonal closure. In the offshore fishing ground catches of *Merluccius merluccius*, *Lophius* spp and *Nephrops norvegicus* represent the 21% of the total demersal catches, whereas in the inshore fishing ground catches of *Squilla mantis*, *Mullus* spp and *Loligo vulgaris* represent 34% of the total demersal catches. The catch data was standardized to kg per fishing hour (CPUE)

The fishing activity at both fishing grounds has seasonal fishing effort variability. From March to June the inshore fishing ground shows a low fishing activity and from September to February shows a high level of effort. The fishing activity at the offshore fishing ground is developed in the opposite way.

#### Results and Discussion

To monitor trawl catches variability in both studied fishing grounds, both CPUE (Kg/h) and catches (Kg) of the three inshore and offshore species were compared before and after the seasonal closure (Fig.1 and Fig.2).

Fig. 1. Catches from the two trawling grounds from January 2002 to June 2004.

Fig. 2. CPUE from the two trawling grounds from January 2002 to June 2004.

Results showed different patterns when catches or CPUE were analysed. Regarding the catches, an evident decrease is observed in the offshore fishing ground after the closure in 2002. Nevertheless, in 2003 catches after the closure don't show clear changes. On the contrary, catches increased spectacularly in the inshore fishing ground after the closure. In relation to CPUE, an evident increase appears after the two months of closure in the two studied years at both fishing grounds.

The analysis of the effect of a two month cessation of trawl fishing activity in two fishing grounds highlighted an increase of CPUE in both trawling grounds after the fishing closure.

# SUMMER ICHTYOPLANKTON DATA IN THE SEA OF MARMARA

Nazli Demirel \*, Ahsen Yuksek and Erdogan Okus

Institute of Marine Sciences and Management, University of Istanbul, Muskule Sok. No:1, 34116, Istanbul, Turkey -

ndemirel@istanbul.edu.tr

## Abstract

Eggs and larvae belonging to 10 species were identified in July 1997 and to 19 species in August 2000 in the Marmara Sea. Erdek Bay, Marmara Island and surrounding areas and Tekirdag-Sarkoy region are especially important spawning areas in the Sea of Marmara. *Keywords : Ichthyoplankton, Sea Of Marmara, Spawning.* 

The Sea of Marmara is an enclosed basin where Atlanto-Mediterranean originated commercial pelagic fishes spawn while migrating from the Mediterranean and the Aegean Sea to the Black Sea [1]. Organic and microbiological pollution increased in recent years in the eastern part of the Sea of Marmara especially Izmit Bay [2]. The Sea of Marmara receives large amounts of water from the northwestern Black Sea via the Strait of Istanbul and became eutrophic [3]. Ichthyoplankton research enables a good evaluation of ecosystem changes via fluctuations in species diversity and stocks [4]. The present study identifies important spawning areas in the Sea of Marmara based on summer ichthyoplankton data.

Ichthyoplankton was sampled at 63 stations with Nansen closing nets (mouth diameter 57 cm, mesh size 500  $\mu$ m) vertically in July 1997 and August 2000.

The average upper layer water temperature was 23.8  $^{\circ}$ C in July 1997 and 24.1  $^{\circ}$ C in August 2000. Eggs and larvae belonging to 10 species were identified in July 1995 and to 19 species in August 2000 (Table 1).

The mean egg abundance per unit area was 336 ind.m<sup>-2</sup> in July 1997 and 634 ind.m<sup>-2</sup> in August 2000. The distribution of eggs was higher generally in the north and west part of the Sea of Marmara in July 1997. The abundance and species number were higher especially in the northwest part (Tekirdag-Sarkoy shores). On the contrary, only 7 larvae were found in July 1997. Higher egg abundances were found in the west part among Tekirdag, Marmara Island and Erdek Bay in August 2000. Species numbers were also high in Tekirdag and Gebze coasts (southeast). Similar to egg distribution, larval distribution was high in the northwest and west parts of the Sea of Marmara. Highest abundance value was 1097 ind.m<sup>-2</sup> at Murefte coast (Figure 1).

Fig. 1. Distribution and abundance of eggs-larvae and number of species.

# CYCLE SEXUEL DU CORB SCIAENA UMBRA (SCIAENIDAE) DU LITTORAL D'ANNABA (ALGERIE EST)

Farid Derbal \* and M. Hichem Kara

\*Laboratoire Bioressources Marines, Université Badji-Mokhtar, Annaba, Algérie - mfderbal@yahoo.fr

## Résumé

Le cycle sexuel et la fécondité sont étudiés chez le corb *Sciaena umbra* du littoral d'Annaba. La population échantillonnée est composée essentiellement d'individus immatures et de femelles (S.R = 39,23%). Les mâles et les femelles se reproduisent une seule fois au cours de l'année entre mars et août, à partir d'une taille de 26,5 cm. Les femelles mesurant respectivement entre 33,7 et 44 cm de longueur totale pondent entre 76140 et 404593 oeufs. La fécondité relative moyenne est estimée à 279 oeufs.g<sup>-1</sup>. Elle a tendance à chuter à partir d'une longueur totale de 43,6 cm.

Mots clès : Algerian Basin, Fishes, Teleostei, Reproduction.

#### Introduction

*Sciaena umbra* (L, 1758) est un poisson téléostéen qui est devenu vulnérable à la pression de la chasse sous-marine et les populations de la Méditerranée nord occidentale ont été réduites d'une manière considérable, aussi bien en zone ouverte chassée qu'au niveau des réserves marines [1, 2]. D'ailleurs, les données de biologie concernant cette espèce proviennent surtout des populations, relativement abondantes du Sud du bassin occidental de la Méditerranée [3, 4, 5]. Sur le littoral d'Annaba, les informations sur le corb ne concernent que son écologie *in situ* [6] et son alimentation en milieu naturel [7]. Le travail présenté ici fournit des données nouvelles sur son cycle sexuel: sex-ratio, période de reproduction, taille à la première maturité sexuelle et fécondité.

#### Matériel et méthodes

La période de reproduction est déterminée à partir de l'évolution du rapport gonado-somatique, entre mars 2001 et mars 2002. La taille à la première maturité est celle pour laquelle 50 % des individus sont mûrs et présentent des gonades bien développées. Le sex-ratio est exprimé par la relation suivante: SR = (nombre de mâles / nombre total) x 100. La fécondité est étudiée chez des femelles au stade IV de maturité sexuelle [8].

Tab. 1. Fécondités absolue  $(F_a)$  et relative  $(F_r)$  des femelles de *S. umbra* du littoral de Annaba (L<sub>t</sub>: longueur totale, P<sub>t</sub>: poids total, P<sub>e</sub>: poids éviscéré, P<sub>g</sub>: poids des gonades).

#### Résultats

La population de *S. umbra* est composée essentiellement d'individus immatures (N = 82) puis de femelles (N = 79) et de mâles (N = 51). Avec une valeur moyenne de 39,23%, le sex-ratio est en faveur des femelles (khi-deux = 6,03; P  $\leq$  0,05), notamment en autome (khi-deux = 9,84; P  $\leq$  0,01). La reproduction débute en mars et s'achève en août. Le corb est gonochorique et se reproduit à partir d'une longueur de 26,5 cm. La fécondité absolue est comprise entre 76140 et 404593 oeufs pour des femelles mesurant respectivement 33,7 cm (Pt = 458 g) et 43,6 cm (Pt = 1116 g) (Tab. 1). La fécondité relative moyenne est estimée à 279 oeufs.g<sup>-1</sup>. Sa valeur maximale est de 387 oeufs.g<sup>1</sup> pour une femelle mesurant 37 cm et pesant 535 g. L'équation exprimant la fécondité absolue en fonction de la longueur totale des poissons examinés est: F<sub>a</sub> = 5,18 L<sub>t</sub> - 2,96 (r = 0,774; P  $\leq$  0,05). Au cours de la phase de maturation ovocytaire, les ovocytes mesurent 540  $\mu$ m de diamètre et 873  $\mu$ m lors de la phase d'hydratation juste avant leur émission.

#### Discussion

La prédominance numérique des femelles, en particulier en période de repos génital (automne), résulterait de l'action de deux facteurs agissant seuls ou ensemble: l'action sélective de l'engin de pêche ou la dispersion des mâles au niveau des aires de fraie. La période de reproduction débute au printemps et s'achève en été, comme sur les cotes tunisiennes [4, 5]. Toutefois, ils se reproduisent plus précocèment (Ls = 18,8 cm) comparés à la population tunisienne dont la taille standard à la première maturité sexuelle est estimée respectivement à 20 et 22 cm chez les mâles et les femelles, alors que [3] la situe plus tardivement, à 30 cm de longueur totale. La précocité de la taille de première maturité sexuelle chez les femelles de S. umbra de l'Est algérien, comparée à celle de la population tunisienne, s'expliquerait par les différences de température des eaux et aussi par la disponibilité des ressources alimentaires ayant pour effet de réduire la taille de maturité sexuelle. Sur le littoral maltais, le corb atteint sa maturité sexuelle tardivement, à l'âge de 5 ans [9]. La valeur élevée de "b" (5,18) pourrait se traduire par une longévité assez importante de cette espèce qui atteindrait 15 années dans l'Est algérien et 21 ans sur les côtes tunisiennes [3].

## Abstract

Data on the distribution and abundance of the holothurian *Ocnus planci* in the northern and central Adriatic Sea were collected by bottom trawl during 11 cruises of the Pipeta Expedition from 1985 to 1994. A total of 518 bottom trawl hauls were performed. The species was collected at depths from 20 to 174 m. The highest mean abundance was recorded on sand-silt-clay sediment (185,97 $\pm$ 565,69 N h<sup>-1</sup>) at depth stratum from 25 to 50 m.

Keywords : Echinodermata, Adriatic Sea.

### Introduction

The holothurian *Ocnus planci* (Brandt, 1835) is distributed in the Eastern Atlantic from the North Sea to West Africa and throughout the Mediterranean Sea on different types of substratum at depths from 5 to 250 m [1, 2]. It is common species in trawl by-catches from the continental shelf in the Adriatic Sea [3]. In this paper we present the distribution and abundance of *O. planci* on the continental shelf of the northern and central Adriatic Sea.

#### Material and methods

Samples were collected using the standard Italian bottom trawl [4] during 11 cruises of the Pipeta Expedition (7<sup>th</sup> - 17<sup>th</sup> cruises) in the Adriatic Sea from 1985 to 1994. The expedition sampled approximately 59000 km<sup>2</sup> of the Adriatic continental shelf at predetermined, permanent stations along ten transects (A - L) over different sediment types at depths of 10 to 430 m (Fig. 1). Total of 518 hauls were performed. The abundance (catch rate) of the species is expressed as the number of specimens per trawling hour (N h<sup>-1</sup>). To calculate mean catch values at different substrata and depth strata only hauls from the area of species distribution were used, i.e., stations where the species was caught at least once. ANOVA and Tukey's test were performed.

Fig. 1. Mean abundance (number of specimens per trawling hour, N  $h^{-1}$ ) of *Ocnus planci* along transects in the Adriatic Sea during the Pipeta Expedition (1985-1994).

## Results and discussion

Holothurian *Ocnus planci* was recorded in 35.5% bottom trawl hauls along all investigated transects in the northern and central Adriatic and is one of the most common species of the mobile bottoms (Fig. 1). The highest mean abundance was recorded at stations in the northernmost part of the northern Adriatic. The species was collected from a shallowest depth of 20 m and a deepest of 174 m, which presents the deepest record of *O. planci* in the Adriatic. The highest mean catch rates were obtained at depth strata up to 50 m. *Ocnus planci* inhabits all types of mobile bottoms investigated during the expedition. The highest mean abundance was recorded at stations on sand-silt-clay sediment ( $185,97\pm565,69 \text{ N h}^{-1}$ ) at depth stratum from 25 to 50 m (Tab. 1). Additionally, high catch rates were recorded on relict sand, clayey relict sand and silty sand and sandy silt up to 50 m. Very small presence of *O. planci* was recorded on clayey silt and silty clay sediment (Tab. 1). The high standard deviation values of means (Tab. 1) denote the uneven species distribution in the area. ANOVA results and Tukey's test results show that the differences between catch rates on each sediment type are statistically significant (*P* <0.001).

Tab. 1. Abundance (number of specimens per trawling hour, N  $h^{-1}$ ) of *Ocnus planci* at different sediment types and depth strata during the Pipeta Expedition (1985-1994) in the Adriatic Sea. n - number of the trawl hauls, n+ - number of positive trawl hauls.

## Abstract

La lecture des otolithes de 675 individus de Tassergal, Pomatomus saltatrix, du golfe de Gabès (Tunisie), a permis de déterminer les paramètres de croissance en longueur de cette espèce. Ces paramètres, pour les deux sexes combinés, sont les suivants : LT = 490,4 mm, k = 0,266 et  $t_0 = -0,352$ .

Keywords : Growth, Teleostei, Gulf Of Gabes.

#### Introduction

Le Tassergal, Pomatomus saltatrix (L. 1766), est exploité dans le golfe de Gabès par tous les engins de pêche en usage et particulièrement par les métiers côtiers, les sennes tournantes et les chaluts. Le potentiel offert par le stock et la fraction qui en est extraite demeurent indéterminés jusqu'à présent. Pour les estimer au moyen d'un modèle analytique, il a fallu déterminer certains paramètres, entre autres ceux de la croissance qui seront présentés dans cette note.

#### Matériel et méthodes

L'étude a porté sur 675 individus ayant chacun une longueur totale (LT) comprise entre 58 et 446 mm, provenant, en majorité, des débarquements commerciaux. Après incision au niveau de l'oreille interne, les otolithes ont été prélevés, nettoyés à l'eau et conservés à sec dans de petites pochettes. Pour révéler les anneaux d'arrêt de croissance, ces otolithes ont été trempés dans une solution d'acide acétique pendant deux minutes puis colorés au bleu de toluidine pendant 30 secondes. L'excès de colorant a été enlevé par l'alcool absolu. Une loupe binoculaire munie d'un micromètre oculaire a servi à l'observation de ces pièces, immergées, in toto, dans un bain éclaircissant de glycérine, sur un fond noir. Le rayon total (R) a été mesuré, sur la face concave, du primordium au bord postérieur de l'otolithe suivant le prolongement du sillon: sulcus acusticus. Les rayons des anneaux d'arrêt de croissance ont été mesurés sur ce même axe. Les divisions micrométriques ont été, ensuite, converties en millimètres.

La relation (LT =  $aR^b$ ) qui lie la taille de chaque individu examiné au rayon de son otolithe a été établie pour décrire l'allométrie entre les deux variables. La valeur de la constante b (proche de 1) a été testée par le test t de Student  $(t_c)$ .

Pour situer la période de l'arrêt de croissance, nous avons analysé les variations mensuelles de l'allongement marginal (AM) des otolithes.

 $AM = (R - R_n)X100/(R_n - R_{n-1}),$ 

où R = rayon total de l'otolithe,  $R_n$  = rayon du dernier anneau et  $R_{n-1}$  = rayon de l'avant dernier anneau.

Pour attribuer un âge approximatif à un individu donné, nous avons pris en compte, en plus du nombre d'anneaux que montrent ses otolithes, trois évènements essentiels : la date de naissance qui correspond à la période de ponte de l'espèce (fin octobre - début novembre), la date de capture et la période d'arrêt de croissance.

Pour déterminer les paramètres théoriques de croissance, nous avons lié, pour chaque individu examiné, sa longueur totale mesurée en mm à son âge estimé en ans. Ensuite, une longueur totale moyenne a été calculée pour un groupe d'âge moyen. Les longueurs -aux âges- ont été utilisées pour l'ajustement de la courbe de croissance de Von Bertalanffy dont l'équation est :

 $\mathbf{L}_t = \mathbf{L} \infty \left( 1 - \mathbf{e}^{-k(t-t0)} \right)$ 

où  $L_t$  = longueur totale du poisson au temps t,  $L\infty$  = longueur maximale théorique que le poisson pourrait atteindre, to= temps théorique correspondant à L = 0 et k = constante de la vitesse de croissance.

#### Résultats

Les deux otolithes du Tassergal, du golfe de Gabès, sont oblongs. Chacun d'eux présente une face convexe (interne), une face concave (externe) et un rostre ventral. C'est la face concave qui se prête à l'observation et à la détection des anneaux. En lumière réfléchie, les otolithes présentent, particulièrement chez les individus âgés de plus d'un an, une alternance de zones opaques de couleur blanche et de zones translucides (hyalines) de couleur sombre. Ces dernières sont toujours les moins larges et correspondent à une croissance très ralentie. Une quinzaine d'individus dont l'âge

était approximativement connu (de 5 à 7 mois) ont été très utiles pour le décryptage du premier anneau. Les otolithes de ces individus présentaient des anneaux bien clairs qui seraient pris pour des anneaux annuels, alors qu'ils n'étaient que les marques du premier hiver (environ 3 mois).

Les relations LT = f(R) sont les suivantes : - pour les femelles : LT = 66,863 R<sup>1,0774</sup> ; R<sup>2</sup> = 0,8958 ; N = 320 ; t<sub>c</sub> = 10,12; p<0,001;

- pour les mâles : LT = 60,361 R<sup>1,1574</sup> ; R<sup>2</sup> = 0,9382 ; N = 339 ; t<sub>c</sub> = 32,46; p<0,001;

Ces relations montrent que la taille du Tassergal a une croissance positive par rapport à celle de ses otolithes (b>1, t<sub>c</sub>>1,96, p<0,001) et que la corrélation entre les deux variables est très significative.

L'analyse des variations mensuelles de l'allongement marginal des otolithes a permis de situer l'arrêt de croissance au mois de janvier (le mois le plus froid en Tunisie). Mais si la plus faible valeur moyenne de ce rapport (AM) a été observée à ce mois, cela ne voudrait pas dire que tous les individus ont forcément formé leurs anneaux à la même époque.

L'ajustement de l'équation de Von Bertalanffy aux longueurs - aux - âges estimées a permis de déterminer les paramètres de croissance du Tassergal du golfe de Gabès qui sont les suivants:

- pour les femelles: LT $\infty$  = 472,3 mm  $\pm$  81,5 mm ; k = 0,292  $\pm$  0,110 et  $t_0 = -0,304 \pm 0,255$ ;

- pour les mâles:  $LT\infty = 512,6 \text{ mm} \pm 76,1 \text{ mm}$ ; k = 0,254  $\pm$  0,076 et t<sub>0</sub>  $= -0,333 \pm 0,200;$ 

- pour les deux sexes combinés (N= 675):  $LT\infty$  = 490,4 mm ± 68,8 mm ; k = 0,266  $\pm$  0,079 et t<sub>0</sub> = - 0,352  $\pm$  0,221.

## Abstract

Data from three consecutive years of trawl surveys were used to characterise the demersal assemblages present on trawling grounds around the Maltese Islands, (Central Mediterranean) in water ranging from 85 to 800 m depth. Five different assemblages were present which seemed related to depth zones that do not coincide with those sampled in existing stock assessment programmes. It is therefore clear that the depth strata sampled in such programmes need to be revised to make them more biologically relevant and to achieve a better sampling representation of each assemblage type.

Keywords : Demersal, Deep Waters, Fisheries, Stock Assessment, Trawl Surveys.

#### Introduction

The modern trend in the management of fish stocks is 'ecosystem-based fisheries management', where fish stocks are no longer considered in isolation but as one component of an integrated ecosystem [1]. In turn, such an approach requires a good knowledge of the constituents of the system. Bottom trawling is an important component of many Mediterranean fisheries, being responsible for a high share of total catches and, in many cases, yielding the highest earnings among all the fishing sub-sectors. In the Mediterranean, bottoms are trawled for commercial fishing at depths ranging from 50 to 800 m [2]. We studied the spatial distribution of demersal resources on muddy bottoms in the depth range from 80 to 800 m within the General Fisheries Commission for the Mediterranean (GFCM) geographical sub-unit 15, and assessed management implications of our results.

#### Methods

Samples were collected from trawling grounds off the Maltese islands within the GFCM geographical sub-unit 15 as part of the ongoing MED-ITS trawl survey programme. Otter trawl samples were collected in June-July of 2003, 2004 and 2005 from 45 stations located at different depths between 80 and 800 m. Each haul lasted for ca 45 minutes, depending on the depth and substratum type, and trawl speed was ca 3 knots; the gear used was IFREMER GOC 73 [3] and consisted of a 40 m long and 22 m wide trawl net with a 1-2 m vertical opening and a cod end stretched mesh size of 20 mm. The entire faunal component from each haul was sorted, identified, weighed and counted. The data for each station were standardised per square kilometre, and were analysed using classification and ordination techniques. Species whose percentage biomass was less than 0.01% were removed from these analyses. Agglomerative hierarchical clustering followed by non-metric multidimensional scaling (nMDS) ordination was then applied on a similarity matrix constructed from the fourth-root transformed data using the Bray-Curtis similarity measure, using the PRIMER 6 software [4]. Since the biomass data yielded more detailed and clearer results than abundance data, the former is presented in this paper.

#### Results and discussion

A total of 552,963 live individuals (22,887 kg) comprising 189 different species (26 elasmobranchs, 111 teleosts, 26 decapods and 26 molluscs) were identified, of which teleosts were the largest component in terms of both abundance and biomass.Cluster analysis and nMDS ordination of the species biomass data resulted in five main clusters at a similarity of 46% (Fig.1). These clusters correspond to two sets of outer continental shelf stations, those from the continental shelf slope (140 - 273 m), those from the shelf break (240 - 440 m) and those from the deep slope (466 - 701 m) stations.

In general, the difference in assemblage structure increases with depth, with the transition from one assemblage to the next being more gradual at shallower depths and sharper as the depth increases. The differences between the continental shelf assemblages (Outer shelf A, Outer shelf B, Shelf break) were mainly quantitative, but were both quantitative and qualitative between the outer and shelf break assemblages and the upper slope assemblages, and between the upper slope assemblages and those of the deep slope.

Fig. 1. Non-metric multidimensional scaling (nMDS) plot for the sampling stations for all the three years, based on biomass. The ovals enclose the groups generated by cluster analysis. OSA - Outer shelf A; OSB -Outer shelf B; SS - Shelf break; SL - Shallow slope; DS - Deep slope.

Based on these results the fishery resources of Maltese trawling grounds are stratified in four main depth ranges: 80-160 m (outer continental shelf: two subgroups), 160-270 m (shelf break), 270-440 m (upper slope), and 440-800 m (deep slope). These strata do not coincide with those sampled in existing stock assessment programmes, which were set up without reference to benthic/demersal assemblage structure and its relation to depth. It is therefore clear that the depth strata sampled in such programmes need revision to make them more biologically relevant and in order to have a better sampling representation of each assemblage structure to detect the impact of various fishing practices on the benthic/demersal assemblages both spatially and temporally, and if any changes found are related to the spatial and temporal effort of the fishing fleet.

## Abstract

Demersal assemblages from trawl surveys made at depths of 45-800 m in trawled areas within the 25NM Fisheries Management Zone round the Maltese Islands were related to environmental characteristics on the seabed. Depth, temperature, and mean grain size all affected the structure of the demersal assemblages but depth and temperature gradient were overall the most important in that order; while mean grain size seemed more important for relatively shallow bottoms (<80 m) than for deep ones. *Keywords : Demersal, Fisheries, Sediments, Temperature, Trawl Surveys.* 

Introduction

Prior to joining the European Union, Malta managed a 25 nautical mile Exclusive Fishing Zone. Post-EU membership, Malta was allowed to retain this zone, which covers an area of 10,700 km<sup>2</sup>, as a Fisheries Management Zone (FMZ) as there are indications that demersal fishery stocks within the zone are distinct from those outside [1]. For shallow shelf resources (<200 m) within the FMZ, adult populations of demersal fish are believed to be isolated to some degree from adjacent populations and exchange of adult individuals between these populations may be limited. At present, there is little information on the distribution of biological assemblages in relation to environmental variables within the Maltese FMZ, even if such information is essential for the management of living resources. A programme of research to address this is being implemented.

#### Methods

Otter trawl samples were collected from stations at depths between 45 and 800 m distributed within the Malta 25NM FMZ in the summer of 2003, 2004 and 2005 as part of the ongoing MEDITS trawl survey programme. Samples were collected with a semipelagic experimental trawl net (IFRE-MER GOC 73) and each haul lasted for ca 45 minutes, depending on the depth and substratum type; trawl speed was ca 3 knots. Bottom temperature was measured with a temperature probe attached to the net. The entire catch from each haul was sorted, and the fauna were identified and counted. Samples for sediment analyses were collected in 2004 and 2005 from a limited number of stations using a 0.0625 mÅš box corer. Sediment granulometry was determined according to the procedures described by Buchanan [2].

The macrofaunal data were analysed by first constructing a similarity matrix from the root-root transformed biomass data using the Bray-Curtis similarity measure and then applying non-metric multidimensional scaling (nMDS) ordination [3]. Relationships between measured abiotic characteristics (depth, temperature, mean grain size) and demersal assemblages were determined using the BIOENV procedure and by superimposing scaled individual variables onto the sample locations on the two-dimensional nMDS ordination plots. All the analyses were made using the PRIMER 6 statistical software package [3].

#### Results and Discussion

The visual correlations between the environmental variables and the groups generated by the nMDS ordination indicate that all three physical parameters seemed to play a role in structuring the demersal assemblages. The BIOENV correlation analyses gave relatively high values of Spearman's coefficient for depth, temperature, and to a lesser extent, for mean grain size. (Figs. 1 and 2).

The most important environmental variable responsible for the observed patterns of change in community structure was depth. Depth has also been shown to be the main factor determining the distribution of marine fauna in other areas of the Mediterranean [4]. Temperature was second in importance, while the correlation coefficient for mean grain size was relatively low when compared to the coefficients for depth and temperature. While mean grain size explained well the distribution of the relatively shallow water stations (46-82 m), it was not as important in structuring the deeper water assemblages. In summary, the depth and temperature gradients, with their accompanying environmental and biological changes, are the main factors responsible for the patterns in community structure observed.

Fig. 1. Non-metric multidimensional scaling (nMDS) plot for the sampling stations from 2004 and 2005, based on biomass with superimposed scaled values of mean grain size ( $\mu$ m). The numbers on each station position give the mean depth for that station.

Fig. 2. nMDS plot with superimposed scaled values of temperature ( $^{o}$ C) for all three years (2003, 2004 and 2005).

# IMPACTS OF CAGE FARMING ON THE DISTRIBUTION ON THE MOLLUSCAN FAUNA IN THE AEGEAN SEA

Alper Doğan \*, Mesut Önen and Bilal Öztürk

Ege University, Faculty of Fisheries, Dept. of Hydrobiology, 35100, Bornova, Izmir, Turkey - alper.dogan@ege.edu.tr

## Abstract

The impacts of the cage culture on the Molluscan fauna in the vicinity of fish farms were studied seasonally at 2 stations in the Aegean Sea. A total of 1064 individuals belonging to 129 species were encountered. Relatively low diversity and evenness index values under the cages were determined.

Keywords : Mollusca, Aegean Sea, Aquaculture.

#### Introduction

Over the last two decades, aquaculture activities have rapidly expanded in the coastal marine areas and resulted in decreasing at qualities of sea water and bottom sediment. Similarly, those activities have a continuous conflict with tourism activities. The effects of fish farming on the benthic fauna in the vicinity of fish cages have been reported from several parts of the world as in the Mediterranean [1, 2].

The present study attempts to determine the effects of the fish farming activities on the mollusc fauna inhabiting under and around of the cages of two fish farms.

## Material and Methods

Samplings were performed seasonally at two stations in the Aegean Sea between September 2002 and June 2003 at station 1 and October 2001 and August 2002 at station 2. At each station three samples were taken with dredge; one under the cages, one at the vicinity of the cages and one from reference point where it is far enough from the stress of the organic enrichment. The samples were washed through 0,5 mm mesh size sieve fixed with 10 % formalin and preserved in 70 % ethanol. Data concerning stations and the fish farm are given in Table 1. Diversity, evenness and similarities were determined by means of PRIMER software.

|         | C 14 P+Sa 6000 |              |        |                                   |                  | bream                    |                               |                     |  |

#### Result and Discussion

In the 24 samples analyzed, a total of 1064 individuals were identified belonging to 129 species. *Bittium latreillii* sampled mainly from the *Posidonia oceanica* meadows was the most abundant species (15,6 %) followed by *Dentalium inequicostatum* (7,99 %) occurred mostly on the muddy bottom of the station 2. *Tellina distorta* considered as a species of semi polluted zone [3] was another abundant species (5,17 %) encountered under the cages having muddy bottom at station 2. *Corbula gibba* considered as tolerant species that can inhabit in semi-polluted or polluted zones where they may form dense populations [4] was sampled relatively less in number under and the vicinity of the cages situated on muddy-sand and sandy bottoms of station 1.

The number of species and the species diversity (H) were lower in the samples collected under the cages while the evenness (J) was relatively constant between the sampling points of the stations. The lowest number of species (27) and diversity value (3,18) were determined under the cages at station 2, whereas the reference point of station 1 was represented with the highest number of species (68) and diversity value (5,37). The maximum numbers of individuals were encountered in the reference points of both stations as 248 at station 1 and 246 at station 2. The lowest number

of individuals (93) was determined at the vicinity of the cages at station 2, and under the cages of station 1 (104).

According to the Bray-Curtis similarity, two stations were linked together with a similarity of 19 % and higher similarity values (49 %, 55 %) were seen in the sub-regions of these two stations (Fig. 1) presumably due to similar bottom structure.

Fig. 1. Bray-Curtis similarity between samples.

The mollusc fauna under the cages especially in station 2 seems to be affected by the earlier installation date of the cages, relatively limited current conditions and shallower depth.

As a result, in order to decrease unfavorable effects of the fish farming activities on the marine ecosystem, the cages should be installed in the locations having appropriate conditions such as depths and strong currents. Beside, certain effects of fish farming on benthic communities can be revealed by more detailed studies including all benthic groups.

# MISE EN EVIDENCE DE LA PRESENCE DES TINTINNIDES DANS LE GOLFE DE GABES (SUD-EST TUNISIEN)

Z. Drira \*, J. Elloumi , H. Ayadi , M. Belhassen , A. Hamza , A. Bouaïn

Laboratoire de planctonologie, Unité de recherche 00/UR/0907 Ecobiologie, Planctonologie et Microbiologie des Ecosystèmes Marins. Département des sciences de la vie. Faculté des sciences de Sfax BP 802. CP 3018.Sfax, Tunisie. - zaherbmc@yahoo.fr

## Résumé

L'étude spatiale du zooplancton dans le golfe de Gabès pendant une campagne estivale en Juillet 2005, a montré qu'à côté des copépodes qui sont dominants et représentant 86% du zooplancton total, les ciliés composés essentiellement par les tintinnides des eaux côtières marines sont peu abondants et constituant 1% du zooplancton total. Ces tintinnides de grande taille sont représentés essentiellement par 7 espèces. Leurs densités peuvent atteindre dans certaines stations  $8.8 \cdot 10^4$  ind.m<sup>-3</sup>. Une relation trophique manifestée par un broutage du phytoplancton par les tintinnides pourrait exister dans le golfe de Gabès pendant la saison estivale. *Mots clès : Gulf Of Gabes, Zooplankton, Copepoda, Phytoplankton.* 

#### Introduction

Les tintinnides sont des Oligotriches planctoniques de 20 à 200  $\mu$ m qui constituent un lien trophique entre le compartiment microbien et métazoaire [1]. Ce sont des importants brouteurs et jouent un rôle fonctionnel dans la chaîne trophique marine [2]. Ils constituent le majeur composé du microzooplancton dans les environnements marins [3]. A fin de dégager la relation trophique entre les tintinnides avec d'autres communautés planc-toniques, nous avons étudié la répartition spatiale du phytoplancton et des copépodes des tintinnides.

#### Matériel & Méthodes

Durant une campagne estivale (Juillet 2005), 33 stations côtières et néritiques ont été prospectées au niveau du golfe de Gabès (Figure 1A) afin d'étudier le peuplement zooplanctonique et phytoplanctonique. La récolte du zooplancton a été effectuée à l'aide d'un bongo de 100  $\mu$ m de porosité et le comptage a été fait à l'aide d'une cuve de Dollfus sous une loupe binoculaire. La récolte du phytoplancton a été réalisée par un dispositif de CTD. La composition phytoplanctonique a été estimée par microscope inversé [4].

#### Résultats & discussion

L'étude qualitative et quantitative du zooplancton dans les différentes stations du golfe de Gabès, a montré que les copépodes constituent le groupe le plus dominant avec une moyenne de 86%. Les tintinnides (1%du zooplancton total) sont composés par 7 espèces à savoir Codonellopsis morchella, Tintinnopsis sp1, Tintinnopsis sp2, Tintinnidium sp, Brandtiella palliata, Laackmanniella naviculaefera et Rhabdonella sp. Ces espèces se caractérisent par une taille variant entre 131 et 405  $\mu$ m et une abondance pouvant atteindre  $8.8 \cdot 10^4$  ind.m<sup>-3</sup>. La répartition spatiale des tintinnides a montré la présence de 3 foyers de concentrations dont 2 sont situés au niveau de l'isobathe de 50 m et le troisième à l'intérieur du golfe (<50 m) (Figure 1B). Les tintinnides peuvent consommées les diatomées et les dinoflagellés [5]. La fluctuation relative de l'abondance des tintinnides est liée à la densité du phytoplancton [6]. En effet, le maximum d'abondance des tintinnides coïncide avec le maximum de concentrations du phytoplancton [7]. Les tintinnides constituent une nourriture importante pour les crustacés tels que les copépodes [8]. Une corrélation positive a été détectée entre l'abondance des copépodes totaux et des tintinnides ( $r^2 = 0.563$ , p < 0.005) qui est due probablement au broutage des tintinnides par les copépodes [9]. L'étude de la répartition spatiale, a montré que les fortes densités de copépodes correspondent à de faibles abondances des tintinnides.

# INVESTIGATION OF CYCLIC CHANGES OF ZOOPLANKTON COUNTS AND SOME ENVIRONMENTAL FACTORS USING FOURIER ANALYSIS IN THE EASTERN HARBOR OF ALEXANDRIA EGYPT

Ahmed El-Gindy<sup>1</sup>\*, Nagwa Abdel Aziz<sup>2</sup> and Mohamed Dorgham<sup>3</sup>

<sup>1</sup> Prof. of Physical Oceanography, Oceanography Dept. Faculty of Science, Alexandria University, AUDO - aelgindy45@yahoo.com <sup>2</sup> Assistant Prof. of biological oceanography, National Institute of Oceanography and Fisheries NIOF.

<sup>3</sup> Prof. of Biological Oceanography, Oceanography Dept. Faculty of Science, Alexandria University. AUDO

## Abstract

Time series data of monthly counts of zooplankton, groups and species, and some environmental factors (water temperature, salinity and chlorophyll) were collected, in the Eastern harbor of Alexandria Egypt, in the period from October 1999 to November 2003. The biological investigation of these data has been dealt with in another publication [1]. In this paper 27 time series, each of length 36 months, for 3 environmental factors, 5 zooplankton groups and 19 zooplankton species, are analyzed using the Fourier analysis to find out the amplitudes and phase angles at the different cycles with periods between 2 and 36 months. The results show the periods of the relevant cycles affecting the movement of the time-series for each of the used variables including the groups, the species and the environmental factors, detected by the peaks of the periodogram (Frequency - amplitude chart).

Keywords : Time Series, Zooplankton.

#### Introduction

The study area is the Eastern harbor of Alexandria that lies at  $(31.2-31.214^{\circ} \text{ N}, 29.880 - 29.908^{\circ} \text{ E})$ . It is a semi-circular basin bounded at the open sea side by an artificial break water to protect the inner part of the harbor from the direct wave action especially in winter time. There are two outlets at the sea, eastern and western outlets. The depths lies between 1 and 9 meters with an average 5 meters and the largest depths are near the outlets. This area is important as a fishing harbor as well as a tourist site.

#### Data and methods of analysis

Time series analysis was applied on biological data [2]. The Fourier analysis is one of the important tools used in the investigation of the of any time series. It aims to fit the equally spaced time series by the summation of sine and cosine functions so that the variable value can be estimated. The main arguments in the equation are the amplitudes and phase angles relative to time series starting.

Tab. 1. Harmonic analysis peaks frequencies for zooplankton groups and environmental factors in the eastern harbor (1999-2003) indicated by sign (x).

|                   |     | 2.118          | 17                       |       |     |   |   |   |   |   |   |   |

The spectra represented as the relation between amplitude as y- axis and frequency as x- axis and the important peaks are corresponding to the main controlling cycles in the time series. The phase angles of the different variables enable to determine the time delay at a given frequency or given period between the occurrences of the maxima in the original time series of any two variables.

In the full text the results are presented as follows:

1- The time series of the three environmental factors and the five zooplankton groups are presented graphically.

2- The amplitudes of the above variables are presented graphically against the frequency.

3- The relevant frequencies in the environmental variables as well as zooplankton groups and species have been tabulated to deduce the common frequencies among the different variables (table 1).

4- For a given frequency (or period) the delay time of occurrence of the

maxima in original time series (blooming times) of any two variables was calculated (tables 2). The negative sign indicates raw variable peak comes first, and positive sign indicates that the column variable peak comes first (table 2).

Tab. 2. Matrix of delay in months (from phase of raw var. - phase of column var.) for the cycle of zooplankton groups and some environmental variables at the periodic time of 12 months from Fourier analysis (- sign indicates raw variable peak comes first, and + sign column variable peak comes first.

#### Conclusions

The most common periods for the different variables are 36, 12, 9 and 6 months. The 12 months is corresponding to seasonal changes, the 36 months may be related to inter-annual climate changes and periods less than 12 months are due to local changes depending on the hydrological exchange between the Eastern harbor and the open Mediterranean coastal waters in-front of the study area. The time lags of the occurrence of the maxima for each variable (groups and environmental factors) relative to the other variables at the important cycles with periods 36, 12, 9 and 6 months are calculated to expresses the response time of the different groups blooming. The cluster and correlation analyses of the different variables have also be done to show the significantly correlated ones.

# THE BIOMASS OF DEMERSAL FISHERIES RESOURCES IN THE EASTERN AEGEAN SEA

N. Emrah Asikoglu, B. Cihangir, H. Avni Benli, A. Unluoglu \*, E. Mumtaz Tirasin, K. Can Bizsel Dokuz Eylül University, Institute of Marine Sciences and Technologyİzmir-Türkiye - aydin.uoglu@deu.edu.tr

## Abstract

Bottom-trawl catch data collected from the Eastern Aegean Sea between July 1991 and August 1995 were analysed. The Eastern Aegean Sea is divided to five main regions according to their ecological properties, and trawl samples were grouped by these subregions. Total biomass values (t/km<sup>2</sup>) for each subregion were calculated. Although the total biomass estimates according to subregions were highly variable, ranging from 0.22 to 8.75 t/km<sup>2</sup>, in general similar biomass distribution patterns were observed. *Keywords : Biomass, Aegean Sea, Trawl Surveys, Demersal.* 

### Introduction

Biomass and/or abundance data are of great importance to fisheries science, because they provide fishery independent indices to assess the demersal fisheries resources. From this perspective, the aim of this work is to evaluate the catch data collected during the "JICA and TUBITAK"trawl survey programs in 1991-1993 and 1993-1995, respectively.

#### Material and Methods

Data were collected by R/V K. Piri Reis during the bottom-trawl surveys conducted between July 1991 and August 1995 from the Eastern Aegean Sea along the Turkish Coastal and Internatial Area. A total of 11 trawl surveys were carried out, and a total of 525 trawls were hauled between depths of 20 to 700 m. The biomass of demersal organisms was estimated using the "Swept Area Method"[1]. For a more accurate calculation of the area swept by the gear the "SCANMAR-Net Sounder system" was used to determine the width between wing nets during the trawling operation. In order to evaluate whether there is a spatial variation in the biomass estimations, the Eastern Aegean Sea was divided into five main regions according to their ecological properties (Fig 1). Trawl samples were grouped by these subregions and the total biomass of demersal organisms were calculated in terms of t/km<sup>2</sup> for each subregion.

Fig. 1. Sampling subregions.

Results and Discussion

A total of 191 species belonging to 62 families were sampled. From

these, 132 species were teleosteans, 42 elasmobranchs, 19 cephalopods and 9 decapod crustaceans. However, the large majority of the cathes was dominated by a small number of taxa. *Mullus barbatus and Merluccius merluccius* were *the* dominant commercial species in most samplings. Some of the other abundant species were *Pagellus acarne*, *Pagellus erythrinus*, *Diplodus annularis*, *Dentex macrophthalmus*, *Lophius piscatorius*, *Chelidonichthys lastoviza*, *Lepidotrigla cavillone*, *Upeneus moluccensis*, *Scyliorhinus canicula*, *Parapeneus longirostris*, *Nephrops norvegicus*, *Octopus vulgaris*, and *Loligo vulgaris*. The occurrence and percentage contributions of the species to the catch composition svaried by subregions, seasons or depths. The number and composition of species observed in this study were similar to those reported by from the North Aegean Sea [2], and from the southern Aegean Sea [3].

Although the total biomass estimates according to sub regions were highly variable ranging from 0.22 to 8.75 t/km<sup>2</sup>, in general similar biomass distribution patterns were observed (Fig 2). The total biomass estimates for the subregions I, II and III were rather similar. While the highest estimated total mean biomass was found in subregion V, the lowest estimate was estimated for subregion IV. Both subregions belong to the Southern part of the Aegean Sea. The reason for discrepancy is probably due to the fact that subregion IV is under the influence of heavy fishing pressure from commercial fishery while subregion V is mostly closed for trawl fishery.

Fig. 2. Total biomass ( $t/km^2$ ) distribution per subregion. An ANOVA showed no significant variation among the sub regions ( $F_{4,109}$ =1.52, p>0.25)

# FEEDING HABITS OF RHINOBATOS RHINOBATOS IN THE GULF OF GABES

Samira Enajjar \*, Mohamed Nejmeddine Bradai and Abderrahmen Bouain

Institut National des Sciences et Technologies de la mer (centre de Sfax) BP. 1035 - 3018 Sfax. Fax: 74497989 - enajjarsamira@yahoo.fr

## Abstract

The stomach contents of 498 common guitarfishes, *Rhinobatos rhinobatos*, from the gulf of Gabès were examined. The number of empty stomachs was higher in juvenile than in adults (97.05% and 80.64%). Crustaceans and Teleostei were the most important prey groups (IRI% were respectively 51.44% and 47.46%) in the diet of adults. Crustaceans were the main prey for juveniles (IRI% = 83.43%). *Keywords : Fishes, Gulf Of Gabes, Fish Behaviour.* 

#### Introduction

*Rhinobatos rhinobatos* is a benthic fish inhabiting soft bottoms, generally in shallow water. Data on its feeding of are scarce, concerning few specimens collected in the lagoon of ElBibans (Southern Tunisia) [1]. The present study provides data on its feeding habits in the Gulf of Gabès.

#### Materials and methods

A total of 498 *R. rhinobatos* landed by bottom trawl in the gulf of Gabès were examined. Specimens were divided in two categories: Juveniles (total length less than 600 mm) and adult (over than 600 mm).

Stomachs were removed, the diet composition was identified to the lowest possible taxon, and each prey was weighted to the nearest 0.1 g. The specimens with empty stomach were recorded (RI%).

To assess the relative importance of each prey item in the diet three indices were used: the numerical index (N%), the gravimetric index (M%) and the relative importance index (standardized; IRI%) [3]. The classification of prey was based on Cortes' methods [2].

We calculated also the overlap index [4] to determine the prey overlap between the two sizes class. The values of this index range from 0 to 1, with values exceeding 0.6 showing 'biologically significant' overlap in resource use [5].

#### Results and discusion

The RI % was relatively hight: 97.05 and 70.64%, respectively, for juveniles and adults.

*R. rhinobatos* consumed a wide range of macrobenthic organism. Prey included shrimps (*Sicyonia carinata, Trachypenaeus curvirostris*), crabs (*Dorippe lanata, Ehtusa sp.*), fishes (represented by *Diplodus annularis, Serranus hepatus, Pagellus erythrinus, Engraulis encrasicolus, Sardina pilchardus*). Sepia officinalis, Loligo vulgaris and Sepiola sp. were the most abundant Mollusca.

Crustacean were the main important prey for juveniles (Table 1). For adults crustacean and teleostei were the main prey (Table 1). The diet overlap index was high, 0.9.

Tab. 1. N %, M % and IRI% for each food item for juvenile and adult of *Rhinobatos rhinobatos*.

# DIRECT GRADIENT ANALYSIS OF THE MOLLUSCAN COMMUNITY AT THE MARINE-LAGOONAL ENVIRONMENTAL TRANSITION AT KALLONI SOLAR SALTWORKS (NE AEGEAN SEA, GREECE)

Athanasios Evagelopoulos \* and Drosos Koutsoubas

Department of Marine Sciences, Faculty of Environment, University of the Aegean, University Hill, 81100, Mytilene, Greece. -

tevagelo@marine.aegean.gr

# Abstract

A direct gradient analysis technique (CCA) was employed for the investigation of (a) the spatial organisation of the molluscan community and (b) the environmental factors structuring the molluscan community, at the part of Kalloni solar saltworks that is in the immediate vicinity of the sea (Kalloni Gulf, NE Aegean Sea). The molluscan community and environmental parameters were sampled at four sites, on a seasonal basis during 2004. The strong environmental gradient that exists across space between the gulf and pond2 site, structures the molluscan community in the study area. Species composition spatial variations imply a marine-lagoonal environmental transition, typicaly observed in coastal lagoons. Sediment type, organic matter % and chloroplastic pigments concentration were found to be among the key components of the environmental gradient in the study area, as has also been observed in natural coastal lagoons. *Keywords : Mollusca, Biodiversity, Lagoons, Aegean Sea.* 

## Introduction

Solar saltworks comprise man-made systems, where a salinity gradient is maintained along a sequence of interconnected ponds for the production of salt by solar evaporation. On the other hand, the ecosystems of solar saltworks are extremely heterogeneous and consequently of great ecological importance and scientific interest [1]. However, solar saltworks ecosystems, in particular the benthic subsystem, have not been sufficiently studied. The aim of this paper is to employ a direct gradient analysis technique [2] for the investigation of the spatial organisation of the molluscan community as well as the evaluation of the environmental factors structuring the molluscan community at the part a solar saltworks that is in the immediate vicinity of the sea.

# Materials and methods

The study area is Kalloni solar saltworks (Kalloni Gulf, Lesvos Island, NE Aegean Sea, Greece). The molluscan community was sampled at four sites, on a seasonal basis during 2004. Environmental variables [water column salinity and temperature, sediment type (measured as sand %), water column and sediment chloroplastic pigments concentration, sediment organic matter %] were also measured. Canonical correspondence analysis [3] was applied to assess the statistical associations between the molluscan abundance data (response variables) and the space aspect of the sampling design, coded as dummy variables (explanatory variables). Environmental variables were projected *post hoc* into the ordination plot (supplementary variables).

## Results

Canonical correspondence analysis (CCA) ordination of the biotic data of all seasons (Fig. 1), performed with explanatory variables representing the spatial aspect of the sampling design, revealed that the differences between sites explained a large part of the total inertia of the biotic data (total inertia=2.292, sum of all canonical eigenvalues=0.821, p=0.001). Two different groups of abundant species (>1 ind.  $m^{-2}$ ) can be distinguished: one group of marine and marine/estuarine species that are associated with the gulf site and, to a lesser extent, with the channel site and a second group of marine/estuarine and typical lagoonal species that are associated with the pond sites. The first axis of the ordination diagram corresponds to a strong spatial gradient that exists between the gulf site and the pond2 site (eigenvalue=0.589, explained 25.7% of total inertia or 71.8% of the total explainable inertia, p=0.001). The second axis corresponds to a comparatively weaker spatial gradient that exists between the gulf site and the channel site (eigenvalue=0.186, explained 8.1% of total inertia or 22.8% of the total explainable inertia). The environmental variables that were best correlated with the primary spatial gradient are the sediment type and organic matter %, whereas sediment chloroplastic pigments concentration correlated best with the secondary spatial gradient.

#### Discussion

The strong environmental gradient that exists across space between the gulf and pond2 site, structures the molluscan community in the study area. Species composition spatial variations imply a marine-lagoonal environmental transition, typically observed in coastal lagoons [4]. Sediment type, organic matter % and chloroplastic pigments concentration were found to be among the key components of the environmental gradient in the study

area, as has also been observed in natural coastal lagoons [5].

Fig. 1. CCA ordination of the biotic data of all seasons, performed with explanatory variables representing the spatial aspect of the sampling design, with environmental variables projected post hoc into the ordination plot as supplementary variables. The explanatory variables (GULF, CHANNEL, POND1 & POND2 sites) are indicated by open circles, whereas the supplementary variables [water column (WCPE) and sediment (SCPE) chloroplastic pigments, sediment type (SAND%) and organic matter (OM), water column salinity (SAL) and temperature (TEMP)] are indicated by arrows. Molluscan species are indicated by open triangles. Only the most abundant species are shown (*Abra segmentum, Bittium reticulatum, Cerastoderma glaucum, Cyclope neritea, Donacilla cornea, Hydrobia acuta, Loripes lacteus, Pirenella conica, Pusillina radiata, Rissoa variabilis, Rissoa ventricosa, Tellina tenuis, Tricolia pullus).*

# AGE ET CROISSANCE D' ELEDONE MOSCHATA (CEPHALOPODA, OCTOPODA) DES EAUX TUNISIENNES

Soufia Ezzeddine-Najaï \* and Bachra Chemmem

INSTM, Rue de 2 mars 1934- Salammbô (2025)- Tunisie - soufia.ezzeddine@instm.rnrt.tn

# Résumé

Le présent travail est une contribution à la biologie de croissance du poulpe musqué *Eledone moschata* des côtes tunisiennes. Il est basé sur un échantillonnage de la pêche au chalut et de la pêche artisanale durant 3 années consécutives (1996-1998). L'évolution des fréquences de taille de la population Nord et Sud-Est (méthode de Battacharya) a permis d'estimer les paramètres de l'équation de von Bertalanffy et d'établir les clés âge-longueur. Selon les résultats, le poulpe musqué atteint une taille maximale estimée à 15 cm dans la zone Nord et à 16 cm dans la région Sud-Est pour une longévité correspondante d'environ 1,5 an et un accroissement notablement plus important dans la première année de vie. Ces résultats attribuent à l'espèce une croissance très rapide et une longévité courte caractéristique des Céphalopodes.

Mots clès : Cephalopods, Growth, Mediterranean Ridge.

## Introduction

L'exploitation du poulpe musqué *Eledone moschata* s'est accrue suite à la surpêche du poulpe commun, *Octopus v ulgaris*, céphalopode de première importance économique nationale. Exception faite aux travaux parus sur la population de la mer catalane [1-3] et sur la reproduction de la population sud-tunisienne [4], peu de données étaient jusqu'alors disponibles sur l'espèce. L'intérêt orienté vers ce produit de substitution a donc suscité son étude biologique et dynamique, accomplie durant la période 1996-1998 sur les côtes tunisiennes.

Dans ce travail, nous avons présenté les résultats obtenus sur les paramètres de croissance d' *Eledone moschata* par classe de taille estimés à partir de deux populations exploitées le long des côtes tunisiennes.

#### Matériel et méthodes

L'étude est basée sur les échantillonnages métriques des débarquements commerciaux des chalutiers et de moindre importance des embarcations de la pêche artisanale exerçant dans la région Nord (de Tabarka à Kélibia, Méditerranée occidentale) et dans la zone Sud-Est (de Kélibia à Zarzis, Méditerranée centrale). Au total, 11241 individus ont été échantillonnés, répartis respectivement entre 4831 dans le Nord et 6410 dans le Sud-Est ; la longueur standard considérée étant la longueur dorsale du manteau délimitée entre la partie postérieure du manteau et le milieu des yeux.

Nous avons adopté le logiciel FISAT [5] pour la décomposition modale mensuelle des fréquences en taille selon la méthode de Battacharya et pour l'estimation des paramètres de l'équation de croissance de Von Bertalanffy.

## Résultats

Analyse de l'unicité du stock des zones Nord et Sud-Est

Avant d'entamer l'étude de la croissance, nous avons tenté de délimiter la population exploitée dans la région Nord, Est et Sud des côtes tunisiennes. Le suivi chronologique des fréquences de taille n'a pas décelé de différence nette dans la structure démographique des populations des 3 zones. Par contre, l'évolution annuelle de la production des pêches de l'élédone par région sur une série d'années (de 1995 à 2000), a permis d'obtenir pour la région Sud et Est deux courbes similaires mais différentes de celle relative à la région Nord. Compte tenu de ces résultats et faute de données sur les prises par unité d'effort respectives qui pourraient trancher sur l'unicité des populations respectives, deux populations d'élédone ont été donc considérées comme étant exploitées par la flotte tunisienne. Il s'agit de la population Nord et la population Sud-Est que nous avons étudiées séparément sans distinction des sexes.

Paramètres de croissance

Les paramètres de l'équation de von Bertalanffy définie par la relation suivante:

sont estimés à partir du logiciel FISAT ; les résultats obtenus sont comme suit:

Pour la Région Nord : L $\infty$ = 16.17cm ; K=1.753 ; t<sub>0</sub>=0.002

Pour la région Sud-Est: L $\infty = 15.0 \text{cm}$  ; K=0.712 ; t\_0=-0.022

D'après la figure ci-dessous, les courbes de croissance des deux populations présentent une allure similaire avec une phase ascendante durant la première année de vie, suivie par un ralentissement de la croissance vers la taille de 11cm pour la population Sud et 14.5cm pour la population Nord, qui correspondent biologiquement à la taille de maturité sexuelle respective d' *Eledone moschata* [4]. Le processus de reproduction sexuelle serait donc un facteur physiologique précurseur du retard de la croissance survenant à la fin de la vie de l'animal.

Comparées aux populations du bassin occidental de la Méditerranée [2], celle des eaux tunisiennes, qu'elle soit du Nord ou du Sud-Est paraît avoir une croissance plus rapide, alors que la taille maximale atteinte est inférieure à celle du poulpe musqué de la mer catalane [2]. Ce décalage dans le rythme de croissance serait en relation avec les facteurs climatiques ambiants, en particulier le paramètre température [2].

Les plus petits individus capturés par chalutage expérimental mesuraient 3 cm de longueur du manteau, ils sont récoltés à partir du mois de juillet de chaque année. Connaissant la période de reproduction de la population des côtes tunisiennes principalement entre mars et juin [4], et la durée d'incubation d'environ 2 à 3 mois, ces petits animaux recrutés dans la pêcherie, auraient donc l'âge de 1 à 2 mois. A partir de l'équation de croissance établie, nous avons estimé la longévité des deux populations ; elle est de l'ordre de 2,5 ans, toutefois les plus grands individus récoltés du milieu naturel ne dépassent pas 1.5an.

Fig. 1. Courbe de croissance de deux populations d' *Eledone moschata* de la région Nord (A) et Sud-Est (B) des côtes tunisiennes

# Abstract

The potential impact induced by the installation of the off-shore gas platform PCMS-1 (Northern Adriatic Sea) on the surrounding sediments and benthic community, as well as bio-accumulation in mussels settled on the submerged part of the rig, was studied for 2 years. A few sediment anomalies were observed in the first survey, but they decreased in the following periods. The only change in zoobenthos occurred after one year from installation, when mussel mounds developed close to the rig. Differences in hydrocarbon and organic matter content between the platform mussels and those collected at a control site were detected only in the first survey year. *Keywords : Adriatic Sea, Bio-accumulation, Monitoring, Sediments, Zoobenthos.* 

## Introduction

In spite of the large number of gas platforms existing in the Adriatic Sea (about 90), only a few studies focusing on the impact of these structures have been carried out. To cover this gap, starting from 1998 multidisciplinary studies have been performed by CNR-ISMAR of Ancona, in co-operation with ENI S.p.A. [1]. We report an example of these studies. Materials and Methods

The one-leg platform PCMS-1 was placed in July 2001 about 20 km far from Ravenna (Northern Adriatic Sea), at 24.5 m depth (clay-silt bottom). In 2002-03 two surveys in winter and two in summer were carried out to evaluate the impact induced by PCMS-1 construction on the surrounding environment. Sediments and benthic communities were sampled along a transect (7 sampling sites at increasing distances from the rig) intersecting the rig and directed from NW to SE, following the main Adriatic currents. Three control sites having the same geo-morphological features of the study area were also sampled. Sediments and benthic community (4 replicates) were collected by box corer and Van Veen grab (sampling surface = 0.11 m<sup>2</sup>) respectively. Polycyclic aromatic (PAH) and aliphatic (AH) hydrocarbons as well as organic matter (OM) contents were measured on the soft parts of mussels ( Mytilus galloprovincialis) taken from the platform leg, both close (CA) and far (FA) from sacrificial anodes and at a control site (C). The multivariate analysis was carried out by MultiDimensional Scaling on 3 data sets: on particle size and content of OM, heavy metals and PAH for the sediments, on density and biomass of species groups for the zoobenthos and on PAH. AH and OM contents for bio-accumulation. Similarity was based on the Bray-Curtis index.

#### Results

In the MDS plot on sediment data set the sample points are arranged according to a seasonal gradient, especially clear during 2002 (Fig.1). In winter, anomalies in Cd, Pb and MO content were observed in PCMS site. They disappeared in the following surveys, hence this station increased its similarity to the others. MDS based on biotic data did not discriminate the PCMS site from the others in winter 2002 (8 months after the rig installation; Fig. 1). Soft-bottom species dominated everywhere, with a prevalence of polychaetes and molluscs. From summer 2002 onward, mussel mounds were recorded close to the rig. They were inhabited by a mixed community, with soft- and hard-bottom species. Such modification also occurred within 30 m from the rig, but only in that season. AH, PAH and MO contents showed similar seasonal variations in CA, FA and C mussels, but no quantitative differences were evidenced among the three sites. The only exception occurred in summer 2002, when AH and PAH contents were higher in C organisms (Fig. 1).

#### Conclusions

PCMS-1 installation did not cause a consistent impact on the surrounding sediments and benthic communities. This was likely due to its small dimensions and its location in an area characterized by a high density of productive platforms, where sediments are frequently remixed. The only evident change was the mussel mound development close to the platform after one year from construction, as already observed at other rigs located at the same depth [1]. No bio-accumulation processes were detected in the mussels settled on the submerged part of PCMS-1, being the hydrocarbons and OM contents similar to those observed in other Adriatic areas [2].

Fig. 1. MDS applied to sediments, zoobenthos and bio-accumulation data.

# TROPHIC RELATIONSHIPS OF TWO MACROURIDS FROM THE BALEARIC BASIN (WESTERN MEDITERRANEAN): TEMPORAL CHANGES IN DIETS AND IN TROPHIC LEVELS

Emanuela Fanelli $^1\ *$  and Joan E. Cartes  $^2$ 

<sup>1</sup> IAMC-CNR Via G. da Verrazzano, 17 91014 Castellammare del Golfo (TP) Italy - e.fanelli@iamc.cnr.it <sup>2</sup> ICM-CSIC Passeig Maritim de la Barceloneta 37-49 08003 Barcelona, Spain

# Abstract

Seasonal changes in dietary habits and resource partitioning of *Hymenocephalus italicus* and *Nezumia aequalis*, two dominant macrourids co-existing at mid-slope depths (between 550 and 750 m) off Cabrera Archipelago (Balearic Basin, Western Mediterranean), were analysed. *H. italicus* and *N. aequalis* prey mainly on mobile prey (suprabenthos), with a dominance of polychaetes and infaunal amphipods in its diet. Dietary overlap was very low (0,28). Changes in  $\delta^{15}$ N signature also occurred with the highest values observed in spring. *N. aequalis* occupied a higher trophic level (4,4) than *H. italicus* (3,8).

Keywords : Deep Sea Ecology, Fishes, Trophic Relations, Western Mediterranean.

## Introduction

Macrourids are a widely diversified family of deep-sea fish, distributed worldwide, and dominant at bathyal and abyssal depths [5]. Because several macrourids coexist at similar habitats and depths, these *taxa* have been the object of different comparative multi-specific studies: some studies regard resource partitioning among these coexisting species [4, 1] but only few investigations aimed to temporal variations in diets [3]. In this context feeding habits of *H. italicus* and *N aequalis* from Cabrera archipelago were analyzed at a temporal scale, focusing on changes of  $\delta^{15}$ N signatures.

# Materials and Methods

224 specimens of H. italicus and 258 of N. aequalis were collected off Cabrera archipelago (Western Mediterranean), within the framework of the project IDEA. Samples were caught during six trawl survey carried out from August 2003 to June 2004, at middle-slope depths (580-750 m). All the specimens were measured, weighted and dissected for stomach contents analysis. From three specimens of each species per month, a portion of white dorsal muscle was collected, dried to constant weight at 60°C, and ground to a fine powder to be processed for stable isotopes analysis [6]. Prey in the stomachs were identified to the lowest taxonomic level, then analysed by means of trophic indices (e.g. %W; %N and %IRI) [2], univariate and multivariate techniques. Month variation of fullness, mean prey weight and mean prey number of each species was tested by oneway ANOVA. In order to detect spatio-temporal changes in diet, nMDS analysis were performed for each species separately; a PERMANOVA design was created on two factors (month fixed 6 levels; depth random 3 levels, nested in month). Secondarily both nMDS and PERMANOVA techniques were used in order to examine the overlap pattern within the two macrourids. In addition the overlap degree within species was calculated by Schoener index [8]. Temporal differences in stable isotopes signature were tested by one-way ANOVA. The trophic level (TL) of macrourids was estimated based on their  $\delta^{15}$ N data and using copepods as reference material.  $\delta^{15}$ N values were converted to trophic level gone upon the assumption that there was a fractionation of 3 permil per trophic level [6] and that the base material (copepods) had a trophic level of 2. All the univariate and multivariate analyses were performed using STATISTICA and PRIMER 6 plus PERMANOVA packages.

## Results and discussion

From 162 stomachs of *H. italicus* containing food, 52 categories of prey items were identified. Mysids were dominant throughout the year, particularly in August (80,98% IRI) and February (66,39% IRI), whereas isopods were dominant in February and April (28,71 and 18,44 % IRI respectively). Changes in diet were observed in September-November and February-April. Symmetrical PERMANOVA provided evidence for significant differences among months ( $F_{5,156}=1,53$ ; p=0,023) and mainly for the interaction between months and depth ( $F_{5,156}=1,49$ ; p=0,004). A total of 185 stomachs of N. aequalis were analyzed for diet composition and 75 prey items were identified. Poychaetes and amphipods were the main prey items ingested in all seasons; however the ingestion of polychaetes increased gradually from August to February and dominated the species' diet. Isopods were abundant throughout the year but mainly in April. Mysids were consumed mainly in April and June (30 and 40% IRI respectively). NMDS analysis delineated a partial seasonal trend (stress: 0,23): April seemed to be period of change in trophic habits, also evidenced by the low value of overlap of Schoener index between February and April. Symmetrical PERMANOVA provided evidence for significant difference both for factor month ( $F_{5,120}=1,86$ ; p=0,01) and depth ( $F_{5,120}=1,58$ ; p=0,004).

Overall, dietary overlap based on Schoener index revealed a very low dietary affinities (0,28), nMDS evidenced a good separation between the diets of the two macrourids (stress: 0,16).

In *H. italicus* the most enriched  $\delta^{15}$ N value was observed in April and the most depleted in September (*F*: 3,85; *p*: 0,026). Differences of  $\delta^{15}$ N values were not significant in *N. aequalis*, though there was a progressive increase from September to June. The estimated trophic levels were 4.47 in *N. aequalis* and 3.85 in *H. italicus*.

The two macrourids inhabiting mid-bathyal depths in the Balearic basin showed very diverse diets, based mainly on suprabenthic prey and infauna. According to [4] *H. italicus* preyed mainly on fauna inhabiting the Benthic Boundary Layer (BBL) than on mesopelagic resources (i.e. copepods and euphausiids). Low levels of dietary overlap was observed in this study, implying high resource partitioning and probably low levels of competition between coexisting species. The patterns of variability in <sup>15</sup>N signatures, with highest values in spring-summer and lower in autumn-winter agreed with other findings [7] according to which temporal changes were found between October and May in a bathyal community off Ibiza (Balearic islands), with highest values in May.

# THE SPATIAL ZOOPLANKTON DISTRIBUTION IN THE NORTH BALEAR FRONT (WESTERN MEDITERRANEAN): EARLY SPRING, 2005

Maria Luz Fernandez De Puelles \*, Ana Morillas , Eva Alou Font and Laura Vicente

Centro Oceanografico de Baleares. Muelle de poniente s/n .07015 Palma de Mallorca Spain - mluz.fernandez@ba.ieo.es

# Abstract

During the early spring, 2005, the micro and mesozooplankton have been analyzed in northern waters off the Balearic islands and related to the main physico-chemical properties of the sea surface water (EFLUBIO cruise). A frontal structure separating the Atlantic from the Mediterranean waters was clearly observed all along the northern part of the Mallorca and Menorca islands (North Balearic Front) which strongly affected the distribution of the main zooplankton groups. Acting those surface water masses as a boundary for the zooplankton structure. Into the mesozooplankton, the copepods were the most abundant group (86%) followed by the appendicularians (9%) and the nauplii into the microzooplankton (77%). A higher abundance of micro and mesozooplankton was observed in the northern area in relation to the higher salinity and enrichment of nutrients, meanwhile the larger organisms exhibited their higher abundance in the southern area. The most pronounced differences were observed for the group of the copepods. To understand the Balearic Sea productivity the impact of the frontal system on the distribution on zooplankton communities is analyzed. *Keywords : Balear Sea, Copepoda, Fronts, Western Mediterranean, Zooplankton*.

## Introduction

The Balearic islands are a geographical barrier into the Western Mediterranean that keeps two sub-basins apart, the Gulf of Lions and the Algerian basin, where different waters masses of northern and southern origin meet. Therefore, the Balearic sea form a hydrographic boundary influenced by all these different waters in the surface [4,5]. The channels between the islands are strategic areas where the different waters masses all flow through. The physical-biological interactions have been studied in other forward areas but little information exits on this relationship in the western Mediterranean [2]. The maximum zooplankton abundance occurs in spring in the Balearic sea [3]. The main goal of this study was to examine the relationship of the frontal system on zooplankton community, spatial distribution and composition.

#### Material and Methods

From March 16th to 30th, 2005 a large survey of 77 stations (EFLU-BIO project\*) was carried out in the surface waters of the Balearic Sea. We present here the main results of the zooplankton community (micro and mesozooplankton) in relation to the hydrographic conditions around the frontal system found in the area. Satellite images were taken every day for temperature and chlorophyll a, only when the weather allowed it. CTD (SBE 911 plus profiles were taken previously each zooplankton haul. Mesozooplankton was sampled by a triple WP2 net, 200  $\mu$ m mesh and the microzooplankton by a double Calvet net 53  $\mu$ m, by means of vertical hauls from 100 m depth to the surface. and the data shown as abundance (ind m-3 and %). Hydrographic samples for oxygen, nutrients and chlorophyll data were collected by a Rosetta with 10 L Niskin bottles at depths of 0, 25, 50, 75, 100 and 200 m depth.

## Results and Discussion

Physical environment- Compared with the last 20 years surface temperature data showed an extremely cool late winter with no spatial gradient and values below  $13.5^{\circ}$ C in the 100 m upper layer. Salinity, however, exhibited a clear gradient between the Atlantic waters (AW <38.0 PSU), just flowing up close to the north Balearic islands (limited by 40°15N; and  $4^{\circ}30^{\circ}E)$  and the further northern Mediterranean surface waters (MSW >38.2 PSU). Moreover, the dynamic topography confirmed the frontal boundary and the current direction. According to the salinity data, an obvious frontal system was observed in the area (NW-SE) and further northeast of Menorca island a filament southward of cool northern waters. The front produces a convergence between the two water masses with a sinking of the denser northern waters where the convective movement was intense. In the southern part of the front the overlapping of more oxygenated and less dense Atlantic Waters produced a vertical density gradient which made the mixing difficult. In the eastern part, the northern filament performed a divergence zone. The highest nutrient concentrations and less oxygen Mediterranean waters were related to the upwelling generated by the previous polar event (March, 2006) in the area and the later relaxed wind forcing which favored the inflow of Atlantic waters in the area. In relation to that nutrients and oxygen concentrations also depicted the frontal system in the upper 100 m layer.

The chlorophyll *a* also showed an intense gradient between both water masses regardless of whether small (<20  $\mu$ m) or large phytoplankton cells

were analyzed [1]. According to such late winter situation in the Mediterranean Sea, very unusual high values (>2  $\mu$ g l-1) for the studied area were found in the northern part of the front. In contrast, very poor but more oxygenated waters were found in the southern part which were influenced by the recent Atlantic waters (<1  $\mu$ g l-1).

Zooplankton - The zooplankton distribution was related to the hydrographic features and both, micro and mesozooplankton, depicted the frontal system. The microzooplankton was 3 times more abundant than the mesozooplankton but accounted for only 10% total biomass. Copepod nauplii and small copepods were the most abundant (75%) into the microzooplankton and both of them were separated by the highest salinity gradient with higher amount of nauplii in the northern part of the front. Copepodites and others, however, were more abundant in the south. In the mesozooplankton the copepods (86%) were the most important group in all the area. The larger size groups but less abundant such as, appendicularians (8%), siphonophors (2%), chaetognaths and doliolids (2%) were more abundant closer to the islands, in those waters less saline and where the convective movements were less important .

More than 50 copepod species were identified in the upper layer of the North Balearic front (0-100 m) and the 25 most abundant species indicated their preference for different properties of the water masses. *Oithona* and *Clausocalanus* were the most abundant copepods (50%). The smaller *Clausocalanus spp.* were the most important species (22%), followed by *Ctenocalanus vanus, Calocalanus styliremis, C. arcuicornis, Paracalanus parvus* and *Centropages typicus* (>1%). Besides the previously mentioned groups, the copepods such as *Nannocalanus minor, Ctenocalanus vanus, Mecynocera clausi, Farranula rostrata* were more abundant in the warmer AW. Meanwhile on the other hand, the smaller copepod nauplii and the bulk of larger Copepods, such as *Calanus helgolandicus, C entropages typicus, Euchirella rostrata* and *Paracalanus parvus*, showed their higher preference for the most saline waters.

# ABUNDANCE AND SIZE STRUCTURE OF OIKOPLEURA DIOICA SOULTH EASTERN

Ali Muzaffer Feyzioglu<sup>1</sup>\*, Nuket Sivri<sup>2</sup> and Elcin Unlu<sup>1</sup>

<sup>1</sup> Karadeniz Technical University, Faculty of Marine Sciences, 61530 Çamburnu Trabzon Turkey - muzaffer@ktu.edu.tr <sup>2</sup> Istanbul University, Faculty of Engineering, Dep. of Environmental Eng. Avcılar Istanbul

# Abstract

*Oikopleura dioica* is a unique species of Apendicularia living in the Black Sea. Seasonal size distribution of *O. dioica* in the southeastern Black Sea was studied between February and September, 2004. Total length of the specimens ranges between 0.15 mm and 2.85 mm, maximal size was observed in late spring.

Keywords : Black Sea, Plankton, Tunicata.

# Introduction

Appendicularias are small pelagic and suspension feeders found in high numbers in the world ocean [1]. The only species living in the Black Sea is *Oikopleura dioica*, and being a filter feeding is extremely important in its food web [2]. *O. dioica* constructs a mucous shell but occasionally is observed "naked" [3]. It is an hermaphrodite, and its well developed ovary occupies the entire apical region of the body [4]. The grazing rate of *O. dioica* in the field can equal or surpass those of copepods [2]. The present study shows that body size is one of the most important factors affecting the clearance rate of *O. dioica* [1]. The aim of this study was to investigate seasonal size structure of *O. dioica* in southeast Black Sea.

### Materials and Methods

Plankton samples were taken by R/V KTU DENAR during February-September 2004 off Trabzon, on the southeastern coast of the Black Sea, using Hensen type closing net with 75 Îijm mesh size, 70 cm mount diameter, and 220 cm long net. The plankton nets were towed vertically from 150 m depth to surface. The volumes of the sea water filtered were calculated by digital flowmeter (Hydro-bios Kiel, No 439115). The samples were preserved in borate-buffered 4% formaldehyde-seawater solution until laboratory analysis [5]. *O. dioica* were removed from the solution and counted Total body length ( $\mu$ m), tail length ( $\mu$ m), trunk length ( $\mu$ m), and trunk height ( $\mu$ m), were measured under the stereomicroscope. Population structure of *O. dioica* was compared by one-way ANOVA. When significant differences were found (p<0.05) comparison among means were made with a Tukey test [6].

#### Result and discussion

Seasonal anomalies were not observed in sea water temperature: minimum and maximum temperature were 9.3 °C (February) and 26.7 °C (August), respectively. Relationship between tail length- total length, total length-trunk length and trunk length- trunk height are shown in figure 1A, figure 1B and figure 1C, respectively. Linear positive relationship was observed between tail length and total lengths. Total length (included tail) of the *O. dioka* ranges between 0.15 mm and 2.85 mm. Small size organisms were observed in February, when average mean length of *O. dioica* was 0.25  $\pm$  0.11 mm. Mean total length was high at April (1.85  $\pm$  0,57 mm) . 11 April 2004 sampling period was statistically different than others months. Although 98% of the *O. dioica* size ranged between 0.2 and 0.8 mm and maximum length (exclude tail) of the organism was 1 mm in the North Black Sea [2], in the present study 99% of the organism size ranged between 0.1 and 0.7 mm and max length was 0.76 mm.

# STATUT DE PATELLA FERRUGINEA (MOLLUSQUE: GASTÉROPODE) SUR LE LITTORAL NORD ET EST DE LA TUNISIE

Hosni Fguiri , Sabiha Tlig Zouari \*, Lotfi Rabaoui and Oum Kalthoum Ben Hassine

Unitéde Recherche de Biologie, Ecologie et Parasitologie des Organismes Aquatiques,Faculté des Sciences de Tunis, Département de Biologie. Université Tunis ElManar 2092 Tunis, Tunisie - hgsbth@yahoo.fr

# Résumé

L'étude écobilogique de *Patella ferruginea* sur les côtes tunisiennes a révélé la présence d'importantes populations dans le Golfe de Tunis (4.5 ind/mlc à Korbous) et sur la pointe du Cap Bon à El Haouaria et Kelibia. Cette espèce partage le substrat rocheux avec d'autres espèces de patelles et l'ensemble obéit à une distribution verticale assez prononcée. *Mots clès : Density, Gastropods, Mollusca, Mediolittoral, Mediterranean Ridge.* 

Patella ferruginea, Gmelin, 1791 est endémique de la Méditerranée occidentale, elle est inféodée à l'horizon moyen du médiolittoral des côtes rocheuses en mode battu [1]. Son aire de distribution s'est fortement réduite à tel point qu'elle ne subsiste qu'en Corse, en Sardaigne, dans le sud-est de l'Espagne et en Afrique du nord. Sur le littoral tunisien, les recherches sur cette espèce sont rares et se limitent aux prospections de Boudouresque effectuées à l'île de Zembra [2]. Pour cela, nous avons en trepris une étude écobiologique sur la patelle géante, au niveau du littoral nord et est de la Tunisie, portant sur sa distribution et l'estimation de ses effectifs ainsi que sur son emplacement au niveau du substrat vertical par comparaison à ceux des autres Patellidés.

Au total 19 stations du littoral rocheux nord et est du pays ont été prospectées durant la période allant de décembre 2005 à août 2006. Ces stations sont reparties dans les 5 sites suivants: le littoral de Tabarka (les Aiguilles, l'île de Tabarka et la plage d'Ettrouche), le littoral de Bizerte (les Grottes, le Canal et Cap Zebib), le golfe de Tunis (Sidi Ali-El-Mekki, Cap Gammart, Sidi Bou-Said, la Goulette, Korbous et Port Prince), la pointe du Cap Bon (El Haouaria et Kelibia), le littoral de Sousse (Hergla, El Kantaoui) et le littoral de Monastir. L'estimation de la densité de P. ferruginea a été effectuée au moyen d'un transect horizontal parallèle à la ligne du rivage de 20 m de long. Ainsi les individus de cette espèce ont été dénombrés et la densité a été déterminée par mètre linéaire de côte rocheuse (ind/mlc). En parallèle, nous avons procédé à l'identification des autres patelles associées à P. ferruginea et à la connaissance de leur répartition verticale, au niveau des stations où P. ferruginea est abondante (Korbous, Kelibia et El Haouaria), par un transect vertical, de 1m de largeur, placé entre le niveau zéro et l'horizon supérieur du médiolittoral.

Selon nos prospections, 5 stations ont révélé la présence de P. f erruginea, à savoir Sidi Bou Said, Korbous et port prince dans le golfe de Tunis et El Haouaria et Kelibia sur la pointe du Cap Bon. A Sidi Bou Said, nous n'avons trouvé que 5 individus dispersés sur la digue du port, ce qui correspond à une faible densité de l'ordre 0.025 ind/mlc. La densité est également faible à Port Prince (0.09 ind/mlc) où nous n'avons recensé que 9 individus clairsemés et fixés sur les rochers. Les massifs rocheux de la région de Korbous, disposés au pied d'une falaise, abritent une importante population de P. ferruginea avec une densité relativement élevée de l'ordre de 4.5 ind/mlc. Les plus grands spécimens ont été rencontrés à ce niveau. P. ferruginea abonde également à la station de El Haouaria (3.4 ind/mlc), qui se situe à l'extrémité occidentale de la pointe du Cap Bon et dont les côtes rocheuses sont fréquemment exposées aux fortes houles. Cette population est dominée par les individus de petite taille. Quant à la station de Kelibia, en dépit de sa situation géographique à proximité du port et de son accès facile, elle présente une densité relativement assez élevée de l'ordre de 2.5 ind/mlc.

Ces résultats semblent indiquer que la répartition de *P. ferruginea* dans les différents sites étudiés n'est pas homogène. Les fortes densités ont été enregistrées à Korbous et El Haouaria dans des biotopes caractérisés par un accès difficile ainsi que par une relative préservation vis-à -vis des apports terrigènes des oueds de la zone et des apports polluants des agglomérations. Ces localités sont brassées par les vents violents du nord-ouest en hiver et les vents d'été assurant ainsi un mouvement des eaux qui se traduit par un élargissement de l'étage médiolittoral.Ceci semble favoriser l'installation et la prospérité d'importantes populations de patelles. En outre, la faible densité, notée à Sidi Bou-Said, pourrait être due à la turbidité des eaux des secteurs nord et nord-ouest du golfe de Tunis. Notons que les valeurs de densité obtenues dans le cadre de ce travail sont plus importantes que celles signalées par Boudouresque à Zembra en Tunisie (0.7ind/mlc) et Laborel-Deguen en Corse (0.79 ind/mlc). Cependant, la densité trouvée à Korbous est égale à celle enregistrée par Boumaza [3] aux îles Habibas à l'ouest Algérien (4.5 ind/mlc) et inférieure à celle estimée par Guerra-Garcia [4] à Ceuta au Maroc (6.7 ind/mlc).

Fig. 1. Variation spatiale de la densité de Patella ferruginea.

Comme il a été signalé par Laborel Deguen (1990) en Corse et Espinoza et al. à Ceuta (2005), nous avons constaté, au niveau des stations assez peuplées (Kourbous, El Haouaria et Kelibia), que P. ferruginea partage le littoral rocheux battu par lesvagues avec d'autres patelles possédant des caractéristiques écologiques et morphologiques bien différentes. A la station de Kourbous, ces espèces suivent une stratification verticale assez remarquable et se répartissent commesuit : P. rustica Linné, 1758 occupe le supralittoral avec une densité pouvant atteindre 35 ind./m<sup>2</sup>. L'horizon supérieur et moyen du médiolittoral est colonisé par P. caerulea Linné, 1758 qui est abondante (12 ind./m<sup>2</sup>) et l'espèce Siphonaria pectinata, Linné, 1758, qui appartient à la sous-classe des pulmonés et qui est présente en très faible densité (0.15 ind./m<sup>2</sup>). Quant à P. ulyssiponensis, Gmelin 1791, elles'installe au niveau du médiolittoral inférieur et apparaît fréquemment couverte d'algues épiphytes avec une densité relativement faible, de l'ordre de 4 ind./mlc. Au niveau des stations de Kelibia et d'El Haouaria, nous avons rencontré, suivant la même répartition verticale, les mêmes espèces mais avec des effectifs moindres que ceux de la station de Korbous.

## Abstract

Eight specimens of very rare species *Cubiceps gracilis* (LOWE, 1843) (Pisces, Nomeidae) were caught from the Sigacik Bay (Aegean Sea). A recent record of the species was confined to Antalya Bay (eastern Mediterranean coast of Turkey). By this record, its distribution range at Turkish seas has extended to the Aegean Sea.

Keywords : Aegean Sea, Biogeography, Eastern Mediterranean, Fishes.

# Introduction

*Cubiceps gracilis* is an oceanic fish distributed in the eastern Atlantic, western Mediterranean [1] and western Pacific [2]. Also, it was well known in Adriatic Sea [3]. A previous record was given from the Turkish coasts of Mediterranean (Antalya Bay) [4]. Therefore, the present report constitutes the first record of this species in the Aegean Sea.

#### Material and methods

On  $11^{st}$  September 2005, eight specimens of *Cubiceps gracilis* (Fig. 1) were sampled by a commercial trawl (F/V Hapuloglu, 23 m length and 550 HP), in Sigacik Bay (from  $38^{\circ}08'$  N,  $26^{\circ}42'$  E to  $37^{\circ}55'$  N,  $26^{\circ}44'$  E). Depth range of the fishing ground was 150-473 m. The specimens were captured during day time (08.00-11.30 a.m.).

Fig. 1. General vew of *Cubiceps gracilis* captured from Sigacik Bay, Aegean Sea.

The specimens were identified according to [5], fixed by 40% formalin and stored in the Ege University Faculty of Fisheries, Turkey. Morphometric measurements were taken to the nearest 0.1 cm (Table 1).

Tab. 1. Meristic and morphometric characters recorde in examined specimens of *C. gracilis* in the Aegean Sea (Sp. specimen; minimum and maximum value are given in parenthesis).

### Diagnosis

Body elongated and compressed. Head large (27.70-29.85), predorsal (32.86-35.82), preanal (55.00-59.15); snout short, round (5.71-7.75), eye large (5.63-7.14) and interorbital distance wide (7.75-9.70); all percentage of standard length (SL). Small mouth reaching back to the vertical of the anterior of the eye. A single row of small conical teeth in both jaws. Small granular teeth in broad patches on the tongue and roof of the mouth. Upper gill arch with nine rakers and lower with 16, the raker below the angle is the largest, sub-equal to the longest gill filament. Two dorsal fins, first with 11 spines, the last four spines and 22 rays. Base of pectoral fin at  $45^{\circ}$  angle to body axis. Pelvic fin with a single spine and five rays, its origin on the vertical of the posterior edge of the pectoral fin base. Scales on the head reach almost to the posterior nostril.

## Acknowledgements

We would like to thank A. Kuruca, captain of F/V Hapuloglu and his crew for their assistance in obtaining the fish samples.

# BENTHIC INDICES ON COMPARISON IN THE NORTHERN ADRIATIC SEA

# Abstract

In order to meet the requirements of the European Water Framework Directive, a new benthic index, named Daphne, has been recently developed for the Northern Adriatic Sea and it is here compared to other benthic indices used along European coasts: AZTI Marine Biotic Index (AMBI), Bentix and Benthic Quality Index (BQI). The results obtained by Daphne are consistent with the environmental characteristics of the study area and with the application of the AMBI index. Some critical points are discussed. *Keywords : Adriatic Sea, Bio-indicators, Coastal Waters, Monitoring, Zoobenthos.* 

## Introduction

In coastal waters, benthic invertebrate fauna is one of the biological elements indicated by the European Water Framework Directive for the classification of the ecological quality status. To this aim several benthic indices have been developed and applied along European coasts: the AMBI (AZTI Marine Biotic Index) [1], the Bentix [2], and the BQI (Benthic Quality Index) [3].

In this work we compare the results obtained by the application on soft bottom benthic fauna, collected along the Emilia Romagna coast (Northern Italy), of all the indices mentioned above and of a new one recently proposed for the Northern Adriatic Sea [4].

AMBI and Bentix indices require the identification of all organisms to species level and the assignment, often controversial, of each species to different ecological groups (EG) on the basis of their sensitivity to pollution. The BQI tries to overcome the problem of species assignment to EG by calculating the species tolerance value by means of an objective analysis.

The new index does not consider the sensibility of each species, but it is based on six characteristics of the benthic community, which do not require in depth taxonomic expertise.

#### Materials and methods

Soft bottom macrobenthos was sampled in May, July and October 2004, at 8m depth, in 4 stations, Porto Garibaldi, Ravenna, Cesenatico and Cattolica, located along the Adriatic main current which runs southwards and therefore differently influenced by the trophic load carried by the Po river. Benthic samples were collected using a 0.06  $\mathrm{m}^2$  van Veen grab; chemical-physical data were measured on an approximately weekly basis. On benthic data we calculated the Ecological Quality Ratio (EQR), defined by the Directive as the ratio of the observed index value versus the value of the same index under Reference Conditions (RC). Due to the difficulty to find unimpaired sites or historical pre-industrial data in order to define RC, we considered "virtual reference conditions", as proposed by Borja et al. [5]. We applied the Multivariate AMBI version (M-AMBI) [5], using the software AMBI 4.0 available on line, and Bentix as reported in Simboura et al. [6]. The calculation of the tolerance species value following Rosenberg's method [3] was applied to a data-set including 222 samples collected in the Northern Adriatic area.

## Results

The average annual values of Daphne index increase gradually southward, from Porto Garibaldi and Ravenna to Cesenatico and Cattolica (Tab. 1). The M-AMBI follows the same trend: the lowest values of EQR were obtained in Porto Garibaldi and Ravenna, while in Cesenatico and Cattolica the EQR increased. Contrasting results were obtained using Bentix, with an EQR value lower in Cattolica than in Porto Garibaldi.

For the application of BQI, the tolerance value was calculated for about 100 species with controversial results: species known from literature to be sensitive result more tolerant than species known as opportunistic. This is probably due to the low number of samplings used to calculate the tolerance values in the Northern Adriatic (222) compared to those used along the Swedish west coast (1114).

The results obtained by Daphne and M-AMBI match the trend of the chemical-physical and structural parameters.

The ecological quality classification indicates that differences in the indices values do not always correspond to differences in the ES. The Daphne index rates the northern stations to be in moderate ES, while Cesenatico and Cattolica in good ES; the AMBI classify in good ES Porto Garibaldi, Ravenna, Cesenatico and in high ES Cattolica. The Bentix classifies in moderate ES both Porto Garibaldi and Cattolica, showing the scarce reliability of the results.

Tab. 1. Average value of the Ecological Quality Ratio (EQR) and corresponding Ecological Status (ES) for Daphne, M-AMBI and Bentix in the 4 sampling stations.

| ES     | moderate           | poor                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | moderate   | moderate   |

## Discussion and conclusion

The Daphne index provide results that are in accordance with the M-AMBI trend and with the environmental condition pattern in the area. Bentix gives contrasting results. Differently from Daphne and AMBI, the Bentix EQR was derived by the relationship between the monitoring result and the theoretical maximum value of the index, so the EQR could be underestimate. The critical point is to determine the correspondence between the EQR value and the ecological quality status. In fact, although Daphne and AMBI show a similar trend, they assess the same stations in different ES, Daphne being more severe. A more reliable definition of the quality class boundaries can be obtained using larger data sets including sites that are in very good or very bad ecological conditions.

# Abstract

Two goby species, *Didogobius splechtnai* and *Thorogobius macrolepis*, are being recorded for the first time from the eastern Mediterranean Sea, based on underwater observations carried ouilet at Turkish coasts. Updated information on the distribution of *Gobius auratus* is also presented.

Keywords : Aegean Sea, Eastern Mediterranean, Levantine Basin, Fishes.

Gobiidae is the most species rich family among fishes, represented roughly by 212 genera and 1875 species worldwide [1]. A diverse gobiid fauna with close to 60 species is encountered in the Mediterranean Sea, where almost half of the recorded species are endemic [2]. Data on the ecology and distribution of several small sized gobiids, which generally inhabit caves and crevices, are remarkably scarce. Such species are difficult to detect and generally overlooked due to their cryptic habits [3].

Until now, 25 gobiid species were known from the eastern Mediterranean Sea [4]. Scuba diving observations conducted along the Aegean Sea and Levant coasts of Turkey revealed the presence of two previously unrecorded species - *Didogobius splechtnai* and *Thorogobius macrolepis*. The data obtained also proved that, *Gobius auratus*, is a common species along Turkish coasts (from eastern Levant shores to northern Aegean Sea), which was previously believed to be rare. Due to the conspicuous and distinctive colour pattern of these species, they were identifiable *in situ* immediately upon discovery. Species accounts are presented below.

# Didogobius splechtnai Ahnelt & Patzner, 1995

This species was observed during 2005 along the southern Aegean Sea coast of Turkey (Bodrum Peninsula / Gokova Bay: 36°56'N, 27°15'E, from 8 m to 45 m depth). More than 10 individuals have been observed in Bodrum, indicating an established local population. All the specimens were found in the innermost parts of caves and were only detectable using artificial light. The size range of the caves inhabited by D. splechtnai varied from small cavities (0.7 m width x 0.5 m height x 1 m depth) to large caves (3 m x 3 m x 5 m) where the fishes were always observed in small cavities (0.2 x 0.2 x 0.3 m) in the innermost part of the cave. The fish usually (80% of the observations) rested on the sandy bottom close to an entrance of a nearby hole. In all cases, the bottom of the hole/cave was sand without mud. Habitat preferences of D. splechtnai from the southern Aegean Sea is well in accordance with those recorded from Ibiza (Balearic islands) coasts [3,5]. The species is included to the eastern Mediterranean ichthyofauna for the first time, where previous records were all confined to the western Mediterranean Sea [3,5,6]

### Gobius auratus Risso, 1810

The golden goby, Gobius auratus (= G. luteus Kolombatovic, 1891), was observed in 2003 at Oludeniz (near Fethiye; 36°33'N, 29°05'E; 26 m depth), in 2004 at Candarli Bay (northern Aegean Sea; 38°55'N, 27°01'E; 16 m depth) and in Kas (eastern Levant; 36°06'N, 29°38'E; 28 m depth), and finally in 2005-2006 along the peninsula of Bodrum (36°56'N, 27°15'E; 20-40 m depth). These fishes all presented a distinct canary yellow body colouration corresponding to the classical pattern described for the northwestern Mediterranean populations, but not the pattern (red dots forming longitudinal lines on head, trunk and median fins) reported from the Adriatic Sea [7]. For most instances, G. auratus specimens were observed hovering at steep fields of large rocky and coralligenous substrates, but specimens hiding in small cavities (mostly less than 10 cm width x 10 cm height) were also determined. The species has probably a larger distribution range along Turkish coasts. Until now, the northernmost verified record of G. auratus in Turkey was given from Saros Bay, northern Aegean Sea [8], but previous records from the Sea of Marmara and Iskenderun Bay are still yet to be substantiated.

Thorogobius macrolepis (Kolombatovic, 1891)

This species has been first observed in 2003 at Oludeniz ( $36^{\circ}33^{\circ}N$ ,  $29^{\circ}05^{\circ}E$ ; 30 m depth), later in 2005 at Bodrum ( $36^{\circ}56^{\circ}N$ ,  $27^{\circ}15^{\circ}E$ ; 20-45 m depth) and at Bozyazi (eastern Levant;  $36^{\circ}04^{\circ}N$ ,  $33^{\circ}05^{\circ}E$ ; 45 m depth). Most recently, a single specimen was observed at Fethiye Bay during July 2006, at a depth of 26 m. All scuba observations indicate that the species occurs on sandy bottom, at the foot of vertical or at least distinctly sloping rock walls, in accordance with previous habitat descriptions [5]. The species is endemic to the Mediterranean, which was previously known as far as to northern Adriatic coasts [9]. Our findings reveal that, *T. macrolepis* has a wide distribution range - extending from the southern Aegean Sea to eastern Levantine coasts.

The aforementioned records expand the known distribution of small sized Mediterranean Gobiidae species, with new species for the eastern Mediterranean basin. The previous discontinuous distribution of those cryptobenthic or shy species may be interpreted as an artefact due to the difficulty of the sampling and *in situ* observation, rather than a true numerical rarity. The accumulation of such data provides further raw material to discuss the biogeography of Gobiidae in the Mediterranean Sea.

# Abstract

The diet of cuttlefish, *Sepia elegans*, discarded by trawls in Thermaikos Gulf, Greece, was examined during one fishing season. The main prey was crustaceans and fish. Its trophic level was estimated to be 3.53. *Keywords : Aegean Sea, Cephalopods, Diet, Fisheries.* 

The geographical distribution of *Sepia elegans* (Blainville, 1827) extends in the eastern Atlantic and throughout the Mediterranean Sea [1]. It is a demersal species that lives on diverse bottoms at depths from 2 to 430 m [1, 2]. The information on the diet of *S. elegans* is limited [2, 3], while there are no references on the diet of the species in the Aegean Sea, Greece.

The study of the diet of *S. elegans* was carried out by examining the stomach contents of 86 specimens caught with bottom trawls in the Thermaikos Gulf (North Aegean Sea) during one fishing season (October 2005 to April 2006). Sampling took place seasonally at 21 stations in conditions of commercial fishery. Each haul lasted 2 to 6 hours. Sampling took place at depths from 32 to 96 m. The cod-end mesh size was 40 mm (stretched).

In general, *S. elegans* was found to feed mainly on crustaceans and secondarily on fish (Table 1). The trophic level of the cuttlefish was calculated at 3.53 (*S.E=0.53*) [4]. The percentage of crustaceans in the gut content increased with the size of cuttlefish, in contrast to the percentage of fish. Seasonal differences were also found, as the proportion of fish increased between autumn and spring, while the proportion of crustacean remained practically the same.

Similar results on the diet of the species were reported in NW Spain (Ría de Vigo) [2, 3]. The other *Sepia* species, *Sepia* officinalis was also reported to has the same diet, as reported in studies off the coast of Portugal [5], in Morbihan Bay, in France [6], and in NW Spain [2, 3].

Tab. 1. Ratio of stomach content of *Sepia elegans* by sex, season and size (N= total number of individuals, ML=mantle length of cuttlefish).

| Stomach    | TN   | males | Females | A utumn | Winter | Spring | ML<41,3 | $ML \geq 41,3$ |
|------------|------|-------|---------|---------|--------|--------|---------|----------------|
| content    | (%)  | (%)   | (%)     | (%)     | (%)    | (%)    | (%)     | (%)            |

# EVIDENCING GROWTH-DEPENDENT SURVIVAL OF ALBORAN SEA SARDINE (*SARDINA PILCHARDUS*) LARVAE IN THE FIELD

Alberto García \*, Dolores Cortés , Jose Quintanilla and J.M. Rodriguez Instituto Español de Oceanografía, 29640 Fuengirola, Málaga, Spain - agarcia@ma.ieo.es

# Abstract

A field exercise based on the collection of pre-flexion sardine larvae in a nursery site at a determined site which was revisited two weeks later aiming to sample the surviving post-flexion larval cohorts showed that back-calculated post-flexion larvae lengths were larger at age than pre-flexion larvae, thereby indicating that survival is linked to higher growth potential, which is corroborated by the significant differences in the average widths of daily increments and the size of the otolith core between the pre- and post-flexion larvae. *Keywords : Alboran Sea, Growth, Larvae.* 

# Introduction

Growth of larvae and juveniles in many fish species may be an important causative factor inducing relative recruitment success [1], because lower growth rates may cause higher mortality by shortening the vulnerable periods of early life. Inshore waters of the Bay of Málaga constitute nursery grounds for sardines and anchovies that were exploited by artisanal fisheries in the past [2]. Advanced larval stages concentrate in shallow waters off Málaga, thus providing ideal conditions to investigate larval growth by otolith analysis. To test the growth mortality hypothesis [1] in the field, larval cohorts at early life periods were sampled in their nursery ground and revisited in the future to analyze the growth characteristics of surviving larval cohorts.

#### Material and Methods

A larval sampling survey on board the *R/V Odón de Buén* was carried out in the inshore nursery sites off the coasts of Málaga during February 14-17 2004 with the objective of collecting pre-flexion larvae (Nursery I). Larval sampling methods and on-board conservation procedures are described in [3]. Over two weeks later (March 2-4) the same site was revisited to sample post-flexion larvae (Nursery II).

Bearing in mind that the relationship between sardine larval size and otolith radius follows non-linear power functions, the back-calculation formula of [4] was applied,

# $\mathbf{L}_i = (\mathbf{S}_i / \mathbf{S}_c)^{\nu} \cdot \mathbf{L}_c$

where, Li is back-calculated standard length (SL) at radius size Si, and Lc and Sc corresponds to the individual SL at catch and radius at catch, respectively, and  $\nu$  is the exponent of the larval size vs otolith radius regression equation. Statistical tests were done by ANCOVA using the natural logarithm of increment counts as covariable.

## Results and Discussion

The Nursery I survey sampled a total of 75 pre-flexion larvae that were born from February 3-11, 2004, while the Nursery II captured a total of 95 post-flexion larvae whose birthdates ranged from 20/01/2004-16/02/2004. Among these, 37 larvae had coincident birthdates with larvae sampled in Nursery I (February 3-11). Since the elapsed time between the first and second sampling period was approximately 17 days, a group of 79 post-flexion larvae that were born from March 27-February 12 was established to trace their early growth trajectories. The back-calculated growth trajectories of the original population sampled in the Nursery I survey was compared to the back-calculated growth history of the surviving larvae (Nursery II) born during the same period (February 3-11) as the original population, as well as, the larval cohort born from March 27-February 12 (Fig. 1). The larvae born during the coincident birthdate period of Nursery I larvae, as well as, those born for the extended dates from the Nursery II samples show significantly greater back-calculated standard lengths at age than the original population (F2,35=71.7, p<0.001). To corroborate this finding through back-calculation procedures, it was necessary to examine otolith growth and increment width deposition in the original and the surviving cohorts, as these parameters are correlated with the somatic daily growth and metabolic rates [5]. The difference in growth between the original larval population and the surviving cohorts sampled at a later period is sustained by the significant difference observed in the mean width of increment deposition (Fig. 2) in favour of the surviving larvae (ANCOVA: F1,23=55.8, p<0.001). This difference is in agreement with otolith growth difference between the original population and their survivors (F1, 23=19,9, p<0.001). Furthermore, the average otolith core at hatch was significantly greater (over  $2\mu$ m) in the surviving cohorts than in the original population (ANOVA, F<sub>1,168</sub>=716.1, p<0.001) in agreement with the difference observed in the estimated larval size at hatch between the back-calculated growth trajectories of both larval populations, which showed an average a difference of 1.5 mm between the surviving and the original larval population, thereby possibly inducing greater growth potential at early life stages as evidenced by [6].

# SUB-SURFACE ICHTHYOPLANKTONIC ASSEMBLAGES OFF THE BALEARIC ARCHIPELAGO DURING THE 2004 BLUEFIN (*THUNNUS THYNNUS*) SPAWNING SEASON

A. García \*, I. Álvarez , F. Alemany , D. Cortés , J. Rodríguez , F. Corregidor , P. Vélez-Belchí Institudo Español de Oceanografía, 29640, Fuengirola, Málaga (Spain) - agarcia@ma.ieo.es

# Abstract

Key ichthyoplanktonic species associations are established on the basis of hydrographic and geographic distribution over the open sea waters surrounding the Balearic archipelago. Tuna species comprise a community linked to open sea waters of Atlántic origin. Another ichthyoplankton community is comprised by neritic species, which show different distributional tendencies based on their preferential water masses and their respective environmental characteristics.

Keywords : Balear Sea, Ichthyoplankton.

# Introduction

The waters off the Balearic archipelago form part of the spawning habitat of larval top predator species, among which bluefin (*Thunnus thynnus*) and other tuna-like species represent an important fraction of the ichthy-oplanktonic assemblages [1]. The hydrography of the area is characterized by the encounter of Atlantic and Mediterranean water masses causing an intense circulation pattern coupled to important mesoscale features such as gyres and fronts [2]. Consequently, contrasting environmental conditions occur that contribute to the high ichthyoplanktonic diversity in the area [3] and the distribution of the early life history stages of many fish species, among which bluefin and its associated species, are strongly influenced by the environmental features of water mass origin.

#### Material and Methods

The ichthyoplankton samples were collected in the TUNIBAL 06/04 survey on board the *R/V Cornide de Saavedra* from June 18-July 10, 2004. A total of 157 sub-surface plankton horizontal tows with a Bongo (500 microns) cuadrangular net whose aperture measures 1 m diagonally were carried out over a regular 10x10 nautical mile station grid, mostly distributed over the southern part of the archipelago (Fig. 1). All tows were fixed at 10 minutes duration. In each station a CTD rosette (Seabird 25) was cast.

To define ichthyoplankton assemblages, a hierarchical cluster analysis of a Bray-Curtis similarity matrix calculated between species by ranked larval abundance was performed [4], considering only those species or groups that represented 1% of the total catch.

Fig. 1. TUNIBAL survey map: dots represent stations and shaded greys salinity at 10 m depth.

## Results and Discussion

A total of 19,993 larvae and pre-juveniles were sorted from one cod-end of the net that were categorized under taxonomy levels of 21 species, 12 genera, 9 families and 1 order. Larvae of top predator species (tuna and swordfish) represented 29% of the total ichthyoplankton catch, among which bluefin (*T. thynnus*) and frigate tuna (*Auxis rochei*) were most abundant (Fig. 2a). The main bulk of the tuna species were distributed in the oceanic waters south of Menorca where transitional and warm water masses of Atlantic origin (23.5-25°C) forming a large anticyclonic gyre in the area (Fig. 1). The tuna species form part of the cluster association A whose distributional grounds is mainly centred south of Menorca.

Mesopelagic species comprised the most important group of the ichthyoplankton (38%), with two species, *Ceratoscopelus maderensis* (15%) and *Cyclothone spp.* (12%) representing the major part. While, *C. maderensis* was mainly distributed over the northern part of Ibiza and the Mallorca Channel in cooler waters of Mediterranean origin, *Cyclothone spp.* was more widely dispersed over the survey area but showing highest abundances in the area south of Menorca. Due to their oceanic distribution both species were grouped under species association A (Fig. 2b).

The B species association defined by the cluster analysis shows two subgroups (B1, B2) differentiated by their spatial location and thereby, its hydrographic characteristics. Among the species of neritic character, the most abundant was *Chromis chromis* (11.3%), which showed more preference for water masses of Mediterranean characteristics (B1).

The main coastal pelagic species found was *Engraulis encrasicolus* (9.3%). It was mainly distributed north of Ibiza, most likely indicating its drifted origin from the northern coasts of Catalonia. The species was mostly found in Mediterranean waters, thus forming part of the B1 species association. In contrast, *Sardinella aurita* (2.6%), as key species of the B2 sub-group, was mainly found north of Menorca. In terms of abundance, the *Trachurus spp.* (3.5%) was important in terms of abundance, showing a distributional overlap with both of the previous species.

Fig. 2. (a) Ichtyoplankton composition, (b)Species cluster dendogram.

# BIOLOGY (GROWTH AND REPRODUCTION) OF THE MEDITERRANEAN DEEP WATER ROSE SHRIMP ( PARAPENAEUS LONGIROSTRIS (LUCAS, 1846) CRUSTACEA, DECAPODA) FROM THE ALICANTE GULF (S.E. SPAIN)

M. Garcia Rodriguez<sup>1</sup> \*, J.L. Perez Gil<sup>2</sup>, E. Barcala<sup>2</sup>, N. Carrasco<sup>2</sup>, A. Esteban<sup>2</sup>

<sup>1</sup> Instituto Español de Oceanografía. Servicios Centrales. Corazon de Maria 8. 28002-Madrid (Spain) - mariano.garcia@md.ieo.es <sup>2</sup> Instituto Español de Oceanografía. Centro Oceanografici de Murcia. San Pedro del Pinatar. Murcia (Spain)

# Abstract

The deep-water rose shrimp (*Parapenaeus longirosntris*) is a demersal species and an important resource for the trawl fishery in the Alicante Gulf (S.E. Spain). This paper describes, for first time in this area, certain biometric relationships, as well as growth parameters and reproductive patterns of the species. The results showed a sexual size dimorphism, with a negative allometry of relative growth and high rates of absolute growth, both particularly in males. However, females dominated in the catch proportion. The spawning period occurred throughout the year, but especially in June-July and in October-November and the maturation stage for females takes place within the second year of life.

Keywords : Decapoda, Growth, Reproduction, Western Mediterranean.

## Introduction

The deep-water rose shrimp (*Parapenaeus longirosntris*) is a demersal species that is found on sandy and muddy bottoms in the Mediterranean Sea and the south Atlantic coast of the Iberian peninsula, being more abundant at depths of between 150 m to 400 m. It is considered a by-catch species of the trawl fishery, except in years of high abundance when it becomes a target species. Landings at the studied port can represent 65 tons per year in average, meanwhile for the whole GSA6 area can reach 332 tons per year. It shows a high inter-annual variations. Despite the fact that it has been studied in others Mediterranean areas [1-2], we describe for the first time some biological parameters of the species from an area defined between Cape Palos and Cape San Antonio (Alicante Gulf).

## Materials and Methods

A total of 60 samples were obtained, by means of monthly random stratified samplings from January 2001 to December 2005 in the Santa Pola port, on the landings come from commercial fleet that operates at the Alicante Gulf. A total of 17.428 specimens were sexed and their cephalothoracic length (CL) measured. In addition, 36 samples were obtained by monthly sampling carried out during the 2003-2005 period, providing 9,785 additional individuals that were analysed in detail. The parameters of the size-weight relationship were determined by regression. The estimates of the Von Bertalanffy growth parameters were obtained from monthly length frequency distributions by sex for the 2001-2005 period. Sexual ratios were calculated by size class. Maturity for females was determined by macroscopic observation, following a scale of three maturity stages: (1) Immature; (2) Developing; (3) Mature. Finally, the percentages of maturity by size for each sex were calculated, in order to determine the size at 50% first maturity, adjusting a logistic model. All calculations were made using the INBIO statistical package in R language.

#### Results and Discussion

The sizes of the females varied from 10.0 mm to 42.0 mm CL, with a mean size of 27.7mm CL. The males varied from 14.0 mm to 33.0 mm CL, with an average of 23.2 mm CL. Males represented 45% of the landings in number, whereas the remaining 55% corresponded to females. The mean size of the landings was 25.7 mm of CL. The contribution of the individuals to the yearly total landings by sex showed a size dimorphism for the species, with males being smaller than females (Fig.1). The results obtained for the different size-weight relationships by sexes ( $W = a^* CL^b$ ) (males: a = 0.0029; b = 2.483;  $R^2 = 0.91$ ; n = 4,258. females: a = 0.0024;  $b = 2.567; R^2 = 0.96; n = 5,527. m + f: a = 0.0020; b = 2.61; R^2 =$ 0.96; n = 9,785) showed a negative allometry, more noticeable in males. Absolute growth parameters gave high growth rate values (males:  $L_{inf}$ = 30 mm; K = 0.742; t0 = -0.5. females:  $L_{inf}$  = 43 mm; K = 0.419; t0 = 0.114. m + f :  $L_{inf}$  = 45 mm; K = 0.344; t0 = -0.057), which were higher in males. The sexual ratio showed that, after an initial stage (19-27 mm) where males predominated significantly, females started to dominate significantly throughout the whole range of sizes above 28.0 mm CL. Ripe females were found throughout the year with two peaks of activity, one from June to July and another from October to November. The percentages of maturity by size class showed a 50% size at first maturity of 25.3 mm for females. Therefore, the maturation stage would have to take place within the second year of life, with a life expectancy of five years.

Fig. 1. Average percentage contribution (2001-2005) by size class and sex, of *Parapenaeus longirostris* landings in the Santa Pola port.

# LES DIGÈNES PARASITES DU MARBRE *LITHOGNATHUS MORMYRUS* (L., 1758) DES CÔTES TUNISIENNES

# Lamia Gargouri Ben Abdallah \* and Fadhila Maamouri

Faculté des Sciences de Tunis, Laboratoire de Biologie Animale, Département de Biologie, Tunisie - Lamiagargouri@yahoo.com

# Résumé

La biodiversité des digènes mésoparasites du marbré, *Lithognathus mormyrus*, a été établie après examen de 84 individus provenant des côtes tunisiennes. Cette étude a permis de recenser 5 espèces de parasites (*Holorchis pycnoporus, Lepocreadium pegorchis, Macvicaria mormyri, Pycnadenoides senegalense, Diphterostomum brusinae*) qui se répartissent différemment au sein du tube digestif de l'hôte. L'étude de la dynamique évolutive des digènes a montré que *H. pycnoporus* et à moindre degré *L. pegorchis* sont les plus fréquents et les plus abondants. Les infracommunautés sont pauvres. Mise à part *D. brusinae* et *P. senegalense* qui se limitent à un ou à deux lieux de récolte, les autres parasites se trouvent dans tous les milieux prospectés. *Mots clès : Biodiversity, Parasitism, Fishes.* 

Introduction

Le présent travail représente la première contribution à la connaissance des digènes parasites du Marbré, *Lithognathus mormyrus*, poisson très estimé par les consommateurs tunisiens. Les recherches effectuées sur ce téléostéen, en Méditerranée occidentale, [1-6] ont montré une faible diversité digénétique. En Méditerranée orientale aucune analyse comparative n'a été réalisée d'où l'intérêt de cette étude.

## Matériel et méthodes

Les marbrés (84 spécimens) examinés proviennent de la baie de Bizerte, du golfe de Tunis et du littoral de la région de Sfax. Les différentes parties du tube digestif prélevé (oesophage, estomac, coecums pyloriques, intestin antérieur, moyen et postérieur) sont placées séparément dans des boites de pétri contenant du liquide physiologique puis disséquées. La place et le nombre de chaque parasite sont notés. Les parasites récoltés sont soit étudiés directement in vivo au microscope, soit fixés entre lame et lamelle dans le bouin-hollande. Ces digènes fixés sont par la suite lavés à l'eau distillée, colorés au carmin boracique, déshydratés, éclaircis dans l'essence de girofle et montés entre lame et lamelle dans une goutte de baume de Canada. La nomenclature appliquée pour la détermination des valeurs globales de la prévalence et de l'abondance des digènes est celle utilisée habituellement [7-8].

#### Résultats et discussions

L'examen du tube digestif du marbré nous a permis de recenser 5 espèces de digènes : deux Lepocreadidae (*Holorchis pycnoporus, Lepocreadium pegorchis*), deux Opecoelidae (*Macvicaria mormyri, Pycnadenoides senegalense*) et un Zoogonidae (*Diphterostomum brusinae*). L'étude de la distribution de ces parasites, au sein du tube digestif de l'hôte, a montré que *L. pegorchis* occupe les caecums pyloriques, l'intestin antérieur et rarement l'intestin moyen. *M. mormyri* se localise au niveau de l'intestin antérieur et moyen. *H. pycnoporus* colonise essentiellement l'intestin moyen et occasionnellement l'intestin antérieur et postérieur. *P. senegalense* et *D. brusinae* se limitent respectivement à l'intestin moyen et à l'intestin postérieur.

Chez un individu hôte, le nombre maximal d'espèces récoltées ne dépasse pas 2. Les infracommunautés sont donc pauvres. La coexistence de deux espèces de parasites de grande taille chez un même individu hôte oblige l'une des espèces à changer d'habitat.

Tab. 1. Prévalence (P %) et abondance (A) des digènes récoltés chez le marbré provenant des côtes tunisiennes et de la Méditerranée occidentale.

|                | Présen | t travail | Méditerranée or | cidentale |
|----------------|--------|-----------|-----------------|-----------|
|                | P (%)  | A         | P (%)           | A         |
| H. pycnoporus  | 28.6   | 1.68      | 50              | 2.1       |
| L. pegorchis   | 15.5   | 1.06      | 5.8             | 0.7       |
| M. mormyri     | 9.52   | 0.46      | 25              | 0.4       |
| P. senegalense | 3.6    | 0.11      | 3.8             | 0.15      |
| D. brusinae    | 2.4    | 0.04      | 3.8             | 0.06      |

Ainsi, *H. pycnoporus* qui, à l'état solitaire, occupe préférentiellement l'intestin moyen, en présence de *M. mormyri*, décale son microbiotope vers l'intestin postérieur pour échapper, sans doute, à la compétition. Si l'une de ces deux espèces se trouve en présence de *L. pegorchis*, trématode de petite taille, la coexistence ne semble pas avoir d'influence sur la répartition de ces parasites. L'évaluation des indices parasitaires montre que

*H. pycnoporus* et à moindre degré *L. pegorchis* sont les espèces les plus fréquentes et les plus abondantes (Tableau 1). En Méditerranée occidentale, la faune digénétique du marbré est dominée par *H. pycnoporus* et *M. mormyri* [6]. Par ailleurs, *H. pycnoporus* est plus fréquent et plus abondant en Méditerranée occidentale que sur les côtes tunisiennes (Tableau 1).

Le suivi de la répartition des parasites suivant les lieux de récolte montre que *M. mormyri*, *H. pycnoporus* et *L. pegorchis* sont présents dans les trois lieux de récolte prospectés. *P. senegalense* se limite au littoral de la région de Sfax et au golfe de Tunis. *D. brusinae* provient uniquement du golfe de Tunis.

#### Conclusion

L'étude de la faune digénétique du marbré provenant des côtes tunisiennes montre une faible diversité (5 espèces). Cette faune, dominée par *H. pycnoporus* et à moindre degré *P. pegorchis*, présente des valeurs épidémiologiques relativement faibles. Ces parasites se répartissent différemment au sein du tube digestif de l'hôte. Les infracommunautés maximales représentées par 2 espèces sont donc pauvres. A l'exception de *P. sene-galense* et *D. brusinae* qui se limitent à un ou à deux lieux de récolte, les autres parasites se trouvent dans tous les milieux prospectés.

# CANNIBALISM IN ANCHOVY ( ENGRAULIS ENCRASICOLUS) IN THE NORTH AEGEAN SEA (GREECE)

Vincent Gennotte \*, Michele Torre and Argyris Kallianiotis

Fisheries Research Institute, N.AG.RE.F., Nea Peramos, 64007, Kavala, Greece - vgennotte@hotmail.com

# Abstract

Egg and larval cannibalism was characterized in the European anchovy (*Engraulis encrasicolus*) during the spawning season in the North Aegean Sea. About 3 % of the sampled fish had consumed eggs and 7 % larvae. Egg consumption was observed during the night and larval consumption during the day. Cannibalism seems to be an opportunistic feeding strategy of anchovy, depending on prey availability and proximity of adults, larvae and eggs in relation with the diel vertical migrations of the fish. *Keywords : Fish Behaviour, Pelagic, Diet, Aegean Sea.* 

In the North Aegean Sea, as in other parts of the Mediterranean Sea, anchovy (*Engraulis encrasicolus*) has a high economic importance. It constitutes one of the main target species of the fisheries and occupies a key role in balancing the energy flows through the food web, being one of the main links between secondary producers and higher level predators. Anchovy is known to be mainly zooplanktivorous and feeds preferentially on copepods and other small prey items [1]. Egg cannibalism has been reported in anchovy [1] but only a few indications have been given on the mechanisms implicated in this behaviour and its incidence. However, conspecific larvae have never been described in anchovy diet. This is the first study of cannibalistic behaviour in anchovy in the North Aegean Sea.

Sampling was carried out in the Thracian Sea and Thermaikos Gulf (North Aegean Sea) during survey cruises in June 2004 and June-July 2005, which corresponded to the spawning season of anchovy in eastern Mediterranean. 21 samples, comprised of 11 to 21 fish each (total number of fish = 356) were caught at different hours of day and night with a semipelagic trawl or a mid-water trawl. Total length and sex were determined and the stomach content qualitatively analyzed. For each fish sample, the volume contribution of anchovy eggs and larvae to the diet was calculated and, when possible (depending on digestion state), their total length was measured.

The total length of the analysed fish ranged between 80-160 mm (mean =  $125 \pm 17$  mm). Females made up 58.1 %. Of the total of 356 anchovies, 11 (3,1 %) were egg-feeders, with their stomachs containing from 1 to 6 anchovy eggs (egg size range = 0,38-1,45 mm; mean size = 0,62 mm; n = 21) and 25 (7,0 %) were larva-feeders, with their stomachs containing from 1 to 24 anchovy larvae (larval size range = 3,75-25 mm; mean size = 10,54 mm; n = 144). Egg-feeders were therefore not abundant and the contribution of eggs to the diet was low, representing at most 0,5 % of the stomach content volume in one sample (caught at 4:16 h; n = 13). In contrast, predation on larvae was a feeding strategy more frequently used by anchovy. In one sample (caught at 18:39 h; n=19), 57 % of the fish were larva-feeders and the diet was clearly dominated by anchovy larvae (volume contribution = 73,6 %).

Fig. 1. Number of anchovy eggs and larvae found in the anchovy stomachs versus sampling time.

Neither sex nor size had a significant effect on the occurrence of canni-

balism (Mann-Whitney U test, difference between two proportions test, p >0.05). On the other hand, the intensity of cannibalistic behaviour varied with time of the day (Fig. 1). Except in one sample where only 1 egg was found in the stomach of one individual, egg consumption was observed only during the night. In contrast, larval cannibalism was only diurnal and a consistent proportion of individuals specialized on anchovy larvae consumption a few hours before sunset.

In our study, cannibal and non-cannibal fish were found in the same samples, suggesting that egg and larval cannibalism must be considered as an opportunistic behaviour underlying prey availability dependence [2]. As observed in the Catalan Sea [1], egg consumption was very low and could result from spatio-temporal segregation of feeding and spawning activity. Eggs were found in the stomach contents during night, when anchovy migrates to the upper layers where the bulk of the eggs are confined [3]. In contrast, consumption of larvae was high in some samples, oriented towards large-sized larvae and observed only during daylight, when fish are close to the bottom. Whereas small larvae are mainly distributed above the thermocline, larvae longer than 10 mm carry out vertical migrations from the surface at night to deeper layers during the day [4]. Thus, larval cannibalism could result from adults and larvae proximity and conditions of reduced availability of other prey items. Indeed, increased consumption of larvae occurred just before sunset, when a consistent proportion of zooplanktonic organisms started to vertically migrate towards the surface lavers

Consequently, the factors influencing egg, larval and adult distributions as well as the diel rhythm of anchovy activity and food availability might play an important role in anchovy feeding and potential cannibalism.

# HARD BOTTOM ASSEMBLAGES IN THE STRAIT OF MESSINA: DISTRIBUTION OF *ERRINA ASPERA* L. (HYDROZOA: STYLASTERIDAE)

Salvatore Giacobbe , Gianmichele Laria and Nunziacarla Spanò \*

Department of Animal Biology and Marine Ecology, University of Messina, Salita Sperone 31 - Contrada Papardo, 98166 Messina. -

spano@unime.it

# Abstract

Distribution of the stylasterid *Errina aspera* L. in the Straits of Messina has been surveyed by means GIS technology. The species is confined to a narrow rocky zone, prone to "intermediate" water upwelling. Potential risks of damage by an increased sedimentation rate are discussed.

Keywords : Biogeography, Endemism, Mapping, Western Mediterranean.

# Introduction

Seismic activity and strong tidal currents determine an erosive regime affecting the Straits of Messina at least down to 300-350 m [1]. The rocky seafloor of the straits is inhabited by rich benthic communities and some particular assemblages that are unknown in other Mediterranean regions [2, 3]. Since the geological and topographical study carried out in the late 1970s [4] no further work was conducted, so most of the continental slopes and related communities are still unexplored. A revision of literature and original data on the distribution of the stylasterid hydrocoral *Errina aspera* and its related community was studied, as part of a larger project investigating biodiversity in the Straits of Messina.

#### Methods

In August 1995, a preliminary survey provided 25h of videotape recordings, and 183 bottom samples, from 10 to 220 m depth. The distribution of *E. aspera* was subsequently verified by means of grab and dredge samplings, ROV observations and direct scuba diver surveying, in additional 53 stations. The data was stored in a geo-database model, tailored specifically for the marine community, with a GIS platform. The coordinate system used was WGS84 UTM Zone 33N.

#### Results and discussion

Surveys provided 35 records of E. aspera, located in the rocky bottoms of the sill and along a narrow area of the Sicilian part of the straits. A single finding was made on the south-eastern Calabrian coast (Capo dell'Armi), thus extending the known area of the species in the Straits of Messina [5]. Our findings suggest the coverage by E. aspera had been overestimated in previous surveys. Due to the erosive and depositional processes that asymmetrically affect seafloors, a narrow rocky zone extends exclusively south-west from the sill, gradually increasing in depth, from 90-150 m down to 150-220 m. Coarse sediment slumpings are responsible for the frequent discontinuities observed in the rocky zone, with a consequent patchy distribution of E. aspera. With regard to this distribution, we show how E. aspera populations, which need an erosive sedimentary regime, could suffer from an altered sedimentation rate. According to Giacobbe [5], E. aspera population density tends to a bipolar distribution, reaching a peak to the north of the sill, and a trough at the lowest depth, to the south. The first record of E. aspera in a deep-water sea cave was videotaped, in this latter area (Giaccone, personal communication). Given only a single finding of E. aspera, distribution on the south-eastern Calabrian side is not well known. Nevertheless, its occurrence near Capo dell'Armi, at 95 m depth, is in accordance with the hydrological regime in the Strait, representing a further indication of the prominent role of "intermediate"upwelling currents [6] in determining E. aspera distribution [5].

# Abstract

Acoustic survey data from June 2004 and 2005 were combined with environmental satellite data to investigate the spatial distribution of the European sardine in the Greek seas (Eastern Mediterranean basin). The link between the presence of sardine with environmental variables was identified by GAMs, while GIS techniques were applied, to map the areas where this set of environmental parameters is present, implying the existence of potential sardine habitat.

Keywords : Aegean Sea, Acoustics, Mapping.

#### Introduction

The present work is a first approach to identify the environmental characteristics that describe areas that serve as potential habitat of the European sardine (*Sardina pilchardus W.*) in the Greek Seas (Eastern Mediterranean Sea) during June. For this purpose acoustic data together with environmental satellite data were used and a specific set of environmental parameters associated with sardine's presence was defined. GIS techniques were applied to map the areas where this set of environmental parameters is met, implying the existence of potential habitat of sardine stocks, which is essential for management purposes.

# Materials and Methods

Acoustic data were collected during two research surveys (June 2004 and 2005) on board the R/V Philia, in the Aegean Sea by a Biosonic Split Beam DT-X echosounder at 38kHz. Sardine echoes were discriminated based on the characteristic echogram shape of the schools and integrated per 1 nautical mile. Environmental data (i.e., mean monthly values of sea surface temperature-SST in °C, chlorophyll-a CHLO in mg/m<sup>3</sup>, sea surface salinity-SSS, sea level anomaly-SLA in cm and photosynthetic active radiation-PAR in Ein/m<sup>2</sup>/day) were derived from satellite imagery using GIS procedures ([1]). Generalized Additive Models (GAMs) were applied in a presence/absence approach in Thracian Sea on pooled data from the examined years, in order to identify the link of sardine's presence with environmental variables and define the set of the parameters values that describe potential areas of sardine presence. Thracian Sea was used as a pilot area, being characterized by strong heterogeneity of environmental conditions. Model selection was based on the minimization of the AIC criterion with a backward selection method [2], a binomial error distribution and the cubic spline smoother (s) was chosen as appropriate. In a next step, GIS techniques used the specific range of values from Thracian Sea (indicated by GAMs results to have a positive effect on sardine presence), to map those areas in the Greek Seas as well as the entire Mediterranean basin, where the specific environmental conditions are met, using mean monthly satellite data from June 2004 and 2005. Acoustic data from Thermaikos and Evoikos gulf in June 2004 and June 2005 as well as acoustic data from past studies in Central Aegean and Ionian Sea in June 1998 and June 1999 ([3]) were used for the cross validation of the results.

# Results and Discussion

GAMs results of the final selected model [s(SST,df=4)+s(PAR,df=4) +s(CHLO,df=4), p<0.01, Deviance explained = 25.9%] indicated a certain range of values of the environmental parameters within the available ones, that there was a higher probability of finding sardine present. GIS mapping of the estimated conditions of environmental parameters derived from the Thracian Sea seems to describe quite reasonably also the areas of the actual sardine distribution in the Thermaikos and Evoikos gulfs in June 2004 and 2005, as well as in the Central Aegean and Ionian Seas as data from June 1998 and 1999 ([3]) are showing in Fig. 1. Mapping also indicated the specific set of environmental conditions for other areas in the Mediterranean Sea (e.g. the Adriatic Sea, the north Tyrrhenian Sea) as well as areas in the Eastern Mediterranean basin where the distribution of sardine is unknown (e.g. in the Nile Delta area, Fig. 2). The use of data from additional areas as well as pooled data from several years could better define the set of the environmental parameters that characterize the areas of the main sardine's concentrations and improve estimations results.

Fig. 1. A GIS extrapolated map of sardine's potential habitat in the Aegean and Ionian Seas based on the set of the parameter values estimated from the Thracian Sea acoustic data and mean monthly satellite data from June 2004.

Fig. 2. A GIS extrapolated map of sardine's potential habitat in the Mediterranean basin based on the set of the parameter values estimated from the Thracian Sea acoustic data and mean monthly satellite data from June 2004.

# Abstract

This note provides data on sepiolid distribution in the Southern Tyrrhenian Sea in which the Sepiolidae have an important commercial value. All three sepiolid subfamilies (Sepiolinae, Heteroteuthinae and Rossiinae) are represented in the Southern Tyrrhenian Sea *Keywords : Cephalopods, Trawl Surveys, Tyrrhenian Sea*.

The diversity of sepiolid species is particularly rich in the Mediterranean Sea. A lot of systematic studies [1-2], faunistic [3-4] life cycle [5] and behaviour have been carried out on sepiolis species in the Mediterranean. Up to now 16 sepiolid species have been listed in the Mediterranean Sea [6-7], amongst these 12 species have been found in the lower Tyrrhenian Sea [8-9].

The data come from ten years of bottom trawl surveys (1994-2004) on the evaluation of demersal resources within the area comprised between Suvero Cape (Calabrian side) and San Vito Cape (Sicilian side) along the Italian coasts (Southern Tyrrhenian Sea).

Material was frozen on board and then fixed in 4% buffered formalin in the laboratory. The identified species were *Sepiola rondeletii* (Leach, 1917), *Sepiola intermedia* (Naef, 1912), *Sepiola ligulata* (Naef, 1912), *Sepiola robusta* (Naef, 1912), *Sepiola affinis* (Naef, 1912), *Sepietta oweniana* (Orbigny, 1941), *Sepietta neglecta* (Naef, 1916), *Sepietta obscura* (Naef, 1916), *Rossia macrosoma* (Delle Chiaje, 1830) *Neorossia caroli* (Joubin, 1902), *Heteroteuthis dispar* (Ruppel, 1844) and *Rondeletiola minor* (Naef, 1912). The identification key was based for the males on the observing of the hectocotylized arm and for the females on the bursa copulatrix characteristics.

A total of 1963 individuals belonging to twelve sepiolid species were collected and 1555 of these were identified. *Sepietta oweniana* (720 specimens), *Rossia macrosoma* (293 specimens), *Rondeletiola minor* (249 specimens) and *Sepiola rondeleti* (156 specimens) were the most common species encountered.

Only one specimens of *Sepiola ligulata* (mature female of 13 mm ML), *Sepiola intermedia* (mature male of 15mm of ML) and *Sepiola robusta* (mature male of 16 mm of ML) were collected between 180 and 260 m of depth. The more coastal species was *Sepietta obscura* (26 specimens), that was caught from 50 to 100 m of depth; the size ranged for males between 13 and 19 mm ML and for females between 12 to 24 mm ML. Only four specimens of *Sepietta neglecta* were found on the continental shelf (50-100 m), three were mature males measuring 12,12.5 and 14 mm ML respectively and one was mature female (15 mm ML).

Sepiola affinis (32 specimens), Heteroteuthis dispar (15 specimens) and Neorossia caroli (57 specimens) were found only in the continental slope, in particular the bathyal range were 200-500 m for Sepiola affinis and 500-800 m for Heteroteuthis dispar, Neorossia caroli and Rossia macrosoma. The mantle length ranged from 18 to 20 mm (males) and 19 to 25 (females) for Sepiola affinis and from 11 to 16 mm (males) and 16-20 mm (females) for Heteroteuthis dispar.

The most abundant species was *Sepietta oweniana*. A total of 720 specimens was taken during twenty trawl surveys (159 in spring and 561 in autumn). The DML size ranging from 11 to 34 mm for females and 12 to 31 mm DML for males while the mean total weight ranging from 1.67 to 8.86 g. Mature females with big eggs (ovary weight between 0.05 and 0.058 g; diameter eggs between 2 and 3.5 mm) were collected. The bursa copulatrix dimension varied from 3 to 16 mm and 0.011 to 0.899 g. For males both immature and mature specimens were found; the spermatophoric complex weight ranging from 0.025 and 0.382 g. This study represent a preliminary note on the presence, distribution and biology of the Sepiolid in the study area.

# DEMERSAL FISH AND MEGAFAUNAL ASSEMBLAGES ON THE CYPRUS CONTINENTAL SHELF AND SLOPE (EASTERN MEDITERRANEAN)

Giorgos Gitarakos<sup>1</sup>\*, Argyris Kallianiotis<sup>1</sup> and Nicos Hadjistefanou<sup>2</sup> <sup>1</sup> NAGREF, Fisheries Research Institute, 64007 Nea Peramos, Kavala, Greece - fri@otenet.gr <sup>2</sup> Fisheries and Marine Research Department, Nicosia, Cyprus

## Abstract

The demersal fish and megafaunal assemblages on the Cyprus continental shelf and slope were sampled for the first time during the MEDITS CY 2005 and 2006 projects. Species distribution and density varied between depth strata. A total of 173 species were recorded, 5 of which were Lessepsian migrants, whereas 1 fish species was recorded for the first time in the Eastern Mediterranean. *Keywords : Demersal, Eastern Mediterranean, Trawl Surveys.* 

# Introduction

The Cyprus continental shelf and slope had never been studied before in terms of composition and bathymetric distribution of fish assemblages. This study was a first attempt for such an approach, based on data taken from the MEDITS surveys of 2005 and 2006. The main objective of the study was to determine species assemblages in different depth zones, given that the sampling stations were bathymetrically stratified. Another point taken into consideration was the abundance and biomass changes in each stratum between the two years, since samplings were not carried out during the exact same season.

# Materials and methods

The survey method was the standard MEDITS protocol, i.e. stratified trawl surveys at depths ranging from 10 to 800 m. 25 hauls were conducted each year covering the area from Agia Napa to Chrysochous Bay. Sampling took place in August 2005 and June 2006. For data analysis, the sampling year was noted as 5 for 2005 and 6 for 2006, and the following strata codes were used: A (10-50 m), B (50-100 m), C (100-200 m), D (200-500 m) and E (500-800 m). Thus C14\_5 is haul 14, which belongs to the 100-200 m stratum, sampled in 2005. The dendrogram of similarities between the 50 stations was calculated with PRIMER, using the triangular similarity matrix, based on the Bray - Curtis similarity index, between stations (using 4th square root transformation) [1]. The statistical testing for the differentiation between strata and the determination of the main species responsible for the calculated differences was done with ANOSIM and SIMPER.

# Results and discussion

A total of 172399 individuals were fished (63528 in 2005 and 108871 in 2006), belonging to 173 species (114 osteichthyes, 16 chondrichthyes, 15 cephalopods and 28 crustaceans). The dendrogram of similarities indicates that stations were grouped per stratum (fig. 1).

Fig. 1. Dendrogram of similarities for 50 stations (cluster analysis, groupaverage linkage) sampled during August 2005 and June 2006.

The average similarity was 50,97%, 49,05%, 54,82%, 66,01% and 53,92% for strata A, B, C, D, and E respectively. The only stations that were grouped outside their actual stratum were B8 and A25. Station 8 was the only station in stratum B with high abundance of *Centracanthus cirrus, Macroramphosus scolopax* and *Trachurus mediterraneus* during both sampling years. These species were mostly occupying strata C and D in their total appearance. Station 25 was the only station of stratum A located

on the northern shore of Cyprus and presented species that were mainly found in stratum B in the southern part of the island. SIMPER revealed that the main species responsible for the grouping of stratum A stations were: Serranus hepatus, Spicara smaris and Serranus cabrilla. The main species responsible for the grouping of stratum B were: S. hepatus, Lepidotrigla cavillone and S. smaris, for Stratum C: M. scolopax, S. hepatus and L. cavillone, for Stratum D: Argentina sphyraena, Capros aper and Aspitrigla cuculus, and Stratum E: Plesionika martia, Chlorophthalmus agassizii and Argyropelecus hemigymnus. Strata differed between them (ANOSIM, R global >0.75, p <0,001). The pair wise comparisons of strata revealed *R*-values higher than 0.84 in every case, apart from the test between strata D and E, (R = 0.68). These were the deepest strata and differed but overlapped (R >0.5). The intra-stratum differentiation between the two sampling years revealed an abundance increase in 2006 for strata C, D and E (252.8%, 376.3% and 92.6% respectively) and decrease for strata A (514%) and B (15.5%). The high abundance in stratum A for 2005 was mainly due to Spicara smaris (73.7% of total individuals caught in stratum), which were just being recruited to the fishery [2]. The 2006 sampling took place in June and therefore recruitment did not started yet. The highest abundance increase in 2006 was noticed in stratum D, mainly due to the presence of A. sphyraena, M. scolopax and C. aper that increased by 567%, 1658% and 308% respectively. The increase in stratum C was also significant and was related with the presence of M. scolopax (76% of total individuals caught in the stratum). During the MEDITS CY surveys 5 Lessepsian migrant species were caught: 4 fish, Pteragogus pelycus (Randall, 1981), Dussumieria elopsoides (Bleeker, 1849), Stephanolepis diaspros (Fraser-Brunner, 1940) and Upeneus moluccencis (Bleeker, 1855) [3] and 1 crustacean species, Thalamita poissonii (Audouin, 1826) [4]. A deep living species of the family Stomiidae, Bathophilus nigerrimus (Giglioli, 1884), was also recorded at a depth of 610 m during the 2006 survey. This species has never been reported before in the eastern Mediterranean. In conclusion, depth zones were characterized by specific assemblages and differentiation between strata was clear.

# IS THE EASTERN MEDITERRANEAN A DEEP-SEA DESERT?

Menachem Goren<sup>1</sup> \* and Bella S. Galil<sup>2</sup>

<sup>1</sup> Department of Zoology, George S. Wise Faculty of Life Sciences, Tel Aviv University, Tel Aviv 69978, Israel - gorenm@post.tau.ac.il <sup>2</sup> Israel Oceanographic and Limnological Research P.O.B. 8030, Haifa 31080, Israel

# Abstract

A study of deep sea (1000-1500 m) fish conducted off the northern coast of Israel added new data. Though extremely sparse, the number of deep-water fish species known from the Levant increased from 8 to 39 (*vs.* 59 in the entire Mediterranean). Our findings suggest that the ichthyofaunal richness is correlated with the intensity of research. Interestingly, ca. 20 species are known from depths greater than reported from the western Mediterranean.

Keywords : Bathyal, Biodiversity, Deep Sea Ecology, Fishes.

The Levantine Sea at the easternmost Mediterranean is isolated from the deep Atlantic and western Mediterranean waters by the shallow Gibraltar Straits and the Siculo-tunisian sill. The Levantine deep waters are ultraoligotrophic and distinguished by temperature values that are higher than in the rest of the sea.

Tab. 1. List of deep sea fish species known from the Levant (\* collected during the present research).

A series of cruises conducted off the northern coast of Israel as part of pollution monitoring surveys at depths between 1000-1500m, afforded us an opportunity to examine the deep Levantine ichthyofauna. Though extremely sparse, the number of deep-water fish species known from the Levant increased to 39 (Table 1), as compared to the number of deepwater fish species known from the entire Mediterranean (59). The species richness in the Levantine Sea is comparable to other Mediterranean basins of a similar size. Contrary to the widely perceived notion of Mediterranean eastward progressive faunistic decline, our findings suggest that the ichthyofaunal richness is correlated with the intensity of research. Among the fish presented in Table 1-2, ca. 20 species are known from depths greater than reported from the western Mediterranean. It may be indeed that the Levant basin's distinct ecological conditions are reflected in bathymetric modifications, with the same species occurring deeper in the Levant than anywhere else in the Mediterranean Sea. Marenzeller's [1] echinoderm depth records, which show similar trend, were considered inaccurate, a result of possible "systematic mistake on the depth measurement that needs to be cleared up in the future" [2]. Recent records support Marenzeller's results of the deepening of the Levantine fauna [3-4].

# Abstract

Zooplankton is considered as indicator of the Global Change impact and may be used to forecast the combined effects of the physical and biological parameters operating at the sea basin scale. A concerted approach is necessary to obtain coherent data from biogeographical studies and retrospective analyses of historical time series. In order to build the ability to determine the composition of past and present assemblages of zooplankton in different Mediterranean geographic locations we propose here to harmonize the sampling, faunistical classification, statistical treatment and data archiving.

Keywords : Zooplankton, Sampling Methods, Time Series, Biometrics, Biodiversity.

#### Introduction

Climate Change has been a major concern in the last decade, not only for the scientific community but also for the general public. One of the major issues is to be able to propose scenarios of changes and foresee the variations that ecosystems will experience in the future. Global climate change is expected to impact the biodiversity, the structure and the functioning of plankton ecosystems [1]. In fact, zooplankton is known to be a good indicator of climate change because most of the species are not being commercially exploited, and the long-term changes observed in their stocks can, therefore, be attributed to changes in environmental conditions. As organisms living in suspension in the water column, they are good indicators of features and dynamics of water masses. In addition, they have a short life span that helps to relate population size to environmental conditions. And finally, plankton, with their non-linear responses to environmental changes, can amplify subtle environmental perturbations that otherwise would not be perceived. It is therefore necessary to study changes of past and present assemblages of zooplankton at interannual and longer time scales [3]). Because of the easy and low cost sampling, long term zooplankton time series are available in a number of locations.

In order to simplify the comparison of zooplankton time series we are proposing here to harmonize the collection methods, facilitate the transfer of samples to secure electronic archives, and share protocols for data summarisation and statistical analysis.

Since zooplankton is considered as indicator of regime shifts and its community composition impacts the fishery and the carbon cycle, a concerted approach is necessary to determine the variability of populations in time and space and the correlation with climate and fishery [2]. In order to intercompare the different series both quantitatively (biovolume, derived weight, community size spectra) and qualitatively (community structure, species assemblages, species ratio, indicator species) the different steps from sample collection, treatment and storing, to quantification, classification and data treatment in the different geographic locations should be coherent.

#### Methods

The proposed approach is based on the net sampling, sample digitization by the ZOOSCAN [4], the use of the free ZooProcess software for image treatment (www.zooscan.com) and the use of the free TANAGRA software (www.obs-vlfr.fr/LOV/ZooPart/ZooScan/article.php3?id\_article=55) for numerical analyses. The proposed methodology allows a standardised non destructive treatment of samples including enumeration, morphometry and faunistical classification of samples for biogeographical or historical time series analyses.

#### Expected results

Using the proposed approach we are expecting to better define the changes in the range and spatial distribution of species, shifts in the location of biogeographical boundaries and provinces, change in the phenology of species (e.g. earlier reproductive season), modification in dominance (e.g. a key species can be replaced by another one), change in diversity, and also change in the structure and dynamics of ecosystem with possible regime shifts (fig. 1).

Fig. 1. Nine years time series of copepods (in blue) abundance concentration and (in red) cumulative deviation from the mean at Point B (Ville-franche sur Mer, France) obtained using the Zooscan.

# Abstract

The SE Mediterranean, the warmest and the most oligotrophic region in the entire Mediterranean, was invaded lately by *Amphistegina lobifera*. This symbiont-bearing larger foraminifera proliferates along the Israeli coast mainly on rocky substrate. *A. lobifera* reproduces once a year, during summer (July-August), unlike its counterparts in the Gulf of Aqaba which reproduce twice a year (June and January). It therefore can survive the low winter temperatures of  $15^{\circ} - 17^{\circ}$  C of the eastern Mediterranean, but it fails to reproduce in the winter. *A. lobifera* is a major carbonate producer, with a contribution of about 200 g CaCO<sub>3</sub> m<sup>-2</sup> yr<sup>-1</sup> on rocky coasts of Israel. *Keywords : Foraminifera, Migrant Species, Eastern Mediterranean, Life Cycles.* 

# Introduction

The opening of the Suez Canal 135 years ago opened the gates to a major faunal invasion from the Red Sea to the eastern Mediterranean. The widespread invasion is changing the biota on the Israeli shelf, in particular suppressing the native inhabitants on rocky environments. *Amphistegina lobifera* is the most common species among the symbiont-bearing larger foraminifera that invaded the southeastern Mediterranean [1, 2]. In this study, we investigate the population dynamics of *A. lobifera*, as an example of an invader species living on the edge of its environmental tolerance. The Mediterranean is one of the northernmost locations in the world where this low latitude shallow water species lives today.

A. *lobifera* was first recorded on the Israeli shelf during the late 1950's [3] occurring in rather low numbers (10%). Recently it was found that this species comprises the majority up to 90% of the rocky foraminiferal assemblage off Akhziv and Haifa, between  $\sim 10$  and 30 m water depth [2].

## Material and methods

The annual population dynamics of *A. lobifera* was studied off Tel Shiqmona, Haifa, Israel in a rocky area densely covered by macroalgae. Sampling was carried out by scuba diving at  $\sim$ 1.5 m water depth, every 3-5 weeks from August 2003 to September 2004, in triplicate samples of intergrowing brown algae *Cystoseira* sp. and the red coralline *Jania rubens*. The abundance of the entire foraminiferal population was normalized against the total dry algal weight.

# Results and discussion

Sea surface temperatures vary between 15 and  $30^{\circ}$  C, salinity between 38.5 and 40 permil, and nutrient concentrations are raised in winter but much lower in summer. *A. lobifera* is the most common larger foraminifera off Shiqmona, occurring throughout the year.

Fig. 1. Variations in relative abundance of *Amphistegina lobifera* population including juveniles <500 um, intermediate growth stage 500-710 um and adults >710 um, off Tel Siqmona, Haifa, Israel.

Its numbers vary considerably indicating patchy distribution with somewhat higher numbers in late summer/early fall and late winter/early spring (650 specimens/g dry algae) and low numbers during summer (100 specimens/g dry algae). The reproduction period is short and is restricted to July and August, as evident by the high percentages of juveniles (Fig. 1). Light intensity and water temperature seems to regulate its reproduction cycle in the eastern Mediterranean. Daily juvenile growth rate during summer is 2.2%, slowing during winter, at adult stage, to 0.3%. Full-sized specimens (up to 1.5mg) were recorded during fall and winter. A. *lobifera* is a major carbonate producing foraminifera, with a contribution of about 200 g CaCO<sub>3</sub> m<sup>-2</sup> yr<sup>-1</sup>on rocky coasts of Israel. In some samples it is the largest single contributor to carbonate production.

# MARINE MAMMAL STRANDINGS ON THE TURKISH AEGEAN SEA COASTS: FISHERMEN REPORTS

Harun Guçlüsoy<sup>1</sup> \* and Şükran Cirik<sup>2</sup>

<sup>1</sup> Institute of Marine Sciences and Technology, Dokuz Eylül University, Izmir - harun.guclusoy@deu.edu.tr <sup>2</sup> Faculty of Fisheries, Çanakkale Onsekiz Mart University, Çanakkale

# Abstract

This study assesses the anecdotal marine mammal stranding reports of fishermen from the central Turkish Aegean fishing ports. For this, a poll survey was conducted with 30 % (n=179) of the fishermen. Forty-four reports involving Delphinidae (n=38), *Physeter macrocephalus* (n=4) and *Monachus monachus* (n=2) were collected. One of the reported *P. macrocephalus* was misidentified. *Keywords : Cetacea, Eastern Mediterranean.* 

### Introduction

Our knowledge of the marine mammals with the exception of the *M. monachus* [e.g. 1] of the Turkish Seas is scarce. To date, a few opportunistic studies were carried out along the Turkish Aegean Sea. The occurrence of *Delphinus delphis*, *Grampus griseus*, *P. macrocephalus*, *Stenella coeruleoalba*, *Tursiops truncatus*, *Ziphius cavirostris* and *Pseudorca crassidens* were reported from this region [2,3,4]. With the present study, we aim to collect and assess the anecdotal marine mammal stranding reports of the fishermen from the central part of the Turkish Aegean Sea coasts.

# Methodology

This study was a part of the poll survey among the fishermen, and was conducted from November 2003 to November 2004 at 8 fishing ports located between Ayvalik and Didim-Taşburun (Fig.1).

Fig. 1. The locality of fishing ports from north to south (1) Ayvalik, (2) Dikili, (3) Foça, (4) Urla, (5) Çeşme Dalyanköy, (6) Siğacik, (7) Kuşadasi and (8) Didim-Taşburun, and stranding localities of marine mammals - 7 of them overlaps - in the Turkish Aegean coasts.

It was aimed that 30 % of the artisanal fishing boat owners at each port to be inquired. Moreover, the same approach - the number of skippers/owners was derived from [5] - was also used for entire fleet of purse-seiners and trawlers - regardless of their port of origin - of the whole study area. The fishermen were interviewed singly so as to prevent being influenced by each other's responses. Prior to questionnaire application, each of them was shown with three cards, measuring 22 x 28 cm, depicted black and white drawings [6] - with scale - of the followings species: *Balaenoptera physalus, Balaenoptera acutorostrata, P. macrocephalus, Z. cavirostris, P. crassidens, Orcinus orca, Globicephala melas, D. delphis, T. truncatus, G. griseus, S. coeruleoalba, Phocoena and M. monachus.* For the present study, each fisherman was asked to show which species he saw stranded and its locality.

#### Results and Discussion

During study period, a total of 179 (30 %) fishermen were inquired. Except in one occasion, involving two unidentified small delphinids, they all reported single animal strandings (n=43), as expected from the vicinity of the ports, between 1989 and 2004 (Fig.1). Though a weak evidence on mass stranding due to an epizootic were reported previously [3], no mass die-off was reported from the region. Because the majority of the stranding reports comprised dead animals (n=37) and/or seen from distance, the fishermen could not accurately identify the small cetacean species from the drawings shown. Therefore, all of them were categorised as Delphinadae in Figure 1. Moreover, they reported four P. macrocephalus strandings among which one of them - the southernmost standing in Figure 1 - was not the species that they claimed. This species well identified to be a B. physalus [7]. In addition, M. monachus (n=2) strandings were also reported from the current distribution range of the species in the region [1]. Though the reported number of injured stranded animals from deliberate killing attempts was expected to be negatively bias, there still be two incidences reported (Tab.1). As mentioned previously [2,3], with the line of our findings (20 strandings between 2001 and 2003), we still believe a functioning stranding network is still required for better monitoring of the marine mega-fauna along the Aegean sea coasts.

# Abstract

We provide the first evidence from satellite telemetry and stable isotope techniques that a small portion of the fin whale population occurring in the north western Mediterranean Sea during summer migrates to Atlantic foraging areas. *Keywords : Cetacea, Western Mediterranean, Circulation.* 

Fin whales (*Balaenoptera physalus*) are the largest marine predator in the Mediterranean Sea, where they feed exclusively on the zooplankter *Meganyctiphanes norvegica*. An estimated 1500 to 3500 individuals concentrate during summer in the northern occidental basin and are heavily exposed to shipping collision [1]. Mediterranean fin whales are genetically distinct from North Atlantic populations and the prevailing hypothesis that these stocks are also geographically isolated [1].

The summer distribution of fin whales was investigated using geostatistics [2]. Fin whales movements were monitored using Argos satellite telemetry and by measuring carbon stable isotope ratio variation along baleen plates indicative of feeding areas. Whale baleen plates grow continuously and thus provide a record of stable isotope variation. Furthermore the year round variation in abundance and distribution in the western Mediterranean sea is currently investigated from ship-surveys conducted along the Dyfamed transects between Marseille and Algeria. The fin whales sightings data base merges data coming from a broad range of organization and associations and cover the period 1993 to 2001. And fin whale were found to be more likely encountered over 2 main areas centred about 43° S, 8°10' E and 42° 40 S and 5° 30. The main oceanographic process taking place in the area is associated with the sinking of denser (i.e. saltier) surface water [3] inducing intense spring bloom which in turns allows the development and growth of *M. norvegica*. These areas of sinking dense waters also induce the creation of cyclonic gyres in locations roughly similar from year to year [3]. The summer distribution of fin whales probably mirror the spatial recurrence of these features while the Northern Current could also play an active role in the transportation and in concentrating the preys.

11 fin whales were tagged in August 2003 with Argos satellite tags, which supplied useful locations for up to 301 days from 8 individuals. The resultant tracks documented 13.356 km of travel and provided the first evidence of a summering Mediterranean fin whale traveling into the Atlantic. Seven whales remained in the northwestern Mediterranean for their entire tracking periods. Stable isotope ratios provided useful information of migration patterns and trophic levels. The  $\delta^{13}C$  was measured every centimeter from base (the most recent growth) to tip (the oldest part) of individual baleen plates from 8 whales stranded along the French Mediterranean. The longitudinal record of  $\delta^{13}$ C values in baleen for all individuals, except one male killed in a ship strike in the northwestern Mediterranean, had similar  $\delta^{13}$ C variation patterns. This lone individual exhibited large cyclic variation of  $\delta^{13}$ C fluctuating consistent with the higher enrichment in  $\delta^{13}$ C typical of both the northwestern Mediterranean and Atlantic, suggesting that this individual undertook migrations between the Mediterranean sea and the Atlantic. The  $\delta^{15}$ N values are consistent with fin whales feeding mainly on M. norvegica both in the Mediterranean and in the Atlantic .

The survey initiated in summer 2006 confirmed that fin whales were most commonly observed in the northwestern Mediterranean sea but could be seen in the southwestern part of the Mediterranean sea in fall. This study show for the first time that most Mediterranean fin whales are resident and foraged mainly in the northwestern part through summer and fall and tended to disperse more widely later in fall. This study also show that a small proportion of the population migrates to the Atlantic. From a conservation perspective, the whales remaining in the northwestern basin during fall and early winter are exposed to more shipping than previously thought.

# REPRODUCTION OF COMMON CUTTLEFISH (SEPIA OFFICINALIS, L., 1758) IN ANTALYA BAY

Olgaç Guven \* and Mehmet Özbaş

Faculty of Aquatic Sciences, Akdeniz University, Antalya, Turkey - olgac@akdeniz.edu.tr

# Abstract

The reproduction of common cuttlefish was studied between September 2002 and March 2004 in Antalya Bay. 490 individuals were collected during the studied period. The mantle lengths and total weight of common cuttlefish varied from 55 to 177 mm, and 29.7 to 652.3 g for females and 45-170 mm, 16.8-510.8 g for males (mean total mantle length and body mass for females and males:  $105\pm1.6$  mm,  $174.83\pm7.79$  g and  $98.8\pm0.15$  mm,  $135.46\pm5.65$  g, respectively). Four maturity stages were described. Based on the proportions of each maturity stage, as well as on various maturity indices, spawning was found to take place throughout the year with an increase between May and August.

Keywords : Cephalopods, Reproduction.

### Introduction

The reproduction of the common cuttlefish of the Eastern Atlantic and Western Mediterranean Sea is known in considerable detail [1,2,3,4,5,6]. Its life cycle is closely related to environmental factors. Thus, in the northern part of their distribution, they begin their reproduction cycle in the second year of their life, during a short breeding season lasting 2 to 3 months. In contrast, in warmer waters such as the Western Mediterranean, the majority of cuttlefish reproduce when 1 year old and over a long period [5]. Little is known about its reproductive biology in the Mediterranean coast of Turkey.

# Material and methods

Samples were collected between September 2002 and March 2004, from local fishermen and the industrial fishing fleet of Antalya Bay. A total of 490 individuals (246 female and 244 male) were examined. Mantle length (ML), to the nearest 1 mm, and total body mass (BM), to the nearest 0.1 g, were recorded. For females the ovary mass (OM), and nidamental gland mass (NGM), and for males testis mass (TM) and spermatophoric complex mass (SCM), were also recorded. Four maturity stages for each sex were determined using a scale proposed by [7]: females, I-immature, II-maturing, III-prespawning and IV-spawning; males, I-immature, II-maturing, III-fully mature, and IV-spawning. The spawning peaks were identified using the indices of reproductive status [3,7]: (a) females: GSI (Gonadosomatic index): 100 x OM / BM, and NGI (Nidamental gland index): 100 x NGM / BM; (b) males: GSI: 100 x TM / BM and SCI (Spermatophoric organ index): 100 x SCM / BM.

### Results and discussion

The length distributions are shown in figure 1a. To determine the spawning season the occurrence of mature females and males was examined [Fig.1b]. Spawning females (Stage IV) were observed from March to July, while most of the males fully matured (Stage III) from March to July. Female maturity indices increased in February and peaked between May and July. All maturity indices declined gradually starting in August, and reached their lowest values between October and December (Fig. 1d). Male maturity indices increased in December and peaked in June and July (Fig. 1c). This coincides with the peak percentage values of specimens in spawning conditions. During the spawning season (from May to August), only one generation can be distinguished based on ML [Fig.1a]. The change in mean number of ova with ML, BM and NGM are shown in Table 1.

Fig. 1. (a) Length frequency distribution of females and males; (b) Monthly frequency distribution of spawning females (Stage IV) and males (Stage III); (c) Variations in monthly means of GSI and SCI for males; (d) Variations in monthly means of GSI and NGI for females.

This study indicated that the main spawning season of S. officinalis in Antalya Bay started in spring and lasted through summer with a peak in June and July. This agrees with most of other studies [8,5,6]. In all months some maturing and mature individuals were found, indicating that this species probably spawns during the whole year, but its reproduction peaks during June-July. Maturity indices show that cuttlefish are able to mature before they are 1 year old in the Mediterranean Sea as noted by [1], while they mature at an age 1 and 2 years in the Atlantic [5].

# REPRODUCTIVE BIOLOGY OF DIPLODUS VULGARIS (FAMILY SPARIDAE) IN THE SYRIAN COAST

Vienna Hammoud <sup>1</sup> \* and Adib Saad <sup>2</sup>

<sup>1</sup> Faculty of Sciences-Tishreen University-Lattakia- syria. - Vienna-h@maktoob.com

<sup>2</sup> Tishreen University, P. O Box 1408 Lattakia, Syria - adibsaad@scs-net.org

# Abstract

In this work, results on the reproductive cycle, the length at first maturity, and hermaphroditism of *Diplodus vulgaris* in the coast of Syria are presented. The spawning period occurs from December to February, and the length at first maturity is 18 and 18.5 cm for females and males. This species is characterized by a rudimentary hermaphroditism, with sexual inversion taking place at 16-19 cm. *Keywords : Fishes, Reproduction, Mediterranean Ridge, Species Introduction.* 

### Introduction

The Sparidae is one of the most important marine fish families that inhabit the Syrian Coast. *Diplodus vulgaris* is one of the most abundant species of the family, but its biology is not well known. The aim of this study is to describe the reproductive biology of *D. vulgaris*, including the spawning season, length at first maturity and hermaphroditism.

#### Materials and methods

Samples of *Diplodus vulgaris* were collected on a monthly basis with a commercial bottom trawler off the coast of Syria from November 1999 to March 2001.

The depth of sampling stations ranged from 5 to 50 m. A total of 435 specimens were collected. The maturity stage was determined using the gross sexual classification scale of Nikolsky [1]. The monthly evolution of GSI mean values and the proportion of spawning specimens during a period of 17 months were used to determine the spawning season. The size at first maturity ( $L_{50}$ ), the size at which 50% of the individuals were mature, was estimated by fitting the logistic function (using non linear least squares regression):

 $P=1/1+exp[b(L-L_{50})]$ 

Lenght frequency distribution was used for calculating the length at sexual inversion.

## Results and discussion

The mean values of GSI% ranged from 0.09% in June to 10.91% in January for females and from 0.05% in August to 4.52% in December for males.

Figure 1 shows that *D.vulgaris* is a winter spawner, with the highest GSI values occurring between December and the end of February for females, with a single annual spawning peak in January. The resting period clearly extends from April to the end of September.

Analysis of advanced maturity stages showed that females were in emission from December to the end of February, with the greatest percentage of females in maturity stage (V) in January. Males showed the same patterns as the females in terms of maturity stages. Nevertheless the presence of stage (V) males in December, with a single spawning peak in December, suggests earlier maturation for males.

The GSI values of the females throughout the year were larger than those for males. This is due to the fact that the eggs as the end product of ovogenesis in females are much heavier than spermatozoa or the end product of spermatogenesis for males, as noticed by ather authors for *D. sargus* [2]. However, the spawning period is different in the Mediterranean, occurring earlier in the North and West and later in the South and East [3-5], reflecting the differences in the environmental conditions in this region.

Length at first maturity was not significantly different between sexes (Hotelling's  $T^2$  test, p>0.05), being 18 cm and 18.5 cm for females and males respectively, corresponding to 2 years of age. Therefore, an increase in the minimum legal length should improve the stock management and conservation of this species.

Histological examination of gonads in the present study indicated that D.vulgaris shows a rudimentary hermaphrodism, in addithion to the rate of individuals that developed directly as a primary females and primary males. We found that 32.16% of the individuals had both male and female tissue, and most often these gonads showed one sex as being more developed than the other, with higher average total length for the individuals with a more developed ovary. Females at the onset of development and with a small male part were found up to the beginning of the spawning

season. Functional males under spermiation (stage V) with a reduced and developing female part were also found in January, during the spawning season.

In all hermaphrodite gonads the testis and ovary were clearly separated by connective tissue. Sexual inversion takes place at approximately 16-19 cm (2-3 years of age).

However the size or age at which sex reversal happens is not established genetically, and this may be dependent on demographic changes [6].

Fig. 1. The mean monthly gonadosomatic indices for females and males of *Diplodus vulgaris*, coast of Syria.

# DEVELOPING AN *FLR* OPERATIONAL MODEL FOR EVALUATION OF FISHERIES MANAGEMENT STRATEGIES: AN APPLICATION TO HAKE FISHERY

John Haralabous, Christos Maravelias \*, George Tserpes and Costas Papaconstantinou

Institute of Marine Biological Resources, Hellenic Centre for Marine Research, HCMR, 46.7 Km Athens-Sounio, P.O Box 712, 190 13

Anavissos, Attica, Greece - cmaravel@ath.hcmr.gr

# Abstract

An operational population model for hake developed in *FLR* framework of the *R* language under the EFIMAS project is presented. Two effort restriction scenarios were tested (10% and 20% reduction of fishing mortality F). The response of the hake fishery in these two management measures was evaluated for a 10-year projection period.

Keywords : Aegean Sea, Demersal, Models, Population Dynamics, Fisheries.

Hake is one of the main target species of several multi-species Mediterranean fisheries and especially of the bottom trawlers exploiting the continental slope. On the basis of the available data most of the hake stocks in the Mediterranean are either fully exploited or overexploited. In most of the cases a decreasing trend in individual lengths of the hake caught and in the catches per unit of effort of the trawlers can be observed. Fisheries management in the Mediterranean is based mainly on technical measures and control effort regimes i.e. a minimum landing size of 20 cm, a prohibition of bottom trawling within three miles of the coast or in depths less than 50 m (whatever comes first), a 40 mm minimum mesh-size of bottom trawls cod-end and a control capacity regime, i.e. limitation on national fleets' horsepower and gross tonnage.

In the Aegean Sea, hake is one of the main target species of the demersal trawl fishery and around to 300 vessels are currently involved into this fishery having an annual hake production of about 3000 t. Demersal trawlers operate from October 1 to May 31 exploiting the continental shelf and the upper part of the continental slope from 30 to 400 m [1].

Under the framework of EU EFIMAS (Operational evaluation tools for fisheries management options) project two management measures and corresponding strategies will be evaluated in the light of potential future increase of hake biomass using either effort or technical measures. The first will deal with effort restrictions, e.g. reduction of fishing mortality F, closed seasons, etc. The scenario will evaluate the trade-offs between effort, fishing intensity and stock status when limiting the trawling intensity to certain bounds (e.g. a single percentage cut off F / Effort, a closed fishing season). It is more than likely that the effect of these bounds on age composition of the stock and thus on interannual catches and yields, in the short term, will be dependent on the initial status of the stock. The second scenario will explore the impact of management regulations addressing specific technical measures, e.g. gear selectivity measures such as mesh type (e.g. knotted or not), on catchability dynamics.Gear selectivity will be evaluated against two scenarios, i.e. 40 mm cod-ends with and without knots. It is anticipated that the above analyses and scenarios testing will highlight if effort- or selectivity-based management is preferable for demersal trawl fisheries of hake.

A population model for hake fishery in the Aegean Sea was developed using the *FLR* (Fisheries Science in *R*) framework of the *R* language [2] in order to estimate future catches. First results are presented here from the application of the operational model to 2004 data of catch at age, weight at age, VPA derived estimates of F-at-age and recruitment. Stochasticity was incorporated in the operational model by introducing random variability in the recruitment values.

Two effort restriction scenarios were tested: one with a single 10% and another with a single 20% cut off F in the following year (2005). Under the assumption of constant catchability these F cuts may well reflect analogous reduction in effort E. The response of the hake fishery in these two management measures was evaluated for a 10-year projection period (Figure 1). Under fixed management rules the catch of the hake fishery remains relatively stable. A 10% cut in the fishing mortality F results in a 6% reduction in that year's catch (2005). However, the fishery soon (2006) returns to the previous level of exploitation and catches gradually increase in the following years (up to 10%). A 20% reduction in F induces a 13% decrease in the following year's catch. Hereafter the catches increase and level at higher values (17.5%) compared to the base and 10% case studies.

Fig. 1. Simulation results of operational model applied to hake catches in the Aegean Sea (2004). Projection period: 10 years. Scenarios with the current F, 10% and 20% reduction of current F.

# NOUVELLE LISTE COMMENTÉE DES RAIES DU BASSIN ALGÉRIEN

Farid Hemida \*, Wafia Sergoua and Rabea Seridji

Faculté des Sciences Biologiques- USTHB BP 32 - 16111 El Alia - Alger, Algérie. - fhemida@usthb.dz

# Résumé

Les raies capturées dans le bassin algérien sont recensées régulièrement depuis 1996. La liste actuelle non exhaustive est comparée à celle de [1]. De nombreux spécimens présentent des caractères morphologiques qui ne correspondent à aucune espèce de Rajidae signalée en Méditerranée . Leur position spécifique n'est toujours pas établie et la liste reste donc largement incompléte. *Mots clès : Biodiversity, Elasmobranchii, Demersal, Algerian Basin.* 

## Introduction

Il existe un grand nombre d'espèces dans la famille des Rajidae dans le monde, réparties en plusieurs genres dont quatre se retrouvent dans le bassin algérien (*Raja, Dipturus Rostroraja* et *Leucoraja*). Malgré leur importance dans l'économie de la pêche locale, les raies ne font toujours pas l'objet de travaux de synthèse. S'il n'existe aucun problème de diagnose pour des espèces comme *Raja miraletus* ou *Leucoraja melitensis*, l'identification de nombreuses espèces reste encore très problématique. L'inventaire réalisé, basé uniquement sur les apports de la pêche commerciale, est un préalable à la connaissance exacte de ce groupe.

### Matériel et méthodes

Les données ont été récoltées à la grande poissonnerie d'Alger, de 1996 à 2004. Les espèces proviennent des différentes régions de la côte algérienne. Après consultation des documents spécialisés [1-8] la détermination des espèces est faite avec vérification de tous les caractères indiqués.

# Résultats et discussion

Quinze espèces ont été recensées, sur les 17 signalées dans le bassin méditerranéen [4] : Rostroraja alba (Lacépéde 1803) ; Dipturus oxyrinchus (Linnaeus 1758) ; Dipturus batis (Linnaeus 1758) ; Raja miraletus Linnaeus, 1758 ; Raja clavata Linnaeus, 1758 ; Raja brachyura Lafont, 1873 ; Raja montagui Fowler, 1910 ; Raja asterias Delaroche, 1809 ; Raja undulata Lacépéde, 1802 ; Raja polystigma Regan, 1923 ; Raja africana Capapé, 1977 ; Leucoraja circularis (Couche, 1838) ; Leucoraja melitensis (Clark, 1926) ; Leucoraja naevus (Müller et Henlé, 1841) ; Raja radula Delaroche 1809.

La liste, actualisée en 2004 a été comparée aux résultats de [1]. On notera que toutes les espèces signalées par ces auteurs ont été rencontrées à l'exception de *R. fullonica* qui n'apparaît plus dans les captures, alors que *R. africana* est signalée pour la première fois dans les eaux algériennes. Certaines raies considérées comme fréquentes et même très fréquentes par [1] ont tendance à se raréfier (*Leucoraja circularis, Leucoraja melitensis* et *Leucoraja naevus*) ou à disparaître (*Rostroraja alba*).

La littérature consultée présente beaucoup d'ambiguïtés et ne facilite pas l'identification des raies, dont les individus sont très polymorphes. La position spécifique de nombreux spécimens n'est toujours pas établie et de ce fait la liste reste toujours ouverte. La confusion et l'erreur subsistent encore pour les espèces suivantes : *Raja asterias* et *R. brachyura*; *R. polystigma* et *R. montagui; Dipturus batis* et *D. oxyrhincus.* 

L'observation d'un grand nombre d'individus de *Raja clavata* confirme la discontinuité morphologique intraspécifique déjà observée par [9]. *R. clavata* caractérisée par un pédoncule caudal où alternent des bandes claires et sombres, présente de nombreux individus dépourvus de boucles. Certaines formes de *Raja clavata* peuvent se confondre avec des espèces voisines, telles que *Raja brachyura, Raja montagui* et surtout *Raja asterias*.

# ANALYSE DES DONNÉES MORPHOMÉTRIQUES DE QUELQUES ESPÈCES DU GENRE *RAJA* LINNAEUS, 1758 DANS LE BASSIN ALGÉRIEN

Farid Hemida \*, Wafia Sergoua and Rabea Seridji

Faculté des Sciences Biologiques - USTHB BP 32 - 16111 El Alia- Alger-Algérie. - hemidafarid@yahoo.fr

# Résumé

Une analyse en composantes principales des données morphométriques est réalisée sur quatre espèces de raies du genre *Raja*, capturées dans le bassin algérien. L'analyse permet de séparer très nettement *R. clavata* en deux catégories, confirmant ainsi la discontinuité morphologique mentionnée par la littérature [1, 2].

Mots clès : Systematics, Elasmobranchii, Demersal, Algerian Basin.

# Introduction

L'étude morphométrique porte sur quelques raies ornées de points, du genre *Raja: R. asterias* Delaroche, 1809 ; *R. brachyura* Lafont, 1873; *R. clavata* Linnaeus, 1758 ; *R. montagui* Fowler, 1910. Le but de nos investigations est de comparer les résultats de l'analyse des données morphométriques de quelques espèces de raies voisines, à ceux de la taxonomie actuelle. La systématique des raies, très délicate, nécessite une amélioration des critères d'identification.

# Matériel et méthodes

Deux cent sept spécimens mâles et femelles provenant de la pêche commerciale de toutes les régions de la côte algérienne ont été mesurés et se répartissent en 60 individus pour R. asterias (I), 53 pour R. brachyura (II), 54 pour R. clavata avec boucles (III), 28 de R. clavata sans boucles (IV) et 12 pour R. montagui (V). Douze caractères en plus de la longueur totale (LT) ont été relevés : largeur du disque (LD) ; longueur du disque (DD); espace inter -orbitaire (IO); espace pré-orbitaire (PO); espace prénasal (PN); longueur pré-buccale (PB) ; espace pré-anal (PA) ; longueur du pédoncule caudal (LQ); distance allant du museau à l'origine de la première nageoire dorsale (LD1); distance allant du museau à l'origine de la deuxième nageoire dorsale (LD2) ; largeur du museau, en avant des yeux (LAM) ; largeur du museau, en arrière des yeux (LAD). Les données morphométriques des quatre espèces de raies, obtenues entre 1998 et 2001 standardisées par le logiciel Sizestd [3], ont fait l'objet d'une analyse en composantes principales avec rotation par Varimax brut, réalisée par le progiciel STATISTICA, 5.1. [4].

### Résultats et discussion

La projection des individus sur le plan I-II-III (fig. 1) forme globalement deux nuages de points : le premier nuage est formé par la majorité des individus de l'espèce *Raja clavata* avec boucles, qui se détachent nettement de l'ensemble et sont par conséquent dissemblables. Le second nuage regroupe *R. asterias, R. brachyura, R. clavata* sans boucles et *R. montagui. Raja brachyura* fait l'objet d'une confusion et est souvent identifiée comme *R. asterias* [5].

Fig. 1. Projection des individus des 4 espèces sur le plan factoriel I-II-III et variables contribuant à la formation des 3 axes.

Quelques individus de *R. clavata* sans boucles (IV) se rapprochent des individus de la même espèce mais portant des boucles (III). L'examen de leurs coordonnées permet de déterminer les caractéristiques des points

voisins : ce sont surtout les mâles des deux catégories de cette espèce. *R. clavata*, présente une grande variabilité relative à la la livrée mais qui se traduit aussi par la présence ou l'absence de boucles; de plus ces boucles sont très polymorphes et réparties différemment sur le disque, d'un individu à l'autre. L'analyse des données morphométriques met en évidence deux catégories de *R. clavata*. Les résultats confirment également les affirmations de [2] et de [3] qui mentionnent l'existence d'une similitude morphologique entre certaines espèces : *R. asterias* (les jeunes surtout), *R. brachyura*, *R. montagui* et *R. clavata* sans boucles. Les descripteurs qui ont été mis en évidence peuvent concrétiser les frontières entre les groupes difficiles à séparer. Ces caractères, qui gagneront à être quantifiés, se retrouvent surtout au niveau du museau (PN, PB, PO, LAM) et de la tête (IO et LAD).

# MUGIL CEPHALUS: COSMOPOLITAN SPECIES OR SPECIES COMPLEX?

Sandra Heras<sup>1</sup>\*, María Inés Roldán<sup>1</sup>, Mariano Gonzáles Castro<sup>2</sup> and Maria Berta Cousseau<sup>2</sup> <sup>1</sup> Laboratori d'Ictiologia Genètica. Universitat de Girona. Campus Montilivi, E-17071. Girona, Spain. - sandra.heras@udg.es <sup>2</sup> Laboratorio de Ictiología.Universidad Nacional de Mar del Plata. Funes 3350. 7600 Mar del Plata, Argentina.

# Abstract

The cosmopolitan distribution of *Mugil cephalus* is under discussion at present. Morphometrics based on Landmark distances, meristics and 12S rRNA (domain 1 and 2), cytochrome c oxidase subunit I (COI) and cytochrome b (cytb) mitochondrial DNA markers data from several locations worldwide are presented. Combined results indicate a global species complex in need of taxonomic revision. *Keywords : Biometrics, Genetics, Fishes, Systematics, Biogeography.* 

*Mugil cephalus*, *Mugil platanus* and *Mugil liza* form species group with close morphological relationships. According to [1] grey mullet, *M. cephalus*, has a worldwide distribution (51N - 42 S) and *M. platanus* is considered as a synonymy in South American waters. Nevertheless, extreme conservative morphology of this species stands in contrast with the degree of allozimic differentiation detected at a global scale [2]. The aim of the present work is to compare the taxonomic relationships of *Mugil cephalus* with *M. platanus* and *M. liza*, based on a multidisciplinary approach, using meristic, morphometric and mitochondrial DNA sequencing techniques.

|----------------|---------------------|---------------------|---------------------|---------------------|--|
| Med-USA        | 0.0170 ± 0.0059     | $0.0163 \pm 0.0061$ | $0.0414 \pm 0.0077$ | $0.0586 \pm 0.0107$ |  |
| Med-Miya       | $0.0101 \pm 0.0046$ | $0.0201 \pm 0.0070$ | $0.0269 \pm 0.0077$ | $0.0574 \pm 0.0100$ |  |
| USA-Miya       | $0.0274 \pm 0.0079$ | $0.0201 \pm 0.0071$ | $0.0420 \pm 0.0082$ | $0.0576 \pm 0.0104$ |  |
| M.pl/M.li-Med  | 0.0139 ± 0.0052     | $0.0168 \pm 0.0057$ | $0.0229 \pm 0.0053$ | $0.0479 \pm 0.0091$ |  |
| M.pl/M.li-USA  | 0.0289 ± 0.0082     | $0.0253 \pm 0.0073$ | $0.0325 \pm 0.0066$ | $0.0498 \pm 0.0090$ |  |
| M.pl/M.li-Miya | $0.0243 \pm 0.0071$ | $0.0269 \pm 0.0077$ | $0.0248 \pm 0.0059$ | $0.0406 \pm 0.0079$ |  |

Samples of *M. cephalus* were collected from the Mediterranean (Med), the western Atlantic (USA); *M. platanus'* from South America, and *M. liza* from the Caribbean. Twenty-one morphometric variables were taken as interlandmark distances of involved species. Meristic data were also considered for each specimen following [3]. Genetic analysis of 12S rRNA (domain 1 and 2), cytochrome c oxidase subunit I (COI) and cytochrome b (cytb) were carried out following [4] and using GenBank *M. cephalus* sequences as reference. Phylogenetic relationships were inferred by neighbor-joining analysis based on Tamura-Nei model.

Fig. 1. Neighbor-Joining tree based on Tamura-Nei distance. *M. cephalus* from the Mediterranean (empty circle), USA (solid circle) and Genbank reference (triangle) and *M. platanus/ M. liza* (square).

The interlandmark distances showed differentiation between the individuals of *M. platanus* and *M. cephalus* analysed. The number of lateral scales differentiated *M. liza*, *M. platanus* and *M. cephalus* being a diagnostic character in meristic analysis. However, the high genetic closeness detected between *M. platanus* and *M. liza* haplotypes and shared haplotypes did not support species level differentiation. Besides, the distances detected among *M. cephalus* samples overlapped with values shown between *M.pl/ M.li* and *M. cephalus* (Table 1). Phylogenetic trees had similar topology for all molecular markers (Figure 1). Although a monophyletic group for *M.pl/ M.li* was detected, it was included in *M. cephalus* lineage.

This evidence coupled with [2] suggest that the cosmopolitan distribution of *M. cephalus* should be reconsidered and new levels of species assignation are expected.

# Abstract

Population dynamic of the exploited demersal fish European hake (*Merluccius merluccius*. L.) off the Balearic Islands were explored in relation to the relative condition index ( $K_n$ ) and mean length-at-age (ML).  $K_n$  was significantly correlated with hake population characteristics as recruitment, spawning stock biomass (*ssb*) or total biomass. Furthermore, ML also appeared to be significantly related to age-0 class abundance, but with a different relationship before and after 1995, driven by a stronger density-dependence effect of *ssb* for low values of ML. This suggests that changes or phase transitions in the population could be occurring, affecting the intraspecific relationships. *Keywords : Balear Islands, Demersal, Fisheries, Recruitment*.

Fish condition is a measure of environmental and biological circumstances during previous periods. Condition indices are often used to represent the amount of energy stored within individual fish, although it is also relevant to estimate condition at the population level. Several morphometric and physiological indices used to be explored using individual observations. However, Mean Length-at-age (ML) can also be used as a proxy of the population condition when computation individual-level observations on weight and length are not readily accessible [1]. Condition of fish could reflect changes in the denso-dependent relationships and the population age structure. Inter-annual fluctuations of marine population can undergo abrupt changes which can be ecological, anthropogenic or climatologically driven [2]. This study aims to explore: 1) the effect of condition indices on the population abundance of European hake (Merluccius merluccius L.) (recruits abundance, rec, spawning stock biomass, ssb, and total biomass, tb) and, 2) explore the occurrence of possible phase transition in the population dynamic using ML as a proxy of condition of fish.

A total of 7447 individuals were sampled over the year from 1980 to 1992 (except 1987), estimating the relative condition index  $(K_n)$ :  $K_n = 100(W_{obs}/W_{est})$ , where  $W_{obs}$  is the observed weight and  $W_{est}$  the estimated weight.  $K_n$  was calculated for two groups, individuals lower that 30 cm (not maturing) and larger than 30 cm (maturing). ML at different ages was also calculated using yearly length distribution from 1980 to 2004. The outputs of the Virtual Population Analysis (VPA) were used in the analysis: rec, ssb, tb and number of individuals per age class [3]. Non-parametric Spearman correlations were used to compare  $K_n$ and hake population time series, being  $K_n$  index values ln transformed. However, as we got relatively longer time series for ML, we used a generalized additive model (GAM) to fit estimates of abundance at different age and ML. For studying the presence of changes in the time series, which may be indicative of phase transitions, changes in the condition as a threshold non-additive effect on ML throughout the time was explored. being the denso-dependency effect included trough ssb, also threshold by ML. The average per year of the ln transformed  $K_n$  (i<30 cm) index was significantly correlated with rec (r = 0.36, p<0.05), showing as well significant correlation with ssb and tb (lagged by one year) (r = 0.77 and r = 0.70 respectively, p<0.05) (Fig. 1a). Correlations with ln transformed  $K_n$  (i>30cm) were not significant (p>0.05). Although similar GAM approaches were followed for other ages, only results for age-0 are shown here. Figure 1b shows the different relationship between the covariate ML at age 0 (ML<sub>0</sub>) and age 0 abundance (N<sub>0</sub>), being 1995 the threshold in the relationship. Although higher N<sub>0</sub> is related to low ML<sub>0</sub> for the entire period, before 1995 around 15.5 cm  $ML_0$  was linked to higher  $N_0$ , while after 1995 higher N<sub>0</sub> of small individuals were related to lower ML<sub>0</sub>, around 14.5 cm. Ssb effect shows an increase of density dependence for low ML<sub>0</sub> values (<15.8 cm).

The results show that the recruits condition and ML are related to the abundance. *Ssb* and *tb* of the previous year could also affect the condition of the offspring between 1980 and 1992. However, the different biological meaning of  $K_n$  and ML must be taken into account. While  $K_n$  reflects the energy allocated to the body, ML shows the mean size of an annual class which can have a positive or negative effect of the population, or being a reflection of the population state. Our results reveal that the density-

dependence effect of *ssb* on  $N_0$  are mediated by  $ML_0$ . This suggests the occurrence of a possible phase transition in the population which must be explained within an ecological and fishery perspective (Hidalgo et al., in prep), because of the fishery-induced truncation of the age structured [4].

Fig. 1. a) Kn (i<30cm), tb and ssb time series from 1980 to 1992. b) Covariates effect of ML at age 0 (ML0) on the abundance of age-0 annual class (N0), under different period effect before and after 1995, and the density-dependent effect of ssb under different groups of ML0.

# Abstract

Seasonal variation in distribution of benthic foraminiferans and polychaetes was studied in the vicinity of a sewage sludge disposal site off the Mediterranean coast of Israel, where a full spectrum of oligotrophic to hyper-eutrophic conditions occurs. The foraminifera *Ammonia tepida* acts as a typical opportunist, reproducing rapidly and colonizing the sea floor anew following each episode of sludge winnowing. Opportunist polychaetes belonging to the Capitellidae respond in extremely high numbers only to the spring event of sludge dispersion. *Keywords : Eastern Mediterranean, Foraminifera, Polychaeta, Sewage Pollution, Eutrophication.* 

The ultra-oligotrophic shallow water environment of the southeastern Mediterranean has been subjected to man-made influences during the last decades. The activated sewage sludge (=biosolids) dumped into the sea off Palmahim exposes marine benthic biota to elevated levels of organic matter and nutrients, and has been monitored for two decades. There is a marked, seasonally dependent, localized impact on the benthic faunas and on sediment quality. Episodes of severe O<sub>2</sub> depletion leads to elimination of all benthic groups close to the sewage outfall, but peripheral eutrophication leads to temporary increase in abundance of opportunistic meio- and macrobenthos species (we studied Foraminifera and Polychaeta) [1, 2]. The opportunistic polychaete family Capitellidae becomes very abundant close to the sewage outfall and is an indicator for organic pollution [3]. We here compare the response of benthic foraminifera in this environment with the polychaete response pattern.

Two stations in the vicinity of the sludge outlet off Palmahim, PL3 (200m N of the outlet; hyper-eutrophic) and PL29 (5.5km to the N; oligotrophic) were sampled at 36m water depth bi-monthly between January 2003 and May 2004, for living (stained with Rose-Bengal) benthic foraminifera and sediment properties (the polychaetes were sampled from July 2003 to May 2004). Formalin-preserved and stained macrofauna >500 $\mu$ m are given as the average of triplicate samples (0.062m<sup>2</sup>).

Comparison between the meio- and macrobenthos at the two stations focused on seasonal variations in opportunists and presence of rare species. The abundance of polychaetes varied seasonally in both stations, with lowest numbers in late fall/winter, doubling in spring (500) at PL29 and much more at PL3 (up to  $14*10^3$ ). The simple diversity is highest at PL29 with 22 polychaete families, and lowest at PL3, with only 5 families. A different seasonality is shown by the foraminifera with the highest total standing stock (TSS) occurring at PL29 during late summer/fall (more than  $10*10^4$ ), and lowest TSS in mid-winter ( $8*10^3$ ). At PL3 TSS is lower, with maximal numbers in January and May (up to  $6*10^3$ ), coinciding with periods of intensive sludge winnowing during storm events (Fig. 1). Species richness at PL29.

The benthic foraminiferan *Ammonia tepida* and the capitellid polychaetes are opportunists that thrive in stressed environments. In the Palmahim stations the TSS maximum of *A. tepida* coincides with maximal abundance of the entire foraminiferal assemblage, comprising 70% of the assemblage. Capitellid polychaetes, the dominant polychaete family at Palmahim, comprise 99% of the polychaetes at PL3 and only 40% at PL29, where they are accompanied by paraonids and cirratulids.

The variations in TSS of *A. tepida* at PL3 track the changes in the sludge accumulation, with highest numbers coinciding with periods of total sludge dispersion during winter (01/04) and spring (05/03, 05/04) (Fig. 1). In fall, the hyper-eutrophic PL3 station became azoic due to water column stratification and high organic matter load (9cm in thickness). *A. tepida* behaves as a typical opportunist, inhabiting the newly exposed sea floor each time sludge is dispersed by winnowing. On the other hand, the opportunist capitellid polychaetes only respond to the spring event of sludge dispersal, at which time they occur in extremely high numbers.

Several foraminiferal species living at PL29 are not present at all at PL3. Their absence suggests that they are long-lived or specialized species that cannot survive the periodic ultra-eutrophic conditions in PL3. We conclude that the macro- and meiobenthos used for tracking the eutrophically overwhelmed environment off the Israeli coast have broadly similar seasonal patterns but differ somewhat in the magnitude of their response. The

foraminiferan *A. tepida* shows the most typical opportunist response, and is less affected by seasonality. It is a sensitive recorder of recurring sea floor aeration episodes at the most disturbed station, and as such has a potential for monitoring similarly disturbed coastal regions.

Fig. 1. Ammonia tepida and Capitellidae abundance (number of specimens per  $0.062m^2$ ), taken at station PL3 from 01/03-05/04 (bars) and the depth accumulation of the sludge on the sediment layers (diamonds).

# A PRELIMINARY STUDY OF ZOOPLANKTON DYNAMICS COUPLED WITH ENVIRONMENTAL PARAMETERS IN AN URBANIZED HARBOR

Ozgur Emek Inanmaz \* and Yesim Buyukates

Çanakkale Onsekiz Mart University, Fisheries Faculty, Terzioglu Campus, 17020, Çanakkale - emekinanmaz@gmail.com

# Abstract

Coastal systems exhibit a wide array of anthropogenic impacts which can alter ecosystem components. Therefore, a through knowledge of the system and the processes affecting it is required to understand the individual and/or mutual effects of physical and biological environments. Field samplings were performed to gather information on the zooplankton community and the environmental parameters of an urbanized harbor located at Kepez-Dardanelles. Weekly observations (between 26 April 2005 and 12 July, 2005) of on site measurements and microscopic analysis showed that environmental parameters and zooplankton community composition changed considerably among sampling depths.

## Keywords : Zooplankton, Dardanelles, Coastal Systems.

Zooplankton biomass, distribution and abundance are of extreme importance in aquatic systems. They maintain a crucial role as the secondary production of aquatic habitats in allowing energy to flow up the food web. Zooplankton are also very sensitive to disturbances, such as nutrient enrichment, fish introductions, thermal discharges, or toxic effluents, therefore make ideal indicators of a healthy aquatic system. In this study we examined the relations between zooplankton abundance and some environmental parameters in Kepez Harbor (Dardanelles). Located between the Sea of Marmara and the Aegean Sea, the flow dynamics in the Dardanelles Strait is complex in many ways. The unique flow dynamics and localization of Kepez Harbor in the Dardanelles Strait makes it an excellent test area for the effects of anthropogenic stress on the water quality and the ecosystem components.

Fig. 1. Zooplankton abundance placed into generic taxonomic groups in the surface, 10 m, 20 m depths in Kepez Harbor between 26 April-12 July 2005.

For this research, water quality and zooplankton data were analyzed from one station located at Kepez Harbor, Dardanelles  $(40^{\circ}09'N, 26^{\circ}24' E)$ . Samples were collected from the surface, 10 m and 20 m depths. Sampling trips were conducted weekly between 26 April 2005 and 12 July, 2005. Water-quality parameters such as temperature, salinity, pH and dissolved oxygen (DO) were measured in situ using an YSI 6600 MPS. Zooplankton samples were collected using a closing plankton net and preserved with 4 % buffered formalin (v/v). Zooplankton species identification was performed according to [1].

Water quality parameters varied considerably among sampling depths. Temperature ranged between 14.2 and 20.5 °C while salinity changed between 20-39 ppt. When different depths were considered pH was less variable changing between 8.7 and 9.3 while DO ranged between 3.3 and 7.1 mg L<sup>-1</sup>. Results showed that all zooplankton groups increased in number starting from the end of May through June (Fig. 1). During this period, Oithona and Acartia species dominated the copepods while *Oikopleura dioica* (Fol, 1872) was abundant in Appendicularians. Considering cladocerans, *Pleopsis polyphemoides* (Leuckart, 1859) was the dominant species by the end of May through arity June. However, after 21 June 2005 *Penilia avirostris* (Dana, 1849) was the common species in all sampling depths. Copepod nauplii showed an increase parallel to an increase in copepod adults in the surface and 10 m depths while numbers were less pronounced in 20 m.

The natural zooplankton community structure in Kepez Harbor was diverse and community structure changed depending on the changes in environmental parameters, i.e., changes in temperature.

Acknowledgments: This research was funded, in part, by Canakkale Onsekiz Mart University Research Foundation (BAP, Project # 2005/85).

# ÉTUDE DE LA FAUNE ASSOCIÉE À L'ESPÈCE INVASIVE *PINCTADA RADIATA* SUR LE LITTORAL NORD ET EST DE LA TUNISIE

Ikram Irathni , Sabiha Tlig-Zouari \* and Oum Kalthoum Ben Hassine

Unité de Recherche de Biologie, Ecologie et Parasitologie des Organismes Aquatiques, Faculté des Sciences de Tunis, Département de Biologie. Université Tunis El Manar 2092 Tunis, Tunisie. - irathni\_ikram@yahoo.fr

# Résumé

L'étude des macro-invertébrés associés à *Pinctada radiata* sur le littoral nord et est de la Tunisie met en évidence la présence de 118 espèces vivantes avec cette espèce. Le calcul de la dominance révèle qu'à l'exception des trois stations de la lagune de Bizerte *P. radiata* compte parmi les plus dominantes dans le reste des stations d'études. Quant aux indices de diversité (H' et E), ils traduisent la présence de peuplements benthiques structurés et équilibrés pour la totalité des stations prospectées. *Mots clès : Mollusca, Bivalves, Migrant Species, Competition, Biodiversity.* 

L'huître perlière *Pinctada radiata* compte parmi les premiers immigrants invasifs arrivés en Méditerranée [1]. En effet, depuis son arrivée en Tunisie [2], ce Mollusque a montré un important pouvoir d'extension, notamment dans le secteur sud. L'introduction des espèces érythréennes pourrait induire des variations touchant parfois l'abondance et la distribution bathymétrique des espèces indigènes [3]. Afin de pouvoir évaluer l'impact de cette espèce invasive sur la diversité de la macrofaune benthique autochtone et d'apprécier les relations interspécifiques éventuelles entre la Pintadine et ces espèces dans les différents biotopes prospectés, nous avons entrepris une étude du peuplement des macro-invertébrés associés à cette espèce.

Pour cela, trois régions ont été prospectées, à savoir le littoral de Bizerte (avec trois stations : Canal, Baie des Carrières et Njila), le golfe de Tunis (avec trois stations : Ecluse d'entrée côté canal Kheireddine, Ecluse d'entrée côté lagune et la Marsa) et le littoral de Monastir (avec deux stations : port de Stah Jaber et Stah Jaber). Les prélèvements des macroinvertébrés (Pintadine et la faune associée) ont été effectués au moyen d'un quadrat de 0,25 m<sup>2</sup> de surface. Le contenu de chaque quadrat a été tamisé à l'aide d'un tamis de 1 mm de vide de maille. Le refus de chaque tamis a été conservé dans une solution d'eau formolée à 7% puis déterminé et dénombré. Des descripteurs numériques classiques ont été utilisés pour la caractérisation des entités faunistiques : richesse spécifique (RS), dominance, diversité spécifique de Shannon Weaver (H') et équitabilité (E).

Tab. 1. Variations spatiales de la dominance, de la richesse spécifique (RS), de l'indice Shannon-Weaver (H') et de l'Equitabilité (E).

| Stah Jaber                                      | 43     | 4.97  | 0.91 | Pinctada radiata (10.7%)<br>Bittium reticulatum (8.7%)<br>Sabellaria alveolata (7.3%)     |

Au total, 118 espèces associées à la Pintadine appartenant à 9 groupes zoologiques ont été identifiées. Les pourcentages calculés des différents taxons, révèlent la dominance des Mollusques (41.2%), suivis par les Crustacés (19.3%) puis par les Annélides (15.2%). Quant aux Tuniciers, ils constituent uniquement 7.6%. Les Echinodermes, les Spongiaires, les Cnidaires, les Bryozoaires et les Sipunculidés sont très faiblement représentés avec des proportions respectivement égales à 5%, 5%, 3.4%, 2.5% et 0.8%. La richesse spécifique atteint son maximum (44 espèces) au niveau du port de Stah Jaber. Quant à la valeur minimale (16 espèces), elle caractérise la station de la Marsa (Tab.1). Les variations de la richesse spécifique semblent être dues aux fluctuations des facteurs environnementaux.

Les valeurs de la dominance (Tab. 1) révèlent qu'à l'exception des trois stations de la lagune de Bizerte (Canal, Baie des carrières et Njila), l'espèce invasive, P. radiata, compte parmi les plus dominantes dans le reste des stations (La Marsa, Ecluse d'entrée côté canal de Kheireddine, Stah Jaber), avec un pourcentage supérieur à 8.2%. Ainsi, au niveau du canal de Bizerte, Balanus eburneus est l'espèce la plus prépondérante. Le Mytillidae Mytilus galloprovincialis (12%) est le plus dominant dans la Baie des carrières. Le Polychète, Sabella pavonina, est prépondérant à Njila et au niveau de l'Ecluse d'entrée côté lagune avec des valeurs respectives de l'ordre de 12.2% et de 8.1%. Le Gastéropode, Bittium reticulatum (14.8%) présente la valeur de dominance la plus élevée au niveau du port de Stah Jaber. Ces données (Tab. 1) plaident en faveur d'une compétition trophique et spatiale entre ces espèces et la Pintadine. En effet, ces espèces partagent avec la Pintadine le même biotope. Elles sont essentiellement des filtreurs comme elle et présentent toutes les mêmes exigences trophiques et occupent ainsi la même niche écologique. Certaines d'entre elles se servent de sa coquille comme substrat, c'est le cas des Polychètes et des Balanes.

Les valeurs de l'indice de Shannon-Weaver oscillent entre un minimum de 3.72 bits, valeur minimale enregistrée à la Marsa et un maximum de l'ordre de 5.04 bits, enregistré au niveau de l'écluse d'entrée côté canal Kheireddine. Les résultats de cet indice (Tab.1) montrent qu'à l'exception de la plage de la Marsa (3.73 bits), toutes les autres stations sont fréquentées par des peuplements normaux, traduisant ainsi une certaine stabilité (Tab.1). Les valeurs de l'équitabilité varient entre 0,88 bits, minimum enregistré au niveau du port de Stah Jaber et 0.95 bits, maximum observé à Njila. Ainsi, ces résultats montrent que les peuplements appartenant à ces différents écosystèmes sont en état d'équilibre et que les espèces rencontrées dans toutes les stations sont équitablement réparties (Tab.1).

Cette analyse met en évidence la présence des peuplements benthiques structurés et équilibrés pour la totalité des stations. En effet, l'introduction de la Pintadine n'a pas constitué un élément perturbateur de l'organisation de la biodiversité de ces écosystèmes littoraux des côtes nord et est de la Tunisie.

# DISTRIBUTION PATTERNS OF MESOPELAGIC FISH LARVAE IN RELATION TO HYDROGRAPHY OF THE NORTH EASTERN AEGEAN SEA

S. Isari <sup>1</sup> \*, N. Fragopoulu <sup>1</sup>, A. Siapatis <sup>2</sup>, A. Machias <sup>2</sup>, S. Somarakis <sup>1</sup>

# Abstract

Distribution of mesopelagic fish larvae was studied during June 2003 and June 2004 in the Northeastern Aegean sea (NEA). In 2003, certain taxa (*Ceratoscopelus maderensis*, *Hygophum benoiti*) showed unusual distribution patterns with increased presence over a continental shelf area.

Keywords : Aegean Sea, Ichthyoplankton.

# Introduction

Fish larvae distribution patterns are defined not only by the living habitat of adults but also by the water circulation pattern that may occasionally drift the reproductive products away from the spawning environment. In the present study, distribution patterns of mesopelagic fish larvae are examined in the NEA, an area characterized by high hydrodynamic complexity due to the movement of Black Sea water [1].

# Materials and Methods

A grid of 24 stations (Fig. 1a) were sampled in 1-12 June 2003 and 31 May-12 June 2004, with a 60 cm bongo-net (0.250 mm meshed net) towed obliquely from 200 m to the surface (bottom permitting). Hydrographic profiles were collected on a denser grid of 68 stations. Preflexion larvae were identified and their abundance was standardized to numbers per 10 m<sup>2</sup>. More details are provided in [1].

### Results and Discussion

A total of 15 mesopelagic taxa were identified in both cruises (Table 1).

Tab. 1. Mean abundance values (larvae per 10 m<sup>2</sup>) of the larval mesopelagic taxa identified in the bongo-net collections. N% per cent of positive stations (frequency of occurrence).

| TOTAL ABUNDANCE              | 195.1                  | 92  | 259.7                  | 79 |  |

In 2003, mesopelagic larvae were collected in 22 stations. Abundance ranged from 8 to 1140 ind. 10 m<sup>-2</sup>. In 2004, it ranged from 4 to 2069 ind.  $10 \text{ m}^{-2}$  in 19 positive stations. Although mean abundance was higher in 2004 (259 ind.  $10m^{-2}$  vs 195 ind.  $10m^{-2}$  in 2003), this difference was not statistically significant (t=0.1359; p>0.1). The myctophiids Hygophum benoiti and Ceratoscopelus maderensis were the most abundant taxa. Early summer is within the peak of the spawning period of these species [2]. Myctophum punctatum was also important in both years. Large concentrations and maximum number of mesopelagic taxa were recorded beyond the continental shelf (depth>200 m). Abundance and species richness was generally low at sites <200 m especially in 2004. However, in 2003 continental shelf stations in the western part of the surveyed area (St. B108, B106) had increased abundance of mesopelagic fish larvae (654 and 293 ind.  $10 \text{ m}^{-2}$ respectively) (Fig. 1b,c), mostly due to thespecies C. maderensis and H. benoiti. Mesopelagic fishes live offshore at depths >200 m, hence the presence of their larvae over the shelf cannot be explained in terms of local spawning. The unusual presence of the mesopelagic larvae over the continental shelf could be explained in terms of hydrology. Horizontal distribution pattern of temperature, salinity and density (eg. Fig. 1b,c) showed that in contrast to 2004, pelagic water intruded over the continental shelf in the western part of the region in 2003, as a result of a meandering cyclonic movement of the prevailing current (the Lemnos-Imvros jet, [1]). Consequently mesopelagic fish larvae were advected inshore, especially *C. maderensis* and *H. benoiti* which are known to have a more surface vertical distribution [3].

Fig. 1. (a) Station map [squares: ichtyoplankton and CTD; circles: CTD] (b,c) Horizontal distribution of water density (kg  $m^{-3}$ ) at 10 m. Total abundance of mesopelagic taxa of the stations is also shown.

# ABUNDANCE OF GELATINOUS ZOOPLANKTON IN IZMIT BAY, THE SEA OF MARMARA

Melek Isinibilir

Istanbul University, Fisheries Faculty, Laleli, Istanbul, Turkey - melekis@istanbul.edu.tr

# Abstract

Distribution and abundance of macrogelationous zooplankton were investigated from a total of 11 stations in Izmit Bay, Sea of Marmara with monthly intervals from July 2001 to September 2002. The maximum abundance of all gelatinous zooplankton was calculated as 0.485 ind.m<sup>-3</sup> in September 2001. *A. aurita* was dominant species in Izmit Bay. Overall, the abundance of gelatinous zooplankton varied greatly spatially and temporally.

Keywords : Zooplankton, Ctenophora, Sea Of Marmara.

## Introduction

Izmit Bay is a 310 km<sup>2</sup> large, elongated semi-enclosed water body with a length of 50 km, and a width varying between 2 and 10 km [1]. The bathymetry of the bay is comprised of three sub-basins separated from each other by shallow sills. Several industries have been developing rather rapidly around Izmit Bay. In addition to the increase of untreated, or partly treated domestic waste disposal enhanced by the heavy demographic pressure, the substantial industrial development, the heavy maritime traffic and the agricultural activities in the surrounding areas have caused a considerable pollution burden to enter Izmit Bay. Under the oceanographic point of view, the latter is an extension of the Sea of Marmara, having a permanent two-layer water system, characterized by the presence of less saline waters (Black Sea origin), overlying a more saline bottom layer (Mediterranean origin). Gelatinous zooplankton may affect pelagic food webs by exerting a top-down control on their ecosystems [2]. This has been well documented for estuaries and enclosed seas [3]. The aim of this study is to describe the abundance and distribution of gelatinous zooplankton in Izmit Bay.

## Material and Methods

Between July 2001 and September 2002, gelatinous zooplankton was collected from the upper layer of the Black Sea waters in Izmit Bay at montly intervals. A total of 11 stations were sampled by horizontal towing, using a WP2 closing net (157  $\mu$ m mesh size, 0.5 m mouth diameter). Gelatinous zooplankton samples were identified and measured onboard immediately after collection.

Fig. 1. Location of sampling stations in Izmit Bay, Sea of Marmara.

## Results and Discussion

Four species of gelatinous macrozooplankton were found in Izmit Bay: one scyphozoan medusae Aurelia aurita and three ctenophores, i.e., Mnemiopsis leidyi, Beroe ovata and Pleurobrachia pileus. Totally, 768 individuals were counted from all the 11 stations, of which 382 specimens of A. aurita, 184 of M. leidyi, 129 of B. ovata and 73 of P. pileus. The maximum abundance of gelatinous zooplankton (0.485 ind.m<sup>-3</sup>) was found in September 2001. At that time A. aurita was the most abundant species (51.4 %), followed by M. leidyi (23.3%), B. ovata (17.5 %), and P. pileus (7.8 %). All 4 species were ubiquitously present in the bay. M. leidyi (38%) was the dominant species in the eastern part of the bay, while A. aurita replaced M. leidyi in the middle (51%) and in the western areas (62 %). The maximum abundance of *B. ovata* (31%) was found in the middle of the bay, whilst P. pileus (12%) was in high quantity in the western part. Overall, the abundance of gelatinous zooplankton in the eastern bay was higher than in the western and middle areas. In general, there was a significant negative correlation between the abundances of A. aurita and M.

*leidyi*, probably due to the high competition between them [4]. Finenko *et al.* (2001) demonstrated that, in the Black Sea, *B. ovata* could control the *M. leidyi* stock. Likewise, the present study reveals that the abundance of *M. leidyi* becomes limited in summer, when *B. ovata* is present in Izmit Bay. In the Black Sea, high abundances of *M. leidyi* were found during winter, while the abundance of *A. aurita* and *P. pileus* increased in summer [4,6,7]. On the other hand, in Izmit Bay, the abundance of *M. leidyi* reached its peak in summer, that of *P. pileus* in spring, whereas *A. aurita* and *B. ovata* were numerous in late summer and autumn. In spring, the latter began to spread all over the bay, although the highest abundances were observed in the eastern part of the bay during summer. As a result, the abundance of gelatinous zooplankton in Izmit Bay displays a great variability, both geographically and temporarily.

Fig. 2. Regional abundance of gelatinous zooplankton in Izmit Bay between July 2001 and September 2002.

# NON-INDIGENOUS SPECIES AT THE ALICANTE HARBOR (SE-SPAIN): OCULINA PATAGONICA DE ANGELIS, 1908 AND BOTRYCAPULUS ACULEATUS (GMELIN, 1791)

Andrés Izquierdo<sup>1</sup>, Angel Loya<sup>2</sup>, Marta Díaz-Valdés<sup>2</sup> and Alfonso A. Ramos-Espla<sup>1</sup>\*

<sup>1</sup> Centro de Investigación Marina (CIMAR). Universidad de Alicante - Ayuntamiento de Santa Pola, Cabo de Santa Pola s/n, Alicante, Spain

# Abstract

Two non-indigenous species, an haermatypic coral (*Oculina patagonica*) and a gastropod (*Bostrycapulus aculeatus*) have been reported 30 years ago from Alicante harbour. But whereas *B. aculeatus* has not spread outside the harbour, *O. patagonica* has colonized an extensive area of the Spanish Mediterranean (from Catalonian to Andalusia) and competes with indigenous species. *Keywords : Species Introduction, Western Mediterranean, Cnidaria, Gastropods.* 

## Introduction

The scleractinian coral *Oculina patagonica* De Angelis, 1908 and *Bostrycapulus aculeatus* (Gmelin 1791) (= *Crepidula aculeata*) are exotic species. The first the originates from the Southwest Atlantic [1] and the second is a cosmopolitan gastropod in the tropics and subtropics [2]. Both species were first recorded in Alicante harbour in 1973 [3,4], probably introduced by way of vessel fouling. Since, *O. patagonia* spread to the rest of the Mediterranean helped by the intense maritime traffic [4,5], whereas *B. aculaeatus* is confined to Alicante harbour. Considering the importance of the development of non-indigenous species in the Mediterranean [6], we present preliminary data on the biology and density of the population of these exotic species in Alicante harbour.

### Materials and methods

The study was carried at spring 2006 at the Alicante harbour in 2 localities: "Levant quay" (N 38°19'52.1" W 00°29'10.3"; 12m depth) near the harbour entrance with good water circulation; and "Fishing Dock" (N 38°20'11.1" W 00° 29'11.8"; 6m depth) in a more enclosed area and low water replacement rate. The sampling has been carried by scuba diving: i) *O. patagonica* by means of 5 underwater pictures (square 20x20cm) per site and 3 sites (0.5, 3 and 6m depth) in each locality (90 pictures), to calculate the % of cover; ii) *B. aculeatus* taking 2 samples by removing 20x20 squares of the substrate at 3 depths (0.5, 3 and 6m) in each locality (total 36 samples).

## Results and discussion

*O. patagonica* is abundant at both localities (fig. 1), but more abundant in shallower depths (0-3m), where in some sites it covers almost 100% of the substrate. It present two morphotypes: encrusting (frequent in shallow sites) and branched (rare in the deeper and shadow sites).

Fig. 1. Cover percentage (%) of *Oculina patagonica* at two localities of Alicante Harbour. (LQ) Levant Quay; (FD) Fishing Dock.

*Bostrycapulus aculeatus* is present in borh localities (fig. 2), with variable density, though more abundant at deeper sites (6m). The maximum density (275 ind/m<sup>2</sup>) was at the LQ, vs. 50 ind/m<sup>2</sup> at FD. The size range has been 13-31mm, and we have observed ovigerous capsules in early November.

The introduction of exotic species across the Mediterranean is increasing [4, 6], and it is important to monitor them. *Oculina patagonica* is a successful invader that spread along the entire coast of Spain (anthropized and natural environments). Thirty years after the first record from Alicante harbour, *Oculina* covers most of the harbour walls from surface to bottom (11m depth), and it spreads quickly to newly built structures within the harbour (unpubl. data).

Fig. 2. Density of *Bostrycapulus aculeatus* at two localities of Alicante Harbour. (LQ) Levant Quay; (FD) Fishing Dock.

It competes with the native fouling species, limiting the space available for new recruits and even covering most of the sessile organisms. *Oculina* may suffer 'bleaching' with high temperatures [8], but at Alicante the bleaching is localised - limited to overshadowed sites and in contact zone with the sponge *Crambre crambe*.

Although *B. aculeatus* is established inside Alicante harbour, its distribution is confined to the harbour, where its density increases with depth, perhaps due to the competition with *Oculina*.

# INFORMATION TECHNOLOGY FOR ENDANGERED MARINE SPECIES MANAGEMENT: AFBIKA GEO-DATABASE

G.K. Kaboğlu<sup>1</sup>\*, H. Harun Güçlüsoy<sup>1</sup>, K.C. Bizsel<sup>1</sup>, H. Eronat<sup>1</sup>, C.O. Kiraç<sup>2</sup>, Y.I. Savaş<sup>2</sup> <sup>1</sup> Institute of Marine Sciences and Technology, Dokuz Eylül University, Izmir - gokhan.kaboglu@yahoo.com.tr

<sup>2</sup> Underwater Research Society-Mediterranean Seal Research Group (SAD-AFAG)

# Abstract

This study presents the Mediterranean Monk Seal Information and Rescue Network (AFBIKA geo-database), which has been designed and constructed to improve the monitoring of the critically endangered Mediterranean monk seal, *Monachus monachus* (Hermann, 1779) in Turkey. Sighting data gathered by SAD-AFAG through various projects and expeditions are entered to the system using Geographic Information System (GIS) and a linked database in order to gather information about distribution and habitat use of the species. With proceeding modifications to the network in the following years, it will probably serve as an effective management tool that may contribute to continuation of species survival.

Keywords : Conservation, Eastern Mediterranean, Gis.

## Introduction

Effective formulation and implementation of any strategies, policies and plans are highly dependent on accurate, comprehensive and timely information [1]. Thus, management of the endangered marine wildlife needs to make use of Information Technology (IT) more frequently to achieve broader conservation goals. GIS, together with Database Management Systems (DBMS), may increase the capability of specialists concerned with endangered species issues. The aim of this study is to present the AF-BIKA geo-database, which was built to enhance already established monk seal sighting database Fok-Data by SAD-AFAG in 1990 [2] which will serve better for the conservation of critically endangered M. monachus -with a population of around 100 individuals [3]- in Turkey.

## Methodology

The field study was performed in 2005 and 2006 on the Aegean and Mediterranean coastal cities and villages of Turkey in order to invite the local stakeholders, who are likely to interact with the species, to AFBIKA membership. In this 72-day field study, 78 settlements were visited, and seal sightings were collected. AFBIKA geo-database was constructed on three components: database (MS Access), internet site and GIS (Manifold 6.5). The database includes each sighting record and member information whereas GIS includes additional tabular and geographical elements in different layers. Landsat satellite images were used as the background of the GIS environment and a grid system was created to map M. monachus sightings since it is often not possible to gather coordinates from observers. Turkish coasts were divided into three differently scaled grid cells: site (15" x15"), parcel (1' x 1') and region (1' x1') grids. Thus, the mappability of the records was increased and analysis in different scales was made possible if required. Seal sighting and member counts per grids were also calculated and entered into grid tables in order to create presence/absence maps by querying and thematic mapping (Figure 1).

#### Results

The reactions of the coastal stakeholders were generally affirmative; the number of AFBIKA members has reached to 186 and 83 seal sightings were recorded from these members. As well as sighting data, the locations of the members were also mapped to manage the expected and unexpected areas of data flow in the future. It was observed that although the number of individuals is few, M. monachus uses a wide geography in the Aegean Sea, Mediterranean Sea and the Sea of Marmara.

## The Way Ahead: Next generation of AFBIKA

It is planned to improve the capabilities of AFBIKA geo-database in both species specific and managerial issues in the following years. The evolution includes addition of new components to the network as well as enhancing the existing GIS, database and web components. With sufficient budget and human capacity, following built-ups are designed to obtain an effective management tool for the conservation of the species:

User-friendly interfaces; for the data providers (AFBIKA members) via internet, and for data input to the system in order to minimize user errors.

Ready-to-use queries; for the specialists and managers for the species specific issues, and for habitat, ecosystem and human activities

management.Sub-programs; for enhancing the integration of existing database and GIS and for adding new capabilities such as link with a statistical software.

Acknowledgement: this study could not have been initiated without the generous support of European Union Turkish Delegation Micro-II Programme, MOm / The Hellenic Society for the Study and Protection of Monk Seal, Regional Environment Centre - Turkey and GIS Department of Dokuz Eylül University.

# SEXUAL MATURITY OF LITTLE TUNNY, *EUTHYNNUS ALLETTERATUS*, IN THE NORTH-EASTERN LEVANTINE BASIN

Abdullah Ekrem Kahraman \* and Tugrul Zahit Alicli

Istanbul University, Fisheries Faculty, Laleli, Istanbul, Turkey - kahraman@istanbul.edu.tr

# Abstract

A total of 96 little tunny, *Euthynnus alletteratus*, caught in the north-eastern Levantine Basin with commercial purse-seiners and trolling lines, were examined in order to determine the sexual maturity and the age and size distribution. The maximum age was 6 years. The length-weight relationship was  $W= 0.0381 L^{2.77}$ . Out of a total of 60 females examined 8 were mature. *Keywords : Fishes, Growth, Reproduction, Spawning, Levantine Basin.* 

In this study, we determined the sexual maturity of the little tunny. The age determination, first maturity length, gonadosomatic index, sex ratio, and spawning period have been investigated by [1, 2, 3] in various areas. The spawning period in the Mediterranean has been reported to occur from June to September [2, 3]. Sexual maturity of the females is reached at 55-60 cm FL [1].

In this study, a total of 96 little tunny were caught by commercial purseseiners and trolling lines used by artisanal fishermen.in the north-eastern Levantine Basin (especially Mersin Bay and northern Cypriot waters-off Kyrenia) between November 2002 and May 2005, and studied. For each specimen, fork length (FL), total weight (TW), and gonad weight (GW) were measured, and their sex was determined. The age analysis was performed according to [4]. Furthermore, the length and weight relationship was calculated. A total of 96 gonads were examined externally, and the reproductive aspects of the species were observed. The gonadsomatic index (GSI) of both males and females were calculated according to [5]. The minimum, maximum, and mean values of FL and TW were 43 cm, 87 cm, 69.5 cm (SE=0.948) and 1215 g, 8930 g, 5070 g (SE=0.183), respectively. The a and b values of the length-weight relationship (Figure 1) were compared with those reported by other authors. In the Mediterranean, these values were 0.0476 and 2.723 for 1085 individuals of sizes 52-97.5 cm [6]; in the south western Spanish coast: 0.0441 and 2.755 for 217 individuals of sizes 56-67.7 cm [7]; and in this study, 0.0381 and 2.77 for 96 individuals (sizes 43-87 cm). Our findings for a and b values are compatible with the results of [6] and [7]. A total of 36 male and 60 female gonads were examined. The sex ratio was 1:1.7 M/F. The GSI values of both males and females are shown in Figure 2. GSI reached a peak in July, and generally GSI remarkably increased in summer, when the reproductive activities were intensive. It is reported that the gonads of the 1 and 2 year old specimens are not mature, as opposed to those of the 3 year old ones [1]. In this study, all specimens were larger than 60 cm, and their ages were 3-4 years. It is reported that the spawning period of the species ranges between May and September [1]. In the Mediterranean, spawning occurs from late spring through summer [8]. In our study, spawning occurred in July and August, being compatible with other studies. Our results support [9] that this basin is a new spawning area.

Fig. 1. Length-weight relationship.

Fig. 2. GSI values of males and females.

# SEASONAL SPECIES ASSEMBLAGES IN AN ARTIFICIAL REEF IN NORTH AEGEAN SEA (GREECE)

Argyris Kallianiotis \*, Vasilis Lekkas and Pavlos Vidoris NAGREF - F.R.I., N. Peramos, 64007, Kavala, Greece - fri@otenet.gr

# Abstract

The seasonal changes in fish assemblages in the artificial reef (AR) in Fanari, (North Aegean, Greece) were studied in January, June and October 2002. Species of the families Labridae, Sparidae, Serranidae and Centracanthidae were responsible for dissimilarities between January and June and the same species together with Mullidae for dissimilarities between June and October. *Keywords : Artificial Reefs, Aegean Sea.* 

The main objective of the study is to determine the seasonal fish assemblages in the artifcal reef (AR) after four years of establishment. The fishing gear used was bottom trawl (cod-end mesh size 10 mm) and samplings were carried out in January, June and October 2002 over a net of 11 stations. Data were analysed using multivariate analysis and groupings were based on species densities with percentage higher than 0,3% of the total monthly catch. Cluster analysis was performed with PRIMER [3] using data transformed with the Bray - Curtis similarity index (between stations) [4]. The determination of the differentiation between seasons and of the species responsible for the calculated differences were based on ANOSIM and SIMPER [3].

Cluster analysis indicated that the stations were grouped per season (Fig. 1). The average station similarity, calculated using ANOSIM, was 68.11% in January, 79.35% in June and 76.06% in October.

SIMPER, showed that the species responsible for the grouping of the January stations were: Symphodus cinereus, Scorpaena notata, Octopus vulgaris, Serranus cabrilla, Scorpaena porcus, Sepia officinalis, Deltentosteus quadrimaculatus, Eledone moschata and Trigloporus lastoviza (total contribution 70.47%); for the June stations: S. cinereus, Serranus hepatus, Coris julis, S. cabrilla, S. notata, Diplodus annularis, S. porcus, Diplodus vulgaris, Symphodus rostratus, O. vulgaris, Symphodus mediterraneus (total contribution 70.71%); and for the October stations: S. cabrilla, S. cinereus, D. annularis, C. julis, O. vulgaris, S. notata, Mullus barbatus, Mullus surmuletus, S. hepatus, Spicara smaris, S. porcus, Sarpa salpa, Boops boops, Scyllarus arctus, D. vulgaris, S. rostratus, Sympathus acus, Symphodus ocellatus (total contribution 71%).

Statistical analysis indicated that the seasons differed among them (ANOSIM, *R* global >0.91, *p* <0.001). In the per pair comparisons of months, the *R* values were higher than 0.93 in every case. The main environmental factor most probably responsible for the presence of different assemblages was temperature, which was 14 °C in January, 18 °C in June and 22 °C in October.

Comparison of the January and June samplings showed an average dissimilarity of 45.5% with 14 species contributing 70.44% to the differentiation. The highest abundances were recorded in June. The species *C. julis, S. cinereus* and *S. rostratus* differentiated the two seasons by 22.83%, *D. annularis, D. vulgaris* and *Pagrus pagrus* by 15.64%, *S. hepatus, S. cabrilla, S. scriba* by 14.87% and *Spicara maena* and *S. Smaris* by 6.56%. The June and October samplings showed an average dissimilarity of 36.8% with species *M. surmuletus, S. salpa, M. barbatus, S. hepatus, Blennius ocellaris, B. boops, Spondyliosoma cantharus, Dentex dentex, C. julis, S. ocellatus, S. smaris, S. cinereus, Gobius niger, D. annularis, S. scriba, S. arctus, Pagellus erythrinus, S. mediterraneus and Diplodus sargus being responsible for 70.47% of the differentiation.* 

*D. vulgaris* was one of the most abundant species in the AR during the whole year. Stomach content studies have shown the importance of polychaetes in the diet of this species that are generally found on the substratum of ARs [5]. The species *C. julis, G. niger, B. ocellaris*, the species of the genus *Symphodus* and the species of the family Serrranidae, assembled near the AR in June for reproduction (which takes place in spring, summer), while *D. quadrimaculatus* in January (reproduction takes place

in early spring) [1]. The presence of *P. pagrus, M. surmuletus, S. salpa* and *M. barbatus* increased in October and this could be due to the recruitment of the species that takes place during summer [1]. Furthermore, young individuals of *P. erythrinus, O. vulgaris* and *D. dentex* were found in all sampling periods. It is believed that they use the AR as a nursery area [1, 6].

In conclusion, each season was characterized by certain species that inhabit or visit the AR for spawning or feeding reasons. Young individuals were present inside the AR during the whole year and sexually mature individuals of most species assembled in the protected area during their reproductive period. So the reef can be considered as spawning and nursery ground.

Fig. 1. Dendogram of similarities for 11 stations (cluster analysis, groupaverage linkage) sampled during January, June and October 2002.

# AGE AND GROWTH OF THE DEEP WATER ROSE SHRIMP PARAPENAEUS LONGIROSTRIS IN THE HELLENIC IONIAN SEA

Kostas Kapiris<sup>1</sup> \*, Chrissi Mytilineou<sup>1</sup>, Stefanos Kavadas<sup>1</sup> and Francesca Capezzuto<sup>2</sup>

<sup>1</sup> Hellenic Centre for Marine Research, Aghios Kosmas, Hellinikon, Athens, 167 77, Greece - kkapir@ath.hcmr.gr

<sup>2</sup> Department of Zoology, University of Bari, ViaOrabona 4, I-70125, Bari, Italy

# Abstract

The age and growth parameters of the deep water rose shrimp *Parapenaeus longirostris* in the unexploited fishing grounds of the Hellenic Ionian Sea were examined in the present work. The data were collected during four experimental surveys in the framework of one scientific project of HCMR, carried out in the Ionian Sea. The mean modal length and the growth parameters showed that females had higher growth rate of males.

Keywords : Deep Waters, Ionian Sea, Decapoda, Growth.

*P. longirostris* constitutes a valuable target species for most fisheries in the Mediterranean Sea. It is considered one of the most important species of the crustacean fishery in Greece, in terms of landings being very widespread both in the Aegean and Ionian Seas, mainly at depths ranging between 150-400 m. In the Hellenic seas, only very few studies exist on its biology and fishery [1-3].

All samples were collected during four trawl surveys in the northern part of the Hellenic Ionian Sea (eastern Mediterranean Sea) (October 1999, April, July, September 2000) (INTERREG project) at a depth range from 300 to 500 m. The Bhattacharya length-based method as implemented in FiSAT was used to estimate the age. The VonBertallanffy model was used for growth parameter estimation as applied by ELEFAN I programme. The growth index  $\phi$ ' was also estimated for comparison purposes.

The carapace length of females ranged from 8 to35 mm, with the bulk of the stock being between 21-29 mm. In males, in spite of the same range of the carapace length, the majority ranged from 18 to 24 mm, in both areas. Size distributions of males showed 1-2 well-separated modes. Modal groups in females varied from 2 (in April and September 2000) to 3 (September1999, July 2000) well discriminated. The standard deviation and separation index values derived from the length-based analysis indicated well-separated age groups. Autumn months were better represented for both sexes as these included more -well separated- age groups (Table 1).

Tab. 1. Identified mean lengths-at-age from the length-frequency analysis of females and males *Parapenaeus longirostris* during the five seasonal surveys in the Ionian Sea, using the Bhattacharya method.

|       |              | MALES        |             |              |
| Modes | 9/1999 N=513 | 4/2000 N=301 | 7/2000 N=67 | 9/2000 N=198 |
|       |              | Mean         | n CL        |              |
| 1     | 12,32        | 18,64        | 21,52       | 21,95        |
| 2     | 21,21        | 24,82        |             | 27,35        |
| 3     | 27,04        |              |             |              |

The parameters of the von Bertalanffy growth equation were estimated as follows: L $\infty$ =33.2 mm, K=0.68 1/yr for males and L $\infty$ =37.2 mm, K=0.76 1/yr for females. Rn was calculated as 0.219 and 0.168 for males and females, respectively. The growth performance index  $\phi'$  was calculated as 2.85 for males, and 3.03 for females. The greater values of L $\infty$ , K and  $\phi'$  and the mean lengths-at-age reinforce the hypothesis that growth is faster in females than males. Similar growth rates for both sexes have been shown in various areas of the Mediterranean [3-4].

# Abstract

In this study, the length frequency distribution, preliminary data of gill and trammel net selectivity and observed sex inversion ratios for blotched picarel in the Aegean Sea are presented. Males were significantly larger than females in mean TL (p < 0.05). Sex reversal was mainly observed when the body length reached 16.0-17.0 cm. Females were observed up to a total length of 18.1 cm. *Keywords : Fishes, Coastal Waters, Aegean Sea*.

# Introduction

The blotched picarel, *Spicara maena* L. 1758, is a common fish species in Turkish waters. It is caught with gill and trammel nets in the Turkish coastal fishery. Published data on the biology and net selectivity of this species are limited. There has been only one study concerning length-weight relationship for this species in Turkish waters [1]. The aim of this study is to give some new information on sex inversion length and preliminary data of trammel and gill net selectivity for the blotched picarel in Turkish waters.

## Materials and methods

Experimental trials were conducted in Gökceada Island (northern Aegean Sea, Turkey), at depths of less than 30 m from April 2004 to February 2005. Multifilament trammel and gill nets of four different mesh sizes (16, 18, 20 and 22 mm bar length) were used. All nets were the same in terms of length, hanging ratio, twine and colour. The constructed nets were also similar to those used by the local fishers. Fish samples obtained by the fishery trials were classified according to their species and the net they have been captured with. A total of 783 *Spicara maena* were analyzed. The student's *t*-test was used to test difference in mean size with sex.

## Results and discussion

Total length of the specimens ranged from 11.0 to 21.9 cm (mean 14.8 $\pm$ 1.9 cm). The length of females (N=133) ranged from 11.5 to 18.1 cm TL (mean 14.6 $\pm$ 1.7 cm) and that of males (N=142) from 13.5 to 21.9 cm TL (17.1 $\pm$ 2.3 cm) (Fig.1). Male picarel was significantly larger than female fish (*p*<0.05).

The blotched picarel is a protogynous hermaphrodite [2]. Dulčić et al.[3] report that in the Adriatic Sea the sex reversal of 56.1% of blotched picarel was observed at lengths between 17.5 and 18 cm; the minimum and maximum sex inversion lengths were 16.7 and 19.8 cm, respectively [3]. In this study, we observed the sex inversion (50% of blotched picarel population) at 16.0 and 17.0 cm TL; we also found that the minimum and maximum sex inversion lengths were 13.5 and 18.9 cm TL, respectively. (Fig.1).

Preliminary data of trammel and gill nets selectivity for blotched picarel are shown in Table 1. The number of captured blotched picarels using gill nets of mesh sizes 16 and 18 mm was more than those captured by other nets. As the mesh size increased, average total length and total weight increased as well.

Tab. 1. Spicara maena. Preliminary data of trammel and gill net selectivity.

| Mesh size | N   | TL        | (cm)     | W (g)      |           |  |

# Abstract

This study presents data on the albacore drift-net fishery which was carried out for the first time in 2006 in the Turkish waters. Fishing was carried out with 18 vessels in Antalya Bay between May and July. The length frequency distribution and length-weight relationship for 171 captured albacore were calculated.

Keywords : Migrant Species, Pelagic, Fisheries, Levantine Basin.

# Introduction

Albacore (*Thunnus alalunga*) is a temperate tuna widely distributed throughout the Atlantic Ocean and the Mediterranean Sea. In the Atlantic, three stocks are commonly recognized by ICCAT (The International Commission for the Conservation of Atlantic Tunas): the northern and southern stocks separated by latitude 5°N, and the Mediterranean stock [1].

Albacore is not a target species in the Turkish waters. It is caught as by-catch in the bluefin tuna purse seine fishery. The catches of albacore had not been recorded for a long time until 2004. The total catch in 2004 was 27 t [2]. In this study, the data of the albacore drift-net fishery, which was carried out firstly in 2006 in the Turkish waters, are presented.

### Materials and methods

Data on the number of fishing vessels, the properties of the nets, fishing areas and non-target species of this fishery which was carried out in 2006 in Antalya Bay (Levantine Basin) were collected on board. Fork length (FL) and weight (TW) of 171 albacore were recorded. The length-weight relationship was calculated by equation  $W=aL^b$ . The obtained coefficients were analysed with ANOVA.

#### Results and Discussion

The albacore drift-net fishery was carried out for the first time between May and July 2006 in the national and international waters in Antalya Bay (Fig. 1). The depth at the fishing grounds ranged from 150 to 2300 m. Albacore fishery was carried out by 18 vessels. These vessels had 14-25 m length and 200-500 engine HP. The drift-nets were approximately 2 km in length and 150 meshes in depth with a 150-170 mm mesh. Illuminated buoys were attached to each side of the net. Nets were set at sunset (20:00 h) and retrieved at sunrise (05:00 h). The fishing period lasted 30-40 days due to the migration of fish, meteorological conditions and the phase of the moon.

Fig. 1. The fishing grounds of albacore in the Levantine Sea

The total catch of the fishing boat, with which this study was realized, was 32 tones. Albacore constituted 94%, swordfish 4% and the remaining fishes 2%.

The total length of albacore ranged from 64.0 to 94.0 cm (mean length 75.7 $\pm$ 0.4 cm (Fig. 2) and the weight from 4.5 to 12.3 kg (mean weight 7.0 $\pm$ 0.1). The length-weight relationship was W= 0.132 x L<sup>2.52</sup> (standard

error of b= 0.095, r=0.927). The slope of the length-weight relationship indicated negative allometry (b<3), and the value of b is similar to that (b=2.88) reported for the Aegean Sea [3].

Fig. 2. Length frequency distribution of albacore caught by driftnets in the Levantine Sea.

Driftnet fishing is a simple method of fishing with a long history of use all around the world. There is, however, a concern that these nets also capture non-target species (e.g. fish near the surface, marine mammals, birds and reptiles) in relatively larger numbers when compared with the non-target catches in demersal trawls [4].

Bluefin tuna (*Thunnus thynnus*), swordfish (*Xiphias gladius*), Atlantic black skipjack (*Euthynnus alletteratus*), bullet tuna (*Auxis rochei*) and dolphinfish (*Coryphaena hippurus*) are non-target species. In this study, no common dolphin, sperm whales and birds were caught, although turtles were trapped in the nets (which, however, were released back into the sea by fishers).

In 2003, ICCAT enforced a recommendation prohibiting the use of driftnets for fishing large pelagic species in the Mediterranean [1]. The driftnet fishery was prohibited in Turkish waters (by the Ministry of Agriculture and Rural Affairs) in September 2006 [5].

# LINSEED OIL AS AN ALTERNATIVE TO FISH OIL IN THE DIET OF NILE TILAPIA (*OREOCHROMIS NILOTICUS*)

Ioannis, T. Karapanagiotidis \*, Michael, V. Bell and David, C. Little

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland - ikarapan@apae.uth.gr

# Abstract

A feeding trial was conducted to determine whether increasing linolenic acid (18:3n-3) in linseed oil based diets would lead to increased tissue deposition of 22:6n-3 in Nile tilapia (*Oreochromis niloticus*). The study suggests that Nile tilapia has a limited capacity to synthesize 20:5n-3 and 22:6n-3 from dietary 18:3n-3. The replacement of fish oil in the diet of farmed tilapia with vegetable oils could therefore lower tissue concentrations of 20:5n-3 and 22:6n-3, and consequently produce an aquaculture product of lower lipid nutritional value for the consumer.

Keywords : Aquaculture, Diet, Fishes.

# Introduction

Today industrialized societies are characterized by an increase in energy intake, saturated fat and n-6 polyunsaturated fatty acids (PUFA) and a decrease in n-3 PUFA intake [1]. This nutritional status has lead to many modern human health disorders [2]. It is recommended to increase the intake of n-3 PUFA, and particularly 20:5n-3 and 22:6n-3, and decrease the dietary intake of n-6 PUFA in the human diet [3]. Fish and marine mammals are by far the richest source of long chain n-3 PUFA in nature. As the farming of fish is becoming a major contributor to world fish supplies, it is important for the aquaculture sector to maintain the high lipid nutritional quality of the product and continue to provide large amounts of the health-promoting n-3 PUFA for the consumer.

# Materials and Methods

Male sex-reversed tilapia fry (*Oreochromis niloticus*) of initial weight 0.5-2 g were grown on five isonitrogenous (32% crude protein) and isoenergetic (17 KJ/g diet) diets that were supplemented with 3% of either a blend of refined palm olein oil with linseed oil (PO-LO 3:2) or a blend of linseed oil with refined palm olein oil (LO-PO 2:1) or linseed oil (LO), fish oil (FO) and corn oil (CO). The fish were stocked into 6 replicate net cages (3 m x 1.8 m x 0.8 m, 3 mm mesh size) per dietary treatment that were suspended in an earthen pond (40 m x 40 m x 1 m). After 20 weeks of feeding, 30 fish from each treatment were taken, the dorsal muscle tissue of each was dissected and used for fatty acids analysis. The fatty acid analysis was performed by using gas liquid chromatography [4]. The fatty acid composition of the five treatments was subjected to one-way analysis of variance (ANOVA) and differences were considered significant at an alpha value of 0.01.

### Results and Discussion

The results suggest that LO and its blends with PO could totally replace fish oil without any negative effects (P>0.01) on the growth, feed efficiency and survival of Nile tilapia. The muscle content of 18:2n-6 and 18:3n-3 strongly reflected dietary intake with the highest (P<0.01) amounts of 18:2n-6 in fish fed the CO diet and 18:3n-3 in fish fed the LO diets, while fish fed the FO diet contained the highest (P<0.01) amounts of long-chain n-3 PUFA (Table 1). The inclusion of increasing levels of LO in the diet, and thus graded amounts of dietary 18:3n-3, resulted in commensurate increases in tissue 18:3n-3 and all n-3 PUFA pathway anabolites. Therefore, the PUFA biosynthetic pathways are active in Nile tilapia. However, when comparing the FA compositions of the LO-based treatments with those of FO-fed fish, it is becoming clear that the conversion of 18:3n-3 to longer chain n-3 PUFA derivatives is not efficient, and particularly the synthesis of 20:5n-3 and 22:6n-3 is low (P>0.01). These findings are in agreement with studies in other fish species [4, 5] fed on vegetable oil (VO) diets. This is a conclusion of great importance indicating that the replacement of FO with VO in diets for farmed fish lowers their content of the nutritionally important long-chain n-3 PUFA.

It is recommended that VO alternatives that are rich in 18:3n-3 and low in 18:2n-6, such as LO, are used if the replacement of FO in fish feeds become inevitable. The inclusion of LO can maximise the retention of desirable 20:5n-3 and 22:6n-3 and can minimise the deposition of undesirable long-chain n-6 PUFA in the edible muscle tissue of fish compared to a VO is rich in 18:2n-6.

Tab. 1. The fatty acid compositions (ug/mg of TL) of muscle TL of fish fed the five diets at the end of the 20-week feeding period. Values are the mean of 6 replicate groups of 6 fish ( $\pm$  S.D.). Values in the same row, which do not share the same superscript letter (i.e. a, b, c, d, e) are significantly different at a=0.01; n.d., not detected.

| Fattyacid        | PO-LO                       | LO-PO                       | LO                          | FO                           | CO                        |

# BATCH FECUNDITY OF PICAREL SPICARA SMARIS (L.) IN THE SARONIKOS GULF (GREECE)

Costantina Karlou-Riga \*, Panagiotis Anastopoulos , Dimitra-Stella Koulmpaloglou and Dimitra Petza Ministry of Rural Development and Food, Fisheries Laboratory, 15 Karaoli and Demetriou st., Pireus 18531, Greece - fishres@otenet.gr

# Abstract

Relative batch fecundity was studied for the multiple spawner *Spicara smaris* in the Saronikos Gulf (Greece) and compared with fecundity values reported in Greek waters. The picarel relative batch fecundity was estimated by the hydrated and migratory-nucleus method and was found to be equal to 339 oocytes per g fish weight.

Keywords : Aegean Sea, Demersal, Fishes, Spawning.

## Introduction

Picarel (*Spicara smaris* L.), is a very common species in the Mediterranean and the Black Sea but it is also found in the eastern Atlantic from Portugal to Morocco including the Canary Islands, inhabiting *Posidonia* beds and muddy bottoms at about 15-100 m [1]. The national catch recorded for 2003 was 4025 t constituting 5% of the total fish yield in Greek waters [2]. The fecundity of picarel has been estimated in Greek waters by counting the total number of oocytes above a certain size threshold [3]. However, this method results in the underestimation of the potential annual fecundity of a species characterized by batch spawning. Picarel is a multiple spawner [4] with a peak of spawning in April-May in the Saronikos Gulf [5]. Batch fecundity of picarel has been primarily estimated in the Saronikos Gulf [5]. In the present work additional females were examined and the overall batch fecundity estimate is compared with fecundity values eported in Greek waters.

## Materials and Methods

Samples of picarel were monthly collected in the Saronikos Gulf during 2003 from February to March by beach seiners and in April and May by nets and trawlers respectively. Specimens were randomly taken from the catch and were measured (total length) to the nearest mm and sexed; their total weight was measured to the nearest g. Females were classified to reproductive stages according to Nikolsky's [6] scale. Ovaries of macroscopically mature females (greater than stage II) were removed, weighed to the nearest 0.1 g and preserved in 10% neutral buffered formalin for histological examination. A piece of each preserved ovary was then dehydrated and embedded in paraffin wax. Sections (3 micron) were taken and stained with Harrish aematoxylin followed by eosin counter stain (H+E). From each ovary two subsamples of approximately 0.050 g were taken and after connecting membrane removal, were weighed to the nearest 0.001 g. The diameters of each oocyte in both subsamples were measured under the stereoscope using the Image Analysis Pro Plus 5.0 and the mean values were taken. Batch fecundity (Fb, number of oocytes per spawn) was taken to be the number of migratory-nucleus stage oocytes (MN) or the number of hydrated oocytes (H), still within their follicles, in the ovary [7]. The estimation of  $F_b$  was done by the gravimetric method [8]. Hydrated oocytes were easily recognized by naked eye. During histological examination it was also observed that the diameter of an oocyte with migratory nucleus ranged from 500 to 800 micron. Therefore, the size of 500 micron was taken as a threshold in order for all the migratory-nucleus stage oocytes to by counted. The ovaries used to estimate  $F_b$  were taken from samples at the peak of spawning (April-May).

#### Results and Discussion

The presence of post ovulatory follicles (pofs) in some ovaries in March showed that the spawning period has already started, while in February samples no spawning characteristics existed (MN, H or pofs). Thirty eight appropriate ovaries (10 with H oocytes and 28 with MN oocytes) ranging in weight from 7.1 to 50.2 g (ovary-free weight) were used for batch fecundity estimation. The numbers of oocytes per g fish weight between spawning states (MN and H) did not differ significantly (ANOVA, P=0.26). The relation between female weight (W, without ovary weight) and batch fecundity (F<sub>b</sub>) was determined by linear regression analysis. In the resulting equation:  $F_b = 369.1 + 321.7$  W with R<sup>2</sup>=84.3%, the intercept for the regression of  $F_b$  to W did not differ from zero (t=0.68). Therefore, the regression line (Fig. 1) was forced through zero (by multiple regression: [9]), weighting the regression line by the inverse of fish weight for each observation, in order that a minimum variance and unbiased estimates of regression coefficients could be obtained [7]. Thus, the resulting equation was:  $F_b = 339$  W with R<sup>2</sup>=96.0% and confidence interval equals to 316-362. Accordingly, the relative batch fecundity  $(F_{bw})$  was estimated as  $F_{bw} = 339$  oocytes per g fish weight. Vidalis [3] estimates for the same species in Greek waters the relative fecundity equal to 358 oocytes per g fish weight. Although this author has used a size threshold (250 micron) for counting the total of oocytes to be mature, his estimation should be considered as underestimated when compared to the present work, as batch fecundity represents here only the number of oocytes for one spawn (339 oocytes per g fish weight).

Fig. 1. Batch fecundity ( $F_b$ ) of picarel, *Spicara smaris*, as a function of female weight (W, ovary-free). Batch fecundity was estimated by counting hydrated oocytes (triangles) or migratory-nucleus stage oocytes (squares). Regression line (forced through zero) is: Fb=339 W.

# DIVERSITY AND DISTRIBUTION OF ASTEROIDEA (ECHINODERMATA) WITHIN THE BAY OF BOKA KOTORSKA (ADRIATIC SEA, MONTENEGRO)

Slavica Kasćelan \* and Sreten Mandić

Institute of Marine Biology, P. box 69, 85330 Kotor, Montenegro - skascelan@yahoo.com

# Abstract

The diversity and distribution of the asteroids in the Bay of Boka Kotorska (Adriatic Sea, Montenegro) were studied for the first time in 30 years. Two species, *Ophidiaster ophidianus* (Lamark, 1816) and *Hacelia attenuata* (Gray, 1840), are new records for the Bay of Boka Kotorska.

Keywords : Adriatic Sea, Echinodermata.

The Bay of Boka Kotorska penetrates about 20 km inland, and because of its complex geography, enjoys unique physico-chemical characteristics, that differ greatly from the open Montenegrin coast. The environmental features impact the diversity and distribution of the local asteroid fauna. The mention on the sea stars of Boka Kotorska bay is found in [1]. Subsequent authors [2-4] added to that knowledge.

Fig. 1. Bay of Boka Kotorska (Adriatic Sea, Montenegro) with studied positions

We studied 9 localities within the bay (fig. 1). Material was collected from may 2005 to may 2006, by diving, to depths of about 30 meters. Collected material was preserved by drying or in 70% ethanol and labeled according to ERMS [5].

We identified 8 asteroid species in an area of about 36km<sup>2</sup>. The most frequent species, found at all stations, were *Echinaster sepositus* (Retzius, 1783) and *Marthasterias glacialis* (Linnaeus, 1758) - species of wide ecological distribution, inhabiting different types of bottom. *Marthasterias glacialis* (Linnaeus, 1758) and *Coscinasterias tenuispina* (Lamarck, 1816) are known as predators in the shellfish farms in the Bay of Boka Kotorska [6]. *Astropecten aranciacus* (Linnaeus, 1758), *Astropecten platyacanthus* (Philippi, 1837), all widely distributed [7], were numerous. Two thermophilic species: *Hacelia attenuata* (Gray, 1840) and *Ophidiaster ophidianus* (Lamark, 1816), consitute new records for the Bay. They are known to inhabit the southern Adriatic Sea, where impact of warm Mediterranean current is strong. They were found on hard substrates, i.e. bedrock and cliffs, from shallow water up to 30 m, in the outer part of the Bay.

Our one-year investigation confirmed the presence of 8 out of 10 species of sea stars that had been recorded from Boka Kotorska Bay, about half of the species known from the Montenegrin shelf. While previous investigations relied on sampling by trawl net, grab and dredge, which are forbidden today, our research was based exclusively on scuba diving.

# ÉTUDE COMPARATIVE DE LA CROISSANCE RELATIVE SAISONNIÈRE CHEZ LE BIVALVE LITHOPHAGA LITHOPHAGA (LINNÉ, 1758) PRÉLEVÉ DANS LA LAGUNE ET LA BAIE DE BIZERTE (TUNISIE)

Ferdaous Jaafar Kefi, Najoua Trigui El Menif \* and Moncef Boumaiza

Université 7 Novembre à Carthage, Laboratoire de Biosurveillance de l'Environnement., Faculté des Sciences de Bizerte, Tunisie. najoua.triguielmenif@fsb.rnu.tn

# Résumé

La croissance relative du bivalve *Lithophaga lithophaga* a été étudiée pendant l'été et l'automne dans la Baie de Bizerte en 2002 et dans la lagune de Bizerte en 2004. Les résultats ont montré que la population lagunaire croit plus en chair et en coquille que celle de la baie. *Mots clès : Mollusca, Bivalves, Infralittoral, Biometrics, Growth.* 

# Introduction

*Lithophaga lithophaga* est un mollusque endolithe des roches essentiellement calcaires, vit dans la zone infralittorale entre deux et huit mètres [1]. Ce bivalve est présent dans pratiquement tout le bassin méditerranéen, en mer Rouge, et en Atlantique, du Maroc au Sénégal. La datte de mer fait parti des espèces menacées et les études relatives à sa biologie sont rares. C'est pourquoi l'objet de ce présent travail a été l'étude de la croissance de la datte de mer en Tunisie.

## Matériels et Méthodes

Des prélèvements mensuels de blocs hébergeant *L. lithophaga*, ont été effectués pendant l'été et l'automne 2002 dans la baie de Bizerte et en 2004 dans lagune de Bizerte à une profondeur variant de trois à quatre mètres. L'extraction de 120 à 150 individus est réalisée au laboratoire suite à la destruction de la roche. Les spécimens, renfermant toutes les classes de taille, ont servi à l'étude comparative de l'évolution saisonnière des paramètres morphomètriques (la largeur : l et l'épaisseur : E) et pondéraux (poids de la chair sèche: Wch-s et le poids sec de la coquille: Wcoq-s) par rapport à une grandeur de référence: la longueur antéropostérieure. Le traitement statistique des données a été effectué à l'aide du test t de Student calculé au seuil de 5 % et des tests de pente (tpe) et de position (tpo).

# Résultats

Les valeurs du coefficient de corrélation montrent une étroite corrélation entre les paramètres étudiés deux à deux.

#### Relation largeur - Longueur

Les valeurs du test t révèlent une allométrie majorante en automne. La largeur croit plus rapidement que la longueur antéro-postérieure dans les deux stations. Entre les deux milieux, les valeurs du test de pente tpe (2.91>1.96), montre une différence significative de croissance entre les deux stations. Cette différence est en faveur de la population marine pour des tailles inférieures à 20mm. En été, la croissance de ces deux paramètres est la même en lagune. Par contre, en mer, l'allométrie est majorante (tab. 1). Le test de pente montre une croissance significativement différente entre les deux stations, elle est en faveur de la population marine pour les tailles inférieures à 55mm.

### Relation Epaisseur - Longueur

Les valeurs du test t montrent une allométrie majorante. Entre les deux stations, la croissance est différente (tpe = 2.56), elle est en faveur de la population lagunaire pour les tailles supérieures à 21 mm. En été, l'allométrie se maintien majorante en mer et devient isométrique en lagune. Le test de pente tpe supérieur à 1.96 montre une croissance différente entre les deux stations. La population de la lagune croit mieux que celle de la mer à partir d'une taille de 35 mm.

#### Relation poids de la chair sèche - Longueur

En automne, les valeurs du test de student reflètent une allométrie minorante pour la population lagunaire et majorante pour celle de la baie. Le test de pente révèle une différence très significative au niveau de la croissance entre les deux stations. La croissance de la chair sèche est meilleure en lagune quelque soit la longueur du bivalve. En été, l'allométrie est minorante pour les deux stations. Le test de pente n'a révélé aucune différence significative. Le test tpo montre une différence significative en faveur de la population lagunaire ayant une taille supérieure à 50 mm. Relation poids de la coquille sèche - Longueur

Les valeurs automnales de la pente révèlent une allométrie minorante dans les deux stations (tabl. 1). Le test tpe montre une différence significative entre les deux milieux en faveur de la population lagunaire quelque soit la taille du bivalve. En été, l'allométrie se maintien minorante. Les tests de pente et de position révèlent une différence significative en faveur de la population lagunaire et ce à partir de la taille 59mm.

Tab. 1. Coefficients de corrélation entre les paramètres suivants: longueur (L), largeur (l), épaisseur (Ep) de la coquille, poids de la chair sèche de la partie molle (Wch-s), poids sec de la coquille (Wcq-s).

#### Conclusion et discussion

La croissance en lagune des différents paramètres morphométriques est meilleure qu'en mer et ce pour les spécimens d'une taille supérieure à 20-25mm. S'agissant des paramètres pondéraux, la croissance, en automne, se maintien en faveur de la population lagunaire quelle que soit la taille, alors qu'en été, c'est à partir de la taille 50-60mm. Selon [1], la température et l'activité sexuelle constituent deux facteurs déterminants dans la croissance somatique et/ou gonadique de la datte de mer. [2] considèrent que la croissance est fonction également de la disponibilité ou non de nourriture dans le milieu environnant. Il est donc très probable que les conditions de la lagune de Bizerte sont plus favorables à la croissance. Reste à vérifier, parmi les travaux en cours, la qualité sanitaire et microbiologique de la chair dans les deux milieux.

# A PRELIMINARY STUDY ON THE FISH COMMUNITY STRUCTURE AROUND GOKCEADA ISLAND, NORTH AEGEAN SEA, TURKEY Cetin Keskin \* and Muammer Oral

Istanbul University, Fisheries Faculty, Ordu St. No: 200, 34470 Laleli- Istanbul/ Turkey - seahorse@istanbul.edu.tr

# Abstract

This preliminary study was carried out in the mixed habitat (*Posidonia aceanica* and rocky) around Gokceada Island. Samples were collected with gill net and trammel net. A total of 2265 individuals were collected belonging to 44 species. *Chromis chromis, Spicara maena* and *Serranus scriba* were the most dominant species. Juvenile or sub-adult represented 16.6% of the total number of individuals. Diversity, species richness, evenness, and dominance had optimal values in May.

Keywords : Fishes, Biodiversity, Aegean Sea.

# Introduction

Nearshore seagrass beds (*Posidonia oceanica*, *Zostera* spp., *Cymodocea nodosa*) are important areas having higher diversity and abundance of fish than nearby bare substrata [1, 2]. High structural complexity of vegetated habitat provides shelter, food and refuge for resident and temporary species [2, 3]. This study provides preliminary data on the fish community structure in a mixed habitat (*P. oceanica* and rocky) around the Gökceada Island.

#### Materials and methods

The sampling was carried out from March to August in 2003 in a mixed habitat (*Posidonia aceanica* and rocky) around Gokceada Island. Samples were collected with gill nets (mesh size: 22 mm; 120 m x 2.4 m) and trammel nets (mesh size: 18 mm; 180 m x 0.9 m), which were set from 5 to 10 m depth. Sampling took place four times per month. The number of individuals per species was determined in the laboratory. Community structure was approached by estimating diversity (H), species richness (D), evenness (J), and dominance (C) [4].

# Results and Discussion

A total of 44 species were collected belonging to 24 families. This is a high value, considering also the short time of sampling, when compared with other studies in the same area [5]. The number of species was highest for the families Labridae (9 species) and Sparidae (8 species). *C. chromis* (23.2%), *S. maena* (18.8%) and *S. scriba* (10.6%) were the dominant species in terms of total number of individuals. *S. scriba* (seranidae), *Symphodus mediterraneus, S. tinca* (Labridae), *Diplodus annularis, D. vulgaris, Sarpa salpa* (Sparidae), and *Scorpaena porcus* (Scorpaenidae) were the most common and abundant species (Figure 1). These are typical in the Mediterranean coastal waters [3, 6]. Similar results were obtained in this study.

Fig. 1. Numerical percentage composition of most abundant species sampled around Gokceada Island from March to August in 2003.

Juveniles represented 16.6% of the total number of individuals, and their numbers increased from March to August. The number of species and individuals increased from March to May (Fig. 2). The diversity, species richness, evenness and dominance generally had optimal values in May (Fig. 2). Conclusively, the coastal waters of Gokceada Island represent

an inportant area with different habitat types for resident and temporary species.

Fig. 2. The number of individuals (N), number of species (S), evenness (E), species richness (D), diversity (H), and dominance (C) around Gokceada Island, March to August in 2003.

# Abstract

Aspects of the reproductive biology of *Melicertus kerathurus* were investigated in Thermaikos Gulf (N. Aegean Sea) from October 2000 to September 2002. Temporal variations in mated females percentage, gonad maturation and gonadosomatic index showed that reproduction begins in spring, peaks in summer and extends to October. Managerial measurements are discussed in relation to the present results. *Keywords : Aegean Sea, Reproduction, Decapoda.* 

## Introduction

The prawn *Melicertus kerathurus* is one of the most valuable resources for both the otter-trawl and artisanal coastal fisheries in the Thermaikos Gulf. Information on its catch rates, size structure and sex ratio has been published only recently [1]. The present work provides the first data on its reproduction.

#### Material and Methods

During two open fishing seasons (October to April 2000-01 and 2001-02) a monthly sampling schedule was followed on board commercial otter-trawlers. Due to unprofitable catches and consequently to fishermen's change of fishing target, samples were obtained from the artisanal fishery in May 2001 and 2002. During the closed season, experimental trawling was carried out (June and September 2001; July, August and September 2002), and additional samples were obtained from the artisanal fishery (June and July 2002). Female carapace length (CL, mm), body (BW, g) and gonad (GW, g) fresh weight, and spermatophore presence were recorded. The gonadosomatic index (GSI) was estimated as GSI = (GW/BW)x100. Ovary maturation was assessed using a five-stage ovary scale [2].

#### Results and Discussion

Out of the 7,206 females studied, about half (3,682) were found to be mated (size range 25.31 - 57.7 mm CL). Between April and July, more than 80% of the females were mated decreasing sharply in August-September (Fig. 1). Comparable maximum mating activity has been reported from Cadiz (Atlantic) [2] and Gabès (Tunisia) [3], while in Amvrakikos Gulf (E. Ionian Sea) maximum frequencies were much lower [5]. In contrast to the Gadiz and Amvrakikos populations, mating activity of the Thermaikos population was significant also during winter. The lowest monthly GSI was observed in winter, steadily increasing thereafter to a maximum in July, and sharply decreasing in August (Fig. 1). A slight increase was also observed in October. In general, GSI monthly values were much lower that those reported from the Atlantic [2].

Fig. 1. *Melicertus kerathurus* from the Thermaikos Gulf: temporal variations of mated females frequency (dashed line) and gonadosomatic index (GSI) (solid line).

In accordance with other geographical locations, the reproductive period of *M. kerathurus* extends from mid spring to early autumn with a June-July peak: high frequency (50-92%) of female maturity stages (ST) 3 and

4 coincided with that of mated individuals (April to July) (Fig. 2). The smallest spawning female had a size (32.24 mm CL) which was between those reported from Amvrakikos [4] and Smirni (Izmir) [6].

Fig. 2. *Melicertus kerathurus* from the Thermaikos Gulf: monthly percentages of ovary maturation stages; ST 1 = undeveloped, ST 2 = developing, ST 3 = early maturing, ST 4 = fully mature, and ST 5 = spent.

Regarding resource management, the trawl banning from June to September implemented in the Greek fishery seems to cover most of the prawn reproductive season. In that period, however, the artisanal fleet targets prawns in shallow waters, where it migrates for spawning. A closed period exists also for the artisanal fishery  $(10^{th} \text{ July-}10^{th} \text{ September})$ , but, according to the present results, it seems to be inefficient, as it covers only partially the main period in which females are functionally reproductive (May to July).

# Abstract

A new method, utilising pots, was succesfully applied for the Rapa whelk fishery in the Black Sea. Blue mussel and fish offal were used as bait to attract whelks. In addition to food preference, additional experiments on whelk speed and pot attraction are conducted. A monthly sampling program has been set up to understand effectiveness of this new gear throughout the year. The advantages and disadvantages of this method are discussed.

Keywords : Gastropods, Fisheries, Black Sea.

# Introduction

The veined Rapa whelk, *Rapana venosa* (syn. *R. thomasiana*) is one of the most important species in the Black Sea after its introduction in 1946 [1] from the far-east. By voraciously feeding mainly on mussels, oysters and other bivalves, its damage on the benthic ecosystem of the Black Sea is devastating. from the Black Sea, it is believed to be transported to Cheaspeake Bay where it is also causing great ecological damage.

Ironically, because of its export value for the far-eastern countries, it became also an important fishery target, and there are regulations to protect its abundant stocks in the southern Black Sea. There are two main methods to catch this species: dredging and diving. The former method damages many other benthic species, and the latter is very risky for the fishermen's health.

We tested "Pots" to catch this species in the Black Sea. Pots were extensively used for the fishery of common whelk in the northern Atlantic [2]. Its use was first mentioned by the first author to local scientists in the 1993, however, its successful application in the Black Sea was realised first time in September 2003, in Sinop Harbour.

## Material and Methods

Since April 2006, monthly sampling using pot system has been performed in this region. Three sets of 10 pots are being used for this aim. The bait used includes bivalve, fish offal and mixture of these.

Each pot is basically a 30 lt hard, thick (4 cm) plastic container (32x28x42 cm) having cement weight in their bottom (10 cm high), to keep the pot always at upright position) and a sole opening at the top covered with an inward net to prevent exit of caught whelks (see Fig. 1).

Fig. 1. General view of the pot.

The walls of the pot has been drilled with tens of holes (12 mm in diameter) around, both to let the smell of bait and to let smaller individuals go. The distance between a set of 10 pots is 10 m. Further details on this gear will be given in the final report. The pots are generally left at sea for three days, at 15, 25 and 35 m depths simultaneously.

#### Results and Discussion

Whelks were successfully caught with the trap (Table 1). Attracted to the bait smell, whelks climbed up along the outside pots, and entered through the net.

Tab. 1. Monthly average numbers and weights of whelks caught during 2006.

|           | Depth (m) |    |    |     |     | Total \A/(m) | A ( )   |
|-----------|-----------|----|----|-----|-----|--------------|---------|
| Months    | 15        | 25 | 35 | ;   | т   | Total VV (g) | Avr (g) |
| April     | 170       | 38 | 7  |     | 215 | 13328        | 61      |
| May       | 87        | 50 | 15 | ; ; | 152 | 11769        | 77      |
| June      | 150       | 6  | 5  | 1   | 161 | 12372        | 76      |
| July      | 52        | 9  | 27 | 1   | 88  | 7866         | 89      |
| August    | 132       | 3  | 5  | 1   | 140 | 9942         | 71      |
| September | 271       | 40 | 91 |     | 402 | 23096        | 57      |
| Average   | 144       | 24 | 25 | ;   | 193 | 13062        | 72      |
| StdDev    | 75        | 19 | 32 | 2   | 110 | 5283         | 10      |

The smallest whelk caught was 12.8 mm in width, confirming that smaller ones were possibly able to get out. Average number of whelks caught monthly in April-September 2006 was 193 and about 13 kg from a total of 30 pots. Although this number is smaller than those caught by a daily diving and individual dredging operation (589 and 1618 ind. in August 2006), the new method has the advantage of (a) environmentally-friendly for the sea bottom (b) no risk to human life, (c) fishing of targeted whelk size and (d) very few by-catch individuals. However, lower catch rates and the use of bivalve as bait are the disadvantages of the pot method. Our efforts are continuing to overcome these disadvantages.

# DISTRIBUTION OF CAULERPA RACEMOSA (FORSSKÅL) J. AGARDH AND RELATIONSHIP WITH POSIDONIA OCEANICA (L.) DELILE IN DATCA BOZBURUN SPECIALLY PROTECTED AREA

E. Memed Koc \*, Ahsen Yüksek and Erdoğan Okuş

Institute of Marine Sciences and Management, Istanbul University, Muskule Sok. No:1, 34174, Vefa, Istanbul, Turkey -

kocmemed@yahoo.com.tr

# Abstract

Present study reflected the general distribution of *Caulerpa racemosa* in Datça-Bozburun SPA. Results pointed out that the invasive *Caulerpa racemosa* is most frequently distributed below 38 m where the bottom limit for the distribution of *Posidonia oceanica* is. *Keywords : Algae, Posidonia, Marine Parks.* 

# Introduction

*Caulerpa racemosa* is described as an invasive species in Mediterranean Sea [1]. The main difference between *C. racemosa* and the other alien invasive species *Caulerpa taxifolia* in Mediterranean Sea is the opportunistic nature rather than the invasive characteristic, since success of *C. racemosa* depends on the failure of other species in the environment instead of the domination [2-3]. This study pointed out to the distribution of lessepsien and invasive marine algae *C. racemosa*, its sighting frequency depth dependency, the percentage of the species sighted within *C. racemosa* and relationship with *Posidonia oceanica* in Datça-Bozburun SPA.

# Materials and Methods

Data is collected by SCUBA divers, 831 SCUBA dives and 27 quadrate count were performed in 2002-2004. In quadrate studies, each group studied facieses at 10, 20, 30, 40 and 50 m depth using 1 m2 square quadrates divided into 400 cm2 (20x20) (a total of 25) squares.

### Results and Discussions

Under water observations indicated that the distribution of *C. racemosa* in the area is between 0.5-70 meters. Its distribution is higher on the sandy substratum between 40-50 meters. These depths are the bottom limits of *P. oceanica* (>40m). In the south of the Datca Peninsula, especially at the region between Datca town center and Knidos, *C. racemosa* was widely distributed at in almost all depths below 40 m. The *C. racemosa* distribution in the north of Datça Peninsula was very close to the southern region (Figure 1). Pollution and physical destruction (anchoring, fish farms) has negative effects on *P. oceanica* distribution and has caused serious facies loss. Important pollution load due to settlements and tourism activities was observed in some areas and negative effects of this pollution on *P. oceanica* meadows were detected [3].

Fig. 1. Distribution of Caulerpa racemosa.

Distribution of *C. racemosa* was detected in 17 quadrate stations out of 27. *C. racemosa* was detected only once between 10 and 20 m contours, 5 times at 30 m contour, 13 times at 40 m contour and 5 times at 50 m contour. *C. racemosa* was observed with *P. oceanica* in all contours except 50 m. Most frequent groups observed with *C. racemosa* were Thallophyta (39%) and Magnoliopyhta (24%) (Table 1).

Detailed studies performed pointed out that there is an important invasion threat by *C. racemosa*. At regions where *P. oceanica* is damaged the advantage is shifted to *C. racemosa*, *P. oceanica* is very sensitive to any kind of alterations in the ecosystem and physical destruction.

# GAMETE RELEASE AND GONAD SIZE IN THE SEA URCHIN *PARACENTROTUS LIVIDUS* FROM FOCA, TURKEY

Aysun Kose \*, Aynur Lok , Sefa Acarli and Serpil Serdar

Ege University, Fishery Faculty, Department of Aquaculture, Izmir/TURKIYE - koseaysun@yahoo.com

# Abstract

Specimens of the edible sea urchin, *Paracentrotus lividus*, were collected monthly from Foca, on the Aegean coast of Turkey, between February 2003 and January 2004. The length and weight of the gonad lop was measured. *P. lividus* maximal gamete release occurs in late winter. A significant relationship was found between gonad lop length and weight ( $p \le 0.05$ ). *Keywords : Aquaculture, Echinodermata, Aegean Sea, Mollusca.* 

# Introduction

*Paracentrotus* (Lamarck) is the most abundant echinoid species in Mediterranean littoral community and plays an important role in the development of benthic macrophyties [1]. Sea urchin gonads, also know as roe or uni, are highly valued seafood commodities and are considered as delicacies in many parts of the world [2] thus they are popular. The aim of the present study was to determine peak time of gamete release and to observe the relationship between gonad lop length and weight.

#### Material and Method

*In situ*, specimens of *P. lividus* were collected from Foca between February 2003 to January 2004 (0380 43, 80, N; 0260 44, 00, E), Izmir. All individuals were dissected into two parts and five gonad lops were measured and weighted individually. The present study defines gamete release individuals as those with gametes that ooze from the gonads. The percentage of gamete releasing individuals were calculated using Microsoft Excel Program. Simple linear regression was applied to determine correlation between gonad lop length and gonad lop weight [3].

## Results

In March, gamete releasing of sea urchins was not observed. An increase in the occurence gamete release in September-January was found. In January, when the most active gamete releasing was observed, a maximum peak was found (52%) (Fig. 1).

Fig. 1. A number of individuals P. lividus released gametes.

The regression analyse showed that there was a significant relationship between gonad lop weight and gonad lop length (r= 0.7226) (Fig. 2). Estimated b value was determined as 0.5417.

#### Discussion

In *Paracentrotus lividus*, gonadal growth occurs during the coldest months [4] and males and females aggregate for spawning, simultaneously release their gametes [5]. Spawning of *P. lividus* has been reported to occur either once or twice in a year [6]. On the other hand, the gamete release of *P. lividus* differs by as much as 4 weeks between years in Ireland [6]. In our study, although little gamete monthly release from gonads were observed throughout the year, the gamete release peaked (52%) once in a year only in late winter (January). It was observed that spawning only occurs during spring and early summer [7]. According to [8], *P. lividus* gonad growth and gametogenesis occurred throughout the year.

In this study, it was determined a significant realitionship between gonad lop weight and gonad lop length. This suggests that there is a direct proportion between these values. Despite the rich literature on gonad size of sea urchins [2, 3, 5], very few studies concerned gonad lop size.

# ICHTHYOFAUNA RECOVERY OF A NEWLY RE-FLOODED MEDITERRANEAN COASTAL LAGOON

E. Koutrakis \*, G. Sylaios , N. Kamidis , D. Markou , A. Sapounidis

N.AG.RE.F. - Fisheries Research Institute, Nea Peramos, 64007, Kavala, Greece - manosk@inale.gr

# Abstract

The ichthyofauna of the illegally drained Drana lagoon (NE Greece) was studied, with the lagoon's hydrographic and water quality characteristics, during pre- and post-restoration works leading to its re-flooding. The low diversity, compared with other lagoonal ichthyofauna, is probably due to the recent re-flooding and the limited sampling intensity. The reduced presence of the mugilids may be related to the prevailing tidal inlet dynamics.

Keywords : Fishes, Lagoons, Restoration, Eastern Mediterranean.

#### Introduction

Fisheries exploitation of coastal lagoons is been applied in Greece since the ancient years. Nowadays most of them are managed by Fishing Cooperatives with "traditional"permanent fish entrapment devices, combined with fish wintering channels. In northern Greece, the lagoons extent in 11500 ha and during the last decade their average landings are 600 t/year, with a clear decreasing trend.

Drana Lagoon, located at the NW site of the Evros River Delta (N.E. Greece), a fishery-exploited lagoon (fish production of 8 to 20 th during 1974-1986) was drained illegally in 1987 by local farmers, under the perception that the lagoon's saline water affects their adjacent cultivations (Figure 1). Lagoon's re-flooding (by the opening of a new 5 m wide entrance for the water), together with other restoration works, were carried out during June 2004. The project was funded by a LIFE-Nature project, aiming to: a) restore lagoon habitats structure and functions, b) conserve protected avifauna species, and c) upgrade the management effectiveness applied in the lagoon's broader area. It is expected that the lagoon's the local cooperative.

#### Materials and Methods

A sampling program to determine the pre- and post-flooding ichthyofauna distribution (in terms of species abundance and diversity) was conducted, in association to hydrographic and water quality studies. Three samplings were attained: one before re-flooding (January 2003) and two after reflooding (October 2004 and April 2005). Fish were collected using a nylon centre-bag seine net (3 mm bar mesh size) of 12 m length and 1.2 m height. The bag seine was hauled for 30-50 m in order to cover an area of 250 m<sup>2</sup>, approximately. The relative abundance was estimated by the Catch per Unit Effort method (CPUE: 1.000 m<sup>2</sup>). Fish samples were preserved in 6% formalin solution and later sorted and measured in the laboratory. Water flow, tidal elevation, water temperature, salinity and dissolved oxygen content were recorded at the lagoon's inlet during two consecutive tidal cycles (24 hrs) for each monitoring period. Nutrients and chlorophyll-a were also determined at 9 sites inside the lagoon, during the ebb and flood periods of each tidal cycle.

Fig. 1. Map of the Drana Lagoon (Evros Delta, Greece) indicating the sampling sites for fish fauna (black triangles) and oceanographic, physical and chemical water conditions (1-9).

## Results and Discussion

Results from all samplings depicted the presence of saline water (up to 41 psu) inside the lagoon, due to sea water intrusion and increased evaporation rate. Dissolved oxygen distribution appeared to be mostly influenced by the wind mixing, rather than by the advection of oxygenated sea water through the inlet. Nutrient and chlorophyll-a levels showed negligible spatial and temporal variability. A mean concentration of 50  $\mu$ gr/l for nitrates, 95  $\mu$ gr/l for phosphates and a mere 0.2  $\mu$ gr/l for chlorophyll-a was observed. Tidal variability at the mouth was approximately 0.2 m, producing tidal currents of up to 0.75 m/s.

Twelve species representing 8 families were caught during the 3 samplings. Seven species were caught during the pre-reflooding period at the entrance. Five new species were collected after re-flooding, while one species caught before re-flooding, was not found again ( Gambusia affinis). Among all species caught, 5 species were characterized as permanent residents of lagoonal ecosystems, 6 as marine migrants and 1 as straggler (Table I). The inner part was dominated by five species. Among them Atherina boyeri, a species that permanently inhabits coastal brackish ecosystems, showed the higher presence (50.8%), followed by Pomatoschistus marmoratus and Aphanius fasciatus, both residents lagoon species, and two migrants, Lithognathus mormyrus and Sygnathus abaster. Generally, reduced species diversity was observed, compared to other lagoon ecosystems, probably due to the recent lagoon re-flooding and the limited sampling intensity. The reduced presence of the Mugilidae family species inside Drana Lagoon (2.1%), which constitutes the higher proportion of the Greek lagoons' catches (60-80%), could be related to the prevailing tidal inlet dynamics (i.e. strong ebb flow at lagoon inlet).

Tab. 1. Relative abundance of the ichthyofauna of the Drana Lagoon (Evros Delta, Greece), before and after restoration (R= resident species, M=migrant species, S=straggler species).

| n  | Family          | Species                   | Life<br>history | Before | After |
|----|-----------------|---------------------------|-----------------|--------|-------|
| 1  | Atherinidae     | Atherina boyeri           | R               |        | 37.6% |
| 2  | Cyprinodontidae | Aphanius fasciatus        | R               | 0.4%   | 7.6%  |
| 3  | Gobiidae        | Pomatoschistus marmoratus | R               |        | 0.2%  |
| 4  |                 | Knipowitschia caucasica   | S               | 5.6%   | 31.7% |
| 5  | Mugilidae       | Mugil cephalus            | M               | 0.7%   | 2.9%  |
| 6  |                 | Liza ramada               | M               | 57.5%  | 0.6%  |
| 7  |                 | Liza aurata               | M               | 32.7%  | 0.2%  |
| 8  |                 | Liza saliens              | M               | 0.9%   | 1.2%  |
| 9  | Poeciliidae     | Gambusia affinis          | R               | 2.2%   |       |
| 10 | Soleidae        | Solea solea               | M               |        | 0.3%  |
| 11 | Sparidae        | Lithognathus mormyrus     | M               |        | 8.1%  |
| 12 | Syngnathidae    | Syngnathus abaster        | R               |        | 9.4%  |

Inlet dynamics characterized by strong flood currents and limited ebb duration were considered to affect the entry of juveniles into Drana Lagoon. An improvement in the design of the lagoon's inlet was suggested, by increasing its width and produce areas of low flow conditions. Lateral friction could be enhanced with the positioning of medium-sized stones at the sides of inlet's banks.

# Abstract

Structure of four ecotonal environments consisted of lagoons, estuaries and marshes were investigated in comparison with their adjacent marine areas across Kalloni Gulf (Island of Lesvos, NE Aegean) for the first time. Significant differences were detected between and within ecotonal and marine ecosystems in terms of benthic community organization. Ecotonal areas were consisted of typical marine/estuarine and lagoonal species in a varying degree of numerical dominance. Observed differences concerning the prevailing environmental conditions at each ecosystem suggest a strong gradient from the sea towards the ecotones. Biocommunities seemed to experience a pronounced environmental stress only in the ecotones and not in the marine areas. Findings of this study support the role of confinement in the paralic domain in the Mediterranean as a function of a number of environmental factors governing biological communities' patterns. *Keywords : Zoobenthos, Brackish Water, Coastal Systems, Aegean Sea, Eastern Mediterranean*.

#### Introduction

Transitional coastal ecosystems, a term used for a variety of ecosystems such as lagoons, estuaries, semi-enclosed bays and saltmarshes, constitute areas of special ecological and economical interest since they are located to the inter-surface of land and sea (land/water ecotone). These ecosystems are characterized by their buffering role towards land effects at the coastal zone (e.g. eutrophication incidents) [1]. Kalloni Gulf (Lesvos Island, NE Aegean Sea, Greece) comprises a rich mosaic of wetland patches such as lagoons, estuaries and marshes along the coastline. The present research effort aims to investigate for the first time marine/land ecotones in various transitional ecosystems of the Kalloni Gulf, in comparison with their adjacent marine areas concerning the prevailing environmental conditions and the benthic biological structure.

#### Materials and methods

The study areas were four Kalloni Gulf wetlands [Polihnitos saltworks (stations Pol-Br and Pol-Mar), Vouvaris estuaries (stations Bou-Br and Bou-Mar), Kalloni saltworks (stations Kal-Br and Kal-mar) and Parakoila marshes (stations Par-Br and Par-Mar)]. Macrobenthic samples were collected in each one of the aforementioned coastal areas (marine site - Mar; ecotone site - Br), by means of a Van-Veen sampler during Spring 2006. Environmental variables either clear physicochemical ones or variables related with food availability (e.g. Salinity, Temperature, Chloroplastic pigments concentration, Inorganic Nutrients, Sediment Organic content) were also measured in the studied areas. Uni- and multivariate methods based on Bray-Curtis similarity index were employed to detect biological and environmental patterns [2].

#### Results

Marine and brackish areas presented pronounced differences concerning environmental conditions (ANOSIM test results Global R: 0.729, p<0.2%). Values of environmental parameters (e.g. Nutrients, Chlorophyll- a and Organic load concentrations) measured, were higher in the Brackish ecosystems (hypo-saline such as estuaries, marshes or hyper-saline areas such as saltworks) in relation to those in the adjacent marine environment. MDS plots of the environmental parameters revealed a strong environmental gradient from the sea towards the ecotones (Fig. 1). As far as the benthic communities are concerned, the most abundant species distributed along the ecotones can be divided into three groups: freshwater species such as the larvae of the Insecta Chironomus sp.; typical lagoonal species of marine ancestry such as the gastropods Hydrobia acuta and Pirenella conica; and marine/estuarine species such as the Molluscs Bittium reticulatum, Abra segmentum, the Polychaetes Hediste diversicolor, Capitella capitata, and the Amphipods Gamarus aequicauda, Microdeutopus gryllotalpa. On the contrary, the dominant species in the marine sites were typical marine species such as the Molluscs Gibbula albida, Pusillina radiate, Loripes lacteus, and typical marine/estuarine species such as the Mollusc Bittium reticulatum. Multivariate analysis (Fig.1) revealed a clear separation between the ecotonal and the marine areas (ANOSIM test results Global R: 0.7, p<0.5%). Application of ABC curves and Geometric class plots techniques on the macrofaunal data have revealed that only the Ecotonal areas constitute stressed ecosystems. Finally, results of the BIOENV analysis have revealed that the macrobenthic community distribution pattern was mainly governed by environmental factors related to food availability (i.e. Chl- a, Nutrients).

Fig. 1. Environmental (a) and Macrobenthic community (b) patterns across the Kalloni Gulf study sites produced from the multivariate analyses

#### Discussion

Comparison of the transitional water ecosystems and the adjacent marine area is a poorly explored issue in the NE Aegean coastline. The observed diversity within and between ecotonal and marine habitats seemed to be comparable denoting no diversity modification or even loss from sea to ecotones, a fact that supports the claim that land/water ecotones constitute habitats of substantial ecological value [3]. Furthermore, the observed diversity levels were similar with these recorded from other Transitional Coastal Ecosystems across the Hellenic coastline [4]. Dominance of certain species was the observed community mode thus confirming the hypothesis that the presence of only few keystone species can support ecosystem functions in ecotonal habitats [5]. The observed marine-brackish gradient in the Kalloni Gulf wetlands corresponds to the zonation model typical for the paralic domain [1]. Perturbation events detected in the ecotonal ecosystems should probably be attributed to the highly dynamic and severely fluctuating environmental conditions known to prevail in transitional ecosystems across the Mediterranean [3].

# Abstract

The aim of this study was to investigate mussel growth of several cultured populations (Kalohori, Halastra and Makrygialos) in Thermaikos gulf. The results revealed that shell length and mussel weight were affected neither by the position where spat attached to the initial ropes nor by the different water culture depths. Reciprocal mussel transplantations between the culture areas of Halastra and Makrygialos revealed that all the populations, native and transplanted, showed a higher shell and weight growth and seemed to grow faster in the area of Halastra than in Makrygialos. The slope values of the length-wet weight and length-dry weight regressions were significantly higher for all populations cultured in the area of Halastra. The analysis of water physicochemical parameters revealed no significant differences between the two culture areas while a relatively small difference of the nutrients' content was observed. *Keywords : Bivalves, Growth, Aegean Sea.* 

#### Introduction

The blue mussel *Mytilus galloprovincialis* predominates in Thermaikos gulf in the Northern Aegean Sea where mussel cultivation has recently become increasingly important. It is a highly variable species and populations frequently differ in growth rate and size as well as in the morphology of shell and soft parts. A large part of this variation may be a result of environmental factors. Reciprocal transplantations are one way to examine the extent to which population differences in growth may be environmentally induced or inherited. The present study is part of a wider one, which aimed at describing the growth characteristics and genetic variation of three mussel populations from three different sites at Thermaikos gulf in the Northern Aegean Sea. In this paper we compare growth characteristics of mussels attached or cultured at different water depths and of mussels reciprocally transplanted among three sites within Thermaikos Gulf.

#### Materials and Methods

The study of mussel growth in suspended culture farms started in May 1995 and was completed by July 1996. Special ropes used for collection of spat, were placed at three stations in Kalohori, Halastra and Makrygialos areas, at 8 m water depth in February 1995. At each station, 30 bands were created and suspended in long-line mussel culture farms at 8 m water depth. In June 1995 reciprocal transplantation of mussels were carried out among the study areas. The mussel density of each unit was controlled and the mussels were spaced out at two months intervals.

Several physicochemical parameters, as well as nutrient content of the water were measured at two months intervals at 1 and 3 m water depths [1]. Comparison of their mean values between the two areas and between the different water depths of mussel culture was performed using Mann-Whitney test. For growth study 22.245 mussels were used, 12.879 from the Halastra and 9.366 from Makrygialos area. Growth was reconstructed by measuring shell length (mm) and the data obtained were formalized using the Von Bertalanffy [2] growth equation (VBGF). Shell lengths were related to weight according to the allometric equation:  $W=aL^b$ . Linear regression analyses on logarithmically transformed values of weight and length were carried out for each sample, followed by covariance analysis to compare estimates of b. For the weight study, 3.760 mussels were used, 2.146 from the Halastra and 1.614 from Makrygialos area.

#### Results and Discussion

Many authors have attempted to compare growth rates within a single species monitored at different water depths and concluded that growth rates differed according to cultivation raft position but not according to culture depth [3]. Our results revealed that shell length and weight of mussels were affected neither by the position where spat attached to the collector ropes nor by the different culture water depth (from 1 to 4 m below surface). Probably, such differences would be detected between moderate depths and depths greater than 6 m.

The most important finding is the fact that in Halastra culture site mussels seem to grow faster than in Makrygialos. Values of Von Bertallanfy K

were significantly higher (t-test p<0.001) for all subpopulations cultured in Halastra compared to the same subpopulations cultured in Makrygialos (mean K for Halastra:  $2.15\pm$ ' 0.04, for Makrygialos:  $1.62\pm$ ' 0.08). The same trend was seen for the values of  $\varphi$ , which represent the rate of shell growth (mean  $\varphi$  for Halastra: 2.09 $\pm$ 0.005, for Makrygialos 2.00 $\pm$ 0.007). This difference in growth rate of mussels between the two culture areas may be a result of more favorable environmental factors [4]. However, during our study, no significant differences were found in any physicochemical parameter measured between the two culture areas that could justify our results. Also, the effect of contamination by various metals on mussel growth has been recorded as high levels of metals have inhibitory effect on mussel filtration. Halastra and Makrygialos areas receive high quantities of agriculture outfall from Axios and Aliakmonas rivers respectively [5]. The difference in mussel growth observed between the two areas could be caused by a possible different metal concentration in the water outfall of the two rivers. However the available data on metal concentration in the two rivers during the experimental period do not show any significant differences (Kravva, unpublished data).

Mussel growth is largely influenced by the water nutrient content as it regulates the phytoplancton concentration, which in turn is the primary food source for mussels [6]. The nutrient concentration in both culture sites is influenced by the waters of the Axios and Aliakmonas rivers. The differences in nutrient concentration observed during our study, especially those in PO<sub>4</sub>-P content (mean value for Halastra: 47.6  $\mu g/l$ , for Makrygia-los: 32.6  $\mu g/l$ ) could justify the faster weight gain of mussels in the area of Halastra as this area receives water from Axios River. Water from this river has the highest nutrient concentration, mainly in phosphates, caused by anthropogenic processes.

# SOFT BOTTOM LUMBRINERIDAE (POLYCHAETA) SPECIES IN IZMIR AND SAROS BAYS (AEGEAN SEA)

Guley Kurt \*, Zeki Ergen and Melih Ertan Çinar

Ege University Faculty of Fisheries Dept. of Hydrobiology 35100 Bornova Izmir, Turkey - guleykurt@mail.ege.edu.tr

# Abstract

The present study deals with Lumbrineridae species on soft substrate in Izmir and Saros Bays located in the Aegean Sea. Benthic samples were collected from 12 stations (20-69 m) in Izmir Bay between 1997 and 1998 and from 18 stations (8-135 m) in Saros Bay in 2000. A total of 13 species were identified, belonging to 6 genera, of which *Lumbricalus adriatica* and *Lumbrinerides* cf. *acuta* are new records for the marine fauna of Turkey. *Lumbrineris gracilis* and *L. latreilli* were the most abundant species in both areas. *Keywords : Polychaeta, Systematics, Aegean Sea.* 

## Introduction

Lumbrineridae Malmgren,1867 were represented by 250 species and 13 genera worldwide, 22 species and 7 genera in the Mediterranean and 11 species and 5 genera on the coasts of Turkey. On the Turkish coasts, 5 species were reported in the Sea of Marmara [1], 7 species in the Aegean Sea [2] and 8 species in the Levantine Sea [3].

The aims of this study are to determine lumbrinerid species in Izmir and Saros Bays and to investigate their distributional patterns in the areas.

## Material and Methods

Lumbrinerids were found a total of 56 samples collected at 30 stations in Izmir (20-69 m, in 1997-1998) and Saros (8-135 m in August 2000) Bays by a van Veen grab (Izmir Bay) and anchor dredge (Saros Bay) (Figure 1). Benthic samples were sieved through 0.5 mm mesh and the retained material was placed in separate jars containing 4% seawater formaldehyde solution. In the laboratory, samples were sorted according to taxonomic groups under a stereomicroscope and preserved in 70% ethanol. Lumbrinerids were separated from other worms, then identified and counted. The Jaccard's Similarity Index was used to assess species associations in the areas.

Fig. 1. Map of investigated area with location of sampling sites.

#### Results and discussion

The examination of materials collected on soft substrate in Izmir and Saros Bays revealed a total of 1829 specimens belonging to 12 species and 1 subspecies (Table 1). *Lumbricalus adriatica* and *Lumbrinerides* cf. *acuta* are newly added to the marine fauna of Turkey. The genus *Lumbrineris* was represented by four species and 1569 individuals (86% of the total individuals). The most dominant species in the areas were *Lumbrineris gracilis* (56% of the total individuals) and L. *latreilli* (24%). The densities of *L. gracilis* and *L. latreilli* reached up to 550 individuals/m<sup>-2</sup> and 370 individuals/m<sup>-2</sup> in Izmir Bay, respectively. As a result of Soyer's frequency (F) categorizations, 5 species can be classified as constant ( $F \ge 50$ ), 3 species as common ( $25 \le F \ge 49$ ) and 4 species as rare (F < 25) in Izmir Bay. When it comes to Saros Bay, 4 species can be classified as constant, 1 species as common and 7 species as rare. The most frequent species in the Bays were *L. gracilis*, *L. latreilli* and *Scoletoma impatiens*.

| Lumbrinerides cf. acuta (Verrill, 1875)             |        |      |       |       | 1     |         |       |
| Lumbrineriopsis paradoxa (Saint-Joseph, 1888)       |        | 11   |       | 1     |       |         |       |
| Lumbricalus adriatica (Fauvel, 1940)                |        | 2    |       |       |       | 20      |       |
| Nince armoricana (Glèmerec, 1968)                   | 3      |      |       |       | 5     |         | 1     |

According to Jaccard's Similarity Index analysis, three mean species associations were found. The first association consisted of the species *Lumbrinerides* cf. acuta and Ninoe armoricana, which were found only in deeper waters (62-69 m). The species Scoletoma funchalensis, S. emandibulata mabiti, Lumbrineriopsis paradoxa and Lumbricalus adriatica were grouped at a similarity level of 38%. These species seemed to prefer Posidonia oceanica meadows in Saros Bay. The other association included the species Lumbrineris gracilis, L. latreilli, L. nonatoi, L. coccinea, S. impatiens and S. fragilis, which were frequent and dominant species on soft bottoms (without phanerogames) in Izmir and Saros Bays. Lumbrinerides amoureuxi was grouped with the latter association at a similarity value of 25%.

A detailed study on lumbrinerids, which was performed along the coast of Crete Island in the Aegean Sea, reported 11 species [4]. *Lumbrineris* gracilis was the most abundant species on the coasts of Crete and Turkey but *Scoletoma emandibulata mabiti* was represented by high number of individuals on the coast of Crete and lower number of individuals on the coast of Turkey. The present study included two species (*Lumbrinerides amoureuxi* and *Lumbrinerides* cf. *acuta*) which were not found on Crete Island. Furthermore, this study provides some information on Lumbrineridae fauna distributed along the Turkish coast of the Aegean Sea. In order to better understand of the distributional and ecological features of Lumbrineridae species in the area, more samples including different depths and habitats should be collected and investigated.

# DIVERSITY AND DISTRIBUTION OF MACROPHYTES ALONG THE COAST OF LEBANON ( LEVANTINE BASIN, EASTERN MEDITERRANEAN)

Sami Lakkis<sup>1</sup> \* and Vanda Novel-Lakkis<sup>2</sup>

<sup>1</sup> Biology Department, Faculty of Sciences, Lebanese University, Beirut, Lebanon - slakkis@ul.edu.lb

<sup>2</sup> Laboratoiry of Marine Ecology and Plankton , NCMS / NCSRL, Batroun, Lebanon

# Abstract

A total of 243 taxa of macroalgae were found along the coast of Lebanon. They include: 25 Cyanophyta, 58 Chlorophyta, 29 Phaeophyta, 127 Rhodophyta, 3 Phanerogams and 1 Xantophyta. Brown algae are very sensitive to organic pollution, on the contrary of green algae which tolerate polluted sites. Several phaeophyte species from the genera: *Cystoseira, Sargassum, Corallina, Laurencia* and *Padina pavonica*, are good indicators of unpolluted coastal seawater, while, *Ulva, Enteromorpha, Colpomenia* and *Cladophora* thrive in organic polluted coastal waters. High taxonomic diversity and biomass occurred in spring and summer; while most of the algae are qualitatively and quantitatively poor during fall and winter. Several introduced species of Indo-Pacific origin were found, many of them have established stable populations.

Keywords : Algae, Coastal Waters, Levantine Basin, Biodiversity, Biomass.

## Introduction

Marine flora of the Levantine Basin, including the coast of Lebanon belongs to the Atlanto-Mediterranean province. However, the occurrence of several introduced Indo-pacific species, attribute to this region a certain tropical and subtropical characteristics .Few data are available regarding the phytobenthos of the Lebanese coast [1-2] 75% of the occurring species inhabit the western Mediterranean [3], whereas many others considered as Lessepsian were introduced in the Levantine Basin, where they established permanent populations. Most Phaeophytes are very sensitive to organic pollution whereas chlorophytes are very tolerant to polluted coast. These circum-tropical species present along the Lebanese coast may be either endemic or relicts from the period of the Tethys, or migrant species introduced, directly, or indirectly, through the Suez Canal into the Mediterranean. In this paper we present the spatio-temporal distribution of macroalgae along the Lebanese coast, focusing on their relation to environmental factors.

## Material, methods and investigated area

Samples were made during 2000 and 2004 at a frequency of two times a year: in spring and in summer, at six sites along the coast of Lebanon. (33°50'-34 55' N and 35°30' E), covering polluted and unpolluted soft and rocky shores. Five sampling points were chosen on each transect, covering the supralittoral, mediolittoral and infralittoral zones [4]. A 0.04 m<sup>2</sup> metallic quadrat was used for quantitative and qualitative sampling. Temperature, salinity, dissolved oxygen and pH were measured in situ, and water samples were collected from surface for chemical analysis, namely ammonia, phosphate and nitrite-nitrate. In the intertidal zone, samples were collected directly, while in sub-tidal, scuba diving was used for collecting algae. In addition to the biomass, the % of algal coverage was estimated. Semi-diurnal tide amplitude along the Levantine coast is very small (15-20 cm.). Hydrology is characterized with two thermal phases: 1) a cold phase during winter (December-March), characterized with cool seawater (min 16°C in February) and moderate salinity (S=39.25psu ), and marked with vertical isothermal conditions in the water column; 2) a warm phase during summer-fall (May-November) characterized with high surface temperature and salinity ( max in August-September T= 30°C and S=39.75psu), accompanied with sharp thermocline in the layer 35-75 m, and with water layer stratification. The Lebanese seawater is highly oligotrophic as in all Levantine Basin.

#### Results

In total 243 taxa were found, in all sites, including 25 Cyanophyta, 58 Chlorophyta, 29 Phaeophyta, 127 Rhodophyta, 3 Phanerogams and 1 Xantophyta. The bathymetric distribution is not very clear since the limit between two adjacent zones is not well defined, due to sea level variability. Many overlaps among species distribution are always observed. In all sites, the supralittoral is the poorest zone, while the infralittoral is the richest in diversity and in algal biomass. The sites St1,St3 and St6 situated in unpolluted coast, are the most rich , while St4 (near thermo-electric power plant) and St5 (near big urban sewer) are very poor; except in green algae. Sciaphile algae, mostly from rhodophytes, are the most important in the mediolittoral. The brown algae grow only in the intertidal zone and are not as tolerant as the green algae, they are very sensible to pollution (St4 and St5).

Supralittoral - Most of the species in this zone are tolerant to changing environmental conditions such as moistening, dryness, dumping of freshwater and organic pollution. *Cyanophycaea* are dominant along with some benthic diatoms. 13 species characterizing this zone were recorded, namely *Hormatonema sphaerica*, *Hyella caespitosa*, *Anabena* sp., *Oscillatoria nigroviridis*, *Chrococcus turgidus*, *Hydrocoleus lyngbyaceus*, *Phromidium ambiguum*, *Rivularia mesenterica* and *R. atra*. The sites St1,St2, St3 and St6 show similar species associations, different from those of polluted sites St4 and St5.

Mediolittoral - The maximum number of species found in all mediolittoral sites was approximately 148. In upper mediolittoral at all sites dominant species are: *Porphyra leucostica, Enteromorpha compressa, E. flexuosa, E. aragoensis, Nemalion helmintoides, Polysiphonia sertularoides, P. tenerrima, Calothrix aerugina.* Several accompanying species from Cyanophyta and Chlorophyta are also present. Lower mediolittoral is dominated by *Neogoniolithon notarisii, Laurencia papillosa, L. pinnatifida, L. obtusa, Cladophora* spp., *Enteromorpha* spp., *Jania rubens* and *Corallina mediterranea*, with 26 accompanying species.

Infralittoral - The subtidal level which is always covered with the seawater, is the richest and the most diversified. The species in this zone grow within stable environmental conditions. About 190 species were recorded in the subtidal at all the investigated sites, St3 being the richest with 115 species. Several species from the mediolittoral are also present in the infralittoral. Cystoseira spp. and Sargassum vulgare are good indicators of the infralittoral low-water tide. Upper infralittoral extending to depth -10 m is dominated by many species such as: Jania rubens, Bryopsis mucosa, B. hypnoides, Liagora farinose, Anadiomene stellata, Lophocladia lallemandii, Hydroclathrus clathrus, Sargassum vulgare, Bryopsis sp., Corallina elongata, Padina pavonica, Udotea patiolata, Dasycladus vermicularis. Several accompanying species are present with less abundance. Lower infralittoral is dominated by sciaphile algae, namely: Acanthophora delilei, Rityphlaea tinctoria, Siphonocladus pusillus and Phanerogams growing on soft bottom: Zostera noltii, Cymodocea nodosa and Halophila stipulacea. On sediment seafloor we also record the caulerpales: Caulerpa scalpelliformis, C. prolifera, C. racemosa. Many accompanying species grow in this level such as: Valonia utricularis, Bryopsis hypnoides, B. pinnata, Lithophyllum incrustans, L. lenormandii, etc.

# Abstract

Based on samples collected seasonally in coastal Iskenderoun Bay, the zooplankton community has revealed high biomass contrasting with low taxonomic diversity. Major Mediterranean groups are present in Levantine Basin, including Iskenderoun Bay. 20 groups were reported, the copepods being the most important, forming between 50% (August) and 96% (January) of the total zooplankton community. Cladocerans in swarming patches, are abundant in summer, whereas Thaliaceans dominate in summer-fall. Winter assemblage is characterized with relative high diversity. Some Lessepsian species were reported in the area, namely from copepods. *Keywords : Biodiversity, Coastal Waters, Levantine Basin, Copepoda, Zooplankton.* 

#### Introduction

Recent studies indicate that hydrobiological changes have happened in the Levantine Basin, including Iskenderoun Bay since the opening of Suez Canal and the construction of Aswan High Dam [1], [2]. Few data with this respect to species composition and dynamicsof zooplankton of the northeastern Levantine Basin are available [3], [4]. More research on taxonomy and distribution of copepods of the area were achieved by [5], [6], [7]. In the present work we describe the composition and the structure of zooplankton community of the coastal Iskenderoun Bay.

#### Material and methods

Seasonal cruises during 2002, were carried out at five coastal stations in north-west Iskenderoun Bay (Fig.1). Vertical hauls were towed at 20 m and 30 m depth using plankton nets of 200 microns of mesh size. Identification up to species level was carried and counts of individuals were reported as number of individuals per sample.

#### Results

The Bay of Iskenderoun covers a relative large area of the continental shelf less than 100 m depth. The annual thermohaline cycle is resumed in two phases: a cold phase in winter characterized with isothermic structure in the water column, with minimum temperature and salinity in February (16°C; 37-38 psu). The warm phase in summer-fall is characterized with a water layer stratification and a heavy thermocline in the depth 30-75 m. Temperature averages reach 29 °C at surface and 19 °C at the bottom in July-August. The primary production estimated from chlorophyll data was higher in the central part of the Bay (annual average 60 g C/m<sup>2</sup>/year) and lower in the eastern Mediterranean (25 g C/m<sup>2</sup>/year) [8]. Most of the zooplanktonic groups found in the Bay are of Atlanto-Mediterranean the copepods constituting the major group, either in diversity and in biomass. Ecological cycle of the planktonis is marked with three seasonal assemblages: winter (January), spring (April) and summer-sall (August-October). During the cold period, the main common groups are: the copepods dominated by Calocalanus spp., Calanus minor, Oncaea spp. and Oithona spp., the Hydromedusae, Siphonophorae, Sagitta friderici and Oikopleura cophocerca. In spring the plankton community is dominated by herbivorous species developing after the spring phytoplankton bloom; the zooplankton is rich and diversified, the copepods being the most common, namely: Paracalanus parvus, Acartia clausi and Centropages kröyeri, Ichtyoplankton (eggs and fish larvae), crustacean decapod larvae, Lamellibranch and Prosobranch larvae, Echinoplutei, Pteropods and Siphonophores. During summer zooplankton is abundant and marked with by swarming cladoceran patches, namely Evadne spinifera and E. tergestina and abundance of Centropages kroyeri, Acartia clausi, A. latisetosa and exotic introduced species Labidocera pavo. Early autumn, advanced stages of decapod larvae, (Zoe and Megalopes) are very common. Larval stages of stomatopods are also present in few number; whereas larvae of Leucosiidae such as: Ilia nucleus, Phylira globulosa are common during the hot and dry season. Some calanoids appear in high number, namely: Temora stylifera, Paracalanus parvus and Clausocalanus furcatus. The hydro-climate seasonality induces a bimodal annual profile of the plankton similar to that existing in other Levantine regions [9] and the Cilicean Sea. Annual cycle is characterized with a peak in abundance of zooplankton in May after the spring phytoplankton, and a break down of the abundance in summer. This is due may be to the circulation and current system in Iskenderoun Bay. The ingression

of oceanic deep water masses inside the Bay. However the zooplankton community is characterized with low species diversity contrasted with high biomass. It is well known that the Levantine Basin is a the most oligotrophic water body in the Mediterranean, excluding the Nile Delta area and the Iskenderoun Bay, where nutrients input from Seyhan and Ceyhan rivers in the sea. Contribute to high productivity.

# HOW HUMAN FORCINGS AFFECT ECOLOGICAL PROPERTIES OF LARGE PELAGIC FISH IN THE MEDITERRANEAN? HISTORICAL GENETIC CHANGES IN THE OVEREXPLOITED BLUEFIN TUNA ( *THUNNUS THYNNUS*)

M. Landi<sup>1</sup>\*, G. Ferrara<sup>1</sup>, M. Sella<sup>1</sup>, L. Orsi Relini<sup>2</sup>, G. Relini<sup>2</sup>, C. Piccinetti<sup>1</sup>, F. Tinti<sup>1</sup> <sup>1</sup>University of Bologna, Dept Experimental Evolutionary Biology, Bologna, Italy - m.landi@unibo.it <sup>2</sup>University of Genoa, DIPTERIS, Genoa, Italy

# Abstract

Based on a comparative analysis of genetic diversity at 7 microsatellite loci in ancient (archived skeletal specimens) and modern (freshly collected individuals) samples of *Thunnus thynnus* collected in the Mediterranean Sea, we assessed temporal changes and spatial variation of genetic and demographic (genetically-related) features in the overexploited Mediterranean stock of bluefin tuna. From the analysis of more than 300 individuals, a temporal stability of genetic diversity over about 90 years but significant changes in the genetic structure of the stock were achieved. Such results argue for an evidence that, in the Mediterranean, stock overexploitation has not yet corrupted the genetic potential of such living resource and that bluefin tunas are not fully pannicite.

Keywords : Biotechnologies, Conservation, Genetics, Fisheries, Western Mediterranean.

The estimation of genetic variability and the identification of temporal variation in genetic structure of a population is crucial for the conservation of endangered species undergoing dramatic ecological and demographic changes linked to strong overexploitation [1], such as the Atlantic bluefin tuna *Thunnus thynnus*. Fishery is having strong impact on bluefin tuna population abundance and serious consequences on genetic potential of Mediterranean populations may occur [2].

Tab. 1. Genetic variation at the 7 microsatellite loci in ancient and modern Mediterranean samples of *Thunnus thynnus*. A<sub>r</sub>, allelic richness; H<sub>o</sub>, observed heterozygosity; H<sub>e</sub>, unbiased expected heterozygosity; P, Hardy-Weinberg equilibrium test: \*\* P <0.01, \* P <0.05. <sup>a</sup> For each genetic diversity estimator, the statistical difference between ancient and modern bluefin tunas was tested by one-way ANOVA (not significant) and pairwise Chi<sup>2</sup> (not significant)

Owing to i) the general interest in assessing and predict historical changes in fish communities of the Southern European Seas (henceforth SES) to develop ecological and socio-economic models for an integrated management of the marine ecosystems at the regional scale [3], ii) the specific interest for the conservation, ownership and sustainable management of bluefin tuna stocks [2], it becomes critical to resolve structure and dynamics of the SES populations of this large pelagic fish over time.

A molecular approach becomes fundamental to unlock ancient genetic features of populations and for genetic comparisons to modern populations. This can be decisive for assessing genetic and demographic changes in fishery resources overexploited since decades [4, 5]. The demonstration of loss of genetic variability in wild populations is empirically limited by lack of samples before heavy overexploitation started. Although rare, archived samples represent a unique opportunity to access ancient populations [4, 5]. In the framework of an Italian PRIN 2005-2007 research project (TUNING; http://:www.dipartimentobiologia.it/tuning/index.htm) and of the EU-FP6 2006-2010 Integrated Project (SESAME), a comparative analyses of genetic diversity at 7 microsatellite loci in ancient (skeletal records collected from 1911 to 1926 by Massimo Sella) and modern samples (from fishing vessels) of Mediterranean bluefin tunas have been carried out to infer historical changes of genetic and demographic properties.

The analysis of about 300 bluefin tunas revealed a temporal stability of genetic diversity over about 90 years and more than 50 years of industrial exploitation of the stock (Table 1). On the other hand, significant changes in the genetic structure of Central Mediterranean bluefin tuna samples were detected. In addition, the results of such work argue for an evidence that, in the Mediterranean, stock overexploitation has not yet corrupted the genetic potential of such relevant fishery resource and that bluefin tunas are not fully pannictic [2, 6]. In general, the results did outcome from the analysis of temporal genetic variation in fishery resources that include comparisons between ancient unexploited and modern (over)exploited populations can really contribute to assess the conservation of fish stocks, based on quantitative genetic data sets that were obtained independently from fishery and tagging data.

# SOME BIOLOGICAL ASPECTS OF SERRANUS HEPATUS L., 1758 IN IZMIR BAY (AEGEAN SEA, TURKEY)

Semih Leblebici, Sercan Yapici \*, Okan Ozaydin and Zafer Tosunoglu

Ege University, Faculty of Fisheries, 35100, Bornova-Izmir, Turkey - syapici@mail.ege.edu.tr

# Abstract

A total of 2304 specimens of brown comber *Serranus hepatus* (Linnaeus, 1758) were collected with bottom trawl from Izmir Bay (Aegean Sea, Turkey) between January 2005-December 2005, monthly. Total length (TL) and weight (W) ranged from 4.4 to 11.7 cm and 1.16 to 25.49 g, respectively. The estimated length-weight relationship for all fishes had a slope of 2.8896. *Keywords : Aegean Sea, Teleostei.* 

### Introduction

Brown comber, *Serranus hepatus* (Linnaeus, 1758), is a small, demersal serranid species distributed in coastal waters, occurring along the coasts of the Eastern Atlantic Ocean from Portugal to the Canaries and the Mediterranean Sea [1]. It is common in *Posidonia* beds, sandy and muddy bottoms down to 100 m depths [2]. Because of its small size, *S. hepatus* has not commercial value in Turkish fisheries. This paper presents some biological parameters of brown comber caught in Izmir Bay.

#### Materials and methods

Samples were monthly obtained from three stations (station I 38° 28'N 26° 46'E; station II 38° 33'N 26° 43' E; station III 38° 32'N 26° 40' E) by R/V Egesüf (27 m LOA, 500 hp) between January 2005 to December 2005 around Uzunada Island, in the western part of Izmir Bay (Figure 1). In the samplings, a traditional bottom trawl net was used to capture small size fish species by a 24 mm strecthed mesh size codend. The towing duration was 30 min for all hauls and the average towing speed was 2.4 knots (ranging between 2.0 and 2.8 knots). Length-weight relationship (W=a \* L <sup>b</sup>) and length-weight frequencies of samples were calculated based on 2304 individuals. Total and standard lengths were measured to the nearest mm and weights were taken using a digital balance with a precision of 0.01 g.

Fig. 1. Izmir Bay and bottom trawl sampling stations.

Results and discussion

The depth range of the sampling stations varied from 40 to 50 m, 55 to 65 m and 15 to 50 m, respectively. Stations I and II have silt sediment, and station III sandy bottom type with dense *Posidonia* meadows.

The total length of all measured specimens ranged from 4.4 to 11.7 cm (9,5  $\pm$  0.8 cm, mean  $\pm$  SD) and weight from 1.16 to 25.49 g (13.42  $\pm$  3.2 g, mean  $\pm$  SD). The length and weight frequencies exhibited peaks between 9.00-10.50 cm (68 %) and 12.00-16.00 g (46 %), respectively (Figure 2).

There was a strong relationship between total length and standard length:  $SL = 0.8625 \text{ TL} - 0.4723 \text{ (n} = 259, r^2 = 0.971).$ 

Length-weight relationship was W = 0.0196 TL<sup>2.8896</sup> (n = 2304, r<sup>2</sup> = 0.8937, SE of slope = 0.020). Negative allometric growth was observed for all fish (t-test, t = 0.54 <tool{0.05}, n > 500 = 1.65). The value of parameter a was lower than that in Iberian Peninsula and Balearic Sea, Spain (a = 0.0044, n = 22, r<sup>2</sup> = 0.928) [3] and Alexandria, Egypt (a = 0.025, n = 153, r<sup>2</sup> = 0.948) [4], and higher than those in Adriatic (a = 0.0112, n =

87,  $r^2 = 0.977$ ) [5] and Thracian Sea, Greece (a = 0.0113, n = 1739,  $r^2 = 0.960$ ) [6]. Our parameter *b* value was lower than those in other areas, *b* = 3.5681 [3], *b* = 3.123 [5] and *b* = 3.157 except for that in Alexandria waters, Egypt (*b* = 2.84) [6]. This study was supported by Ege University, Scientific Research Project Foundation.

# Abstract

The fauna of 5 coastal hypersaline lakes of the Crimea has been studied for the first time. Species assemblages were differently structured according to the season and the lake. *Artemia* sp. was the most common organism, but the population of the Koyashskoye lake is probably a species that is different from those occurring in the other lakes. The species assemblage of the Feodosiyskoye lake was surprisingly dominated by *Onychodiaptomus* sp., a taxon endemic to North America.

Keywords : Black Sea, Zooplankton, Salinity.

Some salt lakes of the Crimea have already been considered for studies on Artemia sp., which is present with both parthenogenetic and bisexual populations in this region [1; 2]. But a complete survey of the Crimean salt-lake fauna has never been carried out. A total of 55 samples were collected from April 2004 to September 2006 (in different seasons) in 5 different salt lakes along the Black Sea coast. The organisms collected were grouped according to 35 categories (11 at the level of species orgenus). The lowest number of categories (6) was typical of the most saline lake (Koyashskoye, 160-300psu). The highest number of categories (20) was found in the only lake (the Bakalskoye) which was affected by a marine ingression during the study period. Artemia sp. was the only ubiquitous organism (at least as eggs, it has been found in all the lakes). On the contrary Mesopodopsis slabberi (Mysidacea), and Acartia tonsa (Calanoida) were present in only one lake. The communities of coastal salt lakes were dominated by Artemia during summer and by Cletocamptus sp. (Harpacticoida) or Moina salina (Cladocera) during spring, in different lakes. The Feodosiyskoye lake had not a stable population of Artemia (only eggs were found) and it was dominated by Onychodiaptomus sp. (Calanoida) during summer, and Brachionus sp. (Rotifera) during spring. It was noted that the plankton showed a benthos-derived composition related to the increase of water salinity. This is probably affected either by the sampling (the reduced water depth deriving from a decrease of water volume forces the net to collect closer to the bottom), and from the floating facilitation that organisms receive from the more salty (and more dense) water. The low number of species of lake Koyashskoye was attributed to its extremely high salinity (never below 160psu in all the study period). The lake was never considered in previous studies, and the Artemia which has been found was never observed before. The Koyashkoye Artemia is evidently dissimilar from all the other Artemia that have been reported from other Crimean lakes [3; 2] and even according our records in the present survey. The Koyashskoye Artemia population is bisexual (contrary to the other populations of the present study, which were parthenogenetic). Many morphological characters [4; 5] allowed us to consider the Koyashskoye population as belonging to a species different from other Crimean Artemia. The most evident differences are the long abdomen, the absence of the furca, and the exceptionally large antennae (A1) of the males. It is known that the morphology of Artemia salina is variable and affected by salinity [6], but the morphology of the Kojashskoye population probably deserves a deepest study.

The typical species composition of the Feodosiyskoye lake allowed us toconsider it as not completely marine derived. Although it is located at 50-70m from the sea-shore, its salinity is probably more affected by continental supplies. The presence of *Branchinella* and *Artemia* eggs suggests that both these anostracans (which were not found as adults), could represent an allochthonous contamination. Otherwise they probably occurred as active organisms in the past (and they probably will occur in the future) under environmental conditions different from the present ones. In the same lake, the Calanoida (which dominated alternatively with Rotifera) were recognised as *Onychodiaptomus* sp., a genus endemic to North America [7] at the present state of knowledge. Feodosiyskoye lake is surrounded by a densely populated area, and a role played by man is the main suspect to explain the presence of a *taxon* never recorded outside of its native area until now. This adds elements to the discussion about the Black Sea area as a sink site for allochthonous bio-invaders [8].

# DETERMINATION OF FISH COMPOSITIONS AT ARTIFICIAL REEFS DEPLOYED THREE DIFFERENT DEPTHS (20, 30 AND 40M) IN AEGEAN SEA COAST OF TURKEY: PRELIMINARY RESULTS

A. Lok \*, B. Gül, A. Ulaş, C. Metin, O. Düzbastilar, A. Çakaloz, A. Özgül Ege University, Faculty of Fisheries, Bornova, 35100, Izmir, TURKEY - altan.lok@ege.edu.tr

## Abstract

Studies aimed at determination of fish assemblages around artificial reefs were conducted mainly 10-25m depths in Mediterranean and Aegean Sea. The goals of this study are determine and compare of fish compositions around artificial reefs which deployed 20, 30 and 40m depths. Underwater visual census technique was used to determine fish species and to record number of individuals. The result shows that fish species number and abundance around artificial reef sets are decrease by increase of depth. *Keywords : Artificial Reefs, Biodiversity, Aegean Sea.* 

## Introduction

Artificial reef researches in Turkey were started at 1991 and mainly took place in the Aegean Sea Coast [1]. Coastal municipalities and fisheries cooperatives showed intensive interest to artificial reef projects after 1995. Ten artificial reef projects were carried out by coastal municipalities between 1995 and 2002. But artificial reef studies improved very slowly during this period.

Monitoring and assessment of artificial reefs to evaluate their effectiveness had gained great importance in recent years [2]. Researches on artificial reefs also increased in Turkey after 2002. The most of the studies related to biological aspects. Limited studies were made on engineering aspects such as stability of reefs [3], effects of waves and currents.

Aim of the present study is to determine and to compare the fish composition around artificial reefs which deployed three different depths (20m, 30m and 40m).

#### Materials and Methods

Gümüldür is a coastal village located in Gulf of Kuşadasi, 60km south of Izmir. Sea bottom between 0-5m is sandy; 5-15m is covered by P. oceanica meadows and than muddy zone extending to deeper areas. Concrete culverts which have 30cm diameter and 105cm long were used to artificial reef unit. Six units, for construct a reef set, were formed like a pyramid (3-2-1). Nine pyramid shape reef sets were constructed and three sets were deployed at each depth (20, 30 and 40m) in April 2006 (Figure 1). The distance between sets was approximately 25m. Underwater visual census technique was used to determine fish species richness and abundance. Three artificial reef sets in each depth were visited during to all observations. Fish species were determined and number of individuals counted. Statistical analyzes consists of 20 and 30 meters, because of few number of species and low abundance records of 40 meters were excluded. Species number and abundance data were compared with One Way ANOVA using SPSS 11.0. Jaccard similarity index was used to measure of the similarity of the structure of fish communities at artificial reef sets in three different depths.

Tab. 1. Frequency of occurrence (%) of species in relation to depths.

| Species               | 20m  | 30m  | 40 m   |
|-----------------------|------|------|--------|
| Conger conger         |      |      | 33.3   |
| Serranus cabrilla     | 100  | 100  | 100    |
| Ephinephelus costae   | 16.7 |      |        |
| Mullus barbatus       |      | 16.7 |        |
| Diplodus annularis    | 16.7 | 16.7 |        |
| Chromis chromis       | 83.3 | 16.7 |        |
| Gobius niger          | 16.7 | 16.7 |        |
| Parablennius rouxi    | 100  | 66.7 |        |
| Scorpaena porcus      | 16.7 |      |        |
| Scorpaena scrofa      | 33.3 | 16.7 |        |
| Balistes carolinensis | 16.7 | 402  | 0.0100 |
| Total no. of species  | 9    | 7    | 2      |

Results

A total of 11 species (126 fishes) belonging to 9 families were recorded in 6 census during September-October 2006 period (Table 1).

The three reef sets in 20m were recorded 9 species (87 fishes), 7 species (28 fishes) at 30m and 2 species (11 fishes) at 40m. *S. cabrilla* was only species which recorded all depths and it was recorded all observations (Table 1). *C. chromis* at 20m and *S. cabrilla* at 30m and 40m were dominant species.

There were no statistically significant differences in fish abundance (p >0.05), however, species richness differ significantly between 20 and 30 meters (p <0.05). The values of Jaccard index between depths were found 50% between 20m and 30m, 10% between 20m and 40m, 14.3% between 30m and 40m.

# Discussion

These preliminary results show that there is a major change in fish composition around 40m depth. But, long-term observations should necessary to make this kind of suggestion. The reason for the absence of many species in this depth may be lack of critical resources such as food. Depth also affects temperature. Thermoclines can be barrier to some organisms [4]. To consider of this kind of result will be important to success of artificial reef projects.

## Abstract

Maintaining species diversity has been recognised internationally as a priority for sustainable fisheries. An appropriate indicator of fish diversity trends resulting from fishing exploitation is still lacking. To shed light on underlying mechanisms of fish communities' responses to fisheries in terms of biodiversity, we analysed predator-prey interactions within demersal fish communities. In particular, we contrasted size-based fish diversity patterns with the spatial distribution of commercial fishing in the Central Tyrrhenian Sea. *Keywords : Biodiversity, Demersal, Fisheries, Trophic Relations, Tyrrhenian Sea.* 

Following the emphasis given to biodiversity within international agreements for sustainable development (Rio 1992 CBD, Jakarta Convention) and in line with the recent shift towards an ecosystem-based approach to fisheries management (EAFM), biodiversity protection has been adopted as a specific objective within fisheries policies (FAO Code of Conduct For Responsible Fisheries, 1995). Fisheries researchers are asked to provide indicators of ecosystem health to underpin such ecosystem-based management approaches [1]; however the way that fish assemblages respond to fishing exploitation in terms of diversity remains poorly understood available studies show contradictory or inconclusive results [e.g. 2]. As a consequence, indicators of fish biodiversity are considered unsatisfactory metrics for management purposes [3], raising concerns regarding the adequacy of scientific support to these political commitments [4]. In particular, the Mediterranean basin, where phenomena such as climate change-driven tropicalization enhanced by Lessepsian immigrations of southern species, are compounded with over-harvesting effects, understanding biodiversity changes represents a crucial challenge for future environmental protection and human activities management.

We argue that an ecologically meaningful approach to the study of fisheries-driven species diversity changes is required. In this view we suggest that diversity should not be measured considering fish assemblages as a whole, as commonly done, but should instead be estimated within each trophic level present within the fish community, since diversity (i.e. species evenness) is known to be related to competition/predation interactions [5]. In marine ecosystems, trophic level scales with size and fishing is also a size-selective activity, generally targeting larger individuals. Thus fishing disturbance, while affecting the size distribution of fish communities, is also affecting their trophic structure [6]. Based on all these observations, we propose that an appropriate indicator of fishing effects on fish species diversity should be size-based.

The analysis of the distribution of biomass or diversity versus individual body size (size-spectra) provides a method to detect the differential response of large versus small size classes to fishing disturbance [7]. It has been frequently observed in strongly exploited marine communities that a reduction of top-predators, compounded with a positive selection induced by fisheries for smaller faster growing species, has triggered an increase in abundance of smaller fish. Based on Huston's Dynamic Equilibrium Model [5], we hypothesized that a further consequence of this is that a few dominant prey species, no longer kept under control by predatory pressure, expand at the expense of other species sharing the same resource, causing diversity to decline within this size-range. Our previous results from a case-study based in the North Sea [8] suggest that over-fishing of large piscivorous fish has indirectly caused a decline of species evenness of smaller forage fish through a predatory-release mechanism. However, the particular character of the Mediterranean basin, where an oligotrophic regime is expected to result in stronger bottom-up limitation than seen in the highly productive North Sea waters and stronger competitive interactions [9]. The fish community spans a smaller size-range, thus showing a lower degree of piscivory than northern regions, and harvesting strategies are more prevalently mixed fisheries. Therefore, different mechanisms are to be expected and call for specific testing of our hypothesis in the area. We present here diversity and biomass size-spectra of demersal assemblages from the Central Tyrrhenian sea, sampled during routine trawl surveys from 1985-2005 (GRUND) and 1994-2005 (MEDITS) (for details see [9]). To detect fishing effects on these communities we compared the diversity patterns of fish assemblages from an area that suffered intense commercial fishing exploitation with those from an area where disturbance has been less intense. Furthermore, in an attempt to disentangle changes in smaller size-classes due to predatory release effects from fisheries-driven positive selection of smaller fast-reproducing individuals, we estimated the predator-prey size ratio for piscivores, based on stomach-content analyses, and explored life-history characteristics of the component of the fish assemblage at the lower end of the size spectrum.

# CAULERPA RACEMOSA ON THE MONTENEGRIAN COAST

Vesna Macić \* and Slavica Kašćelan

Institute of marine biology; P. Box 69; 85330 Kotor; Montenegro - vmacic@ibmk.org

# Abstract

The invasive algae *Caulerpa racemosa* was first recorded from the Montenegrian coast in 2004, and eradication was attempted. Our survey identified three new localities for the alga in 2005, and two more in 2006. *Keywords : Adriatic Sea, Algae.* 

## Introduction

Since beginning of the 1990s the invasive variety *C. racemosa* var. *cylindracea* has been recorded on many localities on the coast of 11 countries around the Mediterranean [1] and the first report for the Adriatic Sea was in 2000 on the Pakleni archipelago (Croatia). [2] The aim of this work is to present the data about its spread along Montenegrian part of the Adriatic coast.

#### Materials and methods

The field research was done by SCUBA diving on 52 localities between 2004 and 2006. Collected material was conserved in 4% formaldehyde solution and photo documentation was done as well.

## Results and discussion

The first record of Caulerpa racemosa for the coast of Montenegro was in August 2004 near Budva (Fig. 1) and in that time algae was growing on 3m depth covering 2m<sup>2</sup> of dead matte substrate. Regarding it was the small patch and in that time the only one known on the Montenegrin coast attempt of eradication was carried out. Eradication was done in September by manual collecting of algae, as much as possible and by covering the colony with black pvc foil. Also, before placing the pvc foil the solution of copper-sulphate and lime were sprinkled. [3] Although during the winter and spring colony of Caulerpa racemosa almost disappeared, in summer 2005 reappearance of algae occurred. The local diving club repeated eradication process in autumn 2005 but the algae is growing still now. On the first known location now we have the oldest patch with 11m in diameter and few smaller patches around. Since first record three new localities were found in 2005 and two localities in 2006. All together six populations on the Montenegrian coast create around 864m<sup>2</sup> of covered and 3,8 ha of affected area with 560m of affected coastline.

Fig. 1. Localities were *Caulerpa racemosa* was found (1. Budva; 2. Island Mala Gospa; 3. Žanjice; 4. Mirište; 5. Cove Veslo and 6. Budva-2).

It should be noted that we registered reticulated depigmented thalii of fertile algae in October 2006 and by microscope observation we noted male and female gametes, but further analysis of gamete conjugations were not done. Also it should be noted that length of fronds on all localities in October 2006 was significantly shorter than last year in same period.

#### Conclusion

Although *Caulerpa racemosa* is spreading on the Montenegrian coast with threat to have a significant impact to autochthonous biocenoses we should say that a few positive outputs emerged. Mapping of *Caulerpa* in this year was project funded by three Ministries together, campaign for public awareness probably helped to reduce man-made dissemination and the most important output, interest for protection of marine environment in general is increased.

# SPECIES ABUNDANCES OBSERVED IN AN ICHTYOPLANKTONIC ASSEMBLAGE IN THE GULF OF IERISSOS (THRACEAN SEA, GREECE)

Valeria Mamouridis \* and Thanos Kallianiotis

NAGREF, Fisheries Research Institute, 64007 Nea Peramos, Kavala, Greece, - fri@otenet.gr - fri@otenet.gr

# Abstract

A series of fish larvae species from the Ierissos Gulf were collected using a bongo-net during three expeditions, in June, September and November 2004. After identifying and analysing the samples, seasonal variations of species characterizing the ichtyoplanktonic assemblages were found. The European anchovy (*Engraulis encrasicolus*) was the dominant species in June and September. *Keywords : Ichthyoplankton, Aegean Sea, Biodiversity.* 

## Introduction

The coastal marine ecosystem of Strymonikos Gulf, is one of the richest fisheries grounds in Greece and major source of income for the local fishermen. The area of Ierissos, a small bay in the eastern side of Strymonicos, is known for its richness in ichtyoplankton [1] due to the local rivers inflow and the strong influence of Black sea water [2]. Trawl fishing is banned in the area of Ierissos Gulf, creating good conditions for the local spawning and nursery grounds. The main objective of this work is to identify characteristic species of the ichtyoplanktonic assemblage and its seasonal changes in the Ierissos Gulf.

## Material and methods

Specimens were collected with a bongo-net (mesh size: 250 and 500  $\mu$ m). Samplings took place in 2004 during three daily surveys carried out in June, September and November. A flowmeter determined the water volume filtered. The sampling grid consisted of 14 stations placed in transects perpendicular to the coast. The larvae were identified to the lowest possible taxonomic level, counted and measured. Maximum tow depth and volume of water filtered were used to standardize abundance in number of larvae per 10 m<sup>2</sup> [3]. PRIMER v5 software [4] was used for the data analysis as well as STATISTICA v7 statistical software. A matrix of taxa abundance per station was constructed and the Bray-Curtis similarity matrix was generated which was subjected to cluster analysis (using forth root transformation in order to give weight to less abundant species). The characteristic species in each month were determined with SIMPER, using forth root transformation (species with contributed less than 10% were not considered in the analysis). Furthermore, differentiations between months was tested with ANOSIM (pairwise test). Samples from stations 1, 11, 13 and 14 during the November survey were omitted because they had less than 6 taxa.

#### Results

A total of 2697 larvae were collected and identified. The species characterizing the larval assemblage in each month and their order according to their percentage contribution were: *Engraulis encrasicolus* (23.97% contribution), *Sardinella aurita* (16.71%) and *Serranus hepatus* (15.79%) in June; *E. encrasicolus* (27.44%), *S. hepatus* (20.04%) and *Cepola macrophtalma* (17.76%) in September; and *C. macrophtalma* (26.45%), *Ceratoscopelus maderensis* (20.13%), *E. encrasicolus* (16.10%) and *Sardina pilchardus* (14.13%) in November.

Cluster analysis (Fig. 1) showed an evident similarity of samples within each month and defined two groups: one for June and September (Summer) and another one in November (Autumn). The pairwise test showed a significant dissimilarity between months (June-September: R=0.84; June-November: R=0.84; September-November: R=0.77).

Fig. 1. Dendrogram of similarities (cluster analysis, group-average linkage, fourth root transformation) of the 36 stations sampled in June, September and November in 2004 in Ierissos Gulf.

#### Discussion

The study showed seasonal changes in fish larval assemblage. The main factors for this differentiation were the predominance of E. encrasicolus in June and September, the presence of S. aurita in June and S. pilchardus in November. E. encrasicolus picked in September, in accordance to Koutrakis et al. [1] and had a long-lasting presence of larval stage in the gulf covering almost six months. C. macrophtalma percentage contribution in the assemblage increased by months: in June was 7.84% while in September was 17.76% and in November 26.45%, when it achieved the maximum abundance. S. hepatus was one of the characteristic species of the assemblage during the warm season, and was completely absent in November, as observed by Koutrakis et al. [1]. Species diversity remained constant although its two components, species richness and evenness showed a shift of their relative importance: June was characterized by a larger species richness and a lower equitability, due to the dominance of E. encrasicolus, in contrast to November, when a lower species richness and a more balanced distribution of individuals between all species were found.

# TAXONOMIC AND FUNCTIONAL STRUCTURE OF SESSILE MACROBENTHOS IN THE LAGOON OF VENICE

Agnese Marchini <sup>1</sup> and Anna Occhipinti-Ambrogi <sup>2</sup> \*

<sup>1</sup> DET - Dipartimento di Ecologia del Territorio, Università di Pavia, Via S. Epifanio 14, I-27100 Pavia, Italia

<sup>2</sup> Dipartimento di Biologia, Università di Ferrara, Via L. Borsari 46, I-44100 Ferrara, Italia - occhipin@unipv.it

# Abstract

The sessile benthos colonizing the wooden piles of the lagoon of Venice was sampled in July 2005 in stations characterized by different types of disturbance, in order to investigate the taxonomic and functional structure of the community. The most unexpected result was the high taxonomic richness observed in stations affected by industrial and urban discharges, that could be related to the environmental changes occurring in the lagoon.

Keywords : Adriatic Sea, Lagoons, Zoobenthos.

## Introduction

We present the results of a recent survey on the sessile zoobenthos colonizing artificial hard-bottoms in the lagoon of Venice. This community has been considered a good indicator of environmental change and used in monitoring programs over the last decades [1, 2]. In this study we analyse both taxonomic and functional composition of the community, in the attempt to identify characteristic species and functional traits related to different environmental conditions.

## Materials and Methods

Biological samples were collected in July 2005 in 12 stations, located in the central and northern sub-basins of the lagoon of Venice and selected as representative of different environments: F1, F2 at the continental margin, influenced by freshwater and agriculture discharges; I1, I2 in the industrial area of Marghera, where a refinery complex is located; U1, U2, U3, U4 in the urban canals of Venice; L1, L2, L3, L4 in the typical lagoon context. Sampling methods of the sessile organisms colonizing artificial hard substrates (wooden piles) are described in [2].

Two different matrices were created, i.e. a matrix of taxa  $\times$  stations (average abundance over three replicates), plus a matrix of functional traits  $\times$  stations, calculated according to [3]: (i) seven functional traits were selected and sub-divided into several categories, for example the trait "body form" included the categories "flat", "mound", "erect"; (ii) individual taxa were scored from 0 to 3 for their affinity to each trait category, using a "fuzzy coding" procedure; (iii) for each taxon its relative abundance was multiplied for the trait category scores, that were then summed over all taxa present at each station. Finally, the Bray-Curtis similarity between couples of stations was calculated for both matrices, and non-metric multidimensional scaling (nm-MDS) plots were generated.

### Results and Discussion

A total number of 44 taxa was identified. The most frequent and abundant taxa were: Didemnidae, Ostreidae, *Mytilus galloprovincialis, Pileolaria militaris, Tricellaria inopinata* and *Ventromma halecioides*. The ascidians Didemnidae, probably of exotic origin, showed invasive character, having never been observed with such high frequency and abundance in all the previous surveys. Conversely, species once characteristic and abundant in the lagoon, in July 2005 were collected only in a few stations, suggesting that the zoobenthos is experiencing deep changes in its taxonomic composition.

Taxa richness evidently varied among stations, with minimum values at the two freshwater stations (mean richness:  $5.8 \pm 2.22$ ) and maximum values at the lagoon and industrial stations ( $15.0 \pm 3.02$  and  $15.0 \pm 2.53$ , respectively). Within the group of urban stations (mean richness:  $10.7 \pm 4.81$ ), over 15 taxa were observed in each replicate of U1 and U2. This is in contrast with the observations of past studies: all the urban stations in the 1990s were characterized by very simplified communities, with only a few opportunistic species [1]. Such a high taxonomic richness in stations affected by industrial and urban discharges was unexpected. The contribution of non-indigenous species has to be taken into account: invasive organisms like the bryozoan *T. inopinata* and the ascidians Didemnidae, being able to colonize even industrial and urban stations, have locally increased the taxonomic richness, but their presence is a symptom of other types of disturbance affecting the lagoon of Venice.

Fig. 1 shows the results of similarity analysis: 4 groups of stations can be detected both from the taxonomic (fig. 1a) and functional (fig. 1b) point of view. However, the constant presence of a few opportunistic species in

most samples influences the results of the similarity analysis: the disturbed urban and industrial stations are no longer clearly separated from the more pristine lagoon stations, as in the past [1].

The urban stations, although being geographically close and having a relatively similar taxonomic composition (fig. 1a), display high functional dissimilarity within themselves and among other groups (fig. 1b), showing an unpredictable pattern. On the contrary, the most characteristic community is observed in stations F1 and F2, which present a set of species with peculiar traits (e.g. erect form, low protection, asexual reproduction by budding).

The environmental changes occurring in the lagoon of Venice, in particular the lowered nutrient discharge from the drainage basin and the increased frequency of the "high water" events, could be responsible for the reduction in differences of sessile benthic communities within the lagoon.

Fig. 1. Similarity analysis: nmMDS plots obtained from the taxa x stations matrix (a) and functional traits x stations matrix (b).

# TAILLE À LA MATURITÉ SEXUELLE DE *SQUALUS BLAINVILLEI* (RISSO, 1826) DU GOLFE DE GABÈS (TUNISIE)

Sondes Marouani<sup>1</sup>\*, Mohamed Nejmeddine Bradai<sup>1</sup> and Abderrahmen Bouain<sup>2</sup>

<sup>1</sup> Institut National des Sciences et Technologies de la Mer (Centre de Sfax) BP. 1035- 3018 Sfax, Tunisie - sondesmarouani@yahoo.fr <sup>2</sup> Faculté des Sciences de Sfax BP. 802 - 3018 Sfax, Tunisie

# Résumé

Dans le golfe de Gabès (côtes sud-est de la Tunisie), la maturité sexuelle de l'aiguillat coq, *Squalus blainvillei*, s'installe chez les mâles et les femelles respectivement à 52 et à 62 cm.

Mots clès : Gulf Of Gabes, Fishes, Reproduction.

## Introduction

*Squalus blainvillei*, est un requin à affinité atlanto-méditerranéenne, se rencontrant sur les deux versants du cadre maritime tunisien [1, 2]. Les études se rapportant à sa biologie ont concerné principalement les populations de la Méditerranée occidentale et centrale [3, 4]. Dans la Méditerranée orientale, les informations concernant sa biologie sont limitées [5, 6]. Dans ce travail, nous estimons la taille à la maturité sexuelle du *S. blainvillei* dans le golfe de Gabès.

#### Matériel et méthodes

La présente étude a porté sur 152 individus (81 femelles, 71 mâles) ayant une longueur totale allant de 34 à 100 cm et provenant d'un échantillonnage étalé sur une année (mai 2004-mai 2005) dans le golfe de Gabès. Les individus ont été classés en trois catégories (juvéniles, subadultes et adultes) selon les critères suggérés par Stehmann [7]. Pour les mâles, la taille de la première maturité sexuelle a été estimée par le suivi de la croissance relative des ptérygopodes (Lpty.) par rapport à la longueur totale (LT). Pour les deux sexes, la taille de la première maturité sexuelle est donnée par le calcul de la proportion des matures par classe de taille qui sera ajustée grâce à un logiciel FSAS [8]. La taille de la première maturité sexuelle est la taille à laquelle 50 % de la population sont matures.

#### Résultats et discussion

La croissance relative des ptérygopodes en fonction de la taille révèle la présence de trois groupes.

Fig. 1. Evolution du pourcentage des femelles et des mâles matures en fonction de la LT chez *S. blainvillei.* 

Les individus dont LT est inférieure à 38 cm présentent des ptérygopodes courts et flexibles. Les individus ayant une LT comprise entre 38 et 56 cm

ayant des ptérygopodes calcifiés. A partir de LT supérieure à 56 cm tous les individus possèdent des ptérygopodes très rigides.

La taille à laquelle 50 % des mâles sont matures est égale à 52 cm (Fig.1). Tous les mâles ayant une LT supérieure à 59 cm sont matures. Ces résultats corroborent ceux de Sion et al. [6] dans les eaux grecques.

La taille à laquelle 50 % des femelles sont matures est égale à 62 cm (Fig.1). A partir de 70 cm, toutes les femelles sont matures. Les différents résultats obtenus par divers auteurs en Méditerranée [4, 6] montrent que la taille de la première maturité sexuelle des femelles du *S. blainvillei* est de l'ordre de 60 cm. Ces résultats reflèteraient que la LT à la maturité de cette espèce ne diffère pas en fonction des secteurs maritimes méditerranéens.

# FIRST RECORDS OF THE RARE STARFISH *MARGINASTER CAPREENSIS* (GASCO, 1876) (ECHINODERMATA, ASTEROIDEA, PORANIIDAE) IN THE STRAIT OF SICILY AND FURTHER INFORMATION ON ITS RECENT FINDING IN THE IONIAN SEA

Daniela Massi <sup>1</sup>, Paola Rinelli <sup>2</sup> and Francesco Mastrototaro <sup>3</sup> \* <sup>1</sup> IAMC-CNR - Mazara del Vallo, Trapani, Italy <sup>2</sup> IAMC-CNR - Messina, Spianata S. Raineri, 86 - 98122 Messina, Italy <sup>3</sup> Department of Zoology, University of Bari, Bari, Italy - aprofeta@unime.it

# Abstract

First records of the rare starfish *Marginaster capreensis* (Echinodermata: Poraniidae) for the Strait of Sicily are reported. Two specimens were collected in 2004 at 87m and 136m depth on the off-shore African shelf. Detailed information on the first specimen, recently reported in literature from the Ionian Sea, is also given. It was collected in 2000 at 707-742 m depth off the Corfù island (Eastern Ionian). *Keywords : Echinodermata, Sicilian Channel, Ionian Sea, Eastern Mediterranean, Western Mediterranean.* 

*Marginaster capreensis* (Gasco, 1876) is a small sized starfish living in a wide depth range (between 50 and 2500m) [1]. It is considered as "one of the rarity of the Mediterranean fauna" [1], where it was found in the Gulf of Naples (Tyrrhenian Sea), between 70 and 84m [2], in the Southern Aegean Sea (597m) [3] and in the Levant Sea (315m) [1]. Recently the species was reported on the bathyal bottoms of the Eastern Ionian Sea [4]. The two specimens of *M. capreensis* from the Strait of Sicily were collected during the 2004 trawl survey (Italian GRUND program). The specimen from the Ionian Sea was collected during a campaign carried out within the Italian-Greek INTERREG program [4]. The main information on catch data and biometries of the two individuals found in the Strait of Sicily and of the specimen from Ionian Sea [4] are reported in Table 1.

Tab. 1. Main information related to the findings of *M. capreensis*. R and r according to [1].

| Area          | Date       | Appr. Lat. | Appr. Lon. | Depth (m) | Diameter (mm) | R/r | Weight (g) |
|---------------|------------|------------|------------|-----------|---------------|-----|------------|
| Sicily Strait | 19/09/2004 | 34°30.00'  | 12°49.00'  | 87        | 23            | 1.2 | 1.15 (wet) |
| Sicily Strait | 12/10/2004 | 34°21.50°  | 13°23.50'  | 135-137   | 21            | 1.2 | 1.15 (wet) |
| Ionian Sea    | 22/7/2000  | 39°18.00'  | 19°55.00'  | 707-742   | 25            | 1.3 | 0.41 (drv) |

Biology of this species is unknown and the information on biogeographical distribution is scanty both in Eastern Atlantic and in Mediterranean. Including the new records from the Strait of Sicily, only eight individuals were reported for the Mediterranean. The specimen from the Eastern Ionian Sea was the deepest record of the Mediterranean. According to available data, the species in the Eastern basin seems to prefer habitats deeper than those of the Tyrrhenian Sea and the Strait of Sicily.

## Abstract

We analysed the relationships between climatic indices, population parameters (abundance, recruitment and spawning stock) and catchability of hake and red shrimp in the trawl fishery off Balearic Islands (western Mediterranean). *Keywords : Demersal, Recruitment, Fisheries, Hydrography, Balear Islands.* 

As in other areas of the western Mediterranean, the hake (*Merluccius merluccius*) and the red shrimp (*Aristeus antennatus*), two target species for the trawl fishery off Balearic Islands, exhibited inter-annual fluctuations in landings during the last decades. Within the IDEA project (www.ba.ieo.es/idea) we have studied relationships between some climatic indices and parental stock, recruitment and accessibility to trawl fishery for these two species.

Available annual catch per unit effort (CPUE; as kg/HP) data series for the period 1960-2004 were used as a proxy for the abundance of these species. Their population parameters recruitment (R) and spawning stock biomass (SSB) could be obtained (for 1980-2004 for hake and for 1992-2004 for red shrimp) from assessments developed within the framework of the General Fisheries Commission for the Mediterranean. As environmental data, the meso-scale IDEA index was used [1]: higher and lower values indicate minor and major presence of WIW for the Ibiza channel, the following spring respectively, which determine the spring-summer oceanographic scenarios around the Balearic Islands. Other large-scale climate indices, North Atlantic Oscillation (NAO) and Mediterranean Oscillation (MO). were also used. These indices could determine the climatic conditions where Mediterranean intermediate waters which could affect hake and red shrimp (WIW and LIW, respectively) are formed. Data series of environmental variables (NAO, MO and IDEA indices) and population dynamics parameters for hake and red shrimp (CPUE, R and SSB) used are shown in Figure 1. To analyse possible links between large- and meso-scale indices with the population dynamics of both species, two approaches have been used: (i) stock-recruitment relationships (SRR) from Ricker and Beverton-Holt models, by incorporating sequentially environment factors; (ii) generalized additive modelling, both classical general and threshold non-additive models were considered, which simulate an abrupt change in explicative variables across different phases (time periods or climatic index values). The strategy of analysis has been to consider the influence of two climatic indices for each species: the regional IDEA index and one global index (NAO for hake and MO for red shrimp). MO index values were considered with a -5 years time lag, because available information estimates that LIW requires up to 5-6 years for reaching the western basin. To avoid the influence of trends in CPUE, R and SSB, these population parameters have been conveniently detrended.

A negative significant relationship between NAO index and abundance (modelled by CPUE) and SSB of hake were found, being this effect more evident during the period 1960-1980. Results also suggest that density-dependent and environmental factors affect its R, both SSB and IDEA index improving our ability to simulate R from SRR Ricker and GAM formulations. The best model for R was obtained from the negative effect of SSB, influenced by NAO index, and IDEA index during 1980-1995. For red shrimp, a positive effect of the global MO index on its abundance and SSB was detected. Results also suggest that density-dependent and environmental factors affect R of this species. A direct positive effect of SSB and negative effect of IDEA index on R have been detected, while MO index also affects R, but indirectly through SSB.

The results indicate that macro and meso-scale climate regimes can influence the population dynamics of hake and red shrimp around the Balearic Islands. Specially for recruitment, which seems to be enhanced during low NAO and IDEA indices periods, when colder-than-normal winters, producing high generation of cold Winter Intermediate Waters in the Gulf of Lions, which flow southwards and reach the Balearic Islands channels in spring, increasing the productivity in the area. This oceanographic scenario could also be favourable to the distribution of hake on the fishing grounds where trawl fleet target to this species, increasing its accessibility to the fishery. Both spawning stock and abundance of red shrimp seems to be also enhanced by high MO index periods, which could reflect the major presence of the saline and warm Levantine Intermediate Waters (LIW) in the study area, which extends over the fishing grounds of this species.

These proposed interactions between external and internal variables on hake and red shrimp populations can be useful to assess and manage these important demersal resources in the Balearic Islands: (i) allowing the identification of reliable environmental indices and their integration into stock assessment models; (ii) and enhancing our ability for recruitment forecasting.

Fig. 1. Data series of environmental variables (NAO, MO and IDEA indices, represented by three years running averaged) and population dynamics (CPUE: catch per unit effort; R: recruitment; SSB: spawning stock biomass) of hake and red shrimp in the Balearic Islands used in this study.

# Résumé

Dans ce travail, nous fournissons de nouvelles données sur la distribution de Zebrus zebrus (Risso, 1826), poisson gobiidé, dans les eaux tunisiennes et mentionnons sa présence, pour la première fois, sur les côtes libyennes. Les caractères méristiques et morphométriques relevés sur les spécimens colletés ont permis de vérifier qu'ils présentent les mêmes caractéristiques que ceux déjà décrits en Méditerranée et en Atlantique.

Mots clès : Biodiversity, Fishes.

## Introduction

La distribution géographique de *Zebrus zebrus* (Risso, 1826), l'unique espèce de son genre, n'est pas clairement délimitée jusqu'à présent [1-2]. En effet, ce poisson est réputé pour son endémisme en Méditerranée [3]. Cependant, Miller [4] a suggéré la présence de ce gobie dans les eaux chaudes de l'Atlantique. Son hypothèse a été par la suite confirmée par la capture de l'espèce sur les côtes sud ouest de l'Espagne [2]. Cette mention a changé radicalement les connaissances sur la distribution géographique de ce gobie et par conséquent son statut de poisson endémique a été remis en cause [5].

En Méditerranée, le gobie zébré a été signalé dans quelques localités des côtes européennes et Est levantines [1, 6]. En 2000, cette espèce a été pêchée dans cinq sites tunisiens qui sont : la lagune de Bizerte, la lagune d'El Biban, le littoral de Tabarka, ainsi que sur les côtes Est allant de Salakta à Sfax [7]. Récemment, la prospection de nouveaux sites en Tunisie à savoir la Lagune Sud de Tunis, la lagune de Lella Hadria (Jerba), Sidi Rais dans le Golfe de Tunis, le littoral de Sousse, nous a permis de capturer des spécimens de ce poisson gobiidé. De même des investigations réalisées dans une lagune libyenne (la lagune de Farawah), située près de la frontière tunisienne, ont révélé la présence de Zebrus zebrus dans ce site.

## Matériel et Méthodes

Les individus collectés de Zebrus zebrus ont été pêchés au moyen d'un mini chalut benthique constitué de deux demi-cercles de 0,85 m de diamètre reliés entre eux par une charnière. Le filet de cet engin est de 0,85 m de large, 4 m de long et 2 mm de maille. En Tunisie, les pêches réalisées sont mensuelles et ont été effectuées durant la période allant de janvier à octobre 2006. En revanche, en Libye, nous avons entrepris une seule campagne de pêche au cours du mois de Mars 2006. Les échantillons ont été identifiés et sexés, en se référant à la forme externe de leurs papilles urogénitales [1]. Sur chaque individu, nous avons prélevé six caractères méristiques (Nombre des rayons de la première nageoire dorsale "D1", nombre des rayons de la deuxième nageoire dorsale "D2", nombre des rayons de la nageoire anale "A", nombre de rayons de la nageoire pectorale "P", nombre des écailles en série longitudinale de l'aisselle de la pectorale jusqu'à la caudale "LL" et nombre de vertèbres "Vert"), et seize caractères morphométriques (Longueur totale "LT", longueur standard "LS", longueur de la tête "T", diamètre de l'oeil "O", distance interorbitaire "IO", hauteur du corps "H", distances prédorsales "PD1 et PD2", distance pelvienne "PV", distance prépectorale "PP", distance préanale "PA", longueur de la base de la première nageoire dorsale "LD1", longueur de la base de la deuxième nageoire dorsale "LD2", longueur de la base de l'anale "LA", longueur de la pectorale "LP").

# Résultats et discussion

Les caractères méristiques relevés sur les spécimens collectés sont D1 : V-VI, D2 : I+10-11, A : I+9-10 et P : 14-16. Le nombre des écailles sur la ligne latérale est compris entre 29 et 32, alors que le nombre des vertèbres est compris entre 26 et 27. Les intervalles de variation de ces caractères sont similaires à ceux cités par Miller [1], Nieto & Alberto [2], Tortonese [6] et Menif [7] sur les côtes Méditerranéennes et Atlantiques.Les données morphométriques des poissons examinés ainsi que leur coloration corporelle, la distribution de leurs papilles sensorielles et de leurs pores céphaliques sont en concordance avec ceux rapportés dans la littérature [1, 6]. Celles-ci confirment qu'il s'agit effectivement de l'espèce *Zebrus zebrus*, poisson gobiidé.Conclusion : Selon ces nouvelles données, nous supposons que *Z. zebrus* est commun le long de toutes les côtes tunisiennes. Quant aux côtes libyennes, d'autres investigations sont nécessaires pour apprécier l'ampleur de la répartition de cette espèce dans cette région.

#### Remerciements

# ALIEN FORAMINIFERS ALONG THE AEGEAN AND SOUTHWESTERN COASTS OF TURKEY

Engin Meric <sup>1</sup>, Niyazi Avsar <sup>2</sup> and Baki Yokes <sup>3</sup> \* <sup>1</sup> Dept. of Molecular Biology and Genetics, Halic University, Istanbul, Turkey <sup>2</sup> Moda Hüseyin Bey Sokak, 15/4 Kadıkoy, Istanbul, Turkey <sup>3</sup> Dept. of Geology, Çukurova University, Adana, Turkey - bakiyokes@turk.net

# Abstract

Many Indo-Pacific originated foraminifer species have been recorded from the Eastern Mediterranean. In the framework of this study, sediment samples collected from various depths in the Aegean and Southwestern Mediterranean coasts of Turkey have been analysed. 26 genera and 32 species of recent benthic foraminifera, commonly known from Indo-Pacific or Atlantic have been identified. 27 of these alien species are observed only on the Turkish coastline in the Mediterranean Sea and 18 of them are new records for the Mediterranean fauna.

Keywords : Aegean Sea, Eastern Mediterranean, Foraminifera, Migrant Species.

Several hundred marine alien species in the Eastern Mediterranean are of Indo-Pacific origin. Alien algae, fishes, molluscs and crustaceans are intensively studied, but little is known about the alien microfauna of the Mediterranean, though some alien foraminiferan species have already been recorded from the Eastern Mediterranean [1, 2]. In the framework of this study, sediment samples from various depths (3-30 m) of the Aegean and southwesternMediterranean coasts of Turkey were analyzed and the composition as well as the distribution of the alien foraminifers were determined.

Twenty-six genera and 32 species of recent alien benthic foraminiferans with various distribution patterns in the eastern Aegean and Mediterranean coasts ofTurkey were recorded. These taxa include; Haddonia spp., Edentostomina cultrata (Brady), Clavulina angularis d'Orbigny, C. cf. multicamerataChapman, Nodopthalmidium antillarum Cushman, Spiroloculina cf .angulata Cushman, S. antillarum d'Orbigny, Schlumbergerina alveoliniformis (Brady), Hauerina diversa Cushman, Quinquemosharrafai Said, Miliolinella cf. hybrida (Terquem), loculinacf. Pseudomassilina reticulata (Heron-Allen and Earland), Pyrgo denticulata (Brady), Triloculinacf. fichteliana d'Orbigny, Articulina alticostata Cushman, Peneroplis arietinus (Batsch), Cycorbiculina compressa (d'Orbigny), Amphisorus hemprichii Ehrenberg, Sorites orbiculus Ehrenberg, S. variabilis Lacroix, Pyramidulina catesbyi (d'Orbigny), P. perversa (Schwager), Astacolus insolitus (Schwager), A. sublegumen (Parr), Entosigmomorphina sp., Cymbaloporetta plana (Cushman), C. squammosa (d'Orbigny), Acervulina inhaerens Schultze, Planogypsina acervalis (Brady), P.squamiformis (Chapman), Amphistegina lobifera Larsen, Elphidium charlottense (Vella), E. striatopunctatum (Fichtel and Moll) and Heterostegina depressa d'Orbigny. 27 of these alien species are observed only along the Turkish coastline in the Mediterranean Sea, whereas, Haddonia sp., Clavulina angularis, C. cf. multicamerata, Schlumbergerina alveoliniformis, Quinqueloculina cf. mosharrafai, Miliolinella cf. hybrida, Pseudomassilina reticulata, Pyrgo denticulata, Triloculina cf. fichteliana, Peneroplis arietinus, Cyclorbiculina compressa, Amphisorus hemprichii, Sorites variabilis, Pyramidulina catesbyi, P. perversa, Cymbaloporetta plana, C. squammosa, Elphidium cf. charlottense aren ew records for the Mediterranean fauna.

Most of the alien foraminiferan species are rare, represented by 1 to 100 individuals per 5gr of sediment. However, *Amphistegina lobifera* Larsen forms dense populations along the southwestern coasts of Turkey with up to 230.-310 individuals/m<sup>2</sup>. The high ratio of tests in the sediment (3.75 grams) results in large amounts of sand formation.

The majority of these alien species are only known from the Indo-Pacific, while some species are recorded both in the Atlantic and the Indo-Pacific (i.e., *C.angularis, N. antillarum, S. antillarum, S. alveoliniformis, H. diversa, C. compressa, A. hemprichii, P. catesbyi, C. squammosa, A. inhaerens, P. acervalis, P. squamiformis, Amphistegina spp., H. depressa)* [3-6]. But since, with the exception *S. orbiculus*, these species have yet to be found in the westernMediterranean, it is suggested that the populations in the eastern Mediterranean most likely originated from the Indo-Pacific.

## Abstract

European hake (*Merluccius merluccius*) is one of the most important species in Greek fisheries due to its high commercial interest. It has been reported to be overexploited and in need of management to preserve its exploitation. The MEFISTO bioeconomic simulation model is proposed in order to test the effect of effort reduction in the bioeconomic indicators of the trawl hake fishery. Two alternative policy scenarios are analyzed compared to the *status quo* scenario. The trends of the biological and economic indicator variables through time are displayed for each scenario.

Keywords : Aegean Sea, Demersal, Fisheries, Models, Population Dynamics.

#### Introduction

European hake, *Merluccius merluccius* is one of the most important resources for the bottom trawl fleets in the Greek territories, both in terms of catch and economic value. The stock has been reported as overexploited [1]. The Saronikos Gulf's trawling fleet is composed of eighteen vessels that operate from October to the end of May, a total of eight months per year. The landings of hake represent 4.5% of the total catches in Saronikos Gulf and 45.5% of the total Greek hake landings and the 5% of the total revenues [2].

## Material and Methods

The objective of the MEFISTO simulation model is to reproduce the bioeconomic fishing conditions of the Mediterranean [3]. The model includes the age-structured dynamics of the target species and a relationship between landings of target and secondary species. This particular instance has been run with constant recruitment and catchability. The prices of target and secondary species are assumed to be constant. The simulations are performed through a vessel level analysis. Vessels are characterized through their technical characteristics including catchability and costs. The fishermen will choose a fishing strategy based in yearly profits obtained after discounted an appropriate cost structure to their revenues [3, 4]. The simulation carries out projections starting from the current situation forwards into the future at a yearly scale with the purpose of analyzing the trends of different indicators of the fishery under different scenarios that represent alternative management actions. The simulations presented here are run deterministically through a fifteen year horizon.

The data source: Biological parameters such as the growth parameters [5], the length-weight relationship parameters [1], the fraction of mature individuals at age [1], the natural mortality [1] assumed as constant and initial populations' data [1] as derived by VPA run assuming steady state [6] are shown in Table 1. Economic data were collected by Karlou-Riga (unpublished data).

The scenarios: *Scenario 0.* The control or *status quo* scenario, represents the outcome of the fisheries biological and economic indicators projecting the situation of 2004 (year t=0 for the simulation).

Tab. 1. Biological parameters (a, b,  $L_{inf}$ , k,  $t_0$ , Mat, M) and initial population data (N, F) at age for hake (a, b: parameters from the length-weight relationship;  $L_{inf}$ , k,  $t_0$ : growth parameters as derived from the von Bertalanffy equation; Mat: maturity fraction at age; M: natural mortality; N: initial number of individuals at age; F: fishing mortality at age).

| 5   |    | 7533    | 1                  | 0.016     |
| 6   |    | 4825    | 1                  | 0.101     |
| 7   |    | 2837    | 1                  | 0.5       |

*Scenario 1.* The effect of an effort reduction in trawlers activity is tested reducing their legal period of fishing by 12% (1 month) at year t=5 of the simulation.

*Scenario* 2. The effect of an effort reduction in trawlers activity is tested through a reduction of their legal period of fishing by 24% (two months) at year t=5 of the simulation.

### Results

The two scenarios tested bring positive results both for conservation (increase in biomass, fig. 1) and economic objectives (increase in profits, fig.1) after two years of the management action. A short-term (one year) crisis after the implementation of the management measure is noted for hake biomass, which however recovers getting values higher than before the management action. The current overexploitation level of this species suggests that a decrease in its fishing mortality would bring positive results for the fishery. However, it should be noted that even with 24% reduction in fishing time (scenario 2), the stock remains overexploited (i.e. it is still beyond the  $Y_{max}$ ) and needs more drastic management measures (i.e. improvement of selectivity).

Fig. 1. Bioeconomic indicators for two effort control scenarios against the base or *status quo*.

## MEDITERRANEAN MONK SEAL SIGHTINGS IN ITALY THROUGH INTERVIEWS: VALIDATING THE INFORMATION (1998-2006)

Giulia Mo \*, Sabrina Agnesi , Taira Di Nora and Leonardo Tunesi ICRAM, Via di Casalotti 300, 00166 Rome, Italy - giulia.mo@icram.org

## Abstract

Despite the fact that the monk seal has been defined as absent from Italian coasts during the last decades sightings are still reported. The present paper illustrates the methodology used to validate monk seal sightings reported along Italian coasts since 1998. The presently outlined sighting validation procedure suggests that a small presence of individuals may still be occurring for short periods throughout Italian coasts.

Keywords : Conservation, Monitoring, Sampling Methods.

The Mediterranean monk seal (*Monachus monachus*) is considered extinct from Italian shores since the mid 1980s, in light of the absence of a stable resident population and of known reproductive activities. The sightings occurring over the last decades have been attributed to vagrant individuals originating from groups of nearby countries [1]. The Italian Central Institute for Marine Research (ICRAM) has collected information on seal observations, recorded by seafarers along the Italian coasts as of 1998, so as to monitor and evaluate the phenomenon. This information is shared with Gruppo Foca Monaca-Italia. Sighting observations are reported following a specific information campaign directed at the wide public (mass media comunications) and involving institutional bodies (Coast Guard, Maritime officers, Marine Protected Area).

The present paper illustrates the data collected by ICRAM for the period 1998-2006 and the methodological approach used to differentiate observations of seal sightings from unattendible incomplete observations. Monk seal observations are recorded through verbal interviews of the observers with a standard interview format aimed at collecting the technical details of the sighting itself taking care not to provide the interviewee with any technical hints on the species' characteristics. The format involves information on: the observer's general details, weather conditions, date and location, distance from the coast and from the sighted animal, number of animals, estimated length, pelage colour, physical characteristics (i.e. description and shape of any body parts), swimming characteristics, general behavior, photographic documentation. To provide a validation of the observations, a score of 1 was given for each of the following phocid physical/behavioural characteristics [2] reported by the observer: 1) rotund head, held out of water during swimming, 2) large ocular orbits, 3) presence of vibrissae/fur, 4) compressed snout/presence of nasal slits, 5) edge of posterior flippers trailing along water surface during surface swimming, 6) lateral oscillations of posterior body trunk during swimming, 7) round head smaller than round shape of body 8) shape and position of flippers with respect to body. The total score was tallied for each observation and those scoring 4 or more, for situations in which the observer was out of the water, were considered acceptable (validated observations). This total value was lowered to 3 for underwater observations because of the reduced visibility under water. Furthermore, sightings having acceptable photographic documentation were automatically considered validated. One or more validated observations occurring in the same location and time were considered as a single seal sighting. Selected features of the validated observations were analysed.

On the overall, 59 observations were recorded of which 38 are validated observations and correspond to 27 sightings. Figure 1 illustrates their distribution. Only two sightings had photographic documentation. The highest number of validated observations was reported by professional and recreational fishers (32 and 24%), followed by boaters (18%), scuba divers (16%) and locals (11%). Only 16% of the observations occurred underwater. Almost 75% of the observations occurred within 20 meters of the seal and almost 48% lasted less than 1 minute. The majority of observed individuals (79%) were estimated as being <1.5 meters long while only 18% of individuals surpassed 1.5 meters.

The concerned sighting areas regard the southernmost continental and insular locations that are most proximate to populations of nearby countries such as Greece and Tunisia [1]. Given the estimated lengths provided by the observers, it is likely that the individuals transiting through Italian coasts are composed principally of juveniles, a size class known to disappear from its original birthsite for unknown destinations for prolonged periods of time [1], followed by a minor amount of adult sized individuals. The generally limited duration of the observations appears to be sufficient in guaranteeing an adequate perception of the principal seal characteristics necessary for sighting validation, this is also probably determined by the close proximity of most seal encounters. The seafarer's typology analysis suggests that information campaigns geared at future data collection on monk seal sightings should address all of the typologies involved so as to guarantee an efficient sighting monitoring. The applied approach allows to screen indirect information in order to distinguish the most accurate seal sightings occurring along the Italian coasts, an aspect that is crucial given the species' rarity.

## BIOLOGICAL CHARACTERISTICS OF MALTESE LONGLINING BLUEFIN TUNA (*THUNNUS THYNNUS*) LANDINGS 2005

Alicia Mosteiro Cabanelas \* and Matthew Camilleri

Malta Centre for Fisheries Sciences, Qajjenza Road, MarsaXlokk, BBG06, Malta - amc@tragsatec.es

## Abstract

This document provides an analysis of the biological characteristics of a sample of bluefin tuna landed by Maltese longliners during 2005. Data collected included length, weight, sex, maturity stage and age, and it can be considered as a sample of the longline fishery in the central Mediterranean. The Maltese longline fishery mainly targets adult specimens in excess of 200cm in length. *Keywords : Fisheries, Monitoring, Pelagic.* 

## Introduction

Due to the annual periodicity and representativeness of the sample, the biological data collected are of great relevance for the assessment of the state of the population exploited by the Maltese longline fishery. Length, weight, age, sex and maturity stage were collected between May and July during the fishing season.

#### Material and Methods

Bluefin tuna specimens were sampled at the landing port by field recorders. Length measurements (n=192) were carried out and spines (n=77) were collected for age reading. Length and weight parameters are collected concurrently. The weight (n=192) was raised to live round weight by a factor of 0.16 (ICCAT conversion factor).

Sex and maturity stage parameters (n=78) were collected through a scheme in collaboration with fishermen (Bluefin tuna is normally gutted at sea) consisting on fishermen taking photos of the gonads of each specimen at sea (specimens were tracked in the fish market by means of numbered tags) [1]. All samples were collected from commercial catches as part of the market sampling programme.

## Results and discussion

The Maltese bluefin tuna fisheries mainly targets mature individuals in excess of 200 cm, which differs from other fisheries in the Mediterranean, which on average catch smaller specimens.

The average length of fish caught in May, June and July were 223, 213 and 210 cm respectively. The size of tuna landed decreased steadily with time. The average length at maturity stages 2, 3 and 4 were 208, 205 and 222 cm respectively.

The length-frequency distribution of the landings of the three months combined showed that the bulk of the specimens landed was found to be within 210 and 230 cm length range.

Fig. 1. Length-Weight relationship of a sample of bluefin tuna landings in 2005.

The length-weight relationship equation obtained using all the 2005 data (Figure 1) shows a coefficient of determination  $(\mathbb{R}^2)$  of 0.6446 which indicates a positive correlation between length and weight of the specimens. The analysis of the L-W relationship by sexes showed a higher coefficient of determination (0.86) in the case of males which indicates a strong positive correlation between length and weight. For females the coefficient was also positive (0.43) but showing a weaker correlation very likely due to the fact that they reach higher weights at same length in the reproduction period.

The study of the length-at-maturity stages showed that the majority of specimens examined presented maturity stages 3 or 4 which indicates that they are mature and ready for spawning. There were no specimens

showing stage 5 (spent). Most males were at stage 4 of maturity and most females at stage 3. The maturity stage is not directly related to size, since during the season, individuals progress in maturity stage whilst length is practically constant. Moreover, large/older individuals could be at an early maturity stage whilst younger specimens could be at a more advanced maturity stage [2].

Fig. 2. von Berthalanffy growth curve and equation ( $L_t = L\infty \cdot (1-\exp(-K \cdot (t - t_0))))$ ) for bluefin tuna data 2005.

The analysis of length-at-age graphs showed that the sampled bluefin tuna were represented by specimens ranging from 6 to 12 years of age (Figure 2). The majority of tuna landed were aged 9 ranging from 160 to 240 cm FL. Male specimens were found to be all of age 9 or 10, while females ranged from 6 to 9 years of age. Size does not seem to increase with age, most likely because this set of data is composed by samples that fit within the plateau of the growth curve (von Berthalanffy growth equation [3]). The parameters L $\infty$ , K and t<sub>0</sub> of the von Berthalanffy equation (y=L $\infty$  ·(1-exp (-k ·(x- t<sub>0</sub>)))) were estimated through the non-linear regression (minimum squares calculated thought the Newton method within Solver-Excel) obtaining, a L $\infty$  = 228.48 cm, K = 0.2316 and t<sub>0</sub> = -7.22 (using 2005 data only).

#### Conclusions

The Maltese longline fishery mainly targets adult specimens in excess of 200 cm in length. Male specimens showed a better length-weight correlation than females, with the former composed mainly of individuals in maturity stage 4 and aged 9 or 10 years whilst the latter was composed mainly of individuals in maturity stage 3 aged 6 to 9 years.

## Abstract

Nowadays the question is no longer whether protected areas are able to maintain species richness but whether protected areas are able to protect other overlooked facets of biodiversity against erosion. Our study aims at evaluating the ability of protected areas to maintain viable populations of the most "original" species on a biological point of view. This question was investigated using a long-term monitoring programme in the Bonifacio Strait Marine Reserve. As a result, our study provides a clear example of how protection against human impact in coastal areas benefits preferentially to the most original fish species in terms of ecomorphological characters. *Keywords : Biodiversity, Trawl Surveys, Strait Of Bonifacio, Marine Parks, Coastal Management.* 

In a natural world increasingly transformed by human activities, it is now widely accepted that biodiversity is being lost rapidly in both terrestrial and marine ecosystems. For aquatic ecosystems, the most important factors are certainly climatic change, biotic exchange and overfishing; the latter being the most direct human disturbance to all coastal ecosystems [1]. If the causes of biodiversity loss seem established, the consequences of such dramatic declines or alterations have spurred considerable research and tremendous debate. Indeed biodiversity should be preserved not only for aesthetic reasons and for its direct usefulness, but also for its indirect benefits. For instance, it has been experimentally demonstrated locally that species richness per se positively influences ecosystem functioning and some fundamental ecosystem properties such as productivity, resistance to invasion, stability and resilience (e.g. [2]). Given the uncertainty of the future, preserving local biodiversity would maximize the probability of a viable response at the community level and would increase the variability of possible alternative types of ecological organization to disturbance and changing environmental conditions [3]. Thus, as alterations of biodiversity may disrupt ecological functions performed by species assemblages, it is urgent to carefully examine the implications of biodiversity loss not only in terms of pure conservation purposes but also in terms of sustainability of ecosystem services upon which human welfare depends.

Protected areas are indisputably the primary tool for in situ biodiversity conservation across the world [4] with more than 100,000 sites covering nearly 11.7 per cent of the land surface of the planet and about one per cent of the marine environment. However protected areas have been set up for reasons which are more based on species and habitat considerations rather than on knowledge and understanding of ecological systems. For instance biodiversity is almost exclusively assimilated to species richness in protected areas (the number of species coexisting on a site) while the definition of biodiversity includes various facets of the diversity of life. It is thus ironic that the main measure of biodiversity ignores what makes species different in an assemblage: their relative abundances and their biological attributes. In addition the two diversity facets of biodiversity, which are closely related to the differences among species, are known to influence ecosystem functioning. Evenness, which measures the relative distribution of abundance among species, is positively related to the resistance against invasion [5]. Functional diversity, which measures the value and range of the functional traits of the organisms, is now widely recognized as a main driver of ecosystem processes in aquatic environments [6]. Thus the question is no longer whether protected areas are able to maintain species richness but whether protected areas are able to protect other overlooked facets of biodiversity against erosion.

When considering the differences among species to assess the biodiversity of an assemblage we can assume that the species that contributes the more to the biological diversity of this assemblage is the one with the more original biology, i.e. the one with the highest average rarity of its features or characters [7]. Consequently the loss of such original species is more likely to provoke the loss of some unique biological features which can be life-history traits, morphological structures or behaviours. This is particularly true for some species-poor families on Earth (rhinos and kiwis) because extinction of species belonging to these families would inevitably lead to the loss of their unique biological characters [8]. Moreover, the degree of originality of species within an assemblage determines the strength and the shape of the relationship between taxonomic and functional diversity [9]. Extinction of species which are functionally equivalent to some others in the assemblage has less impact on functional diversity than the extinction of original species. Thus measuring the biological originality of a species gives insight into its conservation importance in the light of the conservation of ecosystem functioning. Then, a crucial question arises: do protected areas contribute to protect biological originality? In other words our article aims at evaluating the ability of protected areas to maintain viable populations of the most "original"species on a biological point of view. This question was investigated using a long-term monitoring programme in the Bonifacio Strait Marine Reserve. As a result, our study provides a clear example of how protection against human impact in coastal areas benefits preferentially to the most original fish species in terms of ecomorphological characters.

## ASPECTS REPRODUCTIFS DE SPONDYLIOSOMA CANTHARUS (LINNAEUS, 1758) DES CÔTES TUNISIENNES

Nejla Mouine \*, Mohamed-Hédi Ktari and Nadia Chakroun-Marzouk

Faculté des Sciences de Tunis, Laboratoire de Biologie animale, Campus universitaire, 2092 Tunis El Manar, TUNISIE -

nejlamouine@gmail.com

## Résumé

La période de ponte de *Spondyliosoma cantharus* se déroule de mars à mai sur les cotes tunisiennes; la présence de gonades bisexuées, le déséquilibre marqué du sex-ratio en faveur des femelles et la nette supériorité de la taille moyenne des mâles confirment la protogynie de la dorade grise. La taille à la première maturité sexuelle des femelles est de 17,78 cm. *Mots clès : Fishes, Reproduction, Spawning.* 

#### Introduction

Le genre *Spondyliosoma* Cantor, 1849 comprend une seule espèce en Méditerranée; il s'agit de la dorade grise *Spondyliosoma cantharus* (Linnaeus, 1758). Ce Sparidae est présent dans l'Atlantique oriental, de la Scandinavie à l'Angola, dans la Méditerranée, la mer Noire, à Madère, dans les îles Canaries et du Cap-Vert [1]. Les études concernant la biologie de la reproduction de la dorade grise se limitent à l'Atlantique oriental [2, 3, 4, 5, 6]. Par ce travail préliminaire, nous nous proposons d'apporter une contribution à la connaissance des caractéristiques reproductives de la dorade grise des cotes tunisiennes méditerranéennes.

#### Matériel et méthodes

L'échantillonnage a été réalisé, à partir du marché central de Tunis, de janvier 2005 à juin 2006. Pour chaque spécimen nous avons mesuré la longueur totale (LT) au mm prés, le poids éviscéré (Pe) au g prés et le poids des gonades (Pg) au 0,01g prés. Les proportions numériques des sexes sont exprimées sous forme d'un ratio (M : F) et évaluées au moyen du test du  $\chi^2$ . L'analyse des fluctuations mensuelles de l'indice gonadosomatique (IGS = Pg / Pe x 100) et des pourcentages d'individus matures (stades de maturation et de ponte) a permis de délimiter les différentes périodes du cycle sexuel. Enfin, la taille à la première maturité sexuelle a été estimée en utilisant une fonction logistique reliant les proportions d'individus matures aux longueurs totales correspondantes.

## Résultats et Discussion

L'échantillonnage est composé de 330 spécimens de taille comprise entre 13,4 et 36,6 cm (19,0 ± 0,2 cm). La longueur totale moyenne des mâles (26,10 ± 1,48 cm) est très significativement supérieure à celle des femelles (18,70 ± 0,18 cm) (p = 0,00). Le sex-ratio global est nettement en faveur des femelles avec 1: 19,67 ( $\chi^2 \ge 3,84$ ; p <0,05); cette disproportion a aussi été rapportée dans les travaux réalisés en Atlantique [4, 5, 6].

Fig. 1. Variations mensuelles de l'IGS et des pourcentages des individus matures de *S. cantharus*.

La maturation des gonades s'étend de décembre à février (Fig. 1); le frai a lieu de mars à mai alors que le repos sexuel s'étale de juin à novembre. La période de ponte de la dorade grise s'étend d'avril à juin dans la Manche [2, 3], de février à avril sur les cotes sud ouest du Portugal [6], de janvier à février dans les îles Canaries [5] et de mai à août dans le Banc saharien [4]. Ce décalage temporaire de la période du frai est du à des différences locales des paramètres environnementaux qui agissent sur le déclenchement de la ponte. La dorade grise présente en Tunisie un dichromatisme durant la période de ponte; les mâles ont une robe plus sombre que celle des

femelles; cette particularité a également été relevée dans les populations des îles de Canaries [5] et des cotes sud ouest du Portugal [6].

La taille à laquelle 50 % des femelles sont matures est de 17,78 cm (Fig. 2); elle est assez voisine à celle observée sur les cotes canariennes (17,3 cm) [5] mais inférieure à celle des cotes sud ouest du Portugal (20,1 cm) [6] et de la Manche (23 cm) [3].

La présence d'individus présentant des ovotestis (1,82%), le déséquilibre du sex-ratio et l'antagonisme de la répartition des sexes en fonction de la taille suggèrent une modalité d'expression de sexe principalement protogyne. Ce type d'inversion sexuelle a déjà été signalé [7] puis ultérieurement confirmé [4, 5, 6, 8].

Fig. 2. Courbe de la maturité sexuelle de S. cantharus.

## Abstract

Whale-watching activity performed in the Ligurian Sea (off Imperia-Savona) from 2004 to 2006 is analysed to access to the sighting probabilities of fin whale on previous sighting positions, during 7 days time-window. On 62 km<sup>2</sup> area, 15 % of the fin whale sightings occurred near a previous sighting position.

Keywords : Cetacea, Ligurian Sea.

## Introduction

Since nearly 20 years, the whale watching activity has grown considerably in the Ligurian Sea especially to watch fin whales. Indeed, in the early spring and during the summer, fin whale are aggregated in function of the food availability [1]. The implantation of this tourism activity provides also opportunistic research platforms to conduct study on cetaceans habitat [2]. However, it is not clear how results obtained by whale-watching surveys may be biased by the re-sightings of one single individual on a particular position. This work analyse the quantity of fin whale sightings occurring on near one sighting position during the 7 following days.

## Materials and Methods

3 years of the main whale-watching operator in the Ligurian Sea are analyzed. During 362 days of whale-watching aboard the two vessels (the *Corsara* and the *Stenella*), 186 fin whale sightings occurred. To establish the frequency of  $2^{nd}$ -sightings on  $1^{st}$ -sighting positions, we first fix the time-window to 7 days. This window can considered to be representative of the relative oceanographic stability in the Mediterranean Sea. Moreover, it is not expected that a whale remains on a static position during more than 8 days because of obvious changes of oceanographic configuration. In contrast, it is expected that a whale remains quasi-static when its prey is abundant. Therefore the 7 days window should fit for this study. Then, for each  $1^{st}$ -sighting position represented on a grid with a resolution of  $1/60^\circ$ , we calculate the sightings (called later  $2^{nd}$ -sightings) that occurred on surrounding grid-cells during the time-window. 4 different resolution scales were tested: 3, 5, 7 and 9 pixels.

## Results and discussion

In general, the whale-watching boat realized 4 days of "survey" after one fin whale sighting (Table 1). This result indicates indirectly the favourable meteorological condition for surveys, considering that operators in this area exploit all possible occasion when the weather is good enough.

Tab. 1. Sightings results on different extension of areas (I, II, III, IV).

| Туре                                         | Ι     | II    | III   | IV    |
|----------------------------------------------|-------|-------|-------|-------|
| Width (km)                                   | 5     | 8     | 11    | 14    |
| Area (km <sup>2</sup> )                      | 22    | 62    | 122   | 201   |
| Sighting frequency                           | 0.04  | 0.15  | 0.32  | 0.53  |
| Sighting success frequency by return         | 0.05  | 0.11  | 0.19  | 0.28  |
| Effort (NM) by return                        | 298   | 1011  | 1956  | 3049  |
| Encounter rate at the 2nd-sightings position | 0.027 | 0.028 | 0.031 | 0.032 |
| Effort (NM) on the 1st-sightings position    | 395   | 774   | 1081  | 1587  |
| Encounter rate at the 1st-sightings position | 0.471 | 0.240 | 0.172 | 0.117 |

Because daily horizontal pattern of movement of fin whale is not yet known, we have tested different space scale. On the more restricted area, representing about  $22 \text{ km}^2$ , (see Table 1, I), fin whale are not often sighted; the  $2^{nd}$ -sighting frequency is 0.04. However the boat did return a lot of times (153). The success of  $2^{nd}$ -sighting is of 0.05 by return. This results is quite unexpected considering that generally it was supposed to re-find more easily fin whales on previous positions. The relative encounter rate, expressed as the number of sightings divided by the number of the nautical miles done in the area, is quite low 0.027 comparing to the one obtained with casual encounters (0.48) on the even area. This demonstrates that even if the boat is looking for whales in the restricted area,  $2^{nd}$ -sightings are not numerous. Extending the area, on 62 km<sup>2</sup>, the frequency of  $2^{nd}$ -sightings grows to 0.15 (with 28  $2^{nd}$ -sightings on the 1<sup>st</sup>-sightings position) with the success frequency by return of 0.11. In this situation,

the encounter rate is 0.028. Extending then to 122 km<sup>2</sup>, the frequency of  $2^{nd}$ -sightings becomes 0.32 with a relative success frequency 0.19 by return; here, the encounter rate on the delimited area is 0.031. On the most extended area tested (201 km<sup>2</sup>), the frequency of  $2^{nd}$ -sightings reaches 0.53. But the area is extended on the usual features where fin whale is abundant. In the Ligurian Sea, fin whale habitat is characterized by deep water (average 2136 meters), by gentle bottom slope (average of 26m/km) and daily sea surface temperature of 21.8°C [3].

This work gives access to results on whale watching data. The analysis on a restricted area (over 22 km<sup>2</sup>) indicates a low quantity of sightings on a previous position. But on 62 km<sup>2</sup> area, 15 % of the fin whale sightings occurred near a previous sighting position. Extending the area, the quantity of sightings grows indicating that fin whales may move around their primary position during the 7 following days and so may be re-sighted. This study would be greatly improve by photo-identification results, in order to determine the proportion of re-sightings of the same whale.

## Abstract

Continuous daily fishery landings (1977-2003) from four adjacent lagoons of Amvrakikos Gulf (Western Hellas; Ionian Sea) using barrier traps were analyzed herein. During the last 30 years, the general area has been subjected to a high degree of human impacts that might influence the fish and fisheries dynamics. Two of the studied lagoons indicated an alteration in their seasonal pattern that marked by an increase of spring landings and a great reduction of autumn-winter ones. *Keywords : Lagoons, Coastal Management, Ionian Sea, Fisheries.* 

#### Introduction

In lagoons, landings from barrier traps are based on the species-specific inshore-offshore seasonal or ontogenic fish migrations [1]. In this context, we analysed a 27-year (1977-2003) fisheries landings series derived from four lagoons of Amvrakikos Gulf (Western Hellas; Ionian Sea) using barrier traps. Although fishery exploitation is limited during spring (traps are opened), in the studied lagoons the traps are remaining active (closed) allowing only the entrance of juveniles and small-sized fish. Hence, the aim of the study was to detect changes in seasonal species composition though time and to determine possible causes of this pattern.

## Materials and Methods

Fishery exploitation took place by the same fisher cooperation during the study period, a fact that guaranteed data validity, homogeneity and stability of fishing effort variability. Fishing period was considered to start at March, till the end of next February, as there is not any fishery legislation that regulates fishing period inside the lagoons. Data-series were composed by landings per species or group of species. To investigate similarities and/or dissimilarities in seasonal species composition for each lagoon separately, we constructed matrices comprising the percentages of the seasonal composition per year using the Bray-Curtis coefficient [2].

#### Results and Discussion

Multivariate analyses of season landing percentages revealed a quite good separation in time for each different lagoon (Figure 1). Hence, two major year-groups were formed consisted, with some exceptions, by the first 20 years of data-series (Group A: 1977-1999, for Mazoma and Tsopeli; 1977-1998 for Pogonitsa; and 1977-1997 for Vathi) and the most recent ones (Group B: 2000-2003 for Mazoma and Tsopeli; 1999-2001 for Pogonitsa; and 1998-2003 for Vathi). In Group A, summer, autumn, and winter were the seasons with the highest contribution representing more than 85% of annual landings in Mazoma, 68% in Tsopeli, 41% in Pogonitsa and 60% in Vathi. In contrast, for Group B in Mazoma and Vathi, landing percentages indicated a different seasonal pattern marked by an increase in spring landing percentages, especially after 2001 (>21\% of the total annual landings). Subsequently, in Vathi, season landings, except the autumn ones that have been reduced to almost zero level, showed a high fluctuation of its values: in spring they ranged from 0% to 72%; in summer from 0% to 45%; and in winter from 15% to 100%. However, in Tsopeli and Pogonitsa seasonal alterations in landings were not so evident due to lower spring landings (from 0% to 13% and from 0% to 9%, respectively) compared with the other seasons.

Eventually, despite the close geographic proximity among the four lagoons (<15 km) and the presence of the same fishers cooperation, each lagoon indicated different seasonal landing patterns during recent years (after 1997) than before. This could be attributed to the decline in fishery landings due to the combined effect of anthropogenic impacts both on inland and marine environment (e.g., pollution, overexploitation, absence of fishery regulation) [3] accompanied by the influence of global climatic change [4]. Even though the latter needs a better approach, however, it has been shown that climatic shifts was responsible for the loss of several species [4], a fact that it has been also observed in the studied lagoons (Fish. Dep. of Preveza unbl. data). Moreover, the degradation of lagoon biodiversity impacted on fisher's exploitation tactics. Thus, due to low fish prices during autumn-winter, fishers limited the exploitation and thus, the economic costs, in order to land more fish during spring when the prices are getting higher. In this context, it is important the existence of artificial deep channels (wintering channels) where fishers could maintain the trapped fish (especially eels, under-sized Mugilidae and *Sparus aurata*) during the cold months (late autumn and winter) and to land the catches in the next harvest season. Consequently, these phenomena had a significant social effect in the general region as fisher's cooperation forced to reduce the number of fishers that worked in the lagoons (from 10, 9, 6 and 5 in 1980, to 5, 4, 4 and 3 after 1999, in Mazoma, Tsopeli, Pogonitsa and Vathi, respectively) in order to limit the economic loss. Concluding, it is evident that the application of an integrated managerial scheme including marine environment (both coastal and inland ecosystems) together with a socioeconomic approach could be the primary perspective towards ecosystem sustainability.

## FOULING ASSEMBLAGES FROM TWO MALTESE PORTS STUDIED AS PART OF THE PORTAL PROJECT

Graziella Muscat, Alan Deidun \* and Patrick J. Schembri

Department of Biology, University of Malta, Msida MSD 06, Malta - alpra1@mail.global.net.mt

## Abstract

Within the context PORTAL project, which was initiated by CIESM in 2003, a wharf in the Grand Harbour, and a fuel jetty and buoy in Marsaxlokk Harbour were sampled to collect baseline data on alien species. 86 species belonging to 7 targeted taxa were collected, with Crustacea being the dominant taxon in terms of both species richness and individual abundance. The highest species richness and evenness values were recorded at 3 m at both sites. Multivariate analyses and SIMPER showed that the degree of separation of fouling assemblages between the two sites was minimal. The fouling assemblages investigated are broadly similar to those occurring in Italian waters. The only alien species found in the samples was a single juvenile of the grapsid *Percnon gibbesi*. *Keywords : Biodiversity, Coastal Waters, Fouling.* 

### Introduction

PORTAL is a research programme of the International Commission for the Scientific Exploration of the Mediterranean Sea (CIESM) that aims at implementing a Mediterranean-wide port and port-proximate survey using standardized protocols to collect baseline data on alien species, particularly those which might be introduced by shipping. The Valletta harbours (Marsamxett Harbour and Grand Harbour) and Marsaxlokk Bay are the major harbours of the Maltese Islands. Information on fouling assemblages within the Maltese harbours and harbour-like environments is very scarce. Practically, the only work carried out has been a preliminary study of fouling organisms in oyster cultures in three Maltese bays, including at Rinella within the Grand Harbour [1].

#### Methods

Pinto Wharf in Grand Harbour, a fuel jetty and a buoy at Birzebbuga in Marsaxlokk Bay were sampled using the PORTAL standard methodology. Fouling biota was collected from three replicate 0.1  $m^2$  quadrats at each of three depths (0.5 m, 3 m, 7 m), on the vertical wall of the wharf or jetty at three different stations, while on the buoy three replicates were sampled at 0.5 m.

#### Results and discussion

A total of 86 species belonging to the taxa targeted by the PORTAL project and to some other taxa for which good taxonomic knowledge was available (Algae: Chlorophyta, Rhodophyta, Phaeophyta; Cnidaria; Polychaeta; Sipuncula; Crustacea: Cirripedia, Amphipoda, Tanaidacea, Isopoda, Mysidacea, Decapoda; Mollusca: Polyplacophora, Gastropoda, Bivalvia; and Ascidiacea) were recorded from the two sampling sites: 77 species from Birzebbuga (73 from the fuel jetty and 21 from the buoy) and 43 species from Pinto Wharf. In terms of individual abundance, Crustacea was the most abundant taxon, followed by Polychaeta and Ascidiacea, whilst in terms of species richness, Crustacea was the most important taxon (25 species), followed by Mollusca (23 species) and algae (17 species). The melitid amphipod Elasmopus sp. was overall the most abundant species, followed by the sabellid polychaete Sabellidae sp. Other species of the targeted groups were collected, but they have not yet been identified, in particular Bryozoa, while species belonging to groups other than those targeted were present. Surprisingly, no Hydrozoa were found in the samples. Only one alien species of the targeted taxa was present: a single young juvenile of the grapsid crab Percnon gibbesi was collected from the Birzebbuga fuel jetty at 3 m depth; dense populations of this species are now found in suitable habitats all along the Maltese coast [2]. At both sites, the abundance of ascidians, polychaetes, molluscs and algae decreased with depth whilst that of crustaceans and sipunculans increased. The highest species richness and evenness values were recorded at 3 m at both sites; this suggests that in the localities sampled, this depth provides the most favourable conditions for fouling assemblages. The majority of species were recorded in both harbours. In addition, the fouling assemblages from the two sites were not significantly different from each other in terms of species richness and individual abundance. Mean species richness at Birzebbuga was 6.5 (s.d. 1.8) at 0.5 m, 7.9 (2.0) at 3 m; 6.8 (1.2) at 5 m, and 3.4 (0.8) for the buoy, while mean species richness at Pinto Wharf was 3.3 (s.d. 1.17) at 0.5 m, 4.3 (1.3) at 3 m; and 3.4 (1.18) at 7 m. The mean Shannon-Wiener Index (H') was 1.08 (s.d. 0.13) for the Birzebbuga jetty and buoy, and 0.93 (s.d. 0.1) for Pinto Wharf, whilst the mean Pielou's Evenness was 0.25 (s.d.0.03) for the Birzebbuga jetty and buoy and 0.21 (s.d.0.02) for Pinto Wharf. Multivariate classification (group average linkage hierarchical cluster analysis and nMDS) of species-abundance data separated out the Pinto Wharf samples from the Birzebbuga ones (jetty and buoy), however, the degree of separation was low. nMDS also indicated a bathymetric separation of the Birzebbuga samples; the samples from 0.5 m depth and the buoy were different from those at 3 m and 5 m depths. This suggests that for this site, depth, rather than site-specific environmental conditions, is the most important physical factor influencing the distribution of fouling assemblages. There was also a weak separation between the samples from Birzebbuga buoy and the jetty at 0.5 m depth. SIMPER analysis confirmed the low degree of separation between assemblages from the two harbours. The present results are broadly similar to those obtained for fouling assemblages in Italian waters [3,4], although there are some differences in the dominant taxa. The complete absence of hydroids in the present samples is surprising, especially since, along with barnacles and oysters, hydroids are amongst the first organisms to colonise man-made structures and are common in ports [5]. The absence of alien species, except for Percnon gibbesi, was somewhat unexpected in view of the large volumes of marine traffic that passes through Malta ports and their strategic geographic location in the central Mediterranean. Although not recorded in the present study, a number of alien species have been recorded from Malta ports, including the bryozoans *Celleporaria pilaefera* and *C. aperta* [1], the slipper limpet Crepidula fornicata [6,7], the oyster Crassostrea gigas [8], and the echinoid Eucidaris tribuloides [9].

## MORPHOMETRIC AND MERISTIC CHARACTERISTICS OF THE SARDINE, *SARDINA PILCHARDUS* (WALB., 1792), IN THE MIDDLE EASTERN ADRIATIC SEA

Bosiljka Mustać and Gorenka Sinovčić \*

Institute of Oceanography and Fisheries, Šetalište I. Meštrovića 63, 21000 Split, Croatia - sinovcic@izor.hr

## Abstract

A total of 1,219 specimens of sardine, *Sardina pilchardus* (Walbaum, 1792) were obtained from the Middle Eastern Adriatic Sea during the period from March, 2004 to February, 2005. Sardine specimens were caught by purse seine. Total length ranged from 13.0 to 19.0 cm, and weights ranged between 16.72 and 51.45 g. Negative allometry was established (b=2.5538) in the length-weight relationship. *Keywords : Adriatic Sea, Biometrics, Fishes.* 

## Introduction

The aim of this paper is to present the morphometric and meristic characteristics of the sardine, *Sardina pilchardus* (Walbaum, 1792). Based on the differences in gill raker numbers and migratory patterns, it was supposed that two subpopulations of sardine exist in the Adriatic Sea [1]. Results of these studies give the basis for comparisons between sardine biometric characteristics from the Adriatic Sea with other regions. The length-weight relationship is essential in stock assessment models and in estimations of the weight from length observation, as well as in an estimate of fish population condition [2,3] and comparisons among populations of the same species from different habitats or regions [4].

#### Material and methods

Sardine specimens were caught with purse seine in the coastal and open Middle Eastern Adriatic Sea during the period from March 2004 to February 2005. Total length of analysed specimens ranged from 13.0 to 19.0 cm, and weights ranged between 16.72 and 51.45 g. A total of 1219 specimens were analysed for the length-weight relationship and for the morphometric characteristics, whereas 122 specimens were used for the analysis of meristic characteristics. Eight morphometric (LT, LS, LF, LH, LF, H, PE and Ed) as well as two meristic parameters (RD and Vert.) were used for biometry. All lengths were measured to the nearest mm and weights to the nearest g.

The length-weight relationship was determined according to the equation:  $W=aL^b$ 

where *W*=fish weight in g; *L*=total length in cm; *a*=proportionality constant and *b*=regression coefficient. In order to check for isometric growth, the *t* test was used.

#### Results

Overall morphometric and meristic characteristics are presented in Table 1. Mean total length was  $16.03 \pm 0.88$  cm and mean weight was  $31.49 \pm 5.32$  g. All length-length relationships were linear. The relationships *LT-LS*, *LT-LF* and *LF-LS* are: *LS* = 14.019-0.0006 *LT* ( $R^2$  = 0.0817); *LF* = 14.017+0.0003 *LT* ( $R^2$  = 0.0078); *LS*= 14.019-0.0006 *LF* ( $R^2$ =0.0817).

Tab. 1. Morphometric and meristic characteristics of sardine caught in the Middle Eastern Adriatic Sea during the period March, 2004 to February, 2005.

The length-weight relationship for sardine caught in the study area was:  $W = LT^{2.5538}$ ; ( $R^2 = 0.6976$ ; SE = 0.0009) and is shown in Figure 1.

Fig. 1. Length-weight relationship of sardines from catches in the Middle Eastern Adriatic Sea during March, 2004-February, 2005.

#### Discussion

Vertebral numbers ranged from 48 to 52 ( $\bar{X}$ =50), whereas Mužinić [5] found that they ranged from 49 to 54 ( $\bar{X}$ =51) in the Middle Eastern Adriatic Sea. According to Sinovčić [6] the sardine from the coastal Middle and North Eastern Adriatic Sea has 50-53 vertebrae ( $\bar{X}$ =51). The lengthweight relationship for the sardine from the Middle Adriatic Sea showed negative allometry (b=2.5538) (Fig.1). Alegria [7] reported negative allometry for the sardine length-weight relationship for the Middle Adriatic (b=2.851). The same results were also found in the length-weight relationship for sardines from the Ionian Sea in 1995 (b=2.75) [8] and 2003 (b=2.75) [9].

## RECENT DISTRIBUTION OF GELATINOUS ORGANISMS IN THE SOUTHERN BLACK SEA

Erhan Mutlu

Graduate School of Marine Sciences, POB 28, Erdemli, 33731, Mersin, Turkey - mutlu@ims.metu.edu.tr

## Abstract

Since introduction of *Beroe ovata* in 1999 into Black Sea, two cruises in June and October 2006 have determined the distributions of both invading *Mnemiopsis leidyi* and *Beroe ovata*, and the resident *Aurelia aurita* and *Pleurobrachia pileus* in the southern Black Sea. Total biomass of *M. leidyi* in the entire Black Sea was 22.00 and 11.00 million tons, 35.96 and 14. 81 for *P. pileus*, 169.20 and 33.84 for *A. aurita* in June and October 2006, respectively and 3.81 million tons for *B. ovata* in October 2006. As compared to the biomasses in June when no individual of *B. ovata* was caught by the net, the biomasses and abundances of the former species decreased in October when individuals of *B. ovata* were observed.

Keywords : Zooplankton, Biomass, Black Sea.

Spatial distributions of gelatinous organisms (*A. aurita, P. pileus, M. leidyi* and new exotic species, *B. ovata*) in the southern Black Sea (the Turkish EEZ) were studied in June and October 2006. All species were collected using the Hensen plankton net (0.7 m mouth opening and 300  $\mu$ m mesh size). Samples were obtained by vertical hauls from a depth of H<sub>2</sub>S layer at 65 stations in June and 72 stations in October 2006. The gelatinous organisms were sorted out, numerated and weighed with a hand balance on board. In June, individuals of each species found at each station were frozen in a nylon bag for comparison for weight measurements with onboard hand balance and e-balance in the laboratory. Size measurements of the individuals were performed to compare biomasses in the other ways.

Three methods to estimate biomass were used: hand balance, e-balance of frozen specimens and length-weight relationship ([1], [2], [3]). This was purposed for inter-calibration of biomass estimation conducted with different methods. Pairwise of the methods were subjected to the t-student test. No significant differences in the biomasses were found at a level of p<0.05.

Spatial distributions of *M. leidyi* were followed by hydrographic features of the Black Sea. High biomasses ( $150 > gm^{-2}$  in June and  $>50 gm^{-2}$  in October) were found on the rime current between the coastal cyclonic eddies. The maximum abundance and biomass of *M. leidyi* were 13 ind  $m^{-2}$  and 390 g $m^{-2}$  with averages of 1.7 ind  $m^{-2}$  and 52 g $m^{-2}$  in June, and 23 ind  $m^{-2}$  and 130 g $m^{-2}$  with 7 ind  $m^{-2}$  and 26 g $m^{-2}$  in October. Mean biomass and abundance of *M. leidyi* were not however significantly different in the eastern area (51 g $m^{-2}$  and 1.9 ind  $m^{-2}$ , n= 32 stations) than in the western area (53 g $m^{-2}$  and 1.9 ind  $m^{-2}$ , n= 33) of the Turkish Black Sea in June they were significantly higher in the east ( $27 gm^{-2}$  and 10 ind  $m^{-2}$ , n=31) than in the west ( $22 gm^{-2}$  and 5 ind  $m^{-2}$ , n=36) in October (U test, p<0.05). No significant differences in the biomass and abundance were found between inshore (bottom depth<200m) and offshore (>200 m) waters in June (39 g $m^{-2}$  with 1.2 ind  $m^{-2}$ , n=13 and 55.4 g $m^{-2}$  with 1.8 ind  $m^{-2}$ , n=52) and in October (25 g $m^{-2}$  with 6 ind  $m^{-2}$ , n=18 and 26 g $m^{-2}$  with 7 ind  $m^{-2}$ , n=54).

Main concentrations of *P. pileus* were found at the northern peripheries of the anticyclonic eddies. The mean wet weight of *P. pileus* never exceeded 100 g m<sup>-2</sup> (84 g m<sup>-2</sup> in June and 35 g m-2 in October) while the maximum wet weights were recorded to be 234 g m<sup>-2</sup> in June and 91 g m<sup>-2</sup> in October. In contrast to the summer distribution, the mean and abundance were significantly higher in the southeastern (40 g m<sup>-2</sup> and 154 ind m<sup>-2</sup>) than southwestern (30 g m<sup>-2</sup> and 21 ind m<sup>-2</sup>) Black Sea in autumn. A significant difference between inshore (19 g m<sup>-2</sup> with 100 ind m<sup>-2</sup>) and offshore (40 g m<sup>-2</sup> with 151 ind m<sup>-2</sup>) areas was found only in October.

In June 2006 *A. aurita* was found to be mainly distributed in the southwestern Black Sea. The locations of dense patches (>600 g m<sup>-2</sup>) were well correlated with peripheries of the western main gyre. Patches of *Aurelia* occurred in Kizilirmak and Batumi eddies. The density in the central Black Sea was virtually low. Overall, the distribution of individuals and biomass did not differ significantly between the western (498 g with 19 ind m<sup>-2</sup>) and eastern (298 g with 11 ind m<sup>-2</sup>) areas, and between inshore (383 g with 19 ind m<sup>-2</sup> and offshore (404 g with 15 ind m<sup>-2</sup>) waters. Maximum abundance and biomass were 91 ind m<sup>-2</sup> and 3380 g m<sup>-2</sup> with averages values of 16 ind m<sup>-2</sup> and 400 g m<sup>-2</sup> in the southern Black Sea. In October, mean abundance and biomass were 2.5 and 5 times lower than those in June. No statistical differences in abundance and biomass were found either between the western 6.2 ind m<sup>-2</sup> with 106 g m<sup>-2</sup>) and eastern (5.2 ind m<sup>-2</sup> with 55 g m<sup>-2</sup>) areas or between inshore (6.2 ind m<sup>-2</sup> with 113 g m<sup>-2</sup>) and offshore (5.6 ind m<sup>-2</sup> with 69 g m<sup>-2</sup>) areas. *B. ovata* was not found in the entire southern Black Sea during a cruise in June 2006. Mean biomass and abundance of *Beroe* was 8.9 g m<sup>-2</sup> and 1.4 ind m<sup>-2</sup> in October 2006. Individuals of *Beroe* were generally observed in area where *Mnemiopsis* and *Pleurobrachia* were not found, except in the Batumi eddy. Maximum abundance and biomass were recorded to be 16 ind m<sup>-2</sup> and 57 g m<sup>-2</sup>. There was no significant difference in biomass and abundance between the areas. The coastal water yielded little higher biomass (12 g m<sup>-2</sup>) than open waters (8 g m<sup>-2</sup>) with the similar areas shared equal abundance (1.4 ind m<sup>-2</sup>) while the biomass was little higher (11 g m<sup>-2</sup>) than that in the eastern area (7 g m<sup>-2</sup>).

On the board, an experiment was performed to observe visually food choice of *B. ovata*. Specimens in various sizes of *Mnemiopsis* and *Pleurobrachia* and small-sized *Aurelia* were served to *Beroe* in 201 jar. *Beroe* investigated the food at the surface in order presumably to seek existence of *Mnemiopsis*. If there is no *Mnemiopsis* at the surface, *Beroe* dived down to the bottom to catch *Pleurobrachia*. *Beroe* however did not feed on *Aurelia*. *Beroe* swallowed more than one individuals of *Pleurobrachia* at once and the zipped the mouth to start digestion. A few individuals of *Calanus* were observed inside *Beroe*.

## PRELIMINARY RESULTS ON BENTHIC IMPACT OF CAGE FISH FARMING IN A SEMI ENCLOSED GULF OF EASTERN MEDITERRANEAN

Nikos Neofitou \*, Dimitris Vafidis and Spyros Klaoudatos

University of Thessaly, School of Agriculture, Department of Ichthyology and Aquatic Environment, Fytokou str., N. Ionia, 38446 Volos, Greece. - nikneof@uth.gr

## Abstract

The impact of cage culture of marine fish species on the benthic environment was investigated seasonally at two fish farms of Pagasitikos Gulf, between July 2004 and April 2005. The polychaete *Capitella capitata* was the most dominant species in both farm sites (37% and 65% of the total abundance, respectively), whilst the most dominant species at the control sites of two fish farms was the polychaete *Nephthys hystricis* (11% of the total abundance in both sites). Furthermore, *Nephthys hystricis* was found at the control sites and the 50 m stations, but never at 0 m stations which located under the center of the cages. In all cases structure of macrobenthos in the immediate vicinity of the farms changed, but the spatial extent of this effect was quite limited. *Keywords : Aquaculture, Zoobenthos, Pollution, Aegean Sea.* 

Introduction

The impact of fish farming on macrobenthos gradually gains interest in the Mediterranean [1 - 4], where fish farming of marine species, particularly sea bream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*), has grown exponentially during the last 25 years. The objective of this study was to assess the impacts of site specific aquaculture on macrobenthos structure of Pagasitikos Gulf, a semi-enclosed gulf of Eastern Mediterranean where otter trawling is prohibited.

## Materials and methods

Four seasonal samplings were carried out from July 2004 to April 2005 (July and October 2004, January and April 2005) from the two marine fish farms (AS: 39<sup>0</sup>07'38" N 23<sup>0</sup>09'17" E, BS: 39<sup>0</sup>07'13" N 22<sup>0</sup>57'53" E). At the area of each fish-farm, three stations were sampled, one was located in the centre of fish farm, the other at a distance of 50 m from the centre and the last one at a distance of 300 m from the fish farm center, taken upstream from the main current direction in each fish farm. Henceforth these are referred to as AS<sub>1</sub>, AS<sub>2</sub> and AS<sub>3</sub> for the first fish-farm and BS<sub>1</sub>, BS2 and BS3 for the second fish farm. Furthermore, AS1, AS2, BS1 and BS2 stations were the farm sites while AS3, BS3 stations were the control sites. At each sampling station, samples were collected by means of a grab sampler (Eckman-Birge) with an area of 0.0225 m<sup>2</sup>. From all sampling stations, three replicate samples were taken during all seasons, in order to determine natural variability within replicates (72 total samples). Samples were sieved through a 0.5 mm mesh sieve and each sample was placed in plastic vials in 10% formaldehyde. Calculations were done by means of PRIMER software package.

#### Results

A total of 1 193 individuals, belonging to 90 species were identified. In terms of community structure (Table 1), the two areas showed a pattern of spatial change with distance from the cages. The polychaete *Capitella capitata* was the most dominant species in both farm sites (37% and 65% of the total abundance, respectively), whilst the most dominant species at the control sites of two fish farms was the polychaete *Nephthys hystricis* (11% of the total abundance in both sites). Furthermore, *N. hystricis* was found at the control sites and the 50 m stations, but never at the 0 m stations, which were located under the center of the cages.

#### Discussion

The additional food resource supplied by the farms is likely to be exploited by opportunistic species. The polychaete *Capitella capitata* is an opportunistic macrofaunal species, which is commonly found in polluted marine sediments [2]. A number of authors have reported the presence of this species under fish cages [2, 4, 5]. In some cases *C. capitata* reached almost 75% of the total abundance at the farm sites [2]. In our study, *C. capitata* does not exceed 65%. On the other hand, polychaete *Nephthys hystricis* was present only at the control sites and 50 m stations, but was absent at 0 m stations. This finding may imply that *N. hystricis* is an indicator of not polluted marine sediments, which is in agreement with other authors [2]. In all cases the benthic assemblages in the immediate vicinity showed symptoms of disturbance, but the spatial extend of this effect was quite limited.

Tab. 1. Average relative abundance (%) per station of macrofaunal species comprising more than 1% of the total abundance at any one station over all sampling cruises (+: presence <1%; C: Crustacea, E: Echinodermata; M: Mollusca; P: Polychaeta; S: Sipunculida). Species are arranged by decreasing average abundance at the stations in proximity to the cages and increasing average abundance at the control sites.

| Species                        | Phylum | AS <sub>1</sub> | $AS_2$ | $AS_3$ | $BS_1$ | $BS_2$ | $BS_3$ |

## PARTICLE FLUXES UNDERNEATH FISH FARMS IN A SEMI-ENCLOSED GULF OF EASTERN MEDITERRANEAN

Nikos Neofitou \* and Spyros Klaoudatos

University of Thessaly, School of Agriculture, Department of Ichthyology and Aquatic Environment, Fytokou str., N. Ionia, 38446 Volos, Greece - nikneof@uth.gr

## Abstract

A field study was carried out at two fish farms of Pagasitikos Gulf in October 2005 in order to determine particle fluxes during feeding. Sediment trap deployments revealed that sedimentation fluxes of particulate matter (PM) and organic carbon (OC) were higher below the farms compared to the control sites located 300 m away. PM fluxes underneath fish cages ranged between 6.51 and 7.33 g m<sup>-2</sup> day<sup>-1</sup>, while OC fluxes ranged between 0.74 and 1.46 g m<sup>-2</sup> day<sup>-1</sup>. In all cases, the spatial extend of this effect was observed to be relatively limited.

Keywords : Aquaculture, Particle Flux, Aegean Sea.

#### Introduction

Little is known of the fish farming impacts in the Mediterranean [1, 2], where fish farming of marine species, particularly sea bream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*), has grown exponentially during the last 25 years. The most widely documented process associated with intensive mariculture is the accumulation of PM on the seabed due to the deposition of solid waste from undigested feed [3, 4, 5]. The objective of this study was to determine particle fluxes underneath two fish farms of Pagasitikos Gulf, a semi-enclosed gulf of the Eastern Mediterranean.

#### Materials and methods

The study was carried out in the Pagasitikos Gulf, central Greece, at two marine fish farms (AS: 39°07'38" N 23°09'17" E, BS: 39°07'13" N  $22^{\circ}57'53''$  E) between the  $11^{th}$  and  $26^{th}$  of October 2005. Sea bream (Sparus aurata) and sea bass (Dicentrarchus labrax) are intensively cultivated in these farms by using pelleted and extruded diets. The average annual standing stocks were 130 t and 92 t, while the Food Conversion Ratio (FCR) was 1.7 and 2.0 for the AS and BS farms, respectively. Sampling was carried out at two stations, in each fish-farm area. The first station was located in the centre of the fish farm and the second at a 300 m distance from the fish farm center, upstream from the main current direction. Henceforth, these stations are referred as Cage and Control, respectively. At each sampling station, particulates sinking to the seabed were collected with a sediment trap, for a 15 day-period time, in order to determine PM and OC fluxes. Each sediment trap consisted of a PVC tube (diameter = 13 cm; height = 76 cm) with a detachable particle collector at its lower end. The sediment trap was attached to a floating buoy vertically oriented in the water column by means of an anchor. The opening of the sediment trap tube was situated 5 m above the seabed. This depth was chosen in order to measure particle fluxes as close as possible to the seabed and yet prevent artifacts from sediment re-suspension [4]. Sample analysis was performed according to the protocol described in [4].

## Results and discussion

PM and OC results are shown in Figure 1. These results show that both PM and OC fluxes were higher at the farm sites compared to the control ones. The above indicated that a considerable amount of uneaten food and faeces reached the seabed, contributing significantly to the overall solid waste production from fish cage systems. The accumulation of uneaten food and faeces below the fish cages may result in organic enrichment [6], thereby affecting the benthic community regarding macrofaunal succession with large differences in the spatial and temporal extend of the impacts [2]. Similar studies have shown that the environmental impacts of fish cage farming vary greatly, according to the site-specific characteristics [3]. During the course of this study, we concluded that the spatial extend of this effect was observed to be relatively limited.

Fig. 1. Sedimentation fluxes of particulate matter (PM) and organic carbon (OC) recorded in two fish farms (AS and BS).

## PRELIMINARY STUDY ON THE BIVALVIA ASSEMBLAGES OF THE NORTHERN ADRIATIC SOFT BOTTOMS

Vedrana Nerlovic \* and Ana Travizi

Rudjer Boskovic Institute, Center for Marine Research, G.Paliaga 5, 52210 Rovinj, Croatia - vedrana.nerlovic@cim.irb.hr

## Abstract

Present study is a part of comprehensive investigation on the soft bottom benthic communities in the northern Adriatic circalittoral zone. It aimed to compare and characterize the assemblages structure and seasonal dynamics of Bivalvia associated with three different benthic communities, i.e. biocoenoses of coastal detritic (DC), muddy detritic (DE) and shelf-edge detritic bottom (DL). The structure of bivalves fauna was determined by distinctive dominance of families Nuculidae, Tellinidae and Veneridae; species *Tellina donacina* and *Nucula nitidosa*, outstanding position of 5-6 species (>5%) per site, and diversity ranged 23-27 species or 3,18-3,68 bits./ind. *Keywords : Adriatic Sea, Bivalves*.

## Introduction

Benthic communities represent powerful tools for detection of natural and anthropogenic disturbance, but also for assessment of marine ecosystems stability. This study dealt with communities experienced heavy disturbance due to oxygen crisis in 1989 [1]. On that occasion Bivalvia were proved to be an excellent indicators of disturbance and ecosystem instability. The results of biennial post anoxic monitoring indicated partial recovery of benthic communities as well as Bivalvia assemblages [1, 2]. In the meantime the anoxic conditions were not repeated. Thus, we expect that recovery of benthos within investigated area is achieved. To test hypothesis on the resilience of benthic communities, assemblages structure and dynamics of Bivalvia were investigated.

## Materials and Methods

Sampling was performed seasonally from March to December 2005 on three permanent sites SJ005 (45°18.4'N: 13°08.0'E). SJ007 (45°17.0'N: 13°16,0'E) and SJ107 (45°02,8'N; 13°19,0'E). All sites characterized by similar environmental features (depths of 30-36 m, silty-sand type of sediment) and close macrobenthic composition [1]. Benthic biocoenoses are classified according Pérès and Picard [3] as: biocoenosis of muddy detritic bottom (SJ005), biocoenosis of shelf-edge detritic bottom (SJ007) and biocoenosis of coastal detritic bottom (SJ107) [1]. At all sites sediment was classified as poorly sorted silty sand (phi=2,38-3,05), and it was distinguished by high participation of sand (57-69%) dominated by fine and very fine fractions [4]. Samples were collected with 0,1m<sup>2</sup>Van Veen grab. The material was treated according to standard field and laboratory procedure: sieving (2 mm and 1 mm mesh), fixation (neutralized 4%formalin and 70% ethanol), counting and classification of macrofauna [5], as well as taxonomic determination of Bivalvia retained on 2 mm sieve [6]. The data were subjected to multivariate and distributional statistical analyses [7].

#### Results and Discussion

A total of 43 species, belonging to 33 genera and 24 families were identified. Faunistic composition were characterized by dominance of *Tellina donacina* and *Nucula nitidosa*, relatively high abundance (>5%) of 5-6 species and lower single participation of all others (Fig. 1a, 1b, 1c). Bray-Curtis similarity coefficients pointed out moderately high faunistic affinity between sampling sites ( $Q_{SJ005:SJ107}$ =38%,  $Q_{SJ005:SJ007}$ =57%,  $Q_{SJ007:SJ107}$ =53%,). The results of ANOSIM (global R=0,762; T=999, p<0, 1) suggested differences in Bivalvia assemblages structure between SJ107 and two other sites ( $R_{SJ005:SJ107}$ =0,969,  $R_{SJ007:SJ107}$ =0,938), but no difference between SJ005 and SJ007 were found.

Mutual intersection of k-dominance curves belonging to particular seasons suggested the same trend of distribution of individuals per species suggested no differences in diversity pattern within sites (Fig. 1d, 1e, 1f). A general shape, position and elevation of k-dominance curves indicated higher diversity and evenness at SJ107, related SJ005 and SJ007 (Fig. 1g). Compared with results of the previous investigations our results point out relatively high stability of Bivalvia assemblages and indicate resilience of benthic communities.

Fig. 1. Species composition and relative abundance of dominant (d>5%) Bivalvia species (a-c); k-dominance curves for Bivalvia assemblages (d-g).

## ALLOMETRIC SOMATIC GROWTH PATTERNS AND OTOLITH SHAPE CHANGES IN *DIPLODUS SARGUS* (LINNAEUS, 1758) DURING METAMORPHOSIS

Nikolaos Nikolioudakis \*, Sotirios Kiparissis , George Koumoundouros and Stylianos Somarakis Laboratory of Zoology, Department of Biology, University of Patras, 26 500 Patras, Greece - nnikolioud@upatras.gr

## Abstract

A mean length at metamorphosis (Ljuv) is defined for *Diplodus sargus* using a multivariate analysis of morphometric characters. The Ljuv corresponds well to significant changes in relative otolith growth and otolith shape (coefficients of Elliptic Fourier Analysis). *Keywords : Biometrics, Fishes, Larvae, Ionian Sea.* 

## Introduction

In comparative studies of fish development an ontogenetic index is usually used, OL=log(L)/log(Ljuv), where L is the larval length and Ljuv the length at which the species completes metamorhosis [1]. However the definition of metamorphosis is debatable. Recently, a multivariate approach, taking into account a large set of characters has been proposed as more appropriate [1]. In this study, we determine morphometrically a mean length at metamorphosis (Ljuv) in *Diplodus sargus* and compare its consistency with changes in otolith relative growth and shape.

## Materials and Methods

A sample of 145 settled Diplodus sargus individuals was collected using a hand-net at depths ranging from 0.5 m to 1 m at a coastal site in the Ionian Sea, in May 2006. Fishes were anesthetized and individually photographed under a stereomicroscope. Morphometric measurements (Pre-orbital length, Eye diameter, Head length, Pre-pelvic length, Predorsal fin length, Pre-anal length, Pre-anal fin length, Post-dorsal fin length, Post-anal fin length, Standard length, Fork length, Eye depth, Head depth, Body depth, Caudal peduncle depth) were taken as defined in [2]. Logarithmic values of measurements were subjected to Principal Components Analysis (PCA) using the covariance matrix [3]. According to the analysis of [3], in an ontogenetic series where shifts in allometric growth patterns between sequencial stages exist, these shifts would be reflected in a multi-stage PCA as divergent PC2 trajectories (changes in oblique orientation). This point during metamorphosis (inflection point) was defined by plotting PC2 on fish standard length (SL) and fitting of a piecewise regression. The right sagitta was removed from each fish, photographed and measured for otolith area (OA) and perimeter (OP). The outlines of the otoliths were also extracted from the digital images and their 2D shape was studied with Elliptic Fourier Analysis (EFA) (invariant of size, position and rotation) [4]. Canonical Variate Analysis of the coefficients corresponding to the first 24 harmonics was used to study otolith shape changes during metamorphosis. Otolith size - fish size relationships were compared with ANCOVA models for the stages before and after the inflection point defined by the analysis of body morphometrics.

#### Results and Discussion

The plot of the second component of the multi-stage PCA on SL (Fig. 1) showed a marked change in orientation during metamorphosis. The inflection point defined by fitting the piecewise regression was 15.11 mm SL. This length was considered as the mean length at metamorphosis (Ljuv) of D. sargus [5]. The slopes of the OP-on-SL and OA-on-SL relationships differed significantly before and after the Ljuv (F=44.74, p<0.001 and F=19.23, p<0.001, respectively). Furthermore, otolith shape differed significantly for fish smaller (Group 1) and larger (Group 2) than Ljuv (Wilk's  $\lambda = 0.25$ , p<0.001). The results presented here, show a good correspondence between allometric changes defined with the multivariate approach and changes in relative otolith growth and shape in D. sargus, which furthermore support the use of morphometrics for defining a mean size at metamorphosis. Good agreement has also been observed between morphological-osteological changes (not presented here) and Ljuv [5], which provide additional support to the approach used. The definition of a mean length at metamorphosis is useful for comparative studies which express development as a logarithmic function of Ljuv.

## Résumé

Les poissons du genre *Diplodus* (Rafinesque, 1810) constituent une ressource halieutique non négligeable sur les côtes est algériennes d'où leur intérêt économique indéniable. Ces espèces occupent une partie considérable dans les apports des pêcheries d'Annaba et constituent une partie importante du régime alimentaire des habitants. Malgré les nombreux travaux consacrés à la biologie des poissons du golfe d'Annaba, les informations concernant la reproduction de ces espèces ne sont pas encore disponibles. Cette étude vise à fournir ces informations pour gérer de façon efficace cette ressource

Mots clès : Algerian Basin, Fishes, Reproduction, Spawning.

## Introduction

En Méditerranée, le genre *Diplodus* est représenté par 5 espèces; le sparaillon *Diplodus annularis* (Linnaeus, 1758), le sar à tête noir *D. vulgaris* (Geoffroy Saint-Hilaire, 1817), le sar à museau pointu *D. puntazzo* (Cetti, 1777), le sar à grosses lèvres *D. cervinus cervinus* (Lowe, 1838) et le sar commun *D. sargus sargus* (Linnaeus, 1758). Ces espèces coexistent en Méditerranée en milieu peu profond sur des fonds rocheux, seul *D. annularis* se trouve sur des fonds sableux et d'herbiers de posidonies. Ces espèces sont importantes dans les apports des pêcheries du golfe d'Annaba. Ce pendant leur reproduction n'a pas été étudié.

Ainsi, nous avons abordé le cycle sexuel des 4 premières espèces dans le golfe d'Annaba pour orienter leur exploitation.

#### Matériels et Méthodes

Notre échantillon provient du golfe d'Annaba. Au total 719 *D. annularis* (104  $\leq$  Lt  $\leq$ 188 mm ; 17  $\leq$  Pt  $\leq$ 118 g) ; 380 *D. vulgaris* (114  $\leq$  Lt  $\leq$ 288 mm ; 11,39  $\leq$  Pt  $\leq$ 220 g) ; 220 *D.* puntazzo (126  $\leq$  Lt  $\leq$ 418 mm, 27,04  $\leq$  Pt  $\leq$ 1188 g) et 254 *D. cervinus* (11,7  $\leq$  Lt  $\leq$ 532 mm, 24,5  $\leq$ Pt  $\leq$ 2200 g) ont été pêchés par filets maillant. Afin de déterminer la périodede reproduction, l'évolution mensuelle du rapport gonado-somatique a été étudiée

RGS = [(Poids de gonades)/(Poids du poisson éviscéré)] \* 100

#### Résultats et Discussion

Le suivi mensuel des valeurs moyennes des rapports gonado-somatique montre que la période de reproduction de *D. annularis* et *D. cervinus* et printano-estivale. Elle s'étend d'avril à juillet chez le sparaillon, elle est plus précoce en Atlantique où elle s'étend de janvier à mai [1; 2]. La valeur maximale du rapport gonado-somatique est enregistrée en mai (RGS = 5,787) indiquant la maturation des gonades. Le cycle sexuel de *D. cervinus* se déroule entre mars et août (fig. 1).

Fig. 1. Le cycle sexuel de D. cervinus se déroule entre mars et août.

L'activité sexuelle du sar à museau pointu du golfe d'Annaba se déroule entre août et novembre. La valeur maximale du RGS est enregistrée en septembre (3,202) marquant la maturation des gonades. Cette période est identique à celle déterminée dans le golfe de Tunis [3]. (fig. 2)

Fig. 2. Marquant la maturation des gonades entre août et novembre, cette période est identique à celle déterminée dans le golfe de Tunis.

Chez *D. vulgaris*, la période de reproduction est hivernale et s'étend de décembre à février. La valeur maximale du RGS est enregistrée en janvier (2,159). (fig. 2). Sur les côtes Sud-ouest du Portugal, la période d'activité sexuelle s'étend jusqu'à mars [4].

Les espèces de sars présentent une succession temporelle de leurs périodes de ponte qui semble être influencées par le réchauffement ou le refroidissement de l'eau de mer. Ainsi les larves qui fréquentent les mêmes nourriceries s'installent à des périodes différentes.

## Conclusion

L'évolution temporelle du rapport gonadosomatique, pour chacune des 4 espèces étudiées nous a permis de déterminer les différentes périodes du cycle sexuel. Il s'avère que la période de reproduction de *D. annularis* et *D. cervinus* est essentiellement printano-estivale. Elle est estivo-automnale pour *D. puntazzo* et hivernale pour *D. vulgaris*.

## LE SAR *DIPLODUS ANNULARIS* (L., 1758) DU GOLFE D'ANNABA: CROISSANCES LINÉAIRE ET PONDERALE

Sabah Nouacer \* and A. Borhane Djebar

Dép. de biologie, Univ 20 août 1955 Skikda . 3 rue Said Bentouatti BP 69, St Cloud, Annaba 23000, Algérie - nouacersabah@yahoo.fr

## Résumé

Le sparaillon *Diplodus annularis* (L., 1758) est un petit sparidé commun aux fonds d'herbiers à posidonie. Son aire de distribution s'étend sur l'ensemble des eaux atlanto-méditerranéennes. Dans le golfe d'Annaba, cette espèce constitue une ressource non négligeable. Ainsi, nous avons étudié son âge et sa croissance par scalimétrie afin d'orienter sa gestion. Les croissances en longueur et en poids sont décrites par le modèle de von Bertalanffy. *D. annularis* du golfe d'Annaba est caractérisée par une croissance lente et allométrique. La relation taille poids varie au cours de l'année et en fonction de l'état physiologique des géniteurs.

Mots clès : Algerian Basin, Fishes, Growth, Population Dynamics.

## Introduction

Le sparaillon *Diplodus annularis* (L., 1758) est un petit sparidé commun aux fonds d'herbier à posidonie. Son aire de distribution s'étend du golfe de Biscaye au Gibraltar et entre Madeira et les îles Canaries, il est également présent en Méditerranée et en Mer noire. Cette espèce constitue une importante ressource commerciale sur les côtes algériennes. Cependant, son âge et sa croissance n'ont pas été abordés, bien que ces données soient des informations clés pour les modèles exploités en dynamique des populations et en écologie halieutique. Ce travail constitue la première étude traitant l'âge et la croissance de cette espèce dans le golfe d'Annaba (Nord est algérien).

## Matériel et méthodes

L'échantillon ayant servi à cette étude se compose de 648 poissons pêchés dans le golfe d'Annaba par filet maillant. La détermination de l'âge a été réalisée par scalimétrie. Pour chaque poisson, 10 à 15 écailles ont été prélevées sous la nageoire pectorale gauche, nettoyées puis placées entre deux lames et ont été observées sous microscope en lumière transmise. Les mesures du rayon de l'écaille et des rayons des différentes marques d'arrêt de croissance ainsi que l'accroissement marginal sont prises par un micromètre. La période de formation de marques d'arrêt de croissance a été déterminée par le suivi des variations mensuelles de l'allongement marginal calculé par la formule suivante:

$$AM = \frac{r - r_n}{r_n - r_n - 1}$$

Avec rn et rn-1: rayons du dernier et avant dernier annulus. Les moyennes des longueurs standard pour chaque groupe d'âge ont été rétro calculées et les couples de valeurs âge - longueur sont ainsi ajustés au modèle de Von Bertalanffy. Les paramètres de l'équation  $(L\infty, K, t_0)$  sont déterminés par le programme Fishparm. La croissance pondérale est également décrite par l'équation de Von Bertalanffy. La nature de l'allométrie a été évaluée par le test t de Student. L'indice de performance de croissance F'= log k + 2 log  $L\infty$  [1] a été utilisé pour comparer les paramètre de croissance obtenus dans différentes régions.

## Résultats et discussion

Le suivi mensuel de l'allongement marginal chez les différents groupes d'âge montre l'individualisation d'un seul anneau d'arrêt de croissance par an. Ce dernier se forme en août indiquant un ralentissement de la croissance qui semble être influencée par la reproduction. Les tailles des sparaillons à différents âges ont été rétro calculées grâce à l'existence d'une corrélation significative entre la longueur totale du poisson et le rayon de son écaille (r = 0,835, p <0,01). L'âge maximum des poissons péchés était de 6 ans. Les croissances linéaire et pondérale absolues sont respectivement exprimées par les formules suivantes:

$$L_t = 19.54 \left[ 1 - e^{-0.46(t+0.565)} \right]$$

$$P_t = 201.791 \left[ 1 - e^{-0.46(t+0.565)} \right]^{-0.137}$$

Les valeurs observées et théoriques de la longueur et du poids des poissons sont très proches et montrent que les croissances linéaire et pondérale sont parfaitement décrites par le model mathématique choisi avec un coefficient de détermination égal à 98.8 % (fig.1).

Fig. 1. Croissances linéaires absolues de D. annularis du golfe d'Annaba.

Le taux de croissance linéaire est plus important durant la première année de vie au bout de laquelle une taille de 100 mm est atteinte. Ce taux tend à diminuer progressivement jusqu'à 9 mm / an à cinq ans. Avec un indice de performance de croissance égal à 5,17; la croissance linéaire estimée de D. annularis du golfe d'Annaba est plus rapide que celle observée dans le golfe du Lion (F'= 5,08) [2], dans le golfe de Gabès (F'= 4,40) [3] et dans les Iles Canaries où cet indice est égal à 5,11 [4]. Cependant, la vitesse de croissance linéaire de ce poisson est lente par rapport aux autres espèces de sparidés de la même région. Le poids des sparaillons évolue plus rapidement que la taille avec un coefficient d'allométrie de 3,137 (p <0,001). Cette valeur est supérieure à celle obtenue en Tunisie (b = 3,094)[3], aux îles Canaries [4] et à celle obtenue au Portugal (b = 3.096)[5] ce qui indique une bonne croissance pondérale de D. annularis dans le golfe d'Annaba. Toutefois deux cas d'allométrie minorante ont été enregistrés en mars (b = 2,54; p <0,001) et en août (b = 2,29; p <0,001). La croissance relative est meilleure chez les individus matures (b = 3,191 ; p < 0,001) que chez les immatures (b = 3,08 ; p > 0,05). Le taux d'accroissement pondéral annuel est de 24,11 g. / an durant la première année. Ce taux augmente progressivement entre la deuxième et la troisième année, puis commence à diminuer pour atteindre une valeur de 22,8 g / an durant la cinquième année. Le poids maximal théorique est de 156,78 g, il est inférieur au poids maximum échantillonné soit 118,42 g.

## EXPLOITATION DE DEUX ESPÈCES DE CREVETTES PROFONDES *ARISTEUS ANTENNATUS* (RISSO, 1816) ET *PARAPENAEUS LONGIROSTRIS* (LUCAS, 1846) DE LA RÉGION ALGÉROISE

Ahmed Nouar

Laboratoire Halieutique, FSB-USTHB, BP.32 El Alia, Alger, Algérie - ahmednouar@hotmail.com

## Résumé

Les chalutiers du port d'Alger exploitent *Aristeus antennatus* et *Parapenaeus longirostris* durant toute l'année sur des fonds allant de 200 à 400 mètres de profondeur. Un chalutier capture, en moyenne par journée de pêche, 62,5 Kg de *A. antennatus* 18 Kg de *P. longirostris*. Le rendement horaire est de 7 Kg/h pour la crevette rouge et de 2 Kg/h pour la crevette blanche. Les paramètres de croissance et d'exploitation déterminés pour ces deux espèces sont en accord avec ceux des différents travaux méditerranéens. *Mots clès : Algerian Basin, Crustacea, Growth, Fisheries.* 

## Introduction

En Algérie Aristeus antennatus (Risso, 1816) et Parapenaeus longirostris (Lucas, 1846), par leur qualité et leur abondance, constituent la presque totalité des captures en crevettes. Entre 1980 et 2000, les apports en crevettes sont en moyenne de 3000 tonnes par an, représentant environ 4% de la production totale annuelle et 10% de la valeur économique globale [1]. Durant toute l'année, les chalutiers de la région d'Alger exploitent des zones de pêche, de profondeur allant de 200 à 400 mètres, connues pour leur bon rendement en crevettes [2].

## Matériel et méthode

Pour l'année 2004, les indices d'exploitation sont définis par analyse des apports de la pêche commerciale des chalutiers du port d'Alger. Des mensurations effectuées en mai 2005 sur 2330 individus de A. antennatus et 1105 individus de P. longirostris ont permis la détermination de certains paramètres biologiques. Les relevés journaliers (exprimés en kilogramme) sont regroupés en apports mensuels répartis en trois groupes (CR : A. antennatus, CB : P. longirostris et un groupe A représentant l'ensemble des autres espèces de poissons, de Crustacés Décapodes et de Mollusques Céphalopodes). Pour chaque mois, la prise moyenne journalière de l'ensemble des chalutiers actifs est calculée à partir du rapport du total des prises sur le nombre de jours de pêche. Pour un chalutier, considéré comme unité d'effort, la prise par unité d'effort journalière correspond au rapport de la prise moyenne journalière sur le nombre de chalutiers actifs. Les paramètres de croissance de von Bertalanffy sont déterminés par analyse des structures de taille avec les méthodes de Powell-Wetherall [in 3] pour L $\infty$ , de [4] pour K et de [5] pour to. Le coefficient de mortalité totale (Z) est estimé par la méthode de Powell-Wetherall, celui de la naturelle (M) par l'équation de [6]. Connaissant Z et M, le coefficient de mortalité par pêche F est estimé.

#### Résultats

Dans l'ensemble, les apports de *A. antennatus* sont trois fois plus importants que ceux *P. longirostris* (Tableau 1).

Ces deux crevettes, représentant 31% de la capture totale (avec 24% pour la crevette rouge et 7 % pour la crevette blanche), sont exploitées durant toute l'année. Le suivi mensuel des apports indique un maximum en été pour *A. antennatus*, période où la capture des autres espèces est relativement faible. Ces variations sont dues à la fermeture des zones de pêche côtière. Durant l'année 2004, le nombre de jours de pêche des

chalutiers du port d'Alger est de 193 jours, avec en moyenne un nombre de 6 chalutiers actifs (ou opérationnels) par jour. Un chalutier capture, en moyenne, 62.5 Kg de *A. antennatus* et 18 Kg de P. longirostris par journée de pêche. Sachant que la durée de pêche effective est de 9 heures par jour, le rendement horaire est de 7 Kg/h pour *A. antennatus* et de 2 Kg/h pour *P. longirstris*. Les paramètres de croissance et d'exploitation obtenus pour ces deux espèces sont reportés dans le Tableau 2. Ces résultats sont en accord avec ceux des différents travaux méditerranéens ([7, 8] pour *A. antennatus* et [9] pour *P. longirstris*).

Tab. 2. Paramètres de croissance et d'exploitation de *A. antennatus* (CR) et *P. longirostris* (CB). N: effectif; L $\infty$ : longueur céphalothoracique asymptotique (mm); K: coefficient de croissance (an); t<sub>o</sub>: temps où la longueur est nulle; Z, M, F: coefficient instantané de mortalité totale, naturelle et par pêche; E: taux d'exploitation (=F/Z), Ø': taux de croissance.

#### Discussion

Les zones de pêche situées entre 200 et 400 mètres de profondeur correspondent à la répartition optimale de *P. longirostris*. La diminution nette du rendement pour cette espèce, en comparaison avec nos résultats antérieurs [1], traduit une situation de surexploitation. *A. antennatus*, en raison de sa haute valeur commerciale, se trouve très recherchée et donc plus ciblée par l'exploitation. Bien que le rendement de *A. antennatus* a sensiblement diminué, sa valeur commerciale qui, en nette augmentation, compense les faibles apports pour les professionnels.

## Abstract

In order to photo-identify the critically endangered Mediterranean monk seal (*Monachus monachus*) inhabiting the northeastern Mediterranean, the monk seal photographs were processed using three-dimensional construction technique. This results show that in order to reach an accuracy level sufficient to identify a monk seal, which has a specific body shape, at least 4 phonographs taken simultaneously from 4 opposing angles are needed. On each these photos, at least 100 matching reference points are needed to be determined. *Keywords : Conservation, Eastern Mediterranean, Sampling Methods.* 

The Mediterranean monk seal (Monachus monachus, Hermann 1779) has been listed as one of the most endangered mammals [1]. Amongst the Mediterranean coastal areas, the northeastern Turkish coast provide one of the last refuge areas where the monk seal still exists and can successfully reproduce. Status of the monk seal colony in the area has been monitored since 1994 by METU, Institute of Marine Sciences. In general, various direct and indirect methods are used to observe and monitor the monk seal populations. The standard sampling methods that are commonly applied to other animals are not practical for the Mediterranean monk seals due to its critical status. One of the most effective methods for identification. cataloging and monitoring individuals without creating any disturbance in their habitat is to use camera traps to obtain high resolution photographs [2]. This technique was effectively used on monk seals by Scoullos et al. [2] Hiby and Jeffery [3], and Gucu et al. [4]. In this study, 3D model construction from photographs was tested as an alternative photoidentification method for monk seals. This technique is based on matching the points on a set of photographs of the same object taken from different angles.

The photogrammetry software Photomodeler Ver.3.1a was used for 3D model construction of monk seals from photographs. In order to obtain appropriate photographs for the software, some of the caves that are suitable for seal use were equipped with Vigil P-Box infrared monitors that may detect a seal up to 18 meter distance with a passive infrared motion detector and sense heat-in-motion with its conical beam. This system was deployed in the caves from January 2004 to December 2005. Besides, to choose sufficient and appropriate reference points that precisely describe the shape of the monk seal, the object having true proportions of a monk seal was used to estimate the minimum number of reference points. For this estimation, after the 3D model construction, real volume of the object was calculated and compared to those estimated by the model. Total number of reference points used in the estimation was plotted against the error term (the error term: the real volume / the estimated volume by the model. The software has several steps including setting the approximate project size and data unit, defining the parameters of the camera used, importing the photographs, marking and referencing points on each photograph and finally processing the project. In the first trial, the best scenes in a video footage of a seal displaying all aspects of the body were captured in still images. These images were transferred to computer and processed following the steps mentioned above. In the next step, still photographs of a seal taken at the same time from varying angles were required due to the limitation emerged in the use of photo captures from a video footage. Therefore, four digital cameras automatically triggered by infrared sensors were installed to the corners of a hauling platform in 2 different caves in order to capture four main aspect of a seal.

The 90 % accuracy was obtained above 100 reference points to construct 3D model of the monk seal including 25 reference points in the head, 66 reference points in the abdomen and 9 reference points in the tail and the maximum accuracy was reached at 150 reference points (Fig.1). The seal modeling trials using the photographs captured from video footage did not reach the necessary levels to give accurate results because of the plasticity of the body of the seal while swimming or crawling on the land. Increasing the number of the reference points, even higher than 150 did not improve the accuracy. After that, 4 seals were photographed from different direction at their haul out platforms in the resting caves. A total of 98 pictures were taken. The ceiling of one the cave was too low to mount the cameras in the proper position. Therefore, none of the photographs were good enough to display entire body of the seal. In the other cave,

the photographs were able to frame the whole body of the seal. Due to dimmed light in the cave, only 25 reference points could be choosen on the photographs which was not enough for 3D model construction.

In this study, as an alternative photo-identification method for monk seals, 3D construction from photographs by using the Photomodeler Version 3.1a were not yielded successful, however it was proven that the technique is able to provide valuable data on seals without giving any disturbance to the animals. At least 4 cameras should be placed horizontally in a way to capture lateral, anterior and posterior aspects of the animal and at least 100 reference points should be defined. Moreover, wider angle lens may be preferred, source of the light may be improved and infrared film may be used to improve the method.

## Abstract

The demographic structure of the early stages of anchovy (*E. encrasicolus*) and round sardinella (*S. aurita*) in the southern Catalan sea in late June 2005 were analysed and results discussed based on the hydrographic situation. Contrasting to previous studies, distribution patterns showed an important overlap, with most of the larvae of both species located between the coast and the 200 m isobath (horizontal pattern) and between the surface and 30 m (vertical pattern).

Keywords : Ichthyoplankton, Larvae, Spawning, Circulation, Western Mediterranean.

The stratified summer period is the main spawning season for anchovy (*E. encrasicolus*) and round sardinella (*S. aurita*) in the NW Mediterranean [1]. Previous studies have documented that their eggs and larvae have different distribution patterns [2]. The present work investigates the conspicuous overlapping distributions observed in June 2005 throughout the analysis of the demographic structure of their early stages and the hydrographic situation. Horizontal egg and larval distributions of the anchovy and round sardinella, as well as microzooplankton biomass presented the highest concentrations over the continental shelf (<200 m) (Fig. 1).

Fig. 1. Egg distributions and ADCP currents at 17 m depth.

A sharp decrease in egg abundance was observed in both species from stations located at <100 m isobath to those located beyond the shelf break (>200 m) (77% of anchovy eggs and 97% of round sardinella eggs were found inshore of 100 m isobath). Although larvae exhibit a wider inshore-offshore distribution, the pattern of abundance also exhibits the highest concentrations in the coastal band (56% of anchovy and 77% of round sardinella).

An increase in the modal size class was evident from the first to the second group of stations, while mode and size range was maintained in the shelf break stations.

The weak SW surface current velocities on the continental shelf could explain this slight cross-shelf larval displacement, but the strong current at the shelf break region (sometimes reaching the maximum values characteristic of this current [3]) could prevent further dispersal.

This coastal pattern for anchovy eggs and larvae is in opposition to the general trends for the species in the region, in which spawning occurs mainly in the shelf break zone and secondary modal size classes of larger larvae appear offshore-wards [1]. The conspicuous overlapping distributions of the two species, together with the similar size structure of their larvae in the different sectors, imply that, under the environmental situation found in June 2005, larvae had to share the available food resources. The fact that the main microzooplankton biomass was also coincident with the main larval distributions would work in favour of survival likelihood of larvae of these species.

## APERÇU ÉCOLOGIQUE SUR LE ZOOPLANCTON DES EAUX DE LA MER NOIRE SITUÉS AU-DESSUS LE CHAMP A *PHYLLOPHORA* (29.07-01.08.2006)

Teodora Maria Onciu \* and Mihaela Muresan Université "Ovidius" Constanta - tmonciu@univ-ovidius.ro

## Résumé

Some data, based on 11 quantitative zooplankton samples performed in summer 2006 during the cruise of "Akademik" (Bulgaria) in the water column above the *Phyllophora* belt from the Black Sea, are given in the paper. Great density values (2058-2708 ex  $m^{-3}$ ) are common in the deeper zone, where also the biological diversity is higher (14-15 species). There were identified 20 taxa, *Noctiluca scintilans* followed by *Acartia clausi, Paracalanus parvus*, Bivalvia larvae and *Oikopleura dioica* being characteristic for the studied area. *Mots clès : Biodiversity, Black Sea, Zooplankton*.

Une importante caractéristique qui concerne à la mer Noire son statut d'unicité hydrobiologique est l'ainsi nommé champ à *Phyllophora* du Zernov, en effet la biocénose du circalitoral *Mytilus-Phyllophora-Lithothamnion*, dont la surface se réduit de nos jours dramatiquement, dû à l'eutrophisation [1].

On a fait l'étude du zooplancton des eaux au-dessus le champ à *Phyllophora* analysant 11 échantillons qualitatifs prélevés avec un filet à traction verticale avec la maile du tissu filtrant de 90  $\mu$ , durant la croisière du bateau de recherche bulgare "Akademik". On a conservé les organismes par une solution de formaldéhyde (4%). Le triage s'est accompli avec un stéréomicroscope Nikon SMZ-2T et un microscope Nikon E200. On exprime les données de densité (D) en nombre d'exemplaires rapportés à un mètre cube d'eau (ex<sup>-m-3</sup>).

On a identifié 20 organismes zooplanctoniques, dont 15 sont holoplanctoniques, les autres méroplanctoniques (25%) [tableau 1].

Tab. 1. Structure qualitative et quantitative du zooplancton des eaux de la mer Noire au dessus le champ à Phyllophora (29.07-01.08.2006) (F% = fréquence; A = abondance;  $D_{moy}/D_{eco}$ = densité moyenne/ écologique; D%= dominance; W = indice de signifiance écologique;  $R_{kD}$  = rang selon les valeurs de densités).

| Oikopleura dioica                              | 90,91  | 274   | 24,86   | 27,35   | 0,95  | 9,31  | 5   |

Dans la région centrale de la surface investiguée, plus profonde (38-51 m) que celle de la périphérie, la diversité taxonomique est plus grande (14-15 espèces), lui correspondant aussi des hautes valeurs de la densité (2058-2708 ex m<sup>-3</sup>), comparables à celles déterminées pour le pelagial des côtes roumaines [2]. Les valeurs extrêmes (732 ex m<sup>-3</sup> en B1 et 6379 ex m<sup>-3</sup> en D7) on été calculées pour les station marginales, situation bien illustrée par les valeurs de la similarité entre les stations [figure 1].

Fig. 1. Similarité entre les stations d'échantillonnage du zooplancton audessus le champ à *Phyllophora* (29.07-01.08.2006).

Selon les valeurs de l'indice de signifiance écologique, *Noctiluca scintilans* est l'espèce caractéristique de la communauté zooplanctonique étudiée, suivie par les copépodes *Acartia clausi* et *Paracalanus parvus*, les larves veligeres de bivalves et *Oikopleura dioica*.

On peut conclure que la communauté zooplanctonique des couches d'eau au-dessus du champ à *Phyllophora* présente une diversité taxonomique remarquable (20 espèces), dont *Noctiluca* est le taxon caractéristique, indiquant la présence d'une grande quantité de matière organique en suspension.

Remerciements des auteurs pour leur collègue professeur Marian-Traian Gomoiu pour le matériel biologique et l'appui scientifique offert.

## MACRO-EPIBENTHIC ASSEMBLAGES ON THE TRAWLING GROUNDS ALONG THE SHALLOW CONTINENTAL SHELF OFF THE BALEARIC ISLANDS (WESTERN MEDITERRANEAN)

Francesc Ordines \*, Enric Massutí , Antoni Quetglas and Joan Moranta

IEO- Centre Oceanogrifi; fic de les Balears, Moll de Ponent s/n, 07015 Palma de Mallorca - xisco.ordinas@ba.ieo.es

## Abstract

The contents of 183 experimental bottom trawl hauls off the Balearic Islands at depths of 38 to 255 m were analyzed. The macro-epibenthic species assemblages of the shallow and deep shelf appear well separated. On the shallow shelf, soft red algae bottoms had a much higher biomass of non commercial species, mostly echinoderms, than maërl beds and sandy-muddy bottoms. *Keywords : Algae, Biomass, Trawl Surveys, Continental Shelf, Balear Islands.* 

## Introduction

Red algae dominate soft bottoms fishing grounds on the shallow shelf off the Balearic Islands [1, 2]. It is assumed that this habitat may be the source of much of the discards reported by the trawl fisheries [3]. The present study characterizes the macro-epibenthic assemblages and their commercial and non-commercial species.

## Materials and methods

The present work analyzed data collected during the BALAR surveys (2001 - 2005) on the continental shelf off the Balearic Islands (38 to 255 m). Sampling scheme and gear were identical to the MEDITS surveys. Biomass and abundance were based on the swept area method. Cluster, MDS and similarity percentage (SIMPER) were used to analyze the data. ANOVA was applied to test for differences between mean biomass of macro-epibenthic assemblages.

#### Results

A total of 183 hauls were analyzed. Cluster and MDS analyses of demersal resources (individuals/km<sup>2</sup>) and macro-epibenthic species biomass (kg/km<sup>2</sup>) separated hauls carried out on the shallow shelf (between 38-96 m and 38-91 in both analyses, respectively) from those on the deep shelf (between 79-255 m and 90-255 m, respectively) at very low levels of similarity (15 and 25%, respectively). Cluster and MDS analysis of macro-epibenthic species yielded three groups on the shallow shelf at 30-35% of similarity. A SIMPER analysis identified three macro-epibenthic assemblages:

- Soft Red Algae bottoms (SRA), with the highest biomass indices, dominated by the echinoderms *Spatangus purpureus* and *Astropecten aranciacus*, the algae *Codium bursa*, *Phyllophora nervosa* and Corallinacea, the ascidian *Ascidia mentula* and the sponge *Suberites domuncula*. Other important species within this group were the alga *Peysonellia squamaria*, the echinoderms *Echinaster sepositus*, *Stichopus regalis* and *Sphaerechinus granularis*, the ascidians *Phallusia mammillata*, *Microcosmus vulgaris* and *Diazona violacea*, and the crustacean *Dardanus arrosor*.

- Maërl Beds (MB), dominated by Corallinacea. Other important species were *S. domuncula*, *A. mentula*, *D. arrosor* and *D. violacea*, the echinoderms *Luidia ciliaris*, *S. purpureus*, *A. aranciacus* and *E. sepositus*, and the alga *Laminaria rodriguezii*.

- Sandy-Mud bottoms (SM) with the lowest biomass indices and very low biomass of red algae.

The biomass of non-commercial species were higher ( $F_{2,75}$ = 48.78 p<0.001) in SRA bottoms (10535±2534 kg/km<sup>2</sup>) than in MB (1377±452 kg/km<sup>2</sup>), or SM bottoms (519±96 kg/km<sup>2</sup>). No significant differences were found for commercial species yields, 935±88, 801±181, 689±124 kg/km<sup>2</sup> respectively. The average composition of the hauls is detailed on Table 1.

#### Discussion

The trawl fishery off the Balearic Islands often operates on SRA bottoms, consisting of *Peysonellia* spp. in the basal layer (and lower biomass of Corallinacea) and *Phyllophora nervosa* in the erect stratum [1, 2]. Invertebrates, mainly echinoderms (up to 52%), and rodophyte algae constitute much of the high percentage of discards reported for the trawling fleet operating on the shallow shelf [3]. These bottoms presented the highest biomass of non-commercial species. Although the commercial fraction showed different compositions for the three types of bottoms examined, no significant differences were found for the mean biomass of commercial species, which highly increases the percentage of the non-commercial fraction on SRA bottoms. The analysis confirms that the exploitation of

SRA bottoms, which have been considered of special importance in other areas [4, 5], results in the removal of large amounts of non-commercial biomass, without increasing commercial yields. A responsible ecosystembased management of the shallow shelf trawl fishery off the Balearic Islands should take those results into account.

Tab. 1. Average composition (% of the biomass  $\pm$ S.E) of commercial and non-commercial fractions from hauls corresponding to each macro-epibenthic assemblage. SRA: Soft red algae bottoms; MB: Maërl beds; SM: Sandy-mud bottoms.

| Commercial          | SRA           | MB                | $\mathbf{SM}$    |

## SPAWNING PERIOD AND SEXUAL MATURITY OF SYMPHODUS CINEREUS (TELEOSTEI, LABRIDAE) IN THE GABES GULF (TUNISIA)

Amira Ouannes-Ghorbel<sup>1</sup>\*, Othman Jarboui<sup>1</sup> and Abderrahmen Bouain<sup>2</sup>

<sup>1</sup> Institut National des Sciences et Technologies de la Mer, Centre de Sfax, B.P 1035, 3018Sfax, Tunisie. - amira.ouannes@instm.rnrt.tn <sup>2</sup> Faculté des Sciences de Sfax , 3028 Sfax, Tunisie.

## Abstract

In this paper, we studied for the first time in Tunisia the spawning period and the sexual maturity of the Gray wrasse *Symphodus cinereus* in the Gabes gulf. The monthly evolution of the gonado-somatic index GSI, liver-somatic index LSI, and conditional factor K, showed that the spawning period of the Grey wrasse in the Gabes gulf occurs from April to June. The length at 50% of sexual maturity,  $L_{50}$ , was 8.3 cm for males and 7.0 cm for females.

Keywords : Gulf Of Gabes, Spawning, Teleostei.

## Introduction

The Grey wrasse *Symphodus cinereus* was one among the twelve species of wrasses in Tunisia waters [1]. In the Gabes gulf this species is mainly caught by the artisanal fishing gears in spring. In this area, the biology of the wrasses was carried out for the first time [2]. In this work we present data on its spawning period and estimate the size at first sexual maturity.

#### Material and methods

The present study is based on 679 individuals, 534 males and 145 females, having a total length between 6.6 and 13.8 cm. Each individual was weighed for total weight, gonad and liver weight, and its total length was measured. The degree of sexual maturity was estimated. The spawning period was determined by analyzing the monthly evolution of the gonado-somatic index GSI. The liver-somatic index LSI and the condition factor K were also calculated. The degree of maturity was determined after macroscopic observation of the gonads. The percentage of mature specimens by sex was calculated for each size class and the size at first maturity,  $L_{50}$ , was determined using the logistic function [3] which was fitted to the observed data using the software 'FSAS' and the Maquardt non-linear adaptation [4].

#### Results and discussion

The evolution of the GSI, LSI and K showed that *Symphodus cinereus* reproduction takes place from Junuary to June. Gonad maturation took place from Junuary to April; spawning occurred in April, May and June, while sexual resting extended from July to October (Figure 1). At the beginning of the gonad maturation, LSI is decreasing. This can be explained probably by the use of the liver reserves for developing its gonads.

Fig. 1. Monthly evolution of GSI, LSI and K for the female *Symphodus* cinereus.

 $L_{50}$  was estimated equal to 8.4 cm for males and 7 cm for females. The coefficients of the logistic function were: males, a = 0.958; b = 8.013; females, a = 0.592; b = 7.926.

## NOTES ON THE ERYTHREAN ALIEN FISHES OF DATÇA-BOZBURUN PENINSULA - A SPECIALLY PROTECTED AREA IN THE SOUTH EASTERN AEGEAN SEA (TURKEY)

M. İdil Oz \*, Erdoğan Okuş and Ahsen Yüksek

İstanbul University, Institute of Marine Sciences and Management, Vefa, İstanbul, TURKEY - idiloz@gmail.com

## Abstract

Fourteen alien fish of Red Sea origin are reported from Datça-Bozburun Peninsula (SE Aegean Sea, Turkey). Their biology and ecology were explored by underwater visual surveys and interviews with local fishermen. We report the first records of *Etrumeus teres* and *Apogon pharaonis*, and the second occurrence of *Pteragogus pelycus* off the Turkish coast of the Aegean Sea. *Keywords : Aegean Sea, Species Introduction.* 

This study is based on the project "Coastal and Marine Biological Diversity Assessment of Datça-Bozburun Specially Protected Area" [1]. The survey of Erythrean alien fish species was carried in 5 sub-regions specified along the Specially Protected Area (SPA) [Fig.1].

Fig. 1. Datça-Bozburun SPA is situated in the southwestern Anatolia.

The presence of 14 alien fish of Red Sea origin was determined by means of underwater visual assessment and interviews with local fishermen.

1) Etrumeus teres (DeKay, 1848): not observed during dives.

2) Saurida undosquamis (Richardson, 1848): not observed during dives.

3) Atherinomorus lacunosus (Forster in Bloch & Schneider, 1801): one of the most common species, preyed upon by another Red Sea alien, *Fistularia commersonii*. Large schools were observed while snorkeling at the depths of 1 to 2 m. 4) *Sargocentron rubrum* (Forsskål, 1775): one of the most common species, encountered in small groups of 5-10 individuals among rocks and in caverns at depths of 15-40 m. It shares that habitat with *Apogon imberbis*, an indigenous species.

5) *Fistularia commersonii* Rüppell, 1835: first recorded from the Datça-Bozburun Peninsula on 17.5.2002, from Selimiye Bay (III). Solitary or small groups of up to 10 individuals were observed to a maximum depth of 20 m. *F. commersonii* was observed changing its colour patterns and staying motionless while waiting to prey on *A. lacunosus* schools.

6) *Apogon pharaonis* Bellotti, 1874: first recorded from the Datça-Bozburun Peninsula on 11.9.2002, from east of Kocaada Island (III). *A. pharaonis* was mostly observed in turbid waters near fish farms or dockyards.

7) *Alepes djedaba* (Forsskål, 1775) was not observed during dives but its eggs were found in the ichthyoplankton survey [1].

8) *Upeneus moluccensis* (Bleeker, 1855): its eggs were recorded in June and September ichthyoplankton surveys [1]. *U. moluccensis* and the indigenous *Mullus surmuletus* were observed feeding in the same area.

9) *Pempheris vanicolensis* Cuvier, 1821: groups of 10-15 individuals were observed in caverns.

10) *Pteragogus pelycus* Randall, 1981: first recorded from the Datça-Bozburun Peninsula on 16.9.2002, in waters off Bozburun village (II). Solitary individuals were generally seen swimming in and around *Posidonia oceanica* meadows.

11& 12) Siganus luridus Rüppell, 1828, and Siganus rivulatus Forsskål, 1775: The most common species, generally recorded in mixed groups of 10-20 individuals at depths between 2-30 m. Juveniles were seen together with adults at 2-8 m. Both species were observed feeding on algae in rocky areas and on epiphytic algae off *Posidonia oceanica* leaves and *Cystoseira* spp., together with the indigenous *Diplodus vulgaris*, *Diplodus sargus*, *Symphodus tinca* and *Sparisoma cretense*. Interviews with fishermen revealed that siganids are target species for the local artisanal fishery and constitute its main catch between May and October.

13) Scomberomorus commerson (Lacepède, 1800) (no sample obtained):

a rare species seen only in Yeşilova Bay(II). Local fishermen indicated that, *S. commerson* populations have declined sharply in 2005 due to over-exploitation between 2000-2004.

14) Stephanolepis diaspros Fraser-Brunner, 1940: mostly solitary individuals were seen at a depth range of 10-20 m.

*E. teres*, *A. pharaonis* and *P. pelycus* are rarely encountered in the studies carried out along the Aegean Sea coasts. The first records of these species in Aegean waters were from Rhodes Island (SE Aegean Sea-Greece) [2,3,4]. The presence of *P. pelycus* along the Turkish coasts of the Aegean Sea is mentioned in [5] as personal observation, without giving a specific reference. In 2005 it was recorded for the first time from Gökova Bay (SW Aegean Sea-Turkey) [6].

## ON THE RANGE EXTENSION TWO EXOTIC DECAPOD CRUSTACEAN ALONG THE LEVANT SEA COAST OF TURKEY

Tahir Ozcan \*, Kerem Bakir and Ahmet Kocataş

Ege University, Fisheries Faculty, Department of Marine Biology 35100 Bornova-Izmir/Turkey - tahir.ozcan@ege.edu.tr

## Abstract

The decapods of Fethiye bay, on the southwestern coast of Turkey were collected by gill net between 2004 and 2006. For two exotic decapod crustaceans, *Melicertus hathor* and *Charybdis hellerii*, the records constitute significant extension of their range. *Keywords : Decapoda, Crustacea, Red Sea, Levantine Basin.* 

31 species of exotic decapods are known to occur along the Turkish coast [1,2], most are found along the southeastern coast. In recent years many species extended their range westwards along the Turkish coast [3]. of Fethiye bay, on the southwestern coast of Turkey were collected by gill net at depths between 3-20 m, between 2004 and 2006. Two species of Red Sea origin were found, both new record for Fethiye Bay, and a significant range extensions within Turkey.

*Melicertus hathor* (Burkenroad, 1959) was recorded for the first time in the Mediterranean Sea from the coast of Israel [4]. The first Turkish record was collected in Yumurtalik Bight [5], and subsequently off Kaş Peninsula [6], and Antalya Bay [7]. The two male specimens (TL 15.2, 15.8 mm) were collected on sandy bottom from the Fethiye Bay.

The records of *Charybdis hellerii* (A. Milne Edwards, 1867) in Turkey were collected off Iskenderun and Mersin [8,9], and Kaş Peninsula [6]. In September 2004, *C. helleri* was collected off Göcek. The Göcek specimens (1 male CL 56 mm, 5 females CL55-61 mm) were fully developed adults, 4 of 5 females were ovigerous. The eggs were bright yellow in color, their diameter 0.224 - 0.266 mm. The minimum, maximum and average number of the eggs from 4 ovigerous females of *C. hellerii* were examined as 42016, 93913, 106994, 152583 and 98876 respectively. In 2006 the species was widespread in the region. This is the westernmost record of *C. hellerii* along the Turkish coast, and nearly 450 km west of the previous record. *C. hellerii*, like *C. longicollis*, occupies the entire Levantine coast of Turkey. It seems that the habitat preferences, spawning period, egg number and egg diameter do not differ significantly from known records for *C. hellerii*, though the maximum carapace length of both species is very close to the highest values of the early reports.

## ABUNDANCE OF ZOOBENTHIC EXOTIC SPECIES ON ROCKY REEFS IN THE SOUTHERN AEGEAN SEA

Elif Ozgür \* and Bayram Öztürk

Istanbul University, Faculty of Fisheries, Ordu St. No. 200, 34470-Laleli, Istanbul-Turkey - eozgur@istanbul.edu.tr

## Abstract

In order to provide information on the abundance of the zoobenthic exotic species on the rocky reefs in the southern Aegean Sea, samplings were carried out between August 2003 and May 2004. The examination of the 2294 macrozoobenthic specimens collected revealed the presence of ten exotic species among 211 species. The abundance and distributional details of these species are discussed. *Keywords : Aegean Sea, Eastern Mediterranean, Zoobenthos.* 

## Introduction

The Aegean Sea, as part of the Mediterranean Sea, is characterized by numerous islands and islets. Its complicated geomorphology, including caves, reefs etc., creates a high habitat diversity, which leads to high species diversity [1]. The present research aimed to determine the abundance and distribution of the established exotic species on rocky reefs which are partially the most untouched and remote habitats in the southern Aegean Sea.

#### Materials and Methods

This research was carried out between August 2003 and May 2004, in the southern Aegean Sea by SCUBA diving. A total of 80 samples were taken, seasonally, from four depth levels and six stations (Figure1). 400 cm<sup>2</sup> quadrates were sampled, including both sessile and motile species. All samples were sieved through 0.5 mm screens, labeled and preserved in 4% formalin. After the sorting process, the macrofauna was counted and identified at species level.

Fig. 1. Study area indicating sampling sites.

## Results

The examination of the 2294 macrozoobenthic specimens collected revealed the presence of ten exotic species among 211 species (127 molluscs, 9 sponges, 59 crustaceans, 16 echinoderms) [2]. The most abundant (44.2%) and dominant taxon in terms of species richness (46.9%) was Gastropoda on the reefs. Among the total of 99 Gastropod species with an average abundance of 317 individuals/m<sup>2</sup>, there were 5 exotic species with the average abundance of 34,25 ind/m<sup>2</sup>, that comprised mainly by *Strombus persicus* (Table1). The highest amphipod abundance (843,75 ind/m<sup>2</sup>) was found at the depth of 10 m, where there were dense *Cystoseira* canopies, and the abundance decreased with depth. Among 30 amphipod species, the exotic species, *Stenothoe gallensis* constituted 7,1% of the amphipod abundance at 10m.

## Discussion

The present study reports ten exotic species. These species are recognizing as established Lessepsien invaders that entered the Mediterranean Sea through the Suez Canal [3,4,5,6,7]. Among them, *Strombus persicus* was a keystone species that was common and dominant in all stations, seasons and depths. This species occurs in very dense numbers in the Eastern Mediterranean, where it is a major competitor for herbivorous species [8].

Rocky reefs play an important role for migrant species by extending their distribution in the high sea by facilitating the larval dispersal and settlement. This is also relevant for exotic species. Thus, long-term approaches are required to monitor of the exotic species in proportion to local and endemic species and to document the displacement and replacement events. ## ADDITION TO THE KNOWLEDGE OF TURKISH MOLLUSC FAUNA

Bilal Oztürk, Mesut Önen and Alper Dogan \*

Ege University, Faculty of Fisheries, Dept. Hydrobiology, 35100, Bornova, Izmir, Turkey - alper.dogan@ege.edu.tr

## Abstract

The present study reports 15 new mollusc records for the Turkish mollusc fauna. Samples were collected along the Turkish Aegean and Levantine coasts, at depths 0-200 m, between 2000 and 2005. Among the established species, *Tiberia minuscula* Monterosato, 1880, is also reported for the first time from the Aegean Sea. In this study, ecological remarks on the established species are presented. *Keywords : Mollusca, Aegean Sea, Levantine Basin.* 

### Introduction

Nearly 2000 mollusc species are known from the Mediterranean Sea, 745 of which were reported from Turkish seas (1). In recent years additional records were added (2, 3, 4, 5 and 6), and the number of species is estimated at over 800. In the present study, 15 mollusc species are reported for the first time from Aegean and Levantine coasts of Turkey.

#### Materials and methods

The samples were collected along the Turkish Levantine and Aegean coastline in the framework of various studies conducted between years 2000 and 2005 with different purposes. The sampled material was taken at depths ranging from 0 to 200 m. The specimens are deposited at the museum of the Faculty of Fisheries, Ege University, Turkey (ESFM).

## Results and discussion

As a result of our studies, 15 new records to Turkish Seas (14 gastropods and a bivalve) (Table 1) were identified of which 7 species are from northern Aegean Sea, 2 species are from southern Aegean Sea, 3 species are both from northern and southern Aegean Sea and 3 species are from Levantine Sea.

Among the new records, *T. minuscula* is being reported for the first time from the Aegean Sea, which seems to be a new report also for the eastern Mediterranean according to literature. In addition, *Dizoniopsis coppolae* (Aradas, 1870) has also been found in this study. A total of 9 individuals of this species were sampled from Salih Island coast, near Bodrum (Southern Aegean Sea), obtained from *P. oceanica* and sand mixture dredged from a depth of 13 m. *D. coppolae* was reported from the Turkish coasts only once, from the Sea of Marmara (7).

In the last two decades, parallel to the increasing number of researches carried out, the mollusc species known from Turkish coasts was also increased. On the other hand, a rapid increasing of the rate of alien species known from Turkish seas is another remarkable point as a result of these studies. For example, according to the addendum given by (8), 90 alien

mollusc species are recently known from Turkish coasts, of which the majority (84 species) were reported from Levantine coast of Turkey. It should not be neglected that the monitoring of these species (both settled and potential settlers) incoming the region by various pathways is of great importance, in order to determine their probable negative effects on time in the ecosystem where they have been settled, even they make contribution to the biological richness of the region and no evident negative effect to the native fauna has been reported to date.

#### Acknowledgement

The authors are greatly indebted to Prof. Serge Gofas (University of Malaga, Spain) for his help in identifying *D. coppolae* and *T. minuscula*. This work has been financially supported by TUBITAK [Project Number: TBAG 2343 (103T154), coordinated by Bilal Öztürk].

## LITTER AS A SOURCE OF HABITAT ISLANDS ON DEEP WATER MUDDY BOTTOMS

Roberta Pace<sup>1</sup>, Mark Dimech<sup>1</sup>, Matthew Camilleri<sup>2</sup> and Patrick J. Schembri<sup>1</sup>\*

## Abstract

Certain types of marine litter, usually considered as pollutants, may also be a resource, serving as artificial reefs on sedimentary bottoms. In order to study this aspect, marine debris was collected by bottom trawl from muddy bottoms (depths of 45-700m) in the waters around the Maltese islands, during July 2005. The associated fauna was identified and quantified. Litter was found to support a higher abundance of organisms than the surrounding sediment, but a lower species richness. However, the suite of epifaunal species on the debris was different from the infauna of the surrounding substratum. Thus litter was found to increase the overall biodiversity of particular areas. *Keywords : Metals, Plastics, Pollution, Secondary Production, Biodiversity*.

#### Introduction

Litter is usually viewed as a pollutant due to its detrimental effects, especially while still floating or suspended [1,2,3]. However, relatively inert, sunken marine litter may potentially serve as a resource for benthic fauna. Anthropogenic material may act as an artificial reef especially where hard substrata for settlement are at a premium. To explore this aspect, marine litter from sedimentary bottoms in deep water (45-700 m) around the Maltese Islands was sampled. The sessile biota associated with the different kinds of debris was identified and counted. The results obtained were compared with data on the infauna of the sediment on which the litter was settled, in order to evaluate the contribution of such deep-water debris to benthic biodiversity on these grounds.

#### Methods

Samples were collected by trawling during a research cruise on the RV *Sant' Anna* made in July 2005 as part of the ongoing MEDITS trawl survey programme [4]. Litter was gathered from 44 hauls made in deep water (45 - 700m) around the Maltese islands (Fig. 1). The debris was separated into different categories (cloth, glass, metal, plastic, pottery and sacks). For each item, the surface area was measured and any associated live macrofauna were identified and counted; abundance was then standardised per m<sup>2</sup> of litter substratum. The data were analysed using univariate and multivariate (non-metric multidimensional scaling and agglomerative, hierarchical clustering) methods.

Fig. 1. Map of the 44 sampling stations (dots) distributed around Malta.

#### Results and Discussion

The marine debris recovered consisted of 47% plastic, 13% metal, 13% glass, 4% cloth, 3% sack and 2% pottery. The biotic growth density on all litter collectively was 141 (412 s.d.) individuals per m<sup>2</sup> of litter substratum. Biota was more abundant on litter than in the surrounding sediment, where the mean density of infauna was 64 individuals per m<sup>2</sup> as estimated from 0.0625m<sup>2</sup> box core samples (DM unpublished data, 2005). However, the sediment supported a higher species richness (38 species from a collective sediment surface area of 1.88m<sup>2</sup>, DM unpublished data, 2005) than the marine debris (47 species from a collective litter surface area of 635.62m<sup>2</sup>). Nevertheless litter supported a totally different suite of fauna from that of the sediment, which would otherwise have been absent without the debris.

The mean Shannon-Wiener diversity per  $m^2$  of litter substratum was 0.14 (0.30 s.d.). This low value and high standard deviation are a result of many

litter items either without epibiota or with only one species, consequently resulting in a diversity index of zero. The associated mean Pielou's evenness measure per  $m^2$  of litter substratum was 0.7 (0.25 s.d.), calculated excluding those litter items with no growth, or with a Shannon-Wiener index of zero. Calculated thus, evenness was quite high, confirming that an overall low diversity was primarily due to several litter items being colonised by only one species. Metals and pottery items had a relatively high species richness, but both parameters were low for sacks, plastic and cloth. The exception was glass, which had a relatively high species richness but a low abundance of epifauna.

Multivariate classification of the different litter types based on species abundance data resulted in three groups: plastics and glass, pottery and metals, and sacks. This seemed related to the surface texture of each litter type. Plastic (especially bottles) and glass usually had very smooth surfaces, while metal and pottery had much rougher faces. The woven fabric of sacks had a totally different texture from all other litter types. Classification based on presence/absence of different faunal species resulted in three groups: metals, plastics and sacks, and pottery and glass. This classification may be related to the different resting position of the litter types on the seabed, and to the stability of this orientation. Sacks and plastic bags can be easily turned over by slight water movements, while metal cans and plastic bottles are highly prone to being rolled over, smothering the attached fauna. Glass bottles are heavier than both plastic containers and metal cans, therefore are less susceptible to rolling. In contrast, pottery is the litter type on which the orientation of fauna with respect to the substratum and the water column is least liable to change.

## Conclusions

Anthropogenic debris was found to support a higher abundance of organisms than the surrounding sediment, but a lower species richness. However, the suite of epifaunal species on litter was different from the epi- and infauna of the surrounding sediment. Thus the presence of litter on deep water sedimentary bottoms increases the overall biodiversity of particular areas. A more diverse benthic biota may result in a more diverse demersal fish fauna due to the greater scope for trophic specialisation and possibly an increase in secondary production.

## DISTRIBUTION AND DENSITY OF DISCARDED LIMESTONE SLABS USED IN THE TRADITIONAL MALTESE LAMPUKI FISHERY

## Abstract

The Maltese *Coryphaena hippurus* fishery employs fish aggregating devices anchored to the seabed by limestone slabs that are discarded after each season. It is estimated that more than 15,000 such slabs are deposited on the seabed each year, thus the number of limestone blocks left on the seabed by the decades-old fishery must be quite high. This study attempted to estimate the distribution and abundance of limestone slabs in the sea around Malta. The abundance of slabs was much less than expected, implying that a mechanism that gradually removes slabs from the surface of the seabed is operating in the area studied.

Keywords : Pollution, Fisheries, Trawl Surveys.

#### Introduction

*Coryphaena hippurus* (Maltese: *Lampuki*) is a key species targeted by the Maltese fishing industry, accounting for ca 40% by weight of the total annual catch [1]. Lampuki are captured by means of FADs which are anchored using limestone slabs (the same that are generally employed in the Maltese building industry). When the *lampuki* season (September-December) is over, fishermen retrieve the FADs but leave the slabs behind and each year fresh slabs are used. Considering that this traditional fishery is decades-old, and that more than 15,000 FADs are laid each year [2], the number of slabs that have been deposited on the seabed over the years must be substantial. The aim of this study was to estimate the density and distribution of limestone slabs on the seabed around Malta, as a preliminary tstudy of their ecological effects.

#### Methods

Limestone slabs were collected by trawling during a research cruise of the RV *Sant' Anna* made in July 2005 as part of the ongoing MEDITS trawl survey programme [3]. Slabs were recovered from 45 hauls (45-700 m) distributed around the Maltese islands (Fig. 1); 59% of the swept area was located on FADs trajectories (these trajectories have remained constant for decades), while the remaining 41% of the trawled area was non-FAD area where the laying of such devices is illegal. The slabs collected were classified into age categories: pre-1976, 1976-1980 and post-1980; age could be determined from the dimensions of the slabs, since these building blocks have a standard size which was changed at known times [4]. The mean abundance of limestone slabs was calculated. A map showing the abundance of slabs at each station was superimposed on a map of FAD distribution around the Maltese islands to see if the blocks are being dispersed from the points of deposition.

#### Results and discussion

The total number of limestone slabs (l.s.) was 28 in  $3.5 \text{ km}^2$  of swept area (8 l.s. km<sup>-2</sup>), 15 of which were found in  $1.4 \text{ km}^2$  of non-FAD area (10.5 l.s. km<sup>-2</sup>) and the remaining 13 were found in 2.1 km<sup>2</sup> of FAD area (6.1 l.s. km<sup>-2</sup>). This implies that slabs were more common in areas where the laying of FADs is not allowed than in areas where FAD trajectories are allocated (Fig. 1).

The reasons for this can be threefold: (1) the illegal deployment of FADs in non-FAD areas; (2) the use of slabs for other purposes, such as ballast to stabilise fishing boats when empty, the slabs then being disposed of randomly; (3) the movement of the limestone slabs from their point of deposition to other areas. Even though at the depths sampled water currents of sufficient strength to move the heavy slabs are not likely, the blocks may still be moving as a result of trawling activities, which generally involve an initial clearing of the area to be trawled from litter, and disposing of this in other non-trawled areas.

61% of the slabs collected were of recent origin, deposited after 1980; 25% were from the 1976-1980 period, while pre-1976 slabs constituted a mere 14%. Assuming that the number of FADs laid has remained constant over the years, it would appear that in the area surveyed, blocks are being removed from the seabed with time. Two plausible explanations can be either that the slabs were cleaned by trawlers from the area studied (all sampling stations in this study were located in areas where trawling is permitted), or that the limestone blocks are gradually sinking into the sediment until completely buried. However, whilst still on the seabed, the blocks can serve as islands of hard substratum on the otherwise soft sed-

imentary bottoms surrounding the Maltese islands at the depths sampled, thus increasing biodiversity by providing attachment space for epibiota [5]. Nonetheless, the slabs can also have detrimental effects as a result of smothering sessile biota. They can also inhibit exchange between the water column and the interstitial waters of the sediments, although this might be negligible since the overall surface area covered by the blocks is very small (ca  $23 \times 26 \times 60$ cm).

Fig. 1. Standardised abundance of limestone slabs at each station (dots), superimposed on a map of FAD distribution around the Maltese islands.

#### Conclusions

Even though the traditional *lampuki* fishery has been in existence for decades and more than 15,000 slabs are deployed each year, the estimated abundance of limestone slabs was much lower than expected. This implies that in the area studied mechanisms are operating to remove the slabs from the surface of the seabed, counterbalancing the yearly input of blocks.

## MODELLING THE ECOLOGICAL ROLE OF SMALL PELAGIC FISH IN THE CATALAN SEA (NW MEDITERRANEAN)

Isabel Palomera<sup>1</sup> \*, Marta Coll<sup>1</sup> and Sergi Tudela<sup>2</sup>

<sup>1</sup> Institut de Ciències del Mar (CMIMA-CSIC), Passeig Marítim de la Barceloneta, 37-49 - 08003 Barcelona, Spain. - isabel@icm.csic.es <sup>2</sup> WWF Mediterranean Programme Office. Canuda, 37. 08002. Barcelona. Spain.

## Abstract

This contribution aims at investigating the ecological role of small pelagic fish in the South Catalan Sea (NW Mediterranean) by applying mass-balance and trophodynamic modelling. Results describe the high importance of these organisms within Mediterranean food webs and evidence the need of progressing towards a sustainable management of their fisheries. *Keywords : Pelagic, Fishes, Food Webs, Models, Western Mediterranean.* 

Small pelagic fish (SPF) are important elements of marine ecosystems due to their relevant biomasses at intermediate levels in the food web, notably contributing to canalize the energy connecting the lower and upper trophic levels. Fluctuations in SPF populations due to fishing or to environmental factors can contribute to modify the structure and functioning of marine ecosystems [1]. Environmental factors are essential to explain their dynamics, which are subjected to fluctuations due to their relatively short life cycle (3-4 years). Moreover, an intense fishing activity can contribute to impair their populations.

Main SPF inhabiting the NW Mediterranean Sea are anchovy (*Engraulis encrasicolus*), sardine (*Sardina pilchardus*), round sardinella (*Sardinella aurita*) and sprat (*Sprattus sprattus*). Anchovy and sardine represent almost 50% of the total landings in the Catalan Sea and support important biomasses [2]. Both landings statistics and biomass estimates have shown a steadily decline in the area during the last decades. The production of sardine and anchovy in the region is clearly influenced by changes in the environment [3].

An ecological model of the South Catalan Sea [4] using Ecopath with Ecosim (EwE) approach [5] was used to put available ecological data from SPF into an ecosystem context. Global results showed how they are essential mid trophic levels of the food web, in line with results from other Mediterranean and upwelling areas [1,6]. They are involved in main trophic flows and constitute important elements controlling prey and predator populations (Figure 1), most probably related with bottom-up and wasp-waist flow control situations.

Fig. 1. Schematic flow diagram of the South Catalan Sea, where SPF trophic links are highlighted. B = Biomass (t km<sup>-2</sup>); P = Production and Q = Consumption (t km<sup>-2</sup> yr<sup>-1</sup>). Drawings from www.gencat.net.

Results of the ecological model also highlighted how fishing activity had a high impact on these groups during the 1990s (Table 1). SPF were related with high exploitation rates and high primary production required to sustain their catches, and consumption of SPF production by the fishery was also high. These results are in line with an increasing concern of high fishing intensity on these species and a recruitment overfishing situation related with anchovy stocks [7]. Moreover, cross-system comparisons of standardized trophic models of South Catalan Sea with upwelling systems from Humboldt and Benguella regions had evidenced the higher fishing impact on small pelagic fish in the Mediterranean area due to the smaller production and biomass rations and higher fishing rates [8].

Tab. 1. Indicators for small pelagics' fisheries in the Catalan Sea.

| Group       | TL1               | PPR SPF (%) <sup>3</sup> | F/Z <sup>5</sup> | Consumption (%) <sup>6</sup> |
|-------------|-------------------|--------------------------|------------------|------------------------------|
| Anchovy     | 3.09              | 9.78                     | 0.30             | 27.80                        |
| Sardine     | 3.01              | 15.80                    | 0.53             | 54.28                        |
| Other SPF   | 3.05              | 0.19                     | 0.10             | 10.39                        |
| Total Catch | 3.12 <sup>2</sup> | 10.6 <sup>4</sup>        | -                | 20.20 <sup>7</sup>           |

 $^1$  TL = trophic level of species;  $^2$  mean trophic level of the catch;  $^3$  PPR SPF (%) = primary production required to sustain the catch of SPF in relation with total %PPR,  $^4$  Total PPR%;  $^5$  F/Z = exploitation rate;  $^6$  Consumption (%) = consumption of SPF production by fishing;  $^7$  Total consumption of fishable production (%).

The impact of fishing was also analysed by developing dynamic simulations with trophodynamic modelling [5]. The steady decline of pelagic landings between 1994 and 2003, coupled with a decrease of the pelagic biomass within the ecosystem, could be reproduced by the model combining different scenarios of moderate increase of fishing effort and an environmental forcing under wasp-waist flow control [4]. This decline underlined the low resistance of the system in front of perturbations and the relevance of fishing, in conjunction to environmental forcing, to understand the dynamics of small pelagic fish in the area. These results are of relevance in terms of management of exploited marine resources in the area since the high exploitation of small pelagic fish can produce important impacts of the structure and functioning of the exploited ecosystem.

## CYSTOSEIRA CRINITA COMMUNITY IN THE AEGEAN SEA

Panayotis Panayotidis <sup>1</sup>, Sotiris Orfanidis <sup>2</sup> and Konstantinos Tsiamis <sup>1</sup> \* <sup>1</sup> Hellenic Center of Marine Research, 19013 Anavissos, Athens, Greece <sup>2</sup> NAGREF-Fisheries Research Institute, 640 07 Nea Peramos, Kavala, Greece - ppanag@ath.hcmr.gr

## Abstract

The algal community dominated by *Cystoseira crinita* was studied at 26 sites of the Hellenic "NATURA 2000" network in the Aegean Sea. The aim of the study was to give an overall aspect of the community structure, corresponding to its "typical" composition in unpolluted areas of the North-Eastern Mediterranean. A SIMPER analysis was carried out on 62 samples of phytobenthos from the Hellenic "NATURA 2000" data-base. From 113 species identified in total, 9 species contributed cumulatively by 90% in the community, while a group of 34 species contributed cumulatively by 99% in the community.

Keywords : Algae, Phytobenthos, Coastal Management, Aegean Sea, Eastern Mediterranean.

#### Introduction

In the pristine areas of the Mediterranean coastline, the species of the genus *Cystoseira* are usually the dominant benthic vegetation elements at the upper infralittoral zone (0-1 m depth). According to Pérès & Picard the *Cystoseira* algal community is considered as the final stage (climax) of the photophilic algal communities' succession, thus it can be considered as indicative of the environmental conditions ([1]).

In the Aegean Sea the *Cystoseira crinita* Duby community is one of the most common elements of the vegetation in undisturbed areas, with an extensive distribution from exposed to sheltered sites ([2]).

The present paper studies the *C. crinita* algal community at different putatively pristine Aegean Sea sites in order to develop an objective and statistically valid "virtual" list of the most common algal species in the Aegean under undisturbed conditions, and also to test the conceptual model and the biotic index EEI recently developed by Orfanidis *et al.* ([3]) for the implementation of Water Framework Directive (2000/60/EC) in Greek coasts.

## Methodology

The data used in the present paper are part of the Hellenic "NATURA 2000" data-base build up by a scientific consortium (scientists in charge in Panayotidis *et al.*, [4]) in years 2000 to 2001. A selection of 62 *Cystoseira crinita* quantitative (20 x 20 cm or 25 x 25 cm) and destructive samples from 26 putatively pristine Aegean sites was undertaken (Fig. [1]). They were representatives of the photophilic algal community of the rocky upper infralitoral zone. In the laboratory formalin fixed samples were carefully analyzed by identifying species presence and by estimating their vertically projected coverage. The total coverage usually exceeded 100% due to the presence of different vegetation layers (canopy, bushy, crusts and epiphytes). Untransformed data were analyzed by SIMPER-analysis (PRIMER v. 5) to estimate algal species abundance and contribution (%). The species were classified in two Ecological State Groups (ESG), in accordance to Orfanidis *et al.* ([3]) approach.

#### Results and Discussion

In total 113 taxa (73 Rhodophyceae, 25 Phaeophyceae, 15 Chlorophyceae) were identified. Nine (9) major taxa contributed cumulatively by 90%in the community: Haliptilon virgatum, Cystoseira compressa, Jania rubens, Padina pavonica, Herposiphonia secunda, Corallina elongata, Cladophora spp., Sphacelaria cirrosa and Titanoderma cystoseirae (see also [5]). Moreover, 34 taxa contributed cumulatively by 99%. Bushy layer considerably dominated to the community with most common representatives the red coralligenous algae Haliptilon virgatum, Corallina elongata and Jania rubens, and the brown alga Padina pavonica. It was followed by C. crinita epiphytes distinguished in: 1) filamentous green ( Cladophora spp.), brown (Sphacelaria cirrosa) and red (Herposiphonia secunda) algae, and 2) in encrusting red algae (Titanoderma cystoseirae and Hydrolithon spp.). Cystoseira compressa contributed significantly (23.08%) to C. crinita community indicating that these species share common habitat resources in the Aegean Sea, a phenomenon also known, at least at the past ([1]), in the Albéres coasts of France.

Within the most common *Cystoseira crinita* taxa, 21 (62%) belong to opportunistic ESG II, whereas 13 (38%) taxa belong to late-successional ESG I (Table 1). By contrast, the ESG I taxa (87%) dominated quantitatively the ESG II (13%) taxa in the *C. crinita* community. This result is in accordance both: a) to the conceptual model of Orfanidis *et al.* ([3]) that "in less anthropogenic stressed coastal areas (pristine) the late-

successional species dominate" and b) to the basic assumption of the Ecological Evaluation Index (EEI) that ESG II average contribution in undisturbed areas is less than 30%.

## THE IMPACT OF SCAVENGERS ON THE CREEL FISHERY FOR *NEPHROPS NORVEGICUS* IN THE CENTRAL ADRIATIC SEA

Monica Panfili \*, Elisabetta B. Morello and Carlo Froglia

CNR-ISMAR, Sezione Pesca Marittima Ancona, Largo Fiera della Pesca, 60125 Ancona, Italy - m.panfili@an.ismar.cnr.it

## Abstract

Scavenging activity in the western Pomo pit fishing grounds (Adriatic sea) was studied by means of baited funnel traps with the aim of evaluating its impact on a hypothetic creeling activity for *Nephrops*. The isopod *Natatolana borealis* was the main responsible for bait consumption, which took place completely within 24 hours of trap deployment. Amphipods arrived later, not before 12 h. *Keywords : Adriatic Sea, Crustacea, Fisheries, Food Webs*.

## Introduction

In Mediterranean waters, Norway lobster (*Nephrops norvegicus*) is mainly targeted by bottom trawlers. The selectivity of bottom trawls with respect to this species is very poor and large quantities of discards are produced [1, 2]. The reduction of discards and incidental by-catch is a priority in the Common Fishery Policy of the European Union. For these reasons, an alternative fishing method targeting *Nephrops* was sought through the use of baited creels.

The western Pomo pit (200 - 250 m depth, central Adriatic Sea) is an area intensively exploited for *Nephrops* by the Adriatic trawling fleet and thus all experimental work was carried out there. This area has been reported to be characterised by conspicuous numbers of benthic scavengers that could considerably affect creel catches [1]. This paper summarises the results of an investigation into the species composition and activity of scavenging invertebrates living in the area, with the aim of evaluating their impact on a hypothetic creeling activity for *Nephrops*.

#### Materials and methods

In order to identify benthic scavengers, baited funnel traps made from PET bottles (volume = 1 litre; entrance  $\emptyset$ = 18mm) were deployed in the same area as *Nephrops* creels within the western Pomo pit. The traps were baited with salted sardine (3 fish per trap), exactly in the same manner as were the creels. On two occasions (20/08/2004 and 23/08/2004), four separate fleets of traps (n = 10 traps per fleet) were laid at the same time (sunrise) and lifted after 3 h, 6 h, 12 h and 24 h. The contents of each trap were kept and the remaining bait weighed. The species caught were identified, measured and weighed in the laboratory. Differences between soak times in terms of bait consumed, scavenger species, number, weight and length were investigated by means of analysis of variance, following appropriate transformations where necessary. Any significant differences resulting from ANOVA tests were investigated using Student-Newman-Keuls (SNK) a-posteriori pairwise comparisons.

## Results and discussion

A very high scavenger activity was found in the area, with over 30% of bait consumed within 12 h and up to 100% within 24 h (Fig. 1). The organisms responsible for this were the cirolanid isopod, *Natatolana borealis*, which arrived at the bait shortly after the traps were deployed, and the Lysianassid amphipods, *Scopelocheirus hopei*, *Tmentonyx similis* and *Hippomedon bidentatus* (Fig. 1). A few Decapods (*Munida intermedia*, *Processa canaliculata*) were found in the 24 h deployments.

Fig. 1. (a) Bait consumed (+ SD) and (b) individual rates (% number) of occurrence by scavengers over 24 hours.

*Natatolana borealis* always numerically dominated trap catches (Fig. 1) and marked effects of soak time were revealed, with traps of the 12 h deployments catching significantly higher numbers of individuals (mean

= 75.95  $\pm$  13.94 animals per trap) (Fig. 2). In general, arrival time of *N. borealis* tended to be longer for larger individuals: mean size and mean individual biomass were significantly higher at 24 h of soak time (Fig. 2). In the 24 h deployments, the number of isopods significantly decreased implying that the smaller individuals were able to exit the traps. Amphipods arrived later than isopods and were absent in the 3 h and 6 h deployments, whilst they comprised 4% of catch in the 12 h deployments and 38% in the 24 h deployments (Fig. 2).

The results revealed a very intense scavenging activity in the western Pomo pit with very high consumption of bait. This factor, together with the prevalence of small *Nephrops* individuals in the catches, would severely decrease the fishing potential of a hypothetic creeling activity for *Nephrops* in the area, rendering it not feasible economically.

Fig. 2. (a) Mean total number (+SE), (b) mean total length (TL) (+SE) and (c) mean individual biomass (+SE) of Natatolana borealis individuals caught in traps over 24 hours, with an indication of analysis of variance and SNK pairwise comparison results (a) F= 5.06; \* = p<0.05); (b) F= 8.02; c) F = 7.20; \*\* = p<0.01).

## BIOLOGICAL PARAMETERS OF *TRACHYRHYNCHUS TRACHYRHYNCHUS* (RISSO, 1810) (OSTEICHTHYES, MACROURIDAE) IN THE NORTH AEGEAN SEA: PRELIMINARY RESULTS

Anastasios Papadopoulos \*, Michelle Torre, Argyris Kallianiotis and Aris Christidis Fisheries Research Institute, N.AG.RE.F. 64007, Nea Peramos, Kavala, Hellas. - fri@otenet.gr

## Abstract

Aspects of the biology of *Trachyrhynchus trachyrhynchus* (Risso, 1810) were studied in the North Aegean Sea. The male:female (M:F) ratio was 1:1.44. Age determination based on otolith reading showed that the population has a maximum age of 14 years. The species exhibits a positive allometric growth (b=3,37). The von Bertalanffy growth parameters for all individuals are  $L_{inf} = 460.4$  mm, k = 0.2406 year<sup>-1</sup>, and to = -1,07 year. Gonad examination revealed that during the sampling period, the species was mainly immature. *Keywords : Aegean Sea, Deep Waters, Fishes.* 

The Roughsnout grenadier *Trachyrhynchus trachyrhynchus* (Risso, 1810) [1], is a benthopelagic species for which very few studies exist. Its presence has been recorded annually since 1996 at depths between 400-700 m especially in the North Aegean Trench in Lemnos basin. The purpose of this study is to present data on various aspects of its biology.

The samples were collected during the MEDITS expedition (which is conducted during the June and July every year) in the North Aegean Sea from 1996 to 2006. Total length (TL) in mm, and total weight (TW) in gr were measured on board, otoliths were extracted and sex was determined by macroscopic examination of the gonads. A number of otoliths and gonads were processed and examined in the laboratory under stereoscopic and microscopic examination respectively. Counts of opaque zones in otoliths were converted in number of years as an absolute age.

A total of 847 individuals were caught of which 750 were measured. Total length of the individuals ranged from 125 to 507 mm. The length class with most individuals was the 365-374 mm (9.2%).

Otoliths (left sagittae) from 54 individuals were used for age determination (Fig. 1).

Fig. 1. Photomicrograph of otolith from a 437 mm fish.

Due to their thickness, otoliths were polished with sandpaper until the nucleus was reached, immersed in ethanol and read under transmitted light. The otolith reading revealed up to 14 annual increaments indicating a maximum age of 14 years. The von Bertalanffy growth parameters were computed by mean of non linear regression analysis applied to the age-at-length data. The results are (all individuals):  $L_{inf}$  = 460.4mm, k= 0.2406 year<sup>-1</sup>, and to= -1.07 years.

Overall, 360 fish (42,5%) were sexed: 135 were males, 195 females and 30 unsexed with the sex ratio M:F being 1:1.44. Deviations from 1:1 null hypothesis were statistically tested using  $X^2$  - test and revealed no significant difference (P=>0,05) between male and female percentages.

The parameters of the length - weight relationship for males (TL 202-433 mm, TW 20.42-301.30 gr) and females (TL306-456 mm, TW 114.5-324.66 gr) were for males: Ina=-15.85, b=3.57, SEb=0.16,  $R^2$ =0.95; for females: Ina= -10.05, b=2.59, SEb=0.25,  $R^2$ =0.76; and for sexes combined: Ina=-14.71, b=3.37, SEb=0.13,  $R^2$ =0.91.

Gonads from 60 individuals were histologically processed and examined microscopically (Fig 2).

Fig. 2. Histological section of ovary.

The majority of gonads of both male and female were immature. However, ovaries of some females contained few oocytes in vitellogenesis, coupled with atretic vitellogenic oocytes.

The sex ratio indicates that sexes were equally distributed. Males and females had positive and a negative allometric growth respectively, but the species had a positive allometric growth overall. Gonad examination revealed that the species, during the sampling period, was mainly immature. However, the presence of some isolated oocyte in vitellogenesis associated with the presence of vitellogenic oocytes in atretic phase might indicate that spawning occurred recently.

## Abstract

An extensive field study was done in July 2003 to provide a quantitative description of spatial patterns of benthic assemblages in the North Western Adriatic Sea; 288 samples were collected over an area of 240 km<sup>2</sup>. Overall, 115.670 specimens belonging to 209 taxa were identified. The most abbundat taxa were Crustacea (43%), Polychaeta (31%) and Mollusca (21%), while other taxa accounted for about 4% of the total abundance. Four new records of polychaete species, 2 for the Adriatic and 2 for the Mediterranean Sea, were reported. A new species of spionidae was described

Keywords : Adriatic Sea, Biodiversity.

Vatova's [1] classic paper on Adriatic soft bottom macro-zoobenthos has so far provided the baseline for studies investigating patterns of distribution of benthic assemblages in the Adriatic Sea. This work, was aimed at providing a comprehensive regional-scale description of the Adriatic benthic fauna. Following the approach developed by Petersen [2], Vatova [1] classified Northern and Central Adriatic benthic assemblages in "zoocoenoses". Several Authors have re-analysed Vatova data, reinterpreting them in terms of "biocoenoses" [3-6] or using multivariate statistical tools [7]. Results of cluster analises reported by Di Dato et al [7] did not support the "zoocoenosis" identified by Vatova, suggetsing that they derive from a subjective interpretation.

In June 2003 an extensive field study was done to provide a quantitative description of spatial patterns of benthic assemblages in the North Western Adriatic Sea. The aim of the study was to estimate variability of assemblages at different spatial scales. A hierarchical nested design, including spatial scales from hundreds of metres to tens of kilometres. was developed. The sampling area was of about 240 km<sup>2</sup>, delimited by 44.5617 and 44.1254 latitude North, and by the 10 and 30 meters depth contours. To implement the hierarchical sampling design the study area was devided in strata, locations, areas and sites (Fig1). At each sampling site 4 replicated grab samples were collected with a 0.1 m<sup>2</sup> Van Veen grab. Overall 288 samples were collected and processed, obtaining an everage sapling density of 1.2 per km<sup>2</sup>. This large sampling effort allowed the construction of an updated list of macrozoobenthos in the North Western Adriatic.

Fig. 1. Sampling area with the desciption of the structure of the sampling design.

Overall 115.670 specimens belonging to 209 taxa have been identified. The most abbundat taxa were Crustacea (43%), Polychaeta (31%) and Mollusca (21%), wile other taxa were relatively rare. The Amphipod Ampelisca spp, accounted for 41.8% of the total abbundance. The most abbundant polychaete specie were Lumbrineris spp (4.6%), Levinsenia (Levinsenia) gracilis (3.6%), Sternaspis scutata (2.9%), Polydora flava (2.9%) and Paraonis fulgens (2.1%). Two new records of polychaete species for the Adriatic Sea ( Paraonis fulgens (Levinsen, 1883), Harmothoë andreapolis (McIntosh, 1874)); together with 2 new records for the Mediterranean Sea (Ampharete finmarchica (Sars, 1866) and Atheros-

pio disthica (Mackie & Duff, 1986)) were reported. A new species beloning to the Family Spionidae so far named Laonice cf. cirrata was found. Most abbundan molluscs were Corbula gibba (2.3%), Abra nitida (2.1%) and Mysella bidentata (1.7%). Moreover, high densities of the arcid bivalve Andara demiri, an invasive species firstly recorded in the Adriatic Sea in the year 2000, were observed.

## Résumé

Suite aux importants phénomènes de nécrose qui ont affecté les quatre espèces de gorgones présentes en baie de Calvi (*Eunicella verrucosa, E.singularis, E. cavolinii* et *Paramuricea clavata*) entre 1998 et 2006, on a assisté à la colonisation secondaire des axes cornés dénudés. Cinq étapes consécutives de constitution des communautés épibiontes sont décrites. *Mots clès : Cnidaria, Coastal Waters, Zoobenthos.* 

Suite aux importants phénomènes de nécrose qui ont affecté les quatre espèces de gorgones présentes en baie de Calvi (*Eunicella verrucosa, E.singularis, E. cavolinii* et *Paramuricea clavata*) entre 1998 et 2006, on a assisté à la colonisation secondaire des axes cornés dénudés. Cinq étapes consécutives de constitution des communautés épibiontes sont décrites.

Depuis une vingtaine d'années, on a enregistré un nombre croissant de perturbations d'origine climatique ou édaphique, affectant les communautés benthiques à l'échelle de tous les océans [1] ; les épisodes de nécrose qui ont affecté les groupes les plus divers d'invertébrés, et notamment les gorgones en mer Méditerranée ont permis le développement de communautés d'épibiontes au sein desquels la recherche d'organismes traceurs de l'altération environnementale pourrait se révéler prometteuse. Le programme RACE de l'Université de Liège associé à la Station océanographique STARESO (ARC, Convention n°05/10-333) s'inscrit dans ce cadre général de définition des modalités d'analyse et de suivi des impacts en milieu côtier.

Cette étude fait état de la dynamique de colonisation des axes cornés des gorgones lors des phénomènes de nécrose du coenenchyme le long de quatre transects plus ou moins affectés par l'impact touristique, dans la région de Calvi (Corse, Méditerranée occidentale) entre1998 et 2006. Des prélèvements (fragments de colonie à l'interface entre zone "saine" et zone nécrosée et recolonisée) ont été effectués en plongée autonome tous les ans à la mi-juillet et immédiatement et individuellement fixés. Le suivi de l'état de surface des gorgones par microscopie électronique à balayage nous a permis de décrire la cinétique de cette nécrose et de la colonisation secondaire.

Reconnues pour leur qualité de "sentinelles" [2], les gorgones, organismes fixés, filtrants à longue durée de vie, sont particulièrement aptes à offrir un "substrat" aux colonisateurs secondaires dont les variations locales (en diversité et/ou en abondance) peuvent intégrer les variations environnementales, qu'elles soient d'origine locale ou climatique. Les gorgones "saines" ne portent pas d'épibiontes et sont quasiment stériles (phase 0), résultat de la sécrétion de métabolites secondaires induisant une répulsion non seulement chez les organismes prédateurs [3,4], mais aussi assurant un rôle antifungique et antimicrobien et inhibant le dépôt des colonisateurs secondaires [5].

Les premières atteintes morphologiquement visibles se manifestent par le dépôt de bactéries en populations éparses et de diatomées à la surface des tissus ectodermiques (phase 1). Par la suite, la dissociation de ce tissu révèle les spicules sous-jacents (phase 2) et permet une colonisation, puis une prolifération bactérienne en profondeur du coenenchyme. Dans certains cas, les bactéries sont accompagnées de fungi.

L'érosion progressive des spicules (phase3) révèle progressivement l'axe qui, une fois dénudé, se fait rapidement recouvrir d'une épibiose importante, essentiellement composée de diatomées pennées au départ. Ce tapis de diatomées sert de point de départ à une colonisation par des organismes dressés, colonisation essentiellement algale au départ (phase 4), puis à prédominance animale par la suite (foraminifères, annélides polychètes, bryozoaires, ...phase 5).

L'évolution apparaît réversible (recolonisation de l'axe après cicatrisation et croissance du coenenchyme) jusqu'à la phase 3.

Tant l'état intrinsèque des populations des différentes espèces (taux de nécroses) que les informations données par le recouvrement des axes

post nécrose des colonies [2] confirment l'intérêt des populations de gorgones comme outil potentiel d'évaluation et de suivi de la qualité de l'environnement côtier en Méditerranée.

## Résumé

Les quatre espèces de gorgones présentes en baie de Calvi (*Eunicellaverrucosa, E. singularis, E. cavolinii* et *Paramuricea clavata*) ontsubi une nette régression de leurs populations entre 1998 et 2001. Ensuite,entre 2001 et 2006, on a assisté à un recrutement important mais ce recrutement s'est accompagné d'une dégradation significative de l'état de santé des quatreespèces (nécroses et colonisation secondaire). *E. verrucosa* semble avoirdisparu des transects investigués.

Mots clès : Bio-indicators, Coastal Waters, Cnidaria, Population Dynamics, Zoobenthos.

Ces dernières années, on a enregistré un nombre croissant de perturbations des communautés benthiques à l'échelle de tous les océans [1] : de nombreux épisodes de nécrose ou de mortalité ont affecté les groupes les plus divers d'invertébrés (gorgones, éponges, bivalves, échinodermes, ...[2-3]), notamment en mer Méditerranée. Ceci implique la mise en place de réseaux de surveillance des populations d'organismes clé dans des sites de référence [4,5]. Le programme RACE (ARC, Convention n° 05/10-333) dont cette étude est partie prenante s'inscrit dans ce cadre général de la définition des modalités d'analyse et de suivi des impacts en milieu côtier. Cette étude fait état de la dynamique des populations de gorgones dans la région de Calvi (Corse, Méditerranée occidentale) le long de quatre transects définis dans des zones aux caractéristiques bien tranchées (avec impact touristique évident ou non, entre 5 et 47 m de profondeur). Ces transects ont été relevés en plongée autonome (comptages des colonies et évaluation de l'état sanitaire des populations) tous les ans à la mi-juillet. Reconnus pour leur qualité de "sentinelle"[5], ces organismes fixés, filtrants à longue durée de vie, sont particulièrement aptes à intégrer les variations environnementales, qu'elles soient d'origine locale ou climatique. Les quatre espèces présentes dans cette tranche bathymétrique ( Eunicella verrucosa, E. singularis, E. cavolinii et Paramuricea clavata) ont fait l'obiet d'une étude démographique (nombre d'individus sur le transect et spectres de tailles) et d'un suivi temporel de leur état de santé (nécrose, épibiose, ...) entre 1998 et2006.Faisant référence aux épisodes de mortalité enregistrés à la fin de la décennie précédente dans le sud de la France [2], et dont on a souvent attribué l'origine aux anomalies thermiques positives enregistrées dans les eaux de surface [3.6] on a considéré la faune benthique corse comme relativement épargnée. Une vision plus pessimiste ressort de nos mesures : les populations de gorgones, toutes espèces confondues ont subi une dégradation générale au cours de la période 1998-2001. Certains site sont connu des diminutions d'effectif de l'ordre de 50 % : E. cavoliniiet E. singularis de 32 à 58 % de pertes selon les sites et P. clavata, 27 à 41%. E. verrucosa, sténotherme plus froide, tend à disparaître dès 2000 : une seule colonie a subsisté le long d'un transect jusqu'en 2005, de plus en plus nécrosée. Elle a fini par disparaître en 2006. Pour les trois autres espèces, les colonies implantées aux profondeurs plus faibles (au-dessus de la thermocline durant une partie importante de l'année) ont reflété l'impact le plus important. Les différences entre le site "hors baie" et les trois sites dans la baie de Calvi (plus anthropisée) sont peu significatifs. P. clavata, occupant la tranche bathymétrique la plus profonde, entre 25 et >47 m, apparaît la moins touchée par les phénomènes de nécrose. Hormis dans le cas d' E. singularis (populations les plus exposées puis qu'occupant la tranche bathymétrique supéreieure, entre 5 et 18 m dans la zone concernée par cette étude), les différences entre le site "hors baie" et les trois sites dans la baie de Calvi (régulièrement utilisés comme sites de plongée touristique), sont peu significatifs ; ceci aurait tendance à nous faire privilégier l'impact d'un facteur climatique plutôt qu'anthropique. Après 2000-2001, la période est apparue plus favorable au renouvellement des populations avec un recrutement important des trois espèces principales ( E. cavolinii, E. singularis et P.clavata). En revanche, l'état de santé général des colonies tend à se dégrader nettement depuis 2001. En 2005-2006 les populations d' E. singularis étaient atteintes de nécrose dans 60  $\pm$  17 % des cas sur les transects expérimentaux, celles d' *E. cavolinii* dans  $52 \pm 8$  % et celles de P. clavata dans 52  $\pm$  10 % des cas. De telles indications confirment l'intérêt des populations de gorgones comme outil potentiel d'évaluation

et de suivi de la qualité de l'environnement côtier en Méditerranée.

## SPATIO-TEMPORAL DISTRIBUTION OF RECRUITS OF HAKE (*MERLUCCIUS MERLUCCIUS* L.) IN THE CALABRIAN TYRRHENIAN SEA (CENTRAL MEDITERRANEAN)

A. Profeta \*, D. Giordano , F. Perdichizzi , A. Perdichizzi , B. Busalacchi , A. Potoschi , P. Rinelli Institute for the Coastal Marine Environmental (IAMC)-CNR, Spianata S. Raineri, 98122 Messina, Italy - aprofeta@unime.it

## Abstract

The distribution of hake (*M. merluccius*) recruits has been investigated along the Calabrian Tyrrhenian coasts. Data coming from national and international trawl survey projects have been integrated with seasonal catches carried out between 2004 and 2005 in the framework of a regional research SFOP-POR project. Two well defined areas, although characterized by spatio-temporal variability, were identified between 100 and 300 m in the Gulf of S. Eufemia and near C.po Suvero. *Keywords : Fishes, Recruitment, Tyrrhenian Sea, Western Mediterranean.* 

The identification of nursery areas of the hake *Merluccius merluccius* and their variability in space and time is very important for its management. The recruitment patterns of hake have been studied in many Mediterranean sites [1, 2, 3] but the information about seasonal variations in recruitment is still scarce. Along the Tyrrhenian coast of Calabria research trawl surveys (GRUND and MEDITS) which were carried out during the last ten years provided useful information about the distribution of hake recruits [2]. Data coming from these projects have been integrated with seasonal catches carried out between 2004 and 2005 in the framework of a regional research SFOP-POR project.

Data come from eleven seasonal trawl surveys carried out along the Calabrian coast from C.po Suvero to P. ta Pezzo. In particular eight GRUND (spring-summer 1994-2002), eight MEDITS (autumn1994-2002) and three POR surveys (autumn and summer 2004-2005) were analysed. Overall, 140 hauls were carried out between 10 and 800 m of depth, during daylight from dawn to sunset. To separate the recruits from the older specimens a cut-off, elaborated for each survey, is used [2]. On the basis of swept area, the number of recruits "R "of each haul were transformed into R per km<sup>2</sup> (Recruits Density Index-RDI). The nursery areas were identified using a GIS approach.

Despite the variability recorded between the different seasons and years (MEDITS and GRUND data), the density of recruits showed two stable areas (between 100 and 300 m) characterized by high concentrations of juveniles which were identified near C.po Vaticano (the larger one) and inside the S. Eufemia Gulf. The presence of these two areas was confirmed by the RDI found during POR surveys (Figure 1). During November 2004 both areas were found at a depth between 50 and 350 m; the RDI index showed a total mean value of 483 R/km<sup>2</sup> (min 40-max 2588 R/km<sup>2</sup>). On the contrary, during summer survey only the nursery area inside the Gulf was found; the mean RDI recorded was 712 R/km<sup>2</sup> (range 40 - 4170 R/km<sup>2</sup>). Finally in September no nursery area was found (mean RDI=124 R/km<sup>2</sup>).

Fig. 1. Nursery area zones (dark grey) identified along Calabrian coasts during POR survey in November 2004 (A) and July 2005 (B).

# CHANGING CONCENTRATIONS OF BACTERIA IN SHIPS' BALLAST WATER DURING TRANSIT: ARE BALLAST TANKS INCUBATORS?

Gemma Quilez-Badia \*, George Smith and Gregory M Ruiz.

Smithsonian Environmental Research Center, P.O. Box 28, Edgewater, Maryland 21037 USA - quilez-badiag@si.edu

# Abstract

Ships' ballast water is a major source of biological invasions in coastal systems and contains a diversity of microorganisms, yet their population dynamics remain largely unexplored. We measured temporal changes in total bacteria concentration in 75 ballast tanks (34 with mid-ocean exchange and 41 unexchanged controls) across 21 ocean voyages, from multiple departure ports (5% of Mediterranean source, including Fos-sur-Mer and Tel Aviv) and representing all seasons. Bacteria concentration differences were tested as a function of depth, time, ballast management and season. Total bacteria decreased significantly over time, and the decrease was significantly greater in exchanged tanks. Increases over time occurred occasionally but infrequently in a few tanks (4% for both control and exchanged), suggesting growth (incubation). Across tanks, there was not a significant difference due to depth, as most tanks (85% controls and 89% exchanged) showed no vertical stratification. Overall, there were no significant seasonal effects in total bacteria dynamics across ballast tanks.

Keywords : Bacteria, Species Introduction, Migrant Species.

#### Introduction

The movement of ballast water by commercial ships is a major transfer mechanism for organisms throughout the world, resulting in established non-native populations (biological invasions) that are dramatically changing the structure and function of coastal ecosystems. Several recent studies underscore the large concentrations of protists, bacteria, and viruses in ballast water [1 - 4]. The dynamics of microorganisms, however, during transit remains largely unexplored [1, 2]. There has been some suggestion that conditions in ballast tanks may operate to increase microorganism concentrations, serving as incubators. Here, we test whether bacteria increase over time in ballast tanks, comparing the response in tanks that underwent ballast water exchange (BWE or ocean flushing to reduce the risk of invasion) to untreated control tanks.

#### Methods

From 1999-2005, we sampled 75 different ballast tanks to measure changes in total bacteria concentration. One to several ballast tanks were sampled across 21 different ocean voyages, from multiple routes and source ports (including the Mediterranean ports of Fos-sur-Mer (France) and Tel Aviv (Israel)), seasons, and ship types. A subset of the tanks (n=34) underwent BWE and parallel measures were taken for unexchanged control tanks (n=41) on the same voyage. For each tank, replicate samples were collected from at least two discreet depths, preserved for analysis, and quantified using direct counts and flow cytometry. We compared the effect of depth, season, time, and BWE on changes in total bacteria concentration.

#### Results

For both control and exchange tanks, bacteria concentrations differed significantly between the initial samples (T0) and samples after the first exchange was conducted (T1). On average, a lower concentration was found at T1, although some individual tanks (3 out of 23 control tanks and 3 out of 28 exchange tanks) had significantly higher concentrations at T1. In the latter exchange tanks, all observed increases occurred during the summer season. Across all voyages, there was a clear and significant difference between exchanged and control tanks, with exchange exhibiting lower average concentrations independent of depth The sharpest decrease occurred after the first exchange and stabilized afterwards. Even though time had an effect in reducing bacteria concentration, mid-ocean exchange had a greater effect than time alone. An incubation effect was found in 4%of the each control and exchange tanks. Overall, there was not a significant effect of depth on total bacteria concentrations for either exchanged or control tanks. Stratification was observed, however, in some individual tanks. For initial (T0) samples, stratification was found in 11 of 75 tanks, being significantly higher at the surface for all but 1 of these. For a later sampling time (T1), a stratified distribution was found in 6 control and in 2 exchange tanks; of these eight cases, higher numbers of bacteria occurred in deeper water for 2 control and 1 exchange tank. Therefore, a homogeneous distribution was typically found. Stratification only occurred in around 15% and 11% of the cases, for initial and later samples, respectively. Season had an effect on initial (T0) bacteria concentrations, being significantly greater in spring. For control tanks, the bacteria decreased with time for spring, summer and fall voyages, while increasing in the only winter tank. For exchanged tanks, concentration decreased after ballast exchange, except in summer when bacteria appeared to increase but

not significantly, indicating a possible input of bacteria from mid-ocean. Thus, there was not a concrete difference in dynamics among seasons. Discussion

Our results showed that concentration of bacteria decreased over time in both control tanks and exchanged tanks, although the decline in exchanged tanks was significantly greater. Ballast water exchange significantly decreased the bacteria abundance after the first exchange, becoming constant thereafter. This difference between exchange and control tanks was not observed for the single voyage by Drake et al. [2], and also included as 4 tanks in our dataset, where no differences were observed between these treatments. One possible explanation for this disparity may lie in the source water, originating from the eastern Mediterranean (Tel Aviv) in the latter study. In a second voyage from the Mediterranean (Fos-su-Mer), bacteria concentrations followed a similar pattern with no differences between control tanks (n=2) and exchanged tanks (n=2) after exchange (T2). This further suggests a different dynamic for Mediterranean sourced ballast. Overall, we observed an increase in total bacteria in a few control tanks. For the exchanged tanks, the incubation effect appeared in 3 tanks, whose voyages were all in summer; furthermore, 2 of those tanks were from the same ship, indicating more likely an effect of the ballasting spot instead of a growth effect. Murphy et al. [5] found that some crustacean taxa were more abundant in shallow than in deeper ballast waters. Here, the overall result across voyages was a uniform distribution, even though stratification was observed for a few individual tanks, usually with higher numbers in surface waters. Seasonal effects have previously been documented [2], where bacterial abundances were higher in warm seasons than in cold ones. Here, spring concentrations of bacteria were found to be significantly higher than for the other seasons. No taxonomical identification was conducted in this study, such that our data cannot address the dynamics of individual taxa. Specific components (genotypes) of the bacteria may behave differently from the total, and there is likely to have been considerable compensatory changes in genotypes both through time and as a function of exchange.

# DESCRIPTION DE LA FAUNE EPIBIONTE DE *PINNA NOBILIS* SUR LES CÔTES NORD ET EST DE LA TUNISIE

Lotfi Rabaoui, Sabiha Tlig-Zouari \* and Oum Kalthoum Ben Hassine

Unité de Recherche de Biologie, Ecologie et Parasitologie des Organismes Aquatiques - Faculté des Sciences de Tunis - Tunisie -

hgsbth@yahoo.fr

# Résumé

La faune épibionte de *Pinna nobilis* est décrite au niveau de cinq échantillons provenant des cotes nord et est de la Tunisie. Soixante quatre espèces de macro invertébrés appartenant à sept phylums ont été identifiées. Parmi celles-ci, les Mollusques constituent le taxon le plus dominant dans tous les échantillons examinés. La structure de cette faune varie selon le milieu où vit la grande nacre. Les investigations que nous avons menées révèlent que les peuplements épibiontes marins sont plus diversifiés et plus équilibrés que les peuplements lagunaires. *Mots clès : Mediterranean Ridge, Mollusca, Biodiversity*.

La grande nacre représente un important substrat biologique pour plusieurs espèces épibiontes et les communautés qui y sont associées ont été décrites au cours de nombreuses études, effectuées dans certains pays méditerranéens de la rive nord. L'objectif du présent travail est de connaître la faune épibionte de ce mollusque dans un pays de la rive sud, la Tunisie.

Les communautés épibiontes de P. nobilis ont été étudiées, durant la période allant d'août 2004 à août 2005, au niveau de cinq stations, trois marines, une lagunaire et une située entre la lagune et la mer, au niveau du canal de communication. Les stations marines sont du nord au sud, Sidi Rais (située dans le golfe de Tunis), Stah Jaber et Téboulba (localisées sur la façade est du pays). La station lagunaire se situe dans la lagune de Bizerte ; il s'agit de la station de Njila. La cinquième station est celle d'Echaâra, localisée au niveau du canal qui fait communiquer la lagune de Bizerte avec la Mer. Dans chaque station, la faune épibionte de 30 spécimens de P. nobilis a été prélevée en plongée sous marine et à une profondeur qui varie de 3 à 6 mètres. Au laboratoire, l'observation de ces échantillons a permis leur identification au moyen de guides et de clés de détermination appropriés. Une étude, utilisant les indices écologiques (Richesse spécifique, indices de Shannon-Weaver et d'équitabilité de Pielou), a été entreprise, suite au dénombrement des différentes espèces de chaque échantillon. La similitude entre les communautés épibiontes des différents sites prospectés a été analysée au moyen de la classification ascendante hiérarchique de Ward.

Au total, 64 espèces épibiontes appartenant à sept différents phylums ont été identifiées au niveau des cinq échantillons examinés de *P. nobilis*. Le taxon le plus dominant est celui des Mollusques (21,88%), suivi par les Annélides (20,31%), puis viennent, par ordre décroissant, les Ascidies (17,19%), les Spongiaires (15,63%), les Cnidaires (14,06%), les Bryozoaires (7,81%) et les Crustacés (3,13%). Les pourcentages de ces taxons varient selon les stations et donc selon le type d'écosystème et les conditions qui y règnent. La richesse spécifique varie également d'une station à l'autre. Elle est comprise entre un minimum de 15 espèces à Sidi Rais et un maximum de 29 espèces à Stah Jaber (Fig.1).

Fig. 1. Variations de la richesse spécifique (RS) et des indices de Shannon-Weaver (H') et d'équitabilité de Pielou (E) dans les cinq communautés épibiontes de *P.nobilis*.

L'étude de la diversité des communautés épibiontes de *P. nobilis* révèle que l'indice de Shannon-Weaver oscille entre un minimum de 2,19 bits

à Njila et un maximum de 3,11 bits au niveau de la station de Téboulba. Quant à l'indice d'équitabilité, il est compris entre 0,55 à Njila et 0,77 à Sidi Rais (Fig.1). Les valeurs minimales de ces deux indices ont été enregistrées dans la station lagunaire et celle située entre la lagune et la mer. Quant aux valeurs maximales, elles ont été notées au sein des stations marines.

Le dendrogramme de la classification hiérarchique des cinq stations d'étude (Fig.2) a permis de séparer trois assemblages : le premier est formé par les stations marines (Sidi Rais, Stah Jaber et Téboulba), le second est représenté par la station d'Echaâra, située sur le canal reliant la lagune de Bizerte à la mer. Quand au troisième regroupement, il est représenté par la station lagunaire de Njila.

Fig. 2. Dendrogramme de la classification hiérarchique des cinq stations étudiées (EC : Echaâra ; NJ : Njila ; SR : Sidi Rais ; SJ : Stah Jaber ; TB : Téboulba).

Ainsi, malgré la variabilité de la composition spécifique de la faune épibionte du Jambonneau, notée au niveau des communautés étudiées, les Mollusques constituent le taxon le plus dominant quelque soit la station. Ces résultats sont conformes à ceux observés par Zavodnik [1] en Adriatique. En outre, les variations des valeurs des indices de Shannon-Weaver et d'équitabilité de Pielou observées indiquent que les peuplements épibiontes de *P. nobilis* sont plus diversifiés et plus équilibrés en milieu marin qu'en milieu lagunaire. Cette riche faune épibionte met en évidence l'intérêt écologique de ce bivalve. Il s'agit en effet d'"un vrai "micro-écosystème et un abri pour plusieurs espèces de macro-invertébrés. La grande nacre contribue ainsi à la richesse spécifique des écosystèmes où elle se rencontre.

# INTERANNUAL AND BATHYMETRIC VARIATIONS IN BODY SIZE OF *CALANUS HELGOLANDICUS* (COPEPODA: CALANOIDA) DIAPAUSING POPULATIONS IN THE NORTH AEGEAN SEA

A. Ramfos<sup>1</sup> \*, I. Siokou-Frangou<sup>2</sup>, E. Christou<sup>2</sup>, S. Isari<sup>1</sup>, N. Fragopoulu<sup>1</sup>

<sup>1</sup> Laboratory of Zoology, Department of Biology, University of Patras, 26500 Patra, Greece - aramfos@upatras.gr <sup>2</sup> Hellenic Centre of Marine Research, Institute of Oceanography, Greece

### Abstract

Significant interannual differences in abundance and size distributions of diapausing *Calanus helgolandicus* populations were observed between four years in the North Aegean Sea (NA) implying a strong variability in the physical regime during the reproduction period. Moreover, a clear increase of mean size with depth was evident in all diapausing populations, possibly related to the overwintering depth selection of the individuals.

Keywords : Aegean Sea, Copepoda, Deep Waters.

#### Introduction

*Calanus helgolandicus* comprises an important part of the zooplankton biomass in the offshore as well as coastal European waters and presents an interesting vertical distribution pattern during its life cycle [1]. The North Aegean Sea, in Eastern Mediterranean, forms a suitable area for the study of this species due to its topography (a deep basin close to the continental shelf) and hydrology (Black Sea Water influence).

#### Materials and Methods

Stratified mesozooplankton sampling was carried out in September 1989, 1997, 2003 and in July 2004 over the Lemnos deep basin (max. depth 1640m) in the North Aegean Sea with a vertically towed WP2 net (200  $\mu$ m). More details for the sampling layers are shown in Fig.2. Total and relative abundance of *C.helgolandicus* copepodite stage V (CV) were estimated. Prosome length (PL) of up to 400 individuals (CV only) was determined in each sample under a stereomicroscope (accuracy ±40  $\mu$ m).

#### Results and Discussion

*C. helgolandicus* was the dominant species in mesozooplankton below 500 m during all cruises, whereas it was absent in the upper 200 m. Mean abundance values of the population below 500 m (18 ind.m<sup>-3</sup>, 19 ind.m<sup>-3</sup>, 104 ind.m<sup>-3</sup> and 20 ind.m<sup>-3</sup> in 1989, 1997, 2003 and 2004 respectively) were the highest reported in the Mediterranean for diapausing populations of the species [1], thus indicating the existence of favorable conditions during the reproduction period (December-May) at the surface layer [1].

Mean values and range of *C.helgolandicus* PL varied significantly among years (Fig.1). Highest values were observed in 2003 (PL= $2.10\pm0.12$ ) whereas lowest in 1989 (PL= $1.91\pm0.14$ ). Temperature and food are considered as the two main factors controlling body size in copepods [2], hence we may assume that their interannual variability in the surface layer during winter/spring, influenced the body size, as well as the abundance of the species. Temperature variability is expected in the study area due to the seasonal and annual variability of the BSW (colder and less saline than Aegean Sea water) outflow intensity and circulation [3]. Variability in food concentration is also expected as the presence of BSW creates a permanent thermohaline front, strongly affecting phytoplankton and zoo-plankton biomass [4].

A significant increase (ANOVA & SNK tests) in mean prosome length with depth was evident in the overwintering populations (Fig.2). This gradual increase might be indirectly related (mainly through stored lipids) with the maintenance of neutral buoyancy during diapause. The maximum amount of stored lipids has been correlated with PL in *C.finmarchicus* [5] and the depth of neutral buoyancy is strongly affected by the amount of lipids in diapausing organisms [6]. Thus, in our case, a possible scenario is that bigger animals, assuming they have stored more lipids, attain neutral buoyancy at greater depth. Supporting evidence comes from *C. finmarchicus* in the Gulf of Maine [5] where a strong separation in oil-sac fullness between depths was evident in the 0-100 m layer and the authors conclude that "*Strong sorting* (i.e. in oil-sac fullness or size with depth) *apparently requires availability of depths greater than 100 m.*". However, further investigation is needed for any safe conclusions on this topic.

We thank the European Social Fund (ESF), Operational Program for Educational and Vocational Training II (EPEAEK II), and particularly the Program PYTHAGORAS, for funding the above work.

# UNE APPROCHE ÉCOLOGIQUE DE LA STRUCTURE DES PEUPLEMENTS: UNE APPLICATION SUR LE MACROBENTHOS DES MILIEUX PORTUAIRES.

Chafika Rebzani-Zahaf

Faculté des Sciences Biologiques/USTHB BP 32 16111 Alger Algérie - chafika4@caramail.com

# Résumé

L'analyse de la structure des peuplements est décrite à partir les indices de diversité spécifique et des Diagrammes Rangs Fréquences (DRF). L'étude des variabilités saisonnières, spatiales et les changements de structure des peuplements, ont permis d'établir des seuils d'équilibre pour les peuplements du port d'Alger indiquant un peuplement inexistant, en déséquilibre fort, en déséquilibre, en léger déséquilibre et en équilibre. L'application portant sur l'ensemble des analyses révèle des états de peuplement non structuré, peu structuré et structuré.

Mots clès : Bio-indicators, Biodiversity, Zoobenthos, Pollution.

L'étude analytique des peuplements des différentes stations du port d'Alger a permis de décrire et de comprendre la constitution des peuplements, et ce, en réponse aux contraintes du milieu. La structure des peuplements macrobenthiques du port d'Alger a été décrite à partir de la richesse spécifique, de la densité, des indices de diversité spécifique comme l'indice de Shannon (H') et d'équitabilité (E) et pour compléter l'information de la diversité qui est une valeur numérique, une représentation des Diagrammes Rangs Fréquences (DRF) a été utilisé décrivant les variabilités saisonnières et spatiales. De plus, les changements de structure des peuplements, mis en évidence, ont permis de comprendre le fonctionnement des peuplements des milieux soumis à des activités anthropiques [1-2].

Les valeurs obtenues ont montré que la constitution du peuplement est liée au gradient de pollution [1, 3] et des seuils d'équilibre ont été déterminés pour les peuplements de chaque bassin du port d'Alger. Les résultats ont montré que :

- Les plus faibles valeurs de diversité sont observées dans les secteurs les plus confinés ; par contre, les plus élevées dans les secteurs sous l'influence des eaux du large.

- Le peuplement est en équilibre dans les secteurs sous l'influence des eaux du large

- Le peuplement est en léger déséquilibre, au niveau de la passe nord

- Le peuplement est en déséquilibre dans le bassin d'évolution des navires du Vieux Port et la partie adjacente de l'Agha,

- Le peuplement en fort déséquilibre dans le bassin de Mustapha et dans la partie adjacente du bassin de l'Agha.

L'analyse de l'évolution des peuplements du port d'Alger [3-5] a permis de déterminer des états de peuplement non structuré, peu structuré et structuré. Chaque état introduit la dynamique des peuplements qui le composent et de la stratégie adaptative des différentes espèces pour passer d'un état de succession écologique à un autre.

 Pour l'Etat 1 d'évolution, le peuplement peu diversifié, est constitué d'espèces de stratégie r. Cet état permet de passer d'un peuplement non structuré vers un peuplement structuré si les conditions s'améliorent et inversement si les conditions deviennent défavorables

- Pour l'Etat 2, pour la transition d'un peuplement peu structuré vers un peuplement structuré et inversement, le processus est plus complexe. Le peuplement est diversifié et les espèces à stratégie K de différents groupes écologiques se mettent en place.

L'Etat 1 d'évolution de la structure des peuplements est retrouvé dans le bassin de Mustapha du port d'Alger.

L'Etat 2 d'évolution de la structure des peuplements est observé dans le bassin du Vieux Port d'Alger.

Les facteurs biotiques et abiotiques conditionnent l'installation d'un peuplement qui évoluera en fonction du gradient de anthropique permettant la mise en place, la présence, la pérennité et par conséquent la bio-écoéthologie des espèces.

# RELATIONSHIP BETWEEN TEMPERATURE AND FISHERIES: THE CASE OF *PAGELLUS ACARNE* IN THE NW MEDITERRANEAN

L. Recasens \*, A. Sabatés , M. Demestre , P. Martín , P. Sánchez

Institut Ciències Mar Barcelona (ICM-CSIC). Passeig Marítim 37-49, 08003 Barcelona, Spain - laura@icm.cat

# Abstract

Sea Surface Temperature (SST) and landings series of axillary seabream, *Pagellus acarne*, were analysed in order to establish the possible effect of temperature on the abundance of this species. Both series, with a two year lag, showed a similar pattern suggesting a relationship between Mediterranean sea warming and increasing *P. acarne* landings. *Keywords : Temperature, Western Mediterranean, Teleostei, Fisheries.* 

#### Introduction

A warming trend in Mediterranean waters has been reported during the last decades, both at surface, as well as in deep waters [1, 2]. It could be assumed that these changes would mainly affect those species of warmwater origin that spawn in summer. In addition, temperature increase would affect gonad maturation, as well as survival and growth of planktonic eggs and larvae. In this regard, there is evidence in the study area that these changes affect the abundance and distribution of some pelagic fish species [3]. Axillary seabream, *Pagellus acarne*, is a subtropical species distributed in the Eastern Atlantic (Bay of Biscay to Senegal) and the Mediterranean Sea. The spawning period in the Mediterranean extends from July to October and eggs and larvae are planktonic. This species is fished mainly by bottom trawl and artisanal fleets in coastal waters down to 200 m depth, as by-catch species [4]. Landings are mainly made up of individuals belonging to age classes 1+ (mainly 2 years old); individuals smaller than 15 cm are discarded.

In the present study, temperature and landings series were analysed in order to establish the possible effect of temperature on the abundance of axillary seabream in the Catalan coast (NW Mediterranean).

#### Material and Methods

Data on *Pagellus acarne* annual landings (1988 to 2004) were recorded along the Catalan Coast (NW Mediterranean;  $40.5^{\circ}N - 42.4^{\circ}N$ ). Considering the latitudinal pattern of temperature in the area, with higher temperatures south of Barcelona, landings were analysed separately: North area (from Barcelona to the French border;  $42.4^{\circ}N - 41.4^{\circ}N$ ) and South area (southwards Barcelona to the Ebre Delta;  $41.3^{\circ}N - 40.5^{\circ}N$ ). Linear regression was used for the analysis.

Sea Surface Temperature (SST) data (1982 - 2004) were obtained from COADS data base [5] (1° square centre 40.5°N 1.5°E). For comparison with landings data, summer temperatures (July to September), which correspond to the spawning and planktonic life of *P. acarne*, were used. Taking into account the age composition of the landings, a two years lag was considered between both series.

Fig. 1. *Pagellus acarne* annual landings (1988-2004) in the southern (- -) and northern (-o-) Catalan coast (significant increasing trend in the South area, p<0.05).

Results and Discussion

Landings showed an increasing trend (Fig. 1). Both series were highly correlated (r = 0.77), but the increasing trend was only significant in the South area (p<0.05). Therefore, the relationship between SST and land-

ings was analyzed in the southern area. Both series exhibited a similar pattern (Fig. 2). Thus, years with high landings corresponded to high temperature values two years before, and conversely, low landings were related with low temperatures. These results highlight a clear relationship between sea warming and increasing *P. acarne* landings. Considering that *P. acarne* is not a target species, the influence of environmental factors on their reproductive biology could be stronger than in other species more subjected to fishing pressure.

Fig. 2. *P. acarne* annual landings in year (t) (solid line) from the southern area and summer SST in year (t-2) (dashed line).

<sup>3</sup> Whale Watch bluWest, Via Scarincio, 12, Imperia, Italy.

# Abstract

This work aimed to estimate the size of the cuvier's beaked whale population using data collected during 7 years of cetacean survey, carried out in the Ligurian sea. The data collected from 2004 to 2005 lead to an estimation of  $94\pm23$  (using right sides) and  $85\pm18$  (using left sides) different animals.

Keywords : Cetacea, Ligurian Sea, Population Dynamics.

#### Introduction

Cuvier's beaked whale is a poorly-known cetacean species and stranding data indicates that the beaked whale is present all along the Ligurian coast. *Ziphius cavirostris* has been considered common in the Ligurian sea since the sixties but no estimation of population size was carried out until now. This species has hardly been studied, chiefly due to his elusive behaviour. This population, as other population of marine mammals, is subject to different and intensive human activities so conservation and management strategies are needed. An integral part of any management strategy is the assessment of the individual number of the population and any trends in abundance [1]. In order to fill this gap this paper presents the results of a preliminary mark-recapture study, to estimate the absolute size of the population of cuvier's beaked whale in these area.

#### Materials and methods

Photographs were taken from 1998 to 2005 in the Ligurian Sea (Figure 1), during scientific surveys operated by the Department of Biology of the University of Genova and by Woods Hole Oceanographic Institution (WHOI) scientists; during daily whalewatching cruises operated by bluWest. The sampling protocol was to shot as many animals as possible, from both right and left sides, in each herd. The individuals were identified from features such as nicks, scrapes, scars, deformities, and epidermal disease on both their dorsal fin and flanks. Were considered marked only individuals showing one long-lasting mark at least, as described by Ballardini et al. 2005 [2].

All pictures, obtained using 35mm cameras equipped with 100-400 zoom lenses, were examined and ranked according to their quality, from 1 to 6, with 6 representing the highest quality [3], and placed on file. Only photos ranked as  $\geq$ 3 have been used in the analysis.

The data collected during 2004 and 2005 were used to calculate the population size and the analysis were estimated with CAPTURE program, using the model M(h) Chao which supposes an individual heterogeneity in capture probabilities. To obtain the variance and the standard deviation it was applied the method proposed by Wilson and Hammond [4].

#### Results and discussion

During surveys 90 sightings of cuvier's beaked whales heard occured. 52 different hight marked individuals were identified using the left side and 53 by the right side. The estimates of the proportion of hight marked whales for these data set are 0,72 (right) and 0,77 (left) of the whales, these values are greater than the ones found in other species of the ziphidae family, like *Hyperoodon ampullatus* [3]. The estimates of the total number of the cuvier's beaked whales in studied area, during 2004 and 2005, are  $94\pm23$  (mean  $\pm$  st.deviation; cv=0,24) for the right side and  $85\pm18$  (cv=0,21) for the left side, confirming *Ziphius cavirostris* as common species in the northern Ligurian sea.

#### Résumé

Les pêcheries opérant dans le golfe de Gabès capturent accidentellement les requins. Ces engins pêchent les espèces rares et les juvéniles des espèces communes ce qui pourrait porter préjudice aux populations de requins dans la région. *Mots clès : Gulf Of Gabes, Fishes, Fisheries.* 

#### Introduction

Les requins constituent des prises accessoires des pêcheries ciblées sur les poissons osseux et les crustacés. La connaissance de ces pêcheries et de leurs effets sur les espèces sont requis pour des mesures de gestion. Dans ce travail, nous étudions les captures accidentelles des requins dans le golfe de Gabès.

#### Matériel et méthodes

Notre étude a été basée sur l'examen des apports de la pêche dans les principaux ports du golfe de Gabès entre janvier 2001 et juin 2005. Pour chaque spécimen, le sexe et la longueur totale (LT) au mm près sont notés. Pour statuer sur les prises des requins, les structures des débarquements des captures au chalut de deux espèces communes sont analysées.

Fig. 1. Distribution des fréquences des tailles de *Mustelus mustelus* (A) (n = 600) et de *Carcharhinus plumbeus* (B) (n = 350). Tm : Taille de la maturité sexuelle.

#### Résultats et discussions

Dans la région du golfe de Gabès, la production moyenne annuelle en requin est de 750 tonnes. Plus de 20% de cette production provient des captures accidentelles au chalut. Les espèces communes (émissoles *Mustelus* sp et le requin gris *Carcharhinus plumbeus*), ciblées par la pêche artisanale, sont prises accidentellement par le chalut le long de l'année [1]. L'essentiel des débarquements de *M. mustelus* et de *C. plumbeus* par

le chalut est composée d'individus n'ayant pas atteint la taille de première maturité sexuelle (Fig. 1). L'abondance des juvéniles dans les captures suggère que cette région semble être une nursery et une frayère pour ces espèces.

Plus de 80% des captures de *Hexanchus griseus* et environ 30% des captures de *Carchrodon carcharias* sont rapportés au chalut. Par ailleurs, 70 % des captures du requin blanc sont ramenés par la senne tournante.

Les palangres de surface, ciblant l'espadon, ramènent accessoirement *Isurus oxyrinchus* et les Carchahinidés. Les palangres de fond, utilisées surtout pour la capture des mérous, pêchent également les Triakidés et les Squatinidés.

Les caractéristiques biologiques des requins, telles que la maturité sexuelle tardive et la faible productivité, les rend très vulnérables à la pêche [2]. Une gestion judicieuse des requins consiste à réduire l'impact des pêcheries, plus particulièrement dans les zones côtières qui sont utiliseés comme nurseries par plusieurs espèces.

# DIET AND FEEDING HABITS OF *SIGANUS RIVULATUS* AND *S. LURIDUS* TWO RED SEA MIGRANTS IN THE SYRIAN COASTAL WATERS (EASTERN MEDITERRANEAN)

Waad Sabour \* and Sami Lakkis

Dept. of Zoology, Tishreen University, Lattakia , Syria. - t-waad@scs-net.org

# Abstract

Deux espèces de Siganidae : *Siganus luridus* et *S. rivulatus*, originaires de la mer Rouge, ont établit des populations importantes dans les eaux côtières de Syrie ; formant 55% du rendement de la pêche côtière. L'analyse du contenu stomacal de ces deux espèces montre des restes d'espèces d'algues vertes, rouges, brunes, confirmant leur régime alimentaire herbivore sélectif. L'adaptation éco-physiologique et alimentaire au milieu marin des côtes levantines, différent de celui de la mer Rouge, leur a permis d'installer des populations permanentes. *Keywords : Coastal Waters, Fish Behaviour, Algae, Levantine Basin, Fishes.* 

#### Introduction

Being herbivorous, the Siganus species need a big quantity of algal food to assure their biological activities. The stomach of these fishes is an acid medium able to digest marine plants before entering in the digestive tract for complete digestion and thus excreting feces. In addition to algal food, they can feed accidentally on some non digestible substances such as mollusk shells and other invertebrates attached to algae [1, 2]. The diet and nature of food and feeding habits of siganids were the subject of many investigations in several geographical areas. The two considered species in our study Siganus rivulatus and S. luridus, which are of Indo-Pacific and Eritrean origin, have migrated and adapted to the Levantine sea environment, where they found different algal food from that of the Red Sea. They were obliged to change their diet and feeding habits in order to establish populations in the coastal waters. During the last decades, several investigations were conducted with regard to the feeding regime of some siganids in the Red Sea and in the Eastern Mediterranean [3-6]. In this paper we present data on the diet composition and the feeding regime of S. rivulatus and S. luridus in the Syrian coastal waters.

#### Material and Methods

Samples were taken bimonthly during 2002 at three different areas along the Syrian coast: Lattakia, Tartous and Banias ( $34^{\circ} 40'$ - $35^{\circ} 50'$  N;  $35^{\circ} 50$ - $36^{\circ} 05'$  E). Soon after catching, the stomach and intestine were separated and preserved in 10% formaline for further content analysis. The percent of filled intestine was divided into six categories according to their filled volume; 1: completely empty intestine (0% filled), 2: almost empty intestine (1-25% filled), 3: half empty (26-50%), 4: almost filled (51-75%), 5: completely filled (76-100%), 6: over-filled (>100% filled). After measuring the length, the intestine was dissected longitudinally to extract the content, weighted and transferred into Petri dish for microscopic analysis. After the extraction of all the content, the empty intestine was weighted. The nature of the food content and composition were determined under dissecting and research microscopes. Four coefficients were used to describe the digestion efficiency in *Siganus* species [1, 4].

1-Coefficient of Vacuity of the intestine (CV). This coefficient is calculated by the formula:  $CV=EV / N \ge 100$ , where EV is the number of examined individuals with empty stomach, N is the total number of intestines analyzed. This index reflects the richness or poverty of the environment in food.

2-General Nutrition Coefficient (EP). It is calculated by the equation EP=Es/Pt x 100, where Es is the weight of filled intestine, and P is the body weight. It estimates the % exploitation of food resources available in the environment.

3-Environmental Coefficient Factor (RES). This coefficient is calculated by the formula RES = $Pv/Pt \ge 100$ , where Pv is the weight of digestive tube+liver+spleen, and Pt is the total body weight. It represents the ratio of internal viscera weight over the body's weight.

4-Frequency of Predation Coefficient (Fp). It is calculated by the formula  $Fp = N/M \times 100$ , where N is the number of intestine containing the food, and M is the number of filled intestines. It represents the percent of food prey (algae) available in the environment and the frequency of the surveyed fish to exploit it.

#### Results and discussion

In *Siganus rivulatus* during April the CV was 0% when algal coverage was 65%; during September-October CV was 100%, coinciding with 10% coverage. In Tartous area, *S. luridus* showed CV=90% in October and in Lattakia 80% in February.The minimum EP of *S. rivulatus* was 5% in February and the maximum was 18% in April. The RES was 23% in *S. rivulatus* male and 10% in female during March, whereas during July RES was 10% in male *S. rvulatus* and 16% for females. The Fp was 40% for *Cladophora* and *Enteromorpha*, and 2% for *Gigartina*, *Padina* and *Sargassum*.

*S. rivulatus* and *S. luridus* feed all the time without discontinuity, even during the reproduction and spawning periods that take place in spring. Several varieties of algae were identified in the intestine contents, with prevalence of green algae such as *Ulva*, *Cladophora* and *Enteromorpha*. *S. luridus* seems to be less tolerant to food selection, although the frequency of grazing (Fp) was slightly higher than that in *S. rivulatus*. Some non digested substances were observed in the digestive tubes, such as mud, sand grains, and other debris of phanerogams, which are present in the area, namely *Zostera*, *Halophila* and *Cymodocea*.

# POT FISHERY OF RAPANA VENOSA VALENCIENNES 1846 IN THE SOUTHEASTERN BLACK SEA

H. Saglam<sup>1</sup>\*, S. Kutlu<sup>1</sup>, S. Bascinar<sup>1</sup>, M. Dagtekin<sup>1</sup>, E. Duzgunes<sup>2</sup>, A. Sahin<sup>2</sup> <sup>1</sup> Central Fisheries Research Institute, Sana, 61100. Trabzon, Turkey - hemral@yahoo.com <sup>2</sup> Black Sea Technical University, Faculty of Marine Science, Çamburnu 61530, Trabzon, Turkey

# Abstract

A survey was carried out to test the effectiveness of three pot designs and location in catching whelk in the southeastern Black Sea of Turkey in July and August 2006. A total 225 pots and 5 fishing trips were conducted. The type III (plastic container) pot appears to be most suitable for future based on the whelk catch rate.

Keywords : Gastropods, Black Sea.

#### Introduction

*Rapana venosa* are large predatory marine gastropods that, to date, are the progenitors of known successful invasions into estuarine habitats around the world. Although native to Asian waters around Japan and Korea, rapa whelks were discovered in Novorosisk Bay in the Black Sea in the mid 1940s and have spread throughout the Aegean, Adriatic and Mediterranean Seas [1, 2] and entered the Chesapeake Bay, Virginia [3], and Uruguay and Argentina [4].

Whelks are commonly caught using dredging or diving in Turkey. The prohibition for whelk fishing is from 1 May- 31 August. Harvesting whelks using pots is applied commonly Canada, Northern Europe and Japan. Pots are often considered a more beneficial type than dredges because there is less impact on the bottom habitat and by-catch can be minimal, depending on the design of the pot [5].

The objective of this research was to determine whether fishing for whelks using pots is an effective method to catch them, and whether this pot type would capture enough whelks to support a fishery. Both objectives were assessed by measuring catch per fishing effort (CPUE) between different pot types with various types of bait including whiting, mussel and ray. The main objective of the survey was to test three different pot types with respect to the effectiveness for catching whelk, the side effects of by-catching other species and identifying an ideal pot type to be used in future surveys of whelk populations.

#### Material and Method

The survey was carried out in summer 2006 in southeastern Black sea of Turkey (Trabzon and Ordu). Fishing was conducted along the coasts at 10 m depths. The pots were fished on strings of 45 pots, setting pot types I, II and III respectively (Fig. 1). The backline was weighted at either end of the pots with an anchor and terminated on the surface, marked by a buoy. A total 225 pots were used. Fishing was conducted using three different pot types. The gear was rigged with pots on 2 m tails attached to a backline at 15 m interval. Frozen offal mainly of mussel, whiting, and ray was used as bait. The catch in each pot of whelk was weighted and, in most cases, 100 randomly chosen individuals were measured to the end of the siphonal canal. By-catch species were identified. CPUE was expressed as kg per pot.

Fig. 1. Whelk pot types I, II and III respectively.

#### Results

In total, 225 pots in 5 fishing trips were executed in summer. The total catch was 188.87 kg. Total average CPUE of whelk was 0.536, 0.594 and 1.136 kg per pot/day in Trabzon and 0.837, 0.758 and 1.996 kg per pot/day in Ordu for type I, II, III, respectively. CPUE varied significantly between areas and whelk pot types (P<0.05) (Fig. 2). The major by-catch species was harbour crab (*Liarcinus depurator*) and goby (*Gobius sp.*). Whelks in pots were 56.43 $\pm$ 0.808 (30.74 - 96.76) mm for Trabzon and 66.73 $\pm$ 0.873 (39.46-94.86) mm for Ordu in shell length.

Fig. 2. *R. venosa*: CPUE at different whelk pot types in Trabzon (Grey bar) and Ordu (white bar). Error bars represent 95 % confidence intervals.

# HARPACTICOIDS (CRUSTACEA, COPEPODA) ASSOCIATED WITH MACROPHYTES FROM THE ROMANIAN BLACK SEA WATERS

Manuela Diana Samargiu \* and Daciana Sava

"Ovidius" University, Faculty of Natural Sciences, Blvd. Mamaia 124, RO- 900581, Constanta, Romania - manuelasamargiu@rdslink.ro

### Abstract

The paper presents the qualitative composition and makes a synecological evaluation (F %, D %, W %) of harpacticoids variation living associated with macrophytes in the north sector of the Romanian Black Sea shallow waters. Some data about their density in different sites from quantitative algae samples will be analyze, in order to highlight characteristic species and their distribution. *Keywords : Algae, Black Sea, Copepoda, Crustacea.* 

Most of the former studies of Romanian marine harpacticoids associated with macrophytes contain taxonomic observations or represent descriptions of new species. There are only few quantitative data which can explain the modification of qualitative and quantitative state of benthic communities of the Black Sea as result of increasing eutrophication and pollution, mainly in its NW corner [1].

Quantitative samples were taken from the hard substratum, in the north sector of the littoral, seasonally (during a period of five years) from a depth of 0, 5 - 5 m, using a metal scarper and plastic bags, on a  $20 \text{ cm}^2$  area. The most frequent species of algae were *Ceramium rubrum, Enteromorpha intestinalis, Cladophora sp.*, and in spring *Bryopsis plumosa* and *Porphyra leucosticta.* The locations were: Cap Midia - Navodari, Mamaia - Cazino, Mamaia - Fishery, Constanta - Cap Singol. The samples were processed under standard techniques and results were reported at 1 m<sup>2</sup> area. Data from the south sector were presented in a previous paper [2].

26 harpacticoids species were identified. Density values are the greatest for Cap Midia with populations of more than 2000 ind.  $\cdot m^{-2}$  in case of Ameira parvula and Mesochra pontica. Canuella perplexa and Ectinosoma normani recorded around 1000 ind. $m^{-2}$  and another three more than 1500 ind. $\cdot m^{-2}$  (from artificial dams with *Cladophora* and *Entero*morpha). In Mamaia Casino infralittoral waters, even we recorded the most numerous species (20), only five of them have densities values from 700 to 1600 ind. $m^{-2}$ . Canuella perplexa has the highest number of individuals in this zone and it can be considered as characteristic species (Table 1). At Mamaia Fishery density values are less than 600 ind. $\cdot m^{-2}$ . Mesochra pygmaea presents the most numerous individuals being a eudominant, characteristic species for this biocoenosis. Recording great densities is Ameira parvula with a frequency of 60% and an ecological relevance (W %) of 9.05, on rank 2. In Cap Singol (Constanta) zone, Harpacticus littoralis attend more than 750 ind.  $m^{-2}$ , comparing to the other species which have very low densities values.

From synecological data (Table 1, 2) results that the most frequent harpacticoid was *Ectinosoma melaniceps* even it is only an accessory species for most studied zones; the greatest dominance value was recorded in Mamaia Casino for *Canuella perplexa* and the lowest is in the same zone for *Thalestris longimana; Mesochra pontica* records a constant dominance in the first three studied sites; the highest ecological relevance value - W% - is registered for *Harpacticus littoralis* in Constanta shallow waters- as eudominant, characteristic for this zone.

The identified harpacticoids species which are living associated with macrophytes algae are not strictly phytophyle, many of them being encountered on other rocky faces, among mussels or stones fragments; they have eurybiontic particularities, being adapted to great variations of environmental conditions.

The actual algal communities consist only of species belonging to some genera like: *Ulva, Enteromorpha, Cladophora* and *Ceramium* which per-

sist and proliferate in eutrophic waters, covering the hard substratum up to 90%.

# Abstract

Fauna occurring in association with *Loligo vulgaris* was investigated by sampling on board commercial trawlers in two ports of Catalonia (NW Mediterranean) from October 2003 to December 2005. The composition of the hauls was similar in both ports but the biomass (kg/hour) captured by species varied according to the port. *Octopus vulgaris* and *Merluccius merluccius* were found in 100% of the trawls with *L. vulgaris* in both ports.

Keywords : Biomass, Cephalopods, Western Mediterranean.

#### Introduction

*Loligo vulgaris* have a very important economic value in southern European countries. Much is still to be known about this species in northwestern Mediterranean, and one area of particular interest is its interrelationships with the accompanying fauna. In Catalan waters, marine communities have been classified with regard to the most abundant species, both fishes [1] and cephalopods [2] but not the total community. The aim of this study is provide a better insight into the communities where *L. vulgaris* is found.

#### Material and Methods

Sampling was carried out on board commercial trawlers on a monthly basis, from October 2003 to December 2005 in Cambrils and Roses, Catalonia ports (NW Mediterranean). Differences between ports were tested with an "analysis of similarities" randomisation test (ANOSIM) from PRIMER statistical software.

#### Results and Discussion

ANOSIM test revealed that there are significant differences of the species composition in both groups of hauls (P < 0,001; R = 0,759).

Octopus vulgaris and Merluccius merluccius present 100% occurrence with L. vulgaris (Fig.1). Species like Sardinela aurita and Seriola dumerili have only appeared in the hauls carried out in Cambrils, while Eutrigla gurnardus has been captured only in Roses.

However the biomass (kg/hour) captured by species varied according to the port. *Merluccius merluccius* was more abundant in Roses while *Octopus vulgaris* was in Cambrils (Fig 2).

The species associated to the *L.vulgaris* captures showed that although they are mainly the same ones, the proportion of the appearance and mainly the biomass of the species is different in both ports. This can be due to that the characteristics of the habitat are different in the two areas and it rebounds in the species that inhabit each area. Roses area consists mainly of rocky coast, with predominance of sand and sandy muddy bottoms, while in Cambrils area the bottom is generally of muddy-sand and sand next to small formations of rocky barriers close to the coastal line [1].

Fig. 1. Percentage of occurrence of the most important *Loligo vulgaris* associated species in the two study ports.

Fig. 2. Biomass of the most important *Loligo vulgaris* associated species in the two study ports.

#### Abstract

The otter trawl fishing effort from two fishing grounds, located in the Catalan and northern Adriatic Sea was estimated using direct and indirect methods. The direct estimation monitored the trawl fleet activity, whereas the indirect estimation was based on monitoring the trawl tracks on the sea floor by side scan sonar. A significant relationship between the two methods suggested the utility of the indirect estimation as indicator of fishing effort.

Keywords : Adriatic Sea, Western Mediterranean, Fisheries.

#### Introduction

A small-scale estimation of the spatio-temporal distribution of fishing effort on trawling grounds is of paramount importance to develop a management based on fishing effort control. The aim of the present work is to estimate fishing effort at the smallest scale possible by means of direct and indirect methods.

#### Methodology

The study, carried out during 2003 and 2004, analyses the fishing activity of two commercial trawling fleets that operate at Sant Carles de la RÃ pita (Catalan Sea, NW Mediterranean) and Fano (Adriatic Sea, Central Mediterranean).

To obtain a small-scale information on spatio-temporal pattern of fishing activity, different sampling methods have been considered. Firstly, fishing effort was directly estimated by: (i) monitoring daily landings per vessel at the auction, (ii) interviews with fishermen, and (iii) sampling on board. Data on fishing hours per month (h) were converted in Direct Effort Index, D.E.I. = (h ·s ·w ) / A, where s is the mean trawling speed (4.6 km/h in the Catalan Sea and 5.5 km/h in the Adriatic Sea), w is the mean distance between the two doors of the gear (0.06 km), and A is the total surface of each study area.

Secondly, an Indirect Effort Index, I.E.I. was applied, following the temporal evolution of the trawl tracks on the bottom of a 1 km<sup>2</sup> area (S). Data were obtained by Side Scan Sonar (SSS) [1]. I.E.I was calculated as: (w  $\cdot L/2$ ) / S, where L is the total length of the trawl tracks. The relationship between D.E.I. and I.E.I. was estimated with linear regression.

#### Results and Discussion

D.E.I.: three main periods of fishing activity have been identified. In the Catalan Sea: high effort season from September to February, low from March to June, fishing closure in July and August. In the Adriatic Sea: high fishing activity from January to June, low from July to December, fishing closure from August to middle September (Table 1).

Tab. 1. Direct and indirect estimates of the trawl effort (A= Adriatic Sea, B= Catalan Sea).

I.E.I.: the images from SSS reflect the same pattern of fishing effort intensity obtained by the D.E.I.: high, low and cessation of fishing activity. A significant relationship was highlighted by ANOVA between direct and indirect effort indices (test  $F_{1,3}$ : p < 0.05, r = 0.923 for the Adriatic fishing ground; test  $F_{1,4}$ : p < 0.05, r = 0.818 for the Catalan one). In the Catalan Sea the best fit between these two measures was obtained using the accumulate value of three previous months as D.E.I. values, while in the Adriatic Sea the best correlation was obtained considering the values from the same month. These differences are related with the permanence of the trawl tracks on the bottom, a factor that depends by the characteristics of the sediment and determines the relationship with the (real) effort carried out on the trawl ground [2, 3]. These results suggest that SSS may be used as an independent approach for estimating the commercial fishing effort, at least in small areas.

### Abstract

In this study, distribution of anchovy (*Engraulis encrasicolus ponticus* Aleksandrov, 1927) eggs and larvae was investigated off Sinop (southern Black Sea, Turkey) in 2003. The mean egg quantity of anchovy was determined as  $27\pm9.26$  and  $80.6\pm34.52$  in vertical and horizontal plankton tows, respectively. Larvae numbers of anchovy in vertically and horizontally hauls were  $8\pm2.52$  and  $22.3\pm11.3$ , respectively. The spawning season of anchovy was confirmed to be between May and September. *Keywords : Ichthyoplankton, Black Sea*.

#### Introduction

Anchovy is the most important fish of the Black Sea constituting more than 60% of total catch [1]. This study aims to evaluate distribution of anchovy eggs and larvae off the coast Sinop of the southern Black Sea in 2003.

#### Material and Methods

The ichthyoplankton samples were collected at six stations. These stations were 1-4 miles off-shore off Sinop (southern Black Sea, Turkey) having a depth of 40-300 meters. Samples were collected monthly during the period January-December 2003 except August. The samples of the plankton were carried out from vertically tows from anoxic zone to surface using a plankton net (having a 50 cm diameter mouth opening and 210 mm mesh size). Horizontal hauls were also utilized by towing the net for 15 min at vessel speed of 2.5-3 miles  $h^{-1}$ . The samples were preserved with borax buffered 4% formaldehyde solution.

#### Results and Discussion

In generally, anchovy eggs and larvae were found from May to September. In vertical hauls, the most abundant eggs and larvae were found in July. In horizontal hauls, the most abundant eggs were found in July and most larvae were found in June. In vertical hauls, eggs and larvae ranged from 7.5 to 260 ind.m<sup>-2</sup>, and from 5 to 115 ind.m<sup>-2</sup>, respectively. In horizontal hauls eggs and larvae were found in the range of 0.4-159 ind.100 m<sup>-3</sup> and 2.6-52.1 ind.  $100m^{-3}$ , respectively. Previously, it was found that the anchovy eggs and larvae were 0-30 ind.m<sup>-2</sup> and 0-2 ind.m<sup>-2</sup>, respectively in 1991 and were 0-40 ind.m<sup>-2</sup> and 0-26 ind.m<sup>-2</sup>, respectively in 1992 [2].

Tab. 1. Average number  $(ind.m^{-2})$  of anchovy (*Engraulis encrasicolus ponticus*) eggs and larvae in the northern (Sevastopol Region) and the southern (Sinop Region) Black Sea in the summers of 2000, 2001 and 2003, from vertical tows.

\*\*In this study

When results of this study are compared with previous studies, more eggs were found off Sinop coasts of Turkey than those in Sevastopol coast of Ukraine in vertical hauls. Moreover, the numbers were much higher in 2003 compared to 2002 (Table 1). The high numbers of eggs and larvae found in 2003 are in parallel with the highest landing values of anchovy in the same year (about 373 thousand tons [4]).

# DISTRIBUTION OF THE ALIEN GASTROPOD RAPANA VENOSA IN THE NORTHERN ADRIATIC SEA

Dario Savini \*, Anna Occhipinti Ambrogi and Michela Castellazzi

DET- Dipartimento di Ecologia del Territorio, Università di Pavia, Via S. Epifanio 14, I-27100 Pavia - dario.savini@unipv.it

## Abstract

A systematic survey on the invasive alien gastropod *Rapana venosa* was conducted in spring-summer 2004 along the Italian coast of the Northern Adriatic sea in collaboration with squid fishermen. Results showed a scattered distribution of the species between the localities of Marano and Fano (approximately 400 km). Maximum estimated population densities (>500 ind. km<sup>2</sup>) were recorded near the shores of Cesenatico; a comparison with a previous survey demonstrated that the local population of the gastropod has been rapidly increasing thus enhancing risk of invasion and of further spreading.

Keywords : Gastropods, Species Introduction, Coastal Waters, Mapping, Adriatic Sea.

#### Background

*Rapana venosa* (Valenciennes, 1846) represents a good example of a successful marine alien invasive species. This predatory gastropod has been increasing its biogeographical range moving from the native East Asian seas towards Europe and America thanks to ship ballast water and aquaculture transfer vectors. The whelk is internationally considered a serious menace to bivalve fisheries [1,2], being preferentially acclimated in estuarine/brackish water of coastal regions, where intensive bivalve harvesting usually takes place. The first findings of *R. venosa* in the Northern Adriatic Sea occurred in the 1970s when few specimens were collected by the shores of the town of Ravenna [3]; since then the introduced population has been growing undisturbed, being able to colonize the Northern Adriatic coasts of Italy [4]. In this communication we present the results of a field campaign, supported by the Italian Ministry of the Environment, aiming to assess the distribution of the alien gastropod in the Northern Adriatic.

#### Methods

In April 2004 an informative campaign was organised in order to obtain fishermen collaboration in five different localities of the Northern Adriatic: Marano (UD), Chioggia (VE), Goro (FE), Cesenatico (FC), Fano (AN). Three squid fishermen, each fishing over an area of about 10 km<sup>2</sup> per site were involved in the survey. Previous investigations in Cesenatico showed how squid-nets act as efficient sampling devices for the mature reproductive subset of the gastropod population [4]. Therefore squid-fishermen were asked to provide data on: nets location, water depth and number of gastropods captured at each control date for a period of four months (April to July). All samples collected were kept frozen (-18°C) for further structural analysis of the population (biometry, sex ratio, genetics).

Fig. 1. Northern Adriatic distribution of *Rapana venosa* catches by local fishermen in spring-summer 2004. M = Marano (UD); Ch = Chioggia (VE); G = Goro (FE); C = Cesenatico (FC); F = Fano (AN).

#### Results and discussion

Data analysis showed a patchy distribution of Rapana venosa with maximum catches (N >500 ind.  $km^{-2}$ ) concentrated nearby the littoral of Cesenatico at 0.5-10 km from the coast and at 2-15 m depth [Fig.1]. No specimens have been caught South of Fano and North of Marano, which so far represent respectively the southern and northern limit of Rapana distribution. Samples caught at the distribution limits appeared larger, thus older, than individuals caught in Cesenatico [Fig. 2]. In 2001 a survey conducted using the same methods, but only in Cesenatico [4], reported much lower total catches (302) and significative larger dimensions than specimens collected in 2004 (2001 shell height frequency distribution mode = 100; 2004 mode = 90; KS-test, D = 0.45 P < 0.001). Both parameters indicate that the local population of the gastropod was experiencing a phase of expansion. In conclusion this survey has claimed for action to manage and control Rapana population in this area, an important hot spot of dissemination of this NIS towards other localities of the Mediterranean sea.

Fig. 2. Modal values of the size frequency distributions (shell height, mm) of *Rapana venosa* specimens collected in: F = Fano, C'01: Cesenatico, year 2001, C: Cesenatico, G: Goro, Ch: Chioggia. Numbers in brackets represent the total sample size.

# RAPIDO TRAWL FISHERY IN THE NORTH-CENTRAL ADRIATIC SEA

Giuseppe Scarcella \*, Gianna Fabi and Fabio Grati

CNR - Istituto di Scienze Marine (ISMAR) - Sede di Ancona - 60125 Ancona (Italy) - g.scarcella@ismar.cnr.it

### Abstract

This study gives a description of the catches produced by the commercial rapido trawl fleet of Ancona harbour (north-central Adriatic), mainly targeting the common sole, *Solea solea*. Observations onboard were carried out for two years. Catch data showed that the discarded part was greater than the retained one. Discard of commercial species was greater than discard of non-commercial ones, and both of them were dominated by few species.

Keywords : Adriatic Sea, Fisheries, Demersal.

#### Introduction

The rapido trawl fishery has been going on for over 40 years in the western side of the north-central Adriatic Sea where it is carried out all year round on the soft bottoms outside 3 nm offshore. Ancona is an important port for this fishery with a fleet of 10-11 rapido vessels (average Loa =  $27.7\pm0.4$  m) targeting flatfish (*Solea* spp., *Psetta maxima*, *Scophthalmus rhombus*). The rapido trawl is a modified beam trawl, with a rigid mouth fitted with iron teeth (7-10 cm long) along the lower part [1]. A nylon net bag having a codend mesh size ranging from 48 to 52 mm (stretched) is tied to the frame. Ancona vessels typically use 4m-wide rapido trawls and tow 4 gears simultaneously at a speed of 11-13 km h<sup>-1</sup>. Due to the lacking information on this activity, a two-year study was carried out to increase the knowledge on the quali-quantitative composition of the catches.

#### Materials and Methods

Data were collected onboard of randomly chosen professional vessels of the Ancona fleet. A total of 235 hauls were sampled from summer 2000 to spring 2002, without any interference with the fishers' modus operandi. The overall catch was subdivided in retained fraction (target species, Solea solea, and kept by-catch), discard of commercial species (discard C; damaged or smaller than the legally sized specimens), discard of non-commercial species (discard NC; species without any commercial value) and debris (dead shells, wood, stones, anthropic matter, waste, etc.) [2]. The retained fraction was analysed onboard: number of specimens. total weight and size of each individual were recorded for each species. The discard was weighed onboard and a sample was taken and later examined in the laboratory. Discard C and discard NC were determined to the species level; number of individuals and total weight of each taxon were recorded and the specimens of the commercial species measured. Debris was subdivided in categories which were weighed separately. In data analysis, catch (retained and discarded fractions) and debris were treated separately, computing seasonal values for each of them as kg km $^{-2}$ .

#### Results

A total of 188 taxa (58 fishes, 26 crustaceans, 67 molluscs, 14 echinoderms, 23 others) were recorded in the study period. Discard NC included the highest number of taxa, followed by discard C and the retained fraction. Seasonal CPUE ranged from 1080.0±96.5 to 456.4±53.8 kg  $km^{-2}$ (Tab. 1). The retained fraction was always lower than the discard and did not show a clear seasonal trend. S. solea made up from 3 to 18% of the catch, while Bolinus brandaris, Chelidonichthys lucernus, Melicertus kerathurus, Sepia officinalis and Squilla mantis dominated the kept by-catch (Tab. 1). Discard C was the most important fraction of the catch, except in fall '01 and spring '02. The most abundant species were the gastropod Aporrhais pespelecani, the bivalve Ostrea edulis and the decapod Liocarcinus depurator which together made up more than 80% in weight of this fraction in each season (Tab. 1). These species were generally discarded for their low commercial value with respect to the work required for their sorting and, in the case of O. edulis, for subsequent sanitary processes. The remaining portion of discard C was mainly constituted by small specimens of B. brandaris, S. mantis and C. lucernus. As concerns this last species, 94% of individuals caught during the overall period were smaller than the size at first maturity (24.0 cm TL; [3]), and most of them 67% were discarded. Discard NC was the second most important fraction with the highest values in fall '01 and spring '02 (Tab. 1). The main species were the bivalves Anadara inaequivalvis, Anadara demiri and Corbula gibba, the echinoderm Astropecten irregularis and the decapod Goneplax rhomboides (Table 1). Huge amounts of debris were caught in all seasons, sometimes exceeding the total catch (Tab. 1). It included 34 taxa (28 molluscs, 5 echinoderms, 1 phanerogam)

and other materials, such as stones, waste, etc. Dead shells of gastropods and bivalves, belonging to the local thanathocoenoses, always made up the largest portion, constituting 55-86% of the seasonal catches of this fraction.

Tab. 1. Composition of the seasonal catches (kg km<sup>-2</sup>). Wi = winter; Sp = spring, Su = summer; Fa = fall.

#### Conclusions

The rapido trawls were efficient in the exploitation of common sole and most of the other accessory species, being their discard negligible in most of cases. This was due to the fact that all the caught specimens of these species were marketable, independently from the size. Moreover, the rare individuals damaged by the gear were also easily sold. A noticeable discard was detected only for *C. lucernus*, especially when considerable amounts of small and often damaged specimens were caught and discard C mainly included organisms which remained alive when rejected at sea, such as *A. pespelecani* and *O. edulis*. Discard NC consisted of few dominant species of molluscs and decapods, and also in this case most of them were still alive when rejected. Debris showed to be noteworthy in this kind of fishery, affecting sometimes the fihermen' habits as regards the choice of the fishing zone and haul duration.

### Abstract

The trochid gastropod *Gibbula nivosa*, endemic to the Maltese Islands, has recently only been found in two Maltese bays, where it occurred on seagrass leaves and under stones at depths of 1-4m. Intensive sampling of *Cymodocea nodosa* and *Posidonia oceanica* meadows, sediment and pebbles at depths of 2-12m, carried out in 2000 and 2002, resulted only in empty shells but no live animals, suggesting that the species is extinct from these localities where previously good populations were found. However, the occurrence of fresh shells from other Maltese sites suggests that small undiscovered populations may exist. *G.nivosa* is considered to be 'critically endangered'. *Keywords : Biogeography, Conservation, Endemism, Gastropods, Mollusca.* 

#### Introduction

The trochid gastropod *Gibbula nivosa*, first described 1851 has been reported many times from Malta [1,2,3] but not from elsewhere in the Mediterranean or any other sea, and is now widely accepted as endemic to the Maltese Islands [4,5], providing a rare example of a marine point endemism. Within the Maltese Islands, *G. nivosa* appears to be uncommon. Systematic searches in 13 localities distributed round the Maltese Islands made by Palazzi in 1978 [2] resulted in records of empty shells from nine of them, but living animals were only found at St. Thomas Bay, on *Posidonia oceanica* leaves at 1-4m. A later survey [3] reported live specimens from Delimara, close to St. Thomas Bay, and from Santa Marija Bay (Comino) at 2-3m under stones. The most recent catalogue of the marine Mollusca of the Maltese Islands [6] gives this species as common only at St Thomas Bay.

Because of its very restricted regional distribution and rarity, *G. nivosa* is internationally protected (Bern Convention; Protocol Concerning Specially Protected Areas and Biological Diversity in the Mediterranean of the Barcelona Convention) and with the accession of Malta to the European Union, also by the EU's 'Habitats Directive'. As such, there is an obligation to safeguard this species and *G. nivosa* is protected by Maltese legislation. However, no information on its present status exists. To address this, surveys of the two sites from where *G. nivosa* has been reported in recent years - St Thomas Bay (island of Malta) and Santa Marija Bay (island of Comino) - were made in order to assess the status of the species at these localities.

#### Methods

Surveys were made in summer 2000 at St Thomas Bay and in summer 2002 at St Thomas Bay and Santa Marija Bay. Three shore-normal transects were laid at St Thomas Bay varying in length from 150-750m and passing through shallow water (<4m) Cymodocea nodosa meadows, continuous Posidonia oceanica meadows, and reticulate P. oceanica meadows interspersed with sparse patches of sand and pebble beds (4-12m). At Santa Marija Bay, two 400m-long shore-normal transects were laid over P. oceanica meadows interspersed with patches of sand and small pebbles and beds of larger pebbles. In both bays, stations (2m, 4m, 6m, 8m, 10m, and 12m) within these transects were sampled in different ways depending on the substratum. The upper 5cm of sediment was collected from within 0.25m<sup>2</sup> random quadrats (three replicates per station). Seagrass foliar molluscs were sampled using a 20cm x 40cm aperture hand-held net fitted with a 0.5mm mesh pushed 60 times through a 1m distance in the leaves moving forward with each stroke, thus sampling an area of 20m<sup>2</sup> per station (two replicates per station). Sediment and rhizomes at the base of P. oceanica shoots were sampled by pushing a 45cm-diameter circular corer with a toothed edge [7] into the rhizomes, and using a suction sampler to collect sediment and plant debris into a 1mm-mesh net bag (two replicates per station). In the laboratory the molluscs from all samples were sorted by hand, identified and counted, including broken shells of G.nivosa.

#### Results and discussion

A total of 24 whole empty shells and 10 broken shells of *G.nivosa* were collected from St Thomas Bay in summer 2000, with the largest number of whole shells (11) being collected from seagrass from the 6m station using suction sampling. In summer 2002, 100 whole empty shells (and no broken shells) were collected from this bay with the largest number of

whole shells (59) coming from the quadrat sediment samples at the 2m station. At Santa Marija Bay, only 4 whole empty shells (and no broken shells) were collected, half of which came from seagrass at 4m using the suction technique.

*G. nivosa* has been reported from two habitats: on seagrass (*P. oceanica*) leaves and under stones in shallow water (1-4m) [2,3]. In spite of intensive sampling of sediment, pebbles, and seagrass leaves and rhizomes at depths of 2-12m at St Thomas Bay and Santa Marija Bay, no live animals were found. Given that these two bays were a stronghold for *G. nivosa* [2,3], this suggests that this species is almost certainly extinct from these localities.

Although *G. nivosa* has recently only been reported live from these two bays and from Delimara [2,3], empty shells of this species are to be found in sediment from embayments along the entire southeast, east and northeast coasts of the Maltese Islands [6, and authors' unpublished data]. While the bulk of these shells are old and partially eroded, we also have some very fresh-looking shells that suggest that small undiscovered populations may exist in some localities. It is obvious that the status of *G. nivosa* in the Maltese Islands can only be ascertained by intensive sampling of the entire coastline where the reported habitats of this species must now be considered 'critically endangered' under the 2001 IUCN Red List criteria [8,9].

### Abstract

We applied the Daily Egg Production Method (DEPM) to the NE Aegean anchovy, *Engraulis encrasicolus* (Linnaeus, 1758) stock during its peak spawning period in June 2003 and June 2004. Analysis of adult samples revealed significant differences between the two years for the parameters of mean weight of mature females, batch fecundity and spawning frequency which had higher values in 2004. In addition, fish grew faster in weight in 2004. The estimated spawning biomass was about three times lower in 2004 than in 2003. *Keywords : Aegean Sea, Stock Assessment, Reproduction, Spawning.* 

#### Introduction

European anchovy is one of the most important pelagic fish in the Mediterranean and the estimation of the spawning biomass of its stocks is an important tool in their assessment [1]. The DEPM is an ichthyoplanktonic method for estimating the reproductive biomass of multiple spawning fish. The application of this method can provide valuable information on the reproductive ecology of these species [1, 2]. The aim of the present study was to examine interannual changes in the DEPM adult parameters of anchovy in the NE Aegean Sea.

#### Methods

During the application of the DEPM on the NE Aegean anchovy stock in June 2003 and 2004, samples of adult fish were collected from both experimental and commercial fishing. Each sample consisted of random collection of approximately 50 anchovies. Processing of an adult sample in the laboratory consisted of length and weight measurements (both total and gonad free weight), sexing, fecundity measurements for batch fecundity estimation (mean number of eggs per mature female per spawning, F), and histological analysis for spawning frequency estimation (fraction of mature females spawning per day, S).

Gonads of all processed females were weighted (0.01 mg) and preserved in 10% buffered formalin. The gonads of 20 randomly selected females per sample were subjected to histological analysis. The analysis involved the identification of the maturation stage of the most advanced group of oocytes and the presence and histological characteristics of atretic and postovulatory follicles (POFs) [3].

All macroscopically detected hydrated or running females were measured and their gonads weighted and preserved in formalin for subsequent histological and batch fecundity analysis. In order to assess batch fecundity we applied the hydrated oocyte method and the data were used to fit a linear model regressing the number of eggs per batch to gonad free weight [4, 5]. Spawning frequency was assessed by the postovulatory follicles method [3].

#### Results and Conclusions

The biomass and adult parameter estimates of the DEPM are presented in Table 1. In 2004 females were heavier and spawned almost every other day (S = 0.44), while in 2003 they spawned every three days (S = 0.34). Similarly, the number of eggs released per individual was higher in 2004 (7053 eggs per batch) than in 2003 (3936 eggs per batch). The weight-specific sex ratio was higher than 0.6 during both years.

Since fecundity is calculated indirectly through gonad free weight, the two parameters were correlated. However, the regression lines of fecundity on gonad free weight were forced through zero because the intercept was not significant at the 0.05 level. This indicated that the F/W ratio (relative fecundity, eggs g<sup>-1</sup>) was not size dependent. In addition, spawning frequency was not related to weight in 2003 or 2004 (Spearman rank correlation,  $r_s = -0.135$ , P = 0.581 and  $r_s = 0.468$ , P = 0.060 respectively).

In addition, the comparison of total length-gonad free weight relationships revealed that, in 2004, fish were growing in weight significantly faster (slope: b=3.1) than in 2003 (slope: b=2.7) (ANCOVA, F = 69.25, P <0.001), which indicated better feeding conditions in 2004.

These differences in reproductive performance and somatic condition could not be attributed to ambient food availability since concurrently measured zooplankton biomass was similar between years (P>0.05). However, estimates of spawning biomass (Table 1) indicated that the size of the

stock was almost three times larger in 2003 (17600 t) than in 2004 (6251 t). These observations suggest that the aforementioned differences can be explained in terms of density-dependence [2].

Tab. 1. Biomass and adult parameter estimates of the DEPM applied to the NE Aegean anchovy stock in June 2003 and June 2004.

| Parameter                       | 2003       | 2004       |

# OBSERVATIONS ON THE ALIEN CRAB *PERCNON GIBBESI* (DECAPODA, BRACHYURA, GRAPSIDAE) FROM THE MALTESE ISLANDS

Marija Sciberras \* and Patrick J. Schembri

Department of Biology, University of Malta, Msida MSD06, Malta - marija\_sciberras@yahoo.com

# Abstract

A preliminary account on habitat preferences, bathymetric distribution, population density, and aspects of the reproductive biology of the alien grapsid *Percnon gibbesi* in the Maltese Islands is given. This alien was first recorded from Malta in 2001 and has since established breeding populations in suitable habitats throughout the Maltese islands where of its preferred habitat types, upper infralittoral boulder fields or rock faces with a sparse algal cover, are available. The crab breeds in summer and recruits in winter. Female crabs may produce up to 30,000 eggs per spawning. Interactions with the native grapsid *Pachygrapsus marmoratus* were observed. *Keywords : Decapoda, Reproduction, Behaviour, Rocky Shores, Species Introduction.* 

#### Introduction

The subtropical crab, *Percnon gibbesi*, was first recorded in the Mediterranean Sea in 1999 contemporaneously from Linosa Island (Straits of Sicily) [1], Capo Passero (southern Sicily) [2] and Ibiza [3]. Records of its occurrence to date are from the western and central Mediterranean [4,5,6]. It was recorded from the Maltese Islands in 2001 [7]. We made observations on the habitat preferences, bathymetric distribution, population density, and egg production of this species in the Maltese Islands in order to assess if there were any differences in the biology of this species in Malta relative to other Mediterranean sites.

#### Method

Habitat preferences and bathymetric distribution were assessed by carrying out surveys at 23 sites around the Maltese Islands where preliminary observations indicated the crabs to occur. At 20 of the investigated sites, the population density in the preferred habitat was determined by counting the number of crabs in replicate  $1m^2$  virtual quadrats. To estimate reproductive output, egg-masses from 30 ovigerous females were weighed and the number of eggs in triplicate sub-samples from each egg-mass was counted.

#### Results and discussion

All individuals of *P. gibbesi* encountered were wholly submerged and occurred between depths of 0.05m and 4m. The preferred habitats were similar to those reported from elsewhere in the Mediterranean [4,5,6], and consisted of submerged boulders covered by a thin microalgal felt, encrusting algae or algal turf, or rock ledges, crevices and vertical rock walls sparsely covered by macroalgae. Population density ranged between 1.6  $\pm$  0.5 s.d. and 11.9  $\pm$  7.1 s.d. crabs m<sup>-2</sup> (Fig. 1) and was significantly higher (Kruskal-Wallis p <0.001, Dunn's pairwise test p <0.05) at Marsascala, Dahlet Qorrot and Hondoq ir-Rummien, where extensive areas of boulder habitat occurred at depths less than 4m that were not interrupted by unsuitable habitats such as homogeneous rocky or sandy bottoms or seagrass patches as in the other sites.

Fig. 1. Mean abundance (error bars represent the 95% confidence intervals) of *P. gibbesi* at 20 sites in Malta and Gozo.

Diurnal changes in abundance were investigated at Pembroke, where a two-fold increase between morning (counts made before 13.30h) and late afternoon (counts made after 16.00h) abundances ( $5.2 \pm 3.4$  crabs m<sup>-2</sup> and  $10.1 \pm 5.7$  crabs m<sup>-2</sup>, respectively; Mann-Whitney U-test; p<0.05) was recorded hence supporting observations from Pantelleria [4] and Isola delle Femmine [5] that *P. gibbesi* becomes most active towards dusk.

We recorded berried females from June until the end of September, and juvenile crabs (carapace length  $\leq$  15mm) from October until March, suggesting that *P. gibbesi* breeds during the summer months and recruitment takes place throughout the winter. Egg brood size ranged between 254 (the total number of eggs in the smallest egg mass) and 32 040  $\pm$  281 eggs and was found to be positively correlated with carapace length (r = 0.677, p <0.001, df = 27). High fecundity and the relatively long breeding season are factors that may have facilitated the rapid and successful spread of this alien species in the Mediterranean.

Contrary to reports by some authors [4,6], *P. gibbesi* was observed to coexist with the grapsid *Pachygrapsus marmoratus* and the xanthid *Eriphia verrucosa*, which are the two native species that occur in the same habitats. Again contrary to reports, *P. gibbesi* was observed to occasionally interact with *P. marmoratus* when the two approached to within c. 15cm. These observations suggest that in the Maltese Islands the alien species is a potential competitor for resources, mainly space, with the native syntopic grapsid. Studies are clearly necessary to assess and quantify the impacts of the alien on the Mediterranean marine systems where it has become established, including the risk of competitive exclusion of native species with similar patterns of resource utilization.

# INTERSPECIFIC INTERACTIONS BETWEEN THE GRAPSID CRABS PERCNON GIBBESI AND PACHYGRAPSUS MARMORATUS: IMPLICATIONS OF AN INVADER

Marija Sciberras \* and Patrick J. Schembri

Department of Biology, University of Malta, Msida MSD06, Malta - marija\_sciberras@yahoo.com

# Abstract

One-on-one interspecific encounters between the recently introduced alien *Percnon gibbesi* and the native *Pachygrapsus marmoratus*, with which *P. gibbesi* occurs syntopically, were staged in the laboratory to assess the behaviour of these species relative to each other. Unless the encounter involved large *P. gibbesi* with small *P. marmoratus*, the native species was the 'winner'. These results suggest that the native species has competitive superiority over the invader and is unlikely to suffer from spatial resource partitioning or, worse, competitive exclusion from its natural habitat as a result of the invasion by *P. gibbesi*. *Keywords : Decapoda, Behaviour, Competition, Species Introduction.* 

#### Introduction

Human-mediated transport of species from one biogeographical setting to another is now considered to constitute a serious threat to marine ecosystems and biodiversity [1]. Knowledge on the actual impacts of a specific introduced species on native biota is often anecdotal and detailed evidence is rare [2]. This applies also to the subtropical grapsid crab, *Percnon gibbesi*, which was first recorded from the Mediterranean Sea in 1999 and from the Maltese Islands in 2001 [3]. Field observations made in the Maltese Islands suggest that *P. gibbesi* overlaps in habitat with the native grapsid *Pachygrapsus marmoratus* [4], and therefore, the possibility of competition might occur. This study was designed to investigate the outcome of interspecific interactions between the two crabs when space is restricted.

#### Methods

Individuals of both species were collected by hand from Pembroke and Marsascala, Malta. Crabs were divided into three groups according to their carapace length (CL): large = CL>30 mm, medium = CL 20-30mm, and small = CL<20mm. After an acclimation period of 7 days in aerated seawater at 20 deg.C without feeding, one-on-one interspecific interactions between individuals of the two species in different size combinations were staged in rectangular aquaria of dimensions (29.5 x 20 x 19cm) and were recorded using videography. These video records were then analysed by dividing the behavioural sequence into 'acts' (see legend to Fig 1). The behaviour of the crabs was recorded in an alternating sequence, i.e. act by crab 1, act by crab 2, etc. Ten replicate trials for each size combinations were made.

Fig. 1. Percentage distribution of acts following specific initial acts (shown on the y-axis) during the staged encounters between *P. gibbesi* and *P. marmoratus*. The acts considered were: advance of crab 1 towards crab 2; retreat by crab 2, L = low intensity merus display where the crab adopts a neutral posture by holding its body close to the substratum with chelae folded inwards; M& H = medium and high intensity merus display where the crab lifts its body off the substratum on its dactyls and spreads its chelae open; T = physical touch; Fz = complete cessation of movement; Ac = attack with chelae in open position; G& R& Bur refer to grooming, random movement, and burrowing; 0 (does nothing) is an act used to preserve the alternation of acts whenever an intra-individual transition occurred.

#### Results and discussion

*P. marmoratus* was the initiator of an encounter, defined as the crab that made the first move towards or engaged in physical contact with its opponent, in 80.8% of the trials and the winner of an encounter, defined as the crab that elicited repeated retreats from or inflicted harm to or killed its opponent, in 86.9% of the trials. *P. gibbesi* won encounters only when matched with a small *P. marmoratus*, where the ratio of *P. gibbesi* chelae length to that of *P. marmoratus* was >1. This suggests that the native species has a higher resource holding potential than the invader. *P. gibbesi* was never observed to attack its opponent unless the latter advanced towards or engaged in physical contact with the *Percnon*.

In 10 out of 16 encounters between a large or medium *P. marmoratus* and a small *P. gibbesi*, the former deliberately attacked the latter and killed the *Percnon*. In general, all the initial acts performed by *P. marmoratus* significantly affected the distribution of the following acts (p-value associated with chi-square was less than 0.001) indicating that communication between the two species via visual displays is taking place. This may be important in determining the degree to which these two species overlap in their resource utilization. Irrespective of size, *P. gibbesi* exhibited the highest number of retreat or submissive (low intensity merus display, L) actions (which constituted 92.3% of the acts performed by *Percnon*) in response to acts by *P. marmoratus* such as advance, medium and high intensity merus display (M& H), attack with chelae in open position (Ac) and physical contact (T) (Fig. 1).

#### Conclusion

One determinant of invasion success is the nature of competitive interactions with native ecological analogues. Our results suggest that the native species is unlikely to be excluded from its natural habitat by the alien, or even that any significant spatial resource partitioning on the part of *P. marmoratus* will occur. The successful invasion by *Percnon* on Maltese shores (and perhaps other Mediterranean shores) may be due to this species finding habitat space that does not bring it into competition with native crab species with similar resource requirements.

# INTERSPECIFIC RELATIONSHIP BY SIZE SEGREGATION BETWEEN TWO PANDALID SHRIMPS IN THE NORTH AEGEAN SEA

Carla Scigliano \*, Pavlos Vidoris and Argyris Kallianiotis

NAGREF - Fisheries Research Institute 64007, N. Peramos, Kavala, Greece - fri@otenet.gr

# Abstract

Most of the studies on Mediterranean pandalids focused on their spatial distribution, reproduction patterns and diet but few on interspecific relationships. The present work deals with interspecific comparison between two widely distributed pandalids (*P. martia*, *P. heterocarpus*), analyzing size segregation among three different areas in the northern Aegean Sea. *Keywords : Aegean Sea, Decapoda, Crustacea, Population Dynamics, Competition.* 

Logarithmic decline of food energy availability in deep water is the most important factor in shaping of deep water fauna [1]. In the Mediterranean Sea, other factors such as oligotrophic water, scarce energy food availability under 200m and higher water temperatures play a main role in the organization of community structure in order to minimize inter and intra specific competition for exploitation on resources [2].

Intraspecific size segregation by depth is a common pattern in pandalid shrimps. Furthermore, among pandalid species co-occurring at the same depths different size composition and mean carapace length were observed [3]. This observation can be related to the diet composition of the species of similar morphology and trophic habits since interspecific segregation could be an adaptation that allows co-existence [4].

In this context, this study has the objective to investigate size segregation between the two most abundant and widely distributed species of pandalid shrimps in the northern Aegean Sea, *P. heterocarpus* (Costa, 1871) and *P. martia* (A. Milne Edwards, 1883),.

Samplings were carried out during Mediterranean International Trawling Survey (MEDITS) in the years 2003, 2004 and 2005 in the northern Aegean Sea. Specimens were collected from samples where the two species were found co-existing. A total of 15 stations ranging between 350-600m were taken in account. Three main surveyed areas (Hios, Sporades and Halkidiki) were defined within the Medits survey protocol.

The samples were fixed on board in 10% formalin and transferred in laboratory. For each specimen, carapace length (CL) was measured from orbital edge to the median posterior margin of cephalotorax, using a vernier caliper to the nearest 0,01mm.

The variances of CL between species by each area were compared using the parametric analysis of variance (ANOVA) or the non parametric Kruskal-Wallis ANOVA by median test.

Although size overlapping was found in all three areas, significant differences between mean or median CL were observed in Hios and Halkidiki, whereas in Sporades populations didn't show size segregation in their size distribution.

At slope depths, pandalid species, where they co-occur, showed a high dietary overlap [5]. Partitioning among species has been argued to reduce interspecific competition. As feeding strategy, it has been observed that smaller species directed its feeding activities towards smaller prey items within their diets and selection of different prey sizes attenuates the exploitation of the same resource.

In this sense, different mean sizes founded in *P. heterocarpus* and *P. martia* in Hios and Halkidiki regions could be an adaptation to exploit resources in those environments where food scarce availability could determine the presence of competition as factor for resource partitioning.

Pandalids populations examined in Sporades region didn't show a significant segregation. Absence of competition could be postulate.

However, to establish presence of competition it requires determining on dietary overlap and food availability. In future, further studies should be undertaken to evaluate dietary composition of the two species and deep water resource concentration in the studied area.

# DEPTH DISTRIBUTION OF PANDALIDS GENUS IN THE NORTH AEGEAN SEA

Carla Scigliano \*, Pavlos Vidoris and Argyris Kallianiotis

NAGREF - Fisheries Research Institute 64007, N. Peramos, Kavala, Greece - fri@otenet.gr

#### Abstract

Many aspects of pandalids biology and ecology such feeding behaviour and growth were studied in the Mediterranean Sea. However, information from eastern Mediterranean are scarce. The objective of the present study is to describe pandalid species community and the growth of the most widely distributed species in the northern Aegean Sea. *Keywords : Aegean Sea, Decapoda, Population Dynamics, Crustacea.* 

Deep-water pandalid species have an extensive geographical distribution. Since this taxon presents a high diversity and biomass, it has a great potential as a fishery resource in bathyal environments. In western and central Mediterranean, various aspects on trophic habits, depth distribution and reproduction patterns have been investigated.

In eastern Mediterranean, available information on their biology and ecology are limited [1, 2]. The present study has the objective to analyze main characteristics of bathyal distribution and population structure of pandalid shrimps in the northern Aegean Sea.

The material was obtained during 1996-2001 at 64 sampling area in North Aegean Sea within Mediterranean International Trawling Survey (MED-ITS) at depth ranging between 27 to 633 m.

Specimen were preserved in 10% formalin and tranferred in laboratory.

Shrimps were identified at species level. Carapace length (CL) was measured from the post orbital socket to the posterior median edge of the cephalotorax using a digital vernier caliper to the nearest 0,01mm.

General affinities between samples were estabilished using a presenceabsence cluster analysis on a species x hauls matrix. Lenght distribution by depth was studied using mean CL for each haul and plotted versus depth. Correlation and significance level were calculated using Pearson r. In the survey, 9 pandalids species were identified: *Chlorotocus crassicornis* (Costa, 1871), *Pandalina profunda* (Holthuis, 1946), *Plesionika acanthonotus* (Smith, 1882), *P. antigai* (Zariquiey Alvarez, 1955), *P. edwardsi* (Brandt, 1851), *P. gigliolii* (Senna, 1903), *P. heterocarpus* (Costa, 1871), *P. martia* (A.Milne Edwards, 1883) and *P. narval* (Fabricious, 1787).

*C. crassicornis*, *P. antigai*, *P. heterocarpus* and *P. martia* showed the highest occurrence.

Fig. 1. a) Depth range by species. Cc *C. crassicornis*, Pp *P. profunda*, Pn *P. narval*, Pac *P. acanthonotus*, Pan *P antigai*, Pe *P. edwardsii*, Pg *P. gigliolii*, Ph *P. heterocarpus*, Pm *P. martia*.b) Presence-absence cluster: aggregation of pandalids species in the survey samples.

In summary, *P. heterocarpus* and *C. crassicornis* were the shallowest species. *P. profunda, P. antigai, P. edwardsii,* and *P. gigliolii* were species characterizing the upper slope. *P. martia* and *P. acanthonotus* were found at the upper-midle slope depths.

*P. acanthonotus* and *P. martia* occurred in deepest water, reaching the maximum depth of the survey campain (633m).

P. profunda showed a low occurrence since it has been found in 2 hauls

at depth of around 400m. (fig. 1a). However, pandalid species examined in this study showed to inhabit depth strata as described from the western Mediterranean [3]. Neverthless, it was observed for each species a wider depth distributions with their upper limit founded at deeper waters.

Cluster analysis has identified a homogeneous group that includes 5 species (fig. 1b). *C. crassicornis*, *P. antigai*, *P. gigliolii*, *P. heterocarpus* and *P. martia* could represent a community occurring at the upper slope (300-500m) in three sector of the survey area (Hios, Sporades, Halkidiki).

Length distribution by depth was calculated for the most distributed 4 species. Three of them *C. crassicornis*, *P. heterocarpus* and *P. martia* showed a strong linear relationship (p<0.05) of mean size (CL) upon depth (fig. 2). For pandalids, tendency to increase size with depth is a common pattern. This tendency has been correlated to the presence of particulate matter layer that could affect the occurrence of juveniles and adults ontogenetic depth migration [4].

Fig. 2. Plot of mean size (CL) by depth. *C. crassicornis* r = 0,5450; p <0.05; *P. antigai*: r = 0,4294; p >0.05; *P. martia*: r = 0,9394; p <0.05; *P. heterocarpus*: r = 0,7376; p <0.056.

#### Résumé

Durant une année (Mai 2005-Avril 2006), des prélèvements d'eau collectés mensuellement de la colonne d'eau du barrage Nabhéna, nous ont permis de dresser l'inventaire du zooplancton, ainsi de suivre leur évolution. L'analyse des résultats met en évidence une faible richesse spécifique et une hétérogénéité de la colonne d'eau.

Mots clès : Zooplankton, Copepoda.

### Introduction

Le barrage Nabhéna est situé dans le gouvernerat de Kairouan (50 Km de la ville de Kairouan) a été mis en eau en 1966. La superficie totale de cette étendue d'eau est de 532 ha et de hauteur maximale de 62.5m et un volume de  $87x106 \text{ m}^3$ . Il est alimenté par l'oued Nabhéna. Le bassin versant de la retenue draine une superficie d'environ 855 km<sup>2</sup>. Cet écosystème joue un rôle important dans l'irrigation, la protection contre les crues et l'alimentation en eau potable. L'objectif de cette étude est de suivre la dynamique des communautés zooplactoniques en fonction des paramètres physico-chimiques du barrage.

#### Matériel et méthodes

Des prélèvements d'eau destinés aux analyses physico-chimiques et biologiques ont été réalisés de mai 2005 à avril 2006, selon un pas de temps mensuel au niveau d'une station central (0-5-10 et 15m). Les prélèvements du zooplancton ont été réalisés à l'aide d'un filet à plancton de type Juday (1 m de long et de 85  $\mu$ m de vide des mailles). L'étude du zooplancton est réalisée sous loupe binoculaire à l'aide d'une cuve de Dollfus. La biomasse des espèces zooplanctoniques a été calculée par la méthode indirecte développée par Bottrel et al. (1976) [1].

#### Résultats et discussion

Des études antérieures [2], ont monté que les communautés phytoplanctoniques se composent de principaux groupes suivants: diatomées (42 %), dinoflagéllés (24%), cyanobactéries 13%, autres (21%). L'examen de l'ensemble des prélèvements réalisés nous a permis de recenser 10 espèces zooplanctoniques :2 Copépodes Copidodiaptomus numidicus C.n.(Gurney,1909) (963.75µm) et Acanthocyclops robustus A.r (Kiefer, 1927) (900µm) ; 3 Cladocères Diaphanosoma brachyrum D.b (Lievin,1848) (587.5µm), Bosmina longirostris B.1 (Müller, 1976) (400µm) et Ceriodaphnia quadrangula C.q (O.F Müller, 1785) (475µm) ; 5 rotifères Keratella quadrata K.q (O.F.Mûller, 1786) (275µm), Keratella cohlearis Kc (Gosse, 1851) (222.5µm), Asplanchna sp (406.25µm), Filinia longiesta F.1 (Zacharias, 1893) (150µm) et Hexarthra mira H.m (Hudson, 1871). La communauté zooplanctonique regroupe trois catégories (Fig.1) : les copépodes (70 %), les cladocères (25%) et les rotifères (5%). La faible richesse spécifique touche l'ensemble des groupes et plus particulièrement celui des copépodes qui est, toutefois, le groupe le plus représenté quantitativement. La succession saisonnière des différentes espèces zooplanctoniques (Fig. 2) a présenté un cycle annuel caractérisé par la dominance de l'espèce Copidodiaptomus numidicus (67 % du zooplancton total). Cette dernière présente un pic estimé à 89637 Ind. m<sup>-3</sup> (634.46 mg PS/m<sup>3</sup>). En utilisant l'ensemble des données, nous avons illustré une variabilité saisonnière et une ségrégation verticale des différentes espèces zooplanctoniques, ainsi l'espèce Copidodiaptomus numidicus se maintient dans l'épiliminion où elle trouve une quantité suffisamment abondante [3]. Les facteurs environnementaux modulent la succession saisonnière car les diverses espèces ont leurs propre tolérances physico-chimiques [4], ainsi d'autres facteurs telle que la compétition pour l'exploitation des ressources, la prédation. L'évolution des communautés zooplanctoniques en réponse à tous ces facteurs confirme la forte réactivité de ces types de milieux aquatiques peu profonds et renforce l'intérêt de son suivi écologique en raison de l'importance de ce barrage et d'autres barrages de la Tunisie.

# SOFT-BOTTOM CRUSTACEANS FROM THE SAROS BAY (NE AEGEAN SEA)

Murat Sezgin<sup>1</sup>\*, Tuncer Katagan<sup>2</sup>, Fevzi Kirkim<sup>2</sup> and Eylem Aydemir<sup>1</sup>

<sup>1</sup> Department of Hydrobiology, Fisheries Faculty, Ondokuz Mayis University, TR-57 000 Sinop, Turkey - msezgin@omu.edu.tr <sup>2</sup> Department of Hydrobiology, Fisheries Faculty, Ege University, TR-35100 Bornova-Izmir, Turkey

# Abstract

This study was carried out to determine the benthic crustaceans inhabiting on soft bottoms distributed in the sublittoral zone of the Saros Bay (NE Aegean Sea) and their ecological characteristics. Qualitative and quantitative samples of bottom sediments were collected in 12 different stations during single cruise on board R/V K. Piri Reis in January 2002. As a result of the study, a total of 222 individuals belonging to 57 taxa were identified.

Keywords : Crustacea, Aegean Sea, Systematics.

#### Introduction

Marine diversity is often a scope of environmental research especially within the framework of global environmental changes. Benthic macrofauna of soft sediments plays an important role in the degradation of organic matter produced in the pelagic zone and several species serve as food for demersal fish. Saros Bay is an inlet of the Northern Aegean Sea located in the north part of the Gallipoli Peninsula, Turkey (GPS coordinates 40°37'55"N 26°43'25"E). Systematic qualitative and quantitative investigations alongside the Aegean Sea (Turkey shelf) have been conducted since 1970. However, few studies focused on the crustacea fauna of the Saros Bay, and existing ones only analyzed shallow zone ([1], [2], [3], [4], [5]). The aim of the present study is to describe the species composition and diversity of soft-bottom crustacean fauna of Saros Bay.

#### Material and Methods

The material of soft sediments were collected in short periods during January 2002 at 12 stations (sta.1: 25 m, grab; sta.2: 55 m, grab, sta.3: 72 m, grab; sta.4: 32 m, grab; sta.5: 65 m, grab; sta.6: 240 m, dredge; sta.7: 105 m, dredge; sta.8: 590 m, dredge; sta.9: 580 m, dredge; sta.10: 90 m, dredge; sta.11: 520 m, dredge; sta.12: 610 m, dredge) chosen in the Saros Bay: (fig. 1). Samplings were made either by  $0.1 \text{ m}^{-2}$ van Veen grab, or by dredge. At each station, a single replicate was taken for benthic community analyses. Samples were sieved on board through a 0.5 mm sieve and stored in 4% formalin solution. In the laboratory the material was sorted into the taxonomic groups under a stereomicroscope and preserved in 70% ethanol. A presence-absence matrix was constructed for species found in the dredge samples, but was not used for further community analyses. The material was deposited at the laboratory of faculty of Fisheries, Ondokuz Mayis University (SFF).

Fig. 1. Map of the investigated area with the location of sampling sites.

#### Results and Discussion

The soft-bottom samples collected from several stations (five vith van Veen grab and seven with dredge) in the Saros Bay. This collection includes a total of 57 crustacean taxa and 222 specimens: Mysidacea (one species, four individuals), Cumacea (11 species, 27 individuals), Tanaidacea (three species, 57 individuals), Isopoda (six species, 22 individuals), Amphipoda (28 species, 81 individuals) and Decapoda (eight species, 31 individuals). The amphipods Gammaropsis dentata, Pardaliscella boecki are reported for the first time from the Aegean Sea, and the isopod Gnathia maxillaris, the amphipods Urothoe Corsica, Laetmatophilus ledoyeri, Liljeborgia psaltrica, Nicippe tumida are new records for the Turkish fauna. Sediments consist of a sandy-muddy clay mixture and are appareanly well aerated. The tanaid Leptochelia savignyi ranks first in abundance (%12) in the soft-bottoms followed by Apseudes latreillei (10%), the thalassinid Upogebia pusilla (7%), the amphipods Stenothoe marina (5%), Ampelisca planierensis (4%) and Urothoe elegans (3%). Several other species occurred regularly but in small numbers. Regarding the number of individulas, the amphipods made 39% of the fauna, the tanaids 20%, the cumaceans 16%, the decapods 15%, the isopods 8% and the mysids 2%. The most frequent species in all samples were the tanaid A. latreillei (67%), the amphipods S. marina (50%), Harpinia truncata (42%) and the isopod G. maxillaris (33%). The majority of individuals of crustaceans (deposit feeding amphipods were dominant) occurred at 25-240 m depth range. The cumaceans Diastylis cornuta, Ekleptostylis walkeri, Vaunthompsonia cristata, the amphipods Ampelisca calypsonis, A. spinipes, G. dentata, L. ledoveri, Leucothoe incisa, Stenothoe tergestina, P. boecki, M. cornutus, N. tumida, Urothoe intermedia, U. elegans and the decapod Dorchynchus thomsoni were only collected at the 240-610 m depth range. In contrast the mysid Siriella jaltensis, the cumacean Bodotria scarpioides, the tanaid Apseudes acutifrons, the isopod Gnathia vorax, the amphipods Paraphoxus oculatus, H. truncata, Ampelisca pseudosarsi, and the decapods Alpheus glaber, Callinassa subterranea, U. pusilla and Pisidia longimana were only present at the 25-105 depth range. There were include 39 (68%) which are Mediterranean endemic. There are also 18 (32%) species which zoogeographically are Atlanto-Mediterranean originated.

Only a single replicate sampling does not permit the presentation of a complete description of all soft bottom crustaceans. Moreover, since our data is restricted to a small area within the Aegean Sea, future studies on a wider area are needed before we can summarize our findings.

### Abstract

The species of the *Mytilus* complex are difficult to differentiate morphologically because of their high degree of similarity and the impact of the environment on the shell shape. A nuclear DNA marker Me 15 and 16 (adhesive protein gene), which is diagnostic for *Mytilus galloprovincialis, M. edulis* and *M. trossulus* was examined for 262 individuals (wild and cultured) sampled along the south-eastern Adriatic coast. All individuals proved to be *M. galloprovincialis.* 

Keywords : Adriatic Sea, Biodiversity, Bivalves, Genetics.

*Mytilus* spp. are considered key species of the coastal ecosystem in the Adriatic sea and are commercially valuble. Genetic characterization of their populations may serve to monitor changes in diversity, and possibly for understanding the biodiversity changes in the coastal ecosystems in in the Adriatic sea. Changes in current directions, temperature and salinity, related to possible global climate changes, higher number of comercial vessels may impact the distribution of mussels [3]. Around Mali Ston *Mytilus* cultivation has long and succesful tradition, which has been mass-cultured since the second half of the 20th century. The origins of *Mytilus* spp. in Mali Ston culture facilities, as well as in other parts of eastern Adriatic coast, are unknown. During 2005 and 2006, as part of comprehensive project concerning *Mytilus* species complex in the Mediterranean and parts of the eastern Atlantic, we conducted series of samplings along the eastern Adriatic from Boka Kotorska bay to the Limski channel. The results of these investigations are presented in this paper.

#### Me 15 CCA GTA TAC AAA CCT GTG AAG A Me 16 TGT TGT CTT AAT AGG TTT GTA AGA

#### Fig. 1. Sequences of Me15 and 16 PCR primers.

Species within the *Mytilus* complex are difficult to differentiate morphologically because of their high degree of similarity and due the impact of the enviroment on the shell shape [3]. However some differences in certain "variable region" of a sequence in the nonrepetitive domain of the foot protein 1 are correlated with the taxonomic rank of these species. The length of nonrepetitive region fragments amplified with Me15 and 16 [2] is specific to each species and differs interspecifically, enabling the use of these primers as diagnostic markers for determination and comfirmation of the species.

We sampled 262 individuals from 10 locations: 1. Boka Kotorska bay (cultured); 2. Boka Kotorska bay (wild); 3. Konavle Rocks (wild); 4. Rijeka Dubrovacka (wild); 5. Elafiti islands (wild) 6. Vrnjak (wild); 7. Bistrina bay (cultured); 8. Brijesta (wild); 9. Brijesta (cultured); 10. Ploce harbour (wild). Following DNA extraction (Quiagen, Dneasy Tissue kit), and PCR amplification using genetic markers, electophoresis revealed one single and uniform band for all of investigated individuals on the position characteristic for *M. galloprovincialis*. Expected size is 126 bp because the sequence of *M. galloprovincialis* contains deletion of 18 amino acids. For the final verification we obtained the standard confirmed total DNA of *M. galloprovincialis, M. edulis* and *M. trossulus* and upon comparison of these bands on electriphoreses - all of our individuals equaled the band position as that of standard *M. galloprovincialis* (Fig. 2). We suggest that *M. galloprovincialis* is an invasive species by its nature [1] and that trait may be the reason for preserving its purity.

Fig. 2. Photo of electrophoresis gel. Lane 1 to 7: mussels sampled during this investigation; lane 8: standard DNA of *M. galloprovincialis*; lane 9: standard DNA of *M. edulis*; lane 10: standard DNA of M. trossulus; lane 11: DNA ladder.

### Résumé

Le régime alimentaire de *Caranx rhonchus* des côtes sud tunisiennes est étudié d'août 2004 à juillet 2005. Cette espèce est un poisson carnivore dont le bol alimentaire est basé essentiellement sur les Téléostéens notamment les Engraulidae et les Clupeidae. Le coefficient de vacuité digestive est de 56,8%.

Mots clès : Diet, Gulf Of Gabes.

#### Introduction

*Caranx rhonchus* (Saint-Hiliaire, 1817) est le poisson Carangidae le plus commercial du genre *Caranx* sur les côtes tunisiennes et notamment celle de la région sud. Dans ce travail, nous étudions le régime alimentaire de cette espèce selon ses aspects quantitatif et qualitatif par l'analyse du coefficient de vacuité et de certains indices alimentaires.

#### Matériel et méthodes

Les échantillons ont été récoltés aux ports de pêche des côtes sud de la Tunisie (Sfax, Mahdia et Mednine). Durant la période qui s'étend d'août 2004 à septembre 2006, un total de 777 individus, de longueur totale (LT) comprise entre 60 et 306 mm (3,31g<Mt<227,48g), ont été examinés. Après analyse des contenus stomacaux, les différentes proies ingérées sont identifiées, dénombrées puis pesées au centième de gramme près. Les estomacs vides ont été notés. Le coefficient de vacuité stomacale (Cv%) a été déterminé selon les tailles et ses variations ont été analysées en fonction des mois.

Pour étudier l'aspect quantitatif du régime alimentaire et pour classer les proies ingérées, nous avons calculé pour chaque item les indices suivants : pourcentage en nombre (N%), pourcentage en poids (W%), fréquence d'occurrence (F%) et Indice d'Importance Relative (IRI%) [1].

#### Résultats

L'analyse des valeurs moyennes du coefficient de vacuité a montré qu'elles restent toujours élevées, ce qui explique, qu'il y a plus d'estomacs vides que d'estomacs pleins. Ces valeurs varient entre 28% et 69%. Les valeurs moyennes les plus élevées correspondent aux mois de mars (61%), mai (54%), juillet (69%) et août (58%). La valeur du coefficient de vacuité moyen est importante pour *Caranx rhonchus* dépassant 56%. Par ailleurs, la valeur moyenne annuelle est plus grande chez les individus de plus de 20 cm (individus adultes), ceci pourrait s'expliquer par le fait que les gonades occupent la majeure partie de la cavité abdominale chez les adultes matures.

Au total, 822 proies pesant 432g ont été dénombrés, ce qui correspond à un nombre et un poids de 2,69 et 1,4g par estomac.

A partir du calcul des différents indices alimentaires relatifs à l'analyse qualitative notamment le pourcentage de l'indice d'importance relative (IRI%), nous avons établi le classement des différentes proies pour cette espèce.

La première constatation qui ressort de cette analyse est que *Caranx rhonchus* est une espèce carnivore dont le régime alimentaire est basé sur les poissons. L'analyse du tableau 1 montre que *Caranx rhonchus* présente un spectre alimentaire assez varié renfermant les divers groupes zoologiques : Des vertébrés représentés par les poissons appartenant à 6 familles notamment les Engraulidae et les Clupeidae, des crustacés, des annélides et des végétaux.

Les téléostéens constituent le groupe d'aliment majeur pour cette espèce (F%=64,2 ; N% =31,7 ; W%=81,4 et IRI%=59,3), L'anchois *Engraulis engrasicolis* constitue la proie principale avec W%=49,6 et IRI% de l'ordre de 13. Toutefois, la présence de crustacés (notamment les crevettes) dans le régime alimentaire de *Caranx rhonchus* est de moindre importance, avec un IRI de l'ordre de 20%. Nos résultats sont comparables à ceux trouvés par Fischer et al. [2].

# Abstract

Within four different category of fishing in Croatia, sport fishing has the highest number of participants. Research of pole line fishing, which is mainly performed in sport competitions, has been performed during 2005. Sparidae was the most dominant family of the catch, while common pandora, *Pagellus erythrinus*, within species. Bray-Curtis index of similarity showed that resemblance between community compositions is dependent on region and depth.

Keywords : Adriatic Sea, Fisheries, Biodiversity.

Within four different categories of fishing, allowed by regulations in Croatia, sport fishing has the highest number of participants. According to the official data [1] 44927 sport fishing licenses have been issued in 2004. However, research in western Mediterranean area, around island of Majorca [2], showed that only 59% of sport fishermen had legal licenses, which means that even in the eastern Adriatic, the number of actual participants in sport fishing is probably higher than reported. Fishing gear category of hooks and lines is the most important gear category in sport fishing. Within that category pole line is used in most of sport fishing competitions. The description of pole line would be a hooked line attached to a pole. Although this gear is also used in commercial fisheries, e.g. for fishing tuna, it is mainly used for sport fishing. Previously, poles were made of wood, but lately most are made of fiberglass. In commercial fisheries, poles are usually mechanized, with the pole movement being entirely automatic, but in sport fishing poles are hand operated. Pole lines can be operated either from the shore or from any type of vessel, on very wide range of depths. With pole line fishing is possible to catch fish on rough ground, even in their hiding places between the rocks. As the line is much longer than the pole, a moulinet has to be used during fishing. Fish are attracted by the different bait, depending on hook size and target fish. Research has been performed during 2005 and included sport fishing competitions, which are held under the sponsorship of Croatian federation of sport fishing at sea. Competitions that have been monitored included seniors and competitors of U21 category (under 21 year of age), both female and male. According to regulations, at every competition each competitor had the same conditions, from weight and kind of bait to allowed area of fishing. Thus, obtained catch was dependent solely on each competitor's ability and skill. Usually, fishing lasted for 5 hours each day, from 8 am until 1 pm. Total catch was analyzed in the way that all species were determined, while length in mm and weight in g were measured for each specimen. Using Primer 5 software, the similarity of community composition between all areas of research was calculated using the Bray-Curtis index. A total of 8 competitions were analyzed: Lovran, Primošten and Podgora were sites where pole line fishing from the shore occured, while at Lovran, Kukljica, Pag, Rovinj and Volosko fishing was performed from the vessel (Fig. 1).

The total number of fish caught and analyzed during those competitions was 17587, while their total weight was 981.74 kg. 70 different species were determined, of which 69 were Osteichthyes and one was a Chondrichthyan fish. Those species were representative of 24 different families. Sparidae was the most representative family with 14 species. Hence, in total catch Sparidae was the family with highest number and weight of caught specimens: 8233 (46,81%) specimens and 589958 g (60,09%) of weight, respectively. Second dominant family in total catch was Centracanthidae with 3863 specimens and 155195 g of weight, followed by Labridae with 3550 specimens and 133205 g of weight.

The most dominant species was the common pandora, *Pagellus erythrinus*, with 4649 caught specimens and total weight of 370231 g. Second most dominant species was picarel, *Spicara flexuosa*, with 3312 specimens and 119695 g of weight, followed by rainbow wrasse, *Coris julis*, with 3004 caught specimens and weight of 102660 g.

Grouping of adjacent sites showed that similarity between community compositions is dependent on region, as there is more resemblance between adjacent than distant areas (Fig. 2). However, dendrogram showed that such similarity is dependent also on depth as in case of Lovran area, where, in the same time, competitions from shore and vessels occurred. Dendrogram revealed that community structure off coast of Lovran, where pole fishing from vessel occured, is more similar to adjacent off coast community of Volosko area, where same fishing technique was applied, than to nearest littoral community of Lovran, where pole fishing occurred from shore, therefore, at smaller depth.

Fig. 1. Sampling sites: 1 - Rovinj; 2 - Lovran; 3 - Volosko; 4 - Pag; 5 - Kukljica; 6 - Primošten; 7 - Podgora.

Fig. 2. Bray - Curtis dendrogram of similarity between the sites shown in figure 1..

# SPEAR FISHING IN THE EASTERN ADRIATIC

Alen Soldo<sup>1</sup> \*, Frane Å Keljo<sup>2</sup> and Jure Brčić<sup>2</sup>

<sup>1</sup> Institute of Oceanography and Fisheries, P.O. Box 500, 21000 Split, Croatia - soldo@izor.hr <sup>2</sup> Department of Marine Studies, University of Split, Livanjska 5/III, 21000 Split, Croatia

# Abstract

Recent investigations show that spear fishing can have similar effects as commercial fishing. Research of spear fishing competitions in eastern Adriatic was performed during 2005. Overall, 28 different species were determined (26 teleost and 2 chondrichthyan species). The dominant (by number and weight) species were *Labrus merula*, *Diplodus sargus* and *Conger conger*. *Keywords : Adriatic Sea, Coastal Waters, Fisheries, Rocky Shores.* 

The importance of sport and recreational fishing has been consistently understated and under-reported [1]. However, nowadays it has been considered that all fishing activities have environmental impacts, so it is not appropriate to assume that these are negligible until proved otherwise. Hence, latest investigations pointed that such fishing can also cause ecosystem degradation of similar scales and types compared with commercial fishing [2]. Within sport fishing, spear fishing is one of the most popular and increasing fishing techniques in the Adriatic. Additional benefit for spear fishing in the Adriatic is the fact that mean annual sea temperatures are relatively high, which is suitable for performing of such fishing technique throughout the whole year [3]. Latest research of spear fishing in the Balearic Islands (west central Mediterranean) showed that during sport competitions spear fishing affected over 30 species, among which the most abundant were Diplodus sargus, Symphodus tinca, Labrus merula and Mugilidae. Hence, a decreasing trend over time for the mean CPUE was observed [4]. Conversely, it has to be pointed that it is a selective sport, as spearfishers tend to harvest larger individuals within a species. Thus, each target is individually selected, so bycatch should be zero, which is definitely a positive feature. According to Croatian regulations spear fishing using SCUBA gear is banned, as is night spear fishing. Research of five different competitions, which occurred in different locations throughout eastern Adriatic coast and lasted for several days, was performed from June to December 2005. Each caught specimen was identified, while length was measured to the nearest mm and weight to nearest g. CPUE was calculated for each competitor (g/competitor per hour). Overall, 628 specimens, weighing 554,82 kg, were caught, belonging to 28 species (26 teleost and 2 chondrichthyan species). Of 13 families present in total catch, Labridae and Sparidae were most dominant by number, while Congridae and Sparidae by weight (Fig. 1).

Fig. 1. Number and weight % of dominant families in spear fishing.

By species, the highest number of caught specimens belonged to brown wrasse, *Labrus merula*, white seabream, *Diplodus sargus* and european conger, *Conger conger*, while by weight *C. conger* was, due to its size, most dominant, followed by *L. merula* and *D. sargus*. Obtained results are similar to the data from west-central Mediterraenan [4], which means that, due to the same fishing technique, spear fishing targets mainly the larger stationary fish species, which inhabit coastal, mainly rocky, areas of depths up to 40 m. CPUE varied between different sites (Fig. 2) and this shows that prior access by spearfishers to the site is important, e.g. data from the Senj area, where most competitors spent a long period exploring the area prior the competition, due to its importance as National championship, was also the site with the highest recorded CPUE. Another

factor influencing CPUE is the season. This is indicated by checking the data from the Podgora area, where a difference in CPUE can be observed between two competitions held at the same site, but with a 3-month period in between. A decreasing trend in some species' mean sizes was observed by comparing new data to the data obtained a year before [5], but the time period was too short to make a reliable conclusion. Although competition catches are influenced by competition rules, and may bear little relation to regular spearfisher catches, it is presumed that such data can be reliable in determing target species and weight per unit effort, and therefore, useful for the management of recreational fisheries [6]. Thus, both competition and recreational spear fishing seem to have an important effect on target fish in the Adriatic, especially for fish which are not targeted by any other gear, e.g. *Labrus merula*.

Fig. 2. Catch per unit effort (CPUE) for different areas and average (g / spearfisher per hour).

#### Abstract

Anchovy and sardine monthly catch per day from Greek waters for the period 1996-2000 were analysed in order to identify significant trends. Catches for both species were found to be declining throughout the study period, following the eutrophic north to south gradient of the Greek waters. Results are discussed in relation to exploitation patterns of the two stocks and some management proposals are suggested.

Keywords : Fisheries, Time Series, Aegean Sea, Ionian Sea.

#### Introduction

Anchovy (*Engraulis encrasicolus*) and sardine (*Sardina pilchardus*) comprise 30% of the total landings and 60% of the total purse seine landings, being the two most important small-sized pelagic species in Greek waters [1, 2]. Despite their importance there has never been a systematic monitoring of their catch per unit of effort. In this study we present the anchovy and sardine monthly catch/day for the period 1996-2000 in order to identify significant trends.

#### Materials and Methods

Since the second half of 1995, fishing effort and corresponding catch per day for a large number of species have been collected by the Institute of Marine Biological Resources (HCMR). Data have been collected on a monthly basis over a network of 21 stations throughout the Greek Seas, by local Fisheries Inspectors [1]. At each station, data were collected from a sample of vessels displaying full activity, generally covering at least 10% of trawlers and purse seiners, and 2% of artisanal boats. Collected data were stratified by vessel size (based on EU regulations). Raw data subsequently grouped into two categories with respect to vessel size: <20 m and >20 m for trawlers, <15 m for purse-seiners, and <10 m and >10 m for artisanal boats. Data were also aggregated for five fishing subareas (N., C. and S. Aegean, Cretan waters and Ionian Sea), which generally differ in terms of biological productivity (see detailed review by [2]).

Fig. 1. Mean monthly catch per day for purse seiners >15 m in Greek waters, 1996-2000. Anchovy catches in (a) the N. Aegean; (b) C. Aegean; (c) Ionian. Sardine catches in (d) N. Aegean; (e) Ionian; (f) C. Aegean. Trend lines with slope significantly (p<0.05) different from zero are also shown.

A detailed description of the available data set, data processing and analy-

sis is given in [1]. These data overcomes various important drawbacks of all other data sources available, notably that fishing effort is expressed as fishing days at sea.

#### Results and Discussion

During 1996-2000, the mean anchovy and sardine catch/day was significantly higher for purse seiners >15 m, operating in the North and Central Aegean Sea and Ionian Sea (anchovy: >370 kg/day, sardine: >140 kg/day) when compared to those of other gears (i.e. trawl, beach-seine, netters) and areas (i.e. South Aegean Sea and Cretan waters) where the mean catch/day was <125 kg/day for anchovy and <108 kg/day for sardine. This agrees to a large extent with the results of the analysis of the National Statistical Service of Hellas data [2]. The main factors contributing to such a geographical differentiation in mean catch/day could be the gradient in eutrophy of the Aegean Sea waters along a NNW to SSE axis [2].

The catch/day time series for anchovy displayed a downward trend (p<0.05) in all three main areas (Fig. 1a-c). For sardine, declining trends were observed only in the Ionian Sea (Fig. 1d-f). The catch/day series in the North Aegean Sea did not display any trend probably because sardine's variability in this area is mainly affected by market demand.

Although additional information might be required together with catch/day series the negative trends identified indicate that pelagic resources are either heavily exploited or overfished. Declining catch/day trends are regarded as strong indicators of overfishing especially in the light of the fact that fishers maintain high catch rates by fishing in "hot spots"[3]. Thus, the regulations currently enforced for small pelagics (i.e., closed seasons, limited issue of licenses, minimum legal landing sizes, mesh size regulations, banning of pelagic trawl, no allowance to fish small pelagics with bottom trawl or with electric light) are inadequate and alternative management options should be considered. For example, it has been suggested that a displacement of the existing closed season from December-March, protecting the sardine spawning stocks with no effect on anchovy, to September-November, will be beneficial to the latter, which exhibited significant declining trends, by protecting the young of the year, as well as to sardine by protecting its stocks at the onset of the spawning period [4].

# Abstract

The main objective of the present study is to select amongst the zooplankton community characteristics (diversity, quantitative and taxonomic structure, Rotifers/Copepods/Cladocera ratio) relevant descriptors to eutrophication. Plankton fauna in investigated area manifested dissimilar features which greatly correlated with the eutrophic state of the ecosystems Varna Lakes - Varna Bay. The results of Simper and principal component analyses (PCA) gave arguments to suggest the main zooplankton community characteristics as reliable indicators in biomonitorng schemes.

Keywords : Zooplankton, Black Sea, Eutrophication, Coastal Waters.

Varna Bay is the second largest bay along the Western Black Sea coast, connected via two canals to Varna Lake, further prolonged to Beloslav Lake by navigation canal. The studied coastal area (Beloslav Lake- Varna Lake-Varna Bay) is under various types of human pressure, such as urban pollution, chemical industry, agriculture, maritime transport, harbour and electric power plant activities. From the lakes to the Bay, a gradient of decreasing nutrient load and related effects were prominent [1]. Since 1970s, the ecosystems of the area have undergone noteworthy alterations of plankton communities as a result of eutrophication, oxygen deficiencies, and outburst of invasive species [1, 2, 3]. According to water quality index (WQI), the lakes have been categorized as hyper-eutrophic, with "bad" water quality in respect to primary productivity and biomass, abundance of the blooming species and frequency of blooms, whereas Varna Bay was scaled as highly eutrophicated, "poor"water quality [2]. Seasonal data for temperature (T°C), salinity (psu), oxygen, nutrients (N-NO<sub>2</sub>, NO3, NH4, P-PO4, Si-SiO4), chlorophyll-a concentration, phyto- and zooplankton taxonomic composition, plankton abundance and biomass for the period 1998-2005 were focused on. Species richness (S), Shannon index (H) calculated on abundance and biomass data; TRIX (trophic state index), PCA and simper analyses were applied for differentiation of the environmental characteristics along the eutrophic gradient. Obtained results revealed a decreasing trend of zooplankton quantity from the Lakes towards Varna Bay. Zooplankton numerical abundance was 3-15 fold lower in the Bay compared to the Lakes. The dominant taxonomic group for both lakes was the rotifers. Their density and diversity correlated significantly with trophic state indicators Chl a and nutrients [4]. Maximum values of rotifers were recorded in front of Provadiiska River mouth (Beloslav Lake) and close to the ferry terminal. The abundance ratio of major groups Rotifers/Copepods/Cladocera was 41/4/32 in Beloslav, 17/35/6 in Varna Lake (copepods prevailed), and 13/24/10 in Varna Bay (Cladocera significance). The magnitude of rotifers decreased towards the Bay, where benthic larvae and copepods prevailed. The zooplankton biomass structure was dominated by benthic larvae and copepods. The lowest zooplankton quantity and species diversity were registered at sampling stations close to the Varna West Port, thermoelectric power station and sewage plant. The domination of rotifers in the Lakes suggested a higher reproduction rate as a consequence of the disturbed environment compared to the Bay. Further the great share of small sized species and fine filtrators could be indicative for a high phytoplankton concentration. The results of the applied statistical methods figured out dissimilarities between the sites, due to species presence/absence and species abundance. PCA discriminate the three sites (Cluster A-Beloslav, cluster B-Varna Lake, cluster C-Varna Bay), and reveal ecological significance of zooplankton abundance and biomass (mainly Copepods), species occurrence, phytoplankton, Chl a, total inorganic nitrogen, TRIX index, salinity and biodiversity indices. The results gave grounds to suggest as descriptive the above discussed zooplankton characteristics, which could be exploited in the biomonitoring schemes as reliable indicators of indirect eutrophication impacts and water quality assessment.

#### Abstract

The mesozooplankton (>200  $\mu$ m) abundances and biomass spectra and diversity were studied in the southern Tyrrhenian Sea using an image analysis system during two oceanographic cruises. Preliminary results show a clear seasonal cycle of both abundance and biomass structure of the zooplankton community. These are compared to changes in zooplankton biodiversity and environmental conditions. *Keywords : Zooplankton, Tyrrhenian Sea, Copepoda, Circulation.* 

In the framework of the CIESM Zooplankton Indicators program and of the collaboration among the MedZoo group members (http://www.obsvlfr.fr/LOV/ZooPart/MedZoo/), zooplankton spatial distribution was investigated in the southern Tyrrhenian Sea. Eleven stations were visited in July 2005 (cruise SUB 1) and 17 stations in December 2005 (cruise SUB 2). For each station, two replicated samples were collected with a WP2 net by vertical tows in the layers 0-70 m and 0-200 m (figure 1).

Fig. 1. Net sampling stations (square) and CTD stations (cross) during SUB 1 (top) and SUB 2 (bottom).

Samples were analysed using the Zooscan imaging system [1]. This tool enables a fast and reliable enumeration and measurement of zooplankters in preserved net samples. A learning algorithm allows the recognition of some groups as it learns from a training set of different taxa images. In our study, slopes of the biomass spectra [2] are calculated for the meso-zooplankton community and for selected groups such as copepods (450 to 1550  $\mu$ m in Equivalent Spherical Diameter) on 50 samples (more than

50000 individuals measured). The aim was to monitor the spatial distribution of the size spectra of the main zooplankton taxa in the southern Thyrrenian sea, a region that has been seldom studied since the work of 3. Initial results of copepod distributions have shown that both, abundance and size spectra varied within each campaign and were related to the hydrological conditions. Differences were also observed between the two sampling periods. Copepods were more abundant and of a smaller mean size in July than in December. The results indicate that copepods were more abundant in anticyclonic than in cyclonic eddies during both cruises. The higher concentrations in the anticyclonic eddy during SUB 1 can be explained by the retention of organisms in the eddy and/or by the higher phytoplankton resources available for the copepods. Data are still under analysis and will be presented more in details during the congress.

# MOLLUSCAN DIVERSITY IN THE N. EAST AEGEAN - GREECE

Nikos Streftaris \* and Argyro Zenetos

Hellenic Centre for Marine Research, GR-19013, Anavyssos, Greece - nstrefta@ath.hcmr.gr

#### Abstract

The extensive study of the benthic fauna biodiversity in the Greek NE Aegean, using sieves of different mesh sizes, revealed a molluscan community rich in abundance and species in contrast to general notion that tends to regard the area poor in marine benthic fauna. Focusing on the bivalves, seven species were newly recorded for the area and four additional species were reported for the first time in the Greek waters.

Keywords : Aegean Sea, Eastern Mediterranean, Bivalves.

#### Introduction

The traditional approach of regarding the eastern Mediterranean as an area poor in marine fauna [1] has been refuted as research studies carried out in the last two decades have revealed new geographic areas, new bathymetric zones and new species [2]. Focusing on the bivalves of the Greek Seas (territorial waters of the Aegean, Ionian, Cretan and Libyan Seas), and in particular the North Aegean, studies have revealed an increase in reported bivalve species from 212 species in 1995 to 243 species in 2004 [2]. Nevertheless, the North Eastern part of the Aegean Sea (an area of great importance since it is the region where the Black Sea Water enters the Mediterranean through the Dardanelles straits) remains one of the less known seas.

#### Materials and methods

Benthic samples were collected from 26 stations in the course of three cruises (autumns 1998 and 1999 and spring 2000) in the Greek North East Aegean with the aid of Van Veen grab and Box corer samplers. At least three replicates were collected at each station and sieved through 0.5 mm and 1 mm mesh sizes. Molluscan species composition and community structure were analysed separately for the two size fractions (>1 mm, 0.5-1 mm), in order to obtain a more detailed picture of the molluscan diversity in the area, by examining the usually understudied 0.5-1mm fraction. Particularly emphasis was attributed to bivalve species in order to update their inventory in the wider area and across the Greek Seas.

Fig. 1. Species number per increasing sampling area.

#### Results and Discussion

From a total of 105 samples, at depths of 63-1300 m, (sampling area 12.14  $m^2$ ) 3972 molluscs were enumerated, 24.2 % of which were >1mm and 75.8% between 0.5-1mm revealing the dominance of the 0.5-1 mm fraction in benthic studies, a fraction often understudied in the Greek Seas. These numbers represent 19% of the total benthic abundance in the area (a 14% of the fauna >1mm and 22% of the fauna at the 0.5-1mm fraction). Within the Mollusca, Bivalvia accounted for 88.9%, Aplacophora for, 6.5%, Gastropoda for 3.8%, Scaphopoda for 0.6% and Polyplacophora for 0.05%. In the fraction >1 mm 818 Bivalves were counted, 82 Aplacophora, 53 Gastropoda, 9 Scaphopoda and no Polyplacophora, whereas in the 0.5-1mm fraction the numbers were 2716, 179, 99, 14 and 2 respectively, revealing an even distribution of the taxa within the two size fractions.

With regard to the species composition, 124 species were identified, 84 (67.7%) of which were encountered in the >1mm fraction, and 107 (86.3%) in the 0.5-1mm fraction [Fig. 1]. It is interesting that 46 species were found only in the >1mm fraction and 31 only in the 0.5-1mm fraction, thus highlighting the importance of the two fractions in benthic

surveys. The recorded molluscan species represent 20.4% of the total benthic species in the area (17.6% of the species >1mm and 24% of the species at the 0.5-1mm fraction), in accordance to the average contribution of the species abundance and density observed in undisturbed soft bottom macrozoobenthic communities [3].

The expected increase in recorded species number with increasing sampling effort (both in terms of employing two size fractions and increasing the sampling area) is also presented in Fig. 1.

Overall, 83 species of Bivalves were recorded. This number is impressive compared to the 243 species recorded over the entire Greek North Aegean [2], and to the 190 species recorded along the Turkish Aegean Sea [4] areas that include many coastal sites, as opposed to the mainly deep water sites examined here. Among these Bivalve species, seven are new to the fauna of the Greek N. East Aegean waters. The species Coralliophaga lithophagella (Lamarck, 1819), Hyalopecten similes (Laskey, 1811), Propeamussium fenestratum (Forbes, 1844), Scacchia oblonga (Philippi, 1836), Solemya togata (Poli, 1795), Poromya granulata (Nyst & Westendorp, 1839) and Yoldiella lucida (Loven, 1846) are being reported in the Greek North East Aegean for the first time [2]. In addition, Epilepton clarkiae (Clark W., 1852), Haliris berenicensis (Sturany, 1896), Phaseolus ovatus (Seguenza, 1877), and Pholadomya loveni (Jeffreys 1882) are first records of the species in the Greek Seas [2]. The rare E. clarkiae was recorded at 63m depth (northeast of Lemnos island) in sandy bottoms, H. berenicensis at depths of 307 and 135 m (south and southeast of Lemnos island) on soft bottoms characterized by mud and muddy sand respectively, P. ovatus at 151 m in a muddy sand habitat (South east of Lemnos) and P. loveni at 132 m in a sandy mud seabed (South east of Lemnos). The current work of this relatively understudied region of the Greek North East Aegean Sea, covering a variety of bathymetric zones away from the traditional shallow coastal areas has revealed the richness of the molluscan community in the area. An analogous study (28 sites, seasonal sampling, 5 replicates, 0.5 mm fraction) in the south Aegean (Cretan Sea) has revealed a total of 109 molluscan species [5]. This work has added new species to the inventory of the species in the area as well as in Greek waters.

#### Abstract

Our aim was to determine the caulerpenyne production and the antioxidant enzyme activities in *Caulerpa taxifolia* in response to *Bittium reticulatum* feeding. Caulerpenyne production, as well as CAT, SOD and GR activities significantly increased in presence of *Bittium*. *Caulerpa taxifolia* responded to intense herbivorism reducing their palatability and increasing their antioxidant system. *Keywords : Algae, Balear Islands, Bio-indicators, Gastropods.* 

#### Introduction

The seaweed of tropical origin algae *Caulerpa taxifolia* (Vahl) was introduced in the Mediterranean Sea in 1984, covering the infralittoral zone and competing with autochthonous flora [1]. Caulerpenyne is the main secondary metabolite synthesized by Caulerpales, playing a major role in its chemical defense [2]. Cells contain a complex network of antioxidant defence that scavenge or prevent the generation of ROS, and repair or remove the damaged molecules. Small marine herbivores often feed on macroalgae chemically defended against fishes or sea-urchins. In this work, we studied in a controlled environment the antioxidant enzyme response and caulerpenyne production by *Caulerpa taxifolia* under severe herbivorism .

### Materials and Methods

*Caulerpa taxifolia* samples were collected and maintained in two separated aquariums at 24°C. *Bittium reticulatum* were introduced in one aquarium during three days, whereas the other aquarium was considered as negative control. Caulerpenyne contents were measured by HPLC in fronds of *Caulerpa taxifolia* from both aquariums at the end of the experiment [3]. Antioxidant enzyme activities -CAT, GP, SOD and GR were determined in alga homogenates [3].

#### Results and Discussion

In a previous study performed during 2003 and 2004 in the Balearic Islands, we evidenced that *Bittium reticulatum* is one of the most abundant species living in *Caulerpa* meadows. The abundance reached 33 ind/m<sup>2</sup> in *Caulerpa taxifolia*, 133 ind/m<sup>2</sup> in *Caulerpa recemossa* and 208 ind/m<sup>2</sup> in *Caulerpa prolifera*. Herbivorism of *Bittium reticulatum* over *Caulerpa* species was evidenced in the aquarium.

The levels of caulerpenyne were significantly higher in *Caulerpa taxifolia* fronds at the end of the experiment after herbivore exposure compared to the initial values (p<0.05). CAT, SOD and GR activities significantly increased after three days in presence of Bittium *reticulatum* (p<0.05), whereas GP maintained the initial values.

Fig. 1. Caulerpenyne concentration with and without exposure of *Caulerpa taxifolia* to *Bittium reticulatum*.

The presence of *Bittium reticulatum* in the aquarium induces a protective adaptation in *Caulerpa taxifolia* in order to reduce the damage produced by herbivores. The alga responded with an increase in caulerpenyne production in order to protect the algae from herbivorous pressure reducing their palatability. The tissue damage generated by herbivores induces an antioxidant enzyme adaptation, increasing their activities.

Fig. 2. Antioxidant enzyme activities in *Caulerpa taxifolia* with and without exposure to *Bittium reticulatum*.

# BIODIVERSITY AND VERTICAL DISTRIBUTION OF POLYCHAETES ASSOCIATED WITH MUSSEL BEDS ON ARTIFICIAL HARD SUBSTRATES (ROMANIAN COAST, BLACK SEA)

Victor Surugiu \* and Aliona Novac

Alexandru Ioan Cuza University of Iasi, Faculty of Biology, Iasi, Romania - vsurugiu@uaic.ro

# Abstract

Species composition, abundance and diversity of polychaetes associated with rocky mussel biocoenosis of Agigea dyke was analyzed seasonally at 9 different depths. A total of 13 polychaete species belonging to 5 families were identified, including *Eulalia viridis* (Linnaeus, 1767), a new record for the Romanian Black Sea coast. The most abundant polychaete in all seasons was the opportunistic species *Polydora cornuta*, which dominated at depths between 8 m and 16 m. At depths between 0 m and 6 m another species, *Salvatoria clavata*, dominated.

Keywords : Biodiversity, Polychaeta, Black Sea.

#### Introduction

On the Romanian coast of the Black Sea the hard substrate consists of Sarmatian organogenic limestone, covering an area of approximately 70 km<sup>2</sup>. This substrate is of great ecological and economical importance, because it provides high habitat complexity and harbours a rich and diversified fauna [1]. In addition to this natural rocky facies, the hard substrate is also represented by man-made structures such as docks, piers, jetties, breakwaters and shipwrecks. The aim of this study is to assess polychaete species composition and diversity from artificial rocky substrates of the Romanian Black Sea coast and provide information on their seasonal and vertical distribution patterns within these habitats.

#### Material and methods

Seasonal samples ( $16^{th}$  June 2004,  $3^{rd}$  October 2004 and  $16^{th}$  April 2005) were collected by SCUBA divers from the outer part of the southern dyke of Agigea seaport (Fig. 1). Sampling was conducted by scraping off quadrats (400 cm<sup>2</sup> each) along a transect perpendicular to the dyke at 9 different depths (0, 2,4, 6, 8, 10, 12, 14, and 16 m). Samples were washed through a 0.5 mm sieve and the retained organisms were fixed in 10% formalin and then transferred to 70% ethanol. Polychaetes were separated from the other taxa, identified to species level and counted. The community structure of polychaete assemblages was assessed on the basis of Soyer's frequency index (F), Margalef's species richness index (d), Shannon-Wiener's diversity index ( $\log_2$  base, H'), and Pielou's evenness index (J').

Fig. 1. Map of the Agigea seaport on the Romanian Black Sea coast. The Black arrow indicates the location of the study area.

#### Results and discussion

The identification of 8878 polychaete specimens collected provided 13 species belonging to 5 families (Table 1). *Eulalia viridis* (Linnaeus, 1767) is a new record for the Romanian Black Sea fauna. The most abundant species were *Polydora cornuta* (2741 individuals), *Salvatoria clavata* (1667 individuals), *Platynereis dumerilii* (1379 individuals), and *Nean*-*thes succinea* (669 individuals) which accounted for up to 73% of the total number of individuals collected on artificial hard substrates. These four dominant species were also the most frequent species in the mussel beds, occurring in all seasons and at all depths investigated (frequency index F=100%). Other recurrent species within artificial rocky sediments

 $(F \ge 50\%)$  included Harmothoe impar (86%), Prionospio cirrifera (73%) and Syllis gracilis (59%). Nereis zonata (41%) and Eteone picta (32%) were classified as common ( $25 \le F < 50$ ), whereas Nereiphylla rubiginosa (23%), Syllis hyalina (14%), Harmothoe imbricata (13%) and Eulalia viridis (9%) were rare (F < 25).

The community structure of the polychaete assemblages varied among seasons and depths. Number of species tended to increase from spring to autumn and mean abundance was lowest during spring and highest during autumn. The maximum number of species occurred at a depth of 6 m (11 species), whereas the lowest number was found at 0 m (5 species). Total density of polychaetes was highest at 6 m depth (31,325 ind. m<sup>-2</sup>), gradually decreased toward shallower or deeper zones and reached a minimum at 14 m (2375 ind. m<sup>-2</sup>). Margalef's species richness index ranged between 0.90 (in summer at 2 m depth) and 1.76 (in spring at 12 m depth). Shannon diversity index ranged from 1.08 (in summer at 12 m depth) to 2.83 (in spring at 8 m depth) and Pielou's equitability ranged from 0.42 (in summer at 12 m depth) to 0.89 (in spring at 16 m depth).

Tab. 1. Average density of polychaete species (ind.  $m^{-2}$ ) across all seasons, for each of the 9 depths examined.

\* new record for the Romanian Black Sea coast

The results of this study show that the polychaete fauna inhabiting the artificial rocky substrate from Agigea dyke is relatively scarce comparatively to the natural hard seabed from other areas [2, 3, 4]. This is essentially due to the strong influence of the severely polluted and eutrophicated waters of the nearby Agigea seaport and Danube - Black Sea canal.

# A FUZZY LOGIC RULE-BASED MODEL TO EXAMINE THE SPATIO-TEMPORAL RELATION OF DEMERSAL RESOURCES WITH ENVIRONMENTAL CONDITIONS

G. Sylaios \*, M. Torre , A. Khayati , R. Fageot , A. Kallianiotis

Fisheries Research Institute, National Agricultural Foundation, 64007, Nea Peramos, Greece - fri@otenet.gr

# Abstract

A fuzzy rule-based model was developed and applied on the fishery dataset derived from North Aegean Sea MEDITS Survey, during 1998-2001. The model provides a non-linear relationship between total fish biomass and four fish biomass dependent environmental variables (bottom temperature, bottom salinity, water depth and crustaceans biomass), which improves multiple linear regression approaches, and could be utilised for future fish biomass descriptive and predictive purposes. *Keywords : Demersal, Fishes, Models, Biomass, Aegean Sea.* 

Introduction

Understanding the spatial and temporal variability of demersal resources, and its links to the deep sea environment, appears as an important task for trawl fisheries management. Fuzzy logic techniques have recently been applied in fisheries research [1], improving classical fish landings analysis. Data on the distribution of demersal resources biomass in the North Aegean Sea were collected during MEDITS Surveys (1998-2001), and analysed for species assemblages, patterns in spatio-temporal changes related to environmental factors and ecological species interactions [2]. In this work, a fuzzy logic, rule-based model was developed aiming to provide a non-linear relationship between total fish biomass and environmental variables, as station water depth, bottom temperature, bottom salinity and crustaceans biomass.

#### Materials and methods

Fishery and oceanography data were collected and processed according to standard MEDITS protocol [3], at 64 stations throughout the North Aegean Sea during 1998-2001 (n = 165). Biological variables as total fish biomass (kg/km<sup>2</sup>) and total crustaceans biomass (kg/km<sup>2</sup>), along with environmental variables (sea bottom temperature and salinity) were extracted from the above database. The software DECISIA SPAD 5.5 for Windows was utilized for multiple linear regression analysis and a fuzzy logic model was developed on a simple MS-Excel spreadsheet following Sylaios et al. [4], to derive a complex relation between total fish biomass and the above described environmental factors.

Fig. 1. Scattergram of modeled versus observed Log(Fish Biomass) values.

Results and Discussion

The multiple regression model derived from the data considered was highly significant (p<0.01) but with a poor predictive capability ( $R^2$ =0.33).

Figure 1 illustrates the scattergrams of fuzzy estimated fish biomass versus the observed fish biomass values imported in the model. A linear regression equation formed as:

Recorded Data [log(Fish Biomass)] = 1.00103 \* Fuzzy Model Results [log(Fish Biomass)] - 0.0026

produced a line which coincides with the best-fit line (1:1 slope), as shown

in Figure 1. Fish biomass values produced by the model were slightly overestimated with the slope  $\gamma$  obtaining a value of 1.009. The squared correlation coefficient of modelled and observed data obtained adequately high values ( $R^2 = 0.751$ ), while the Sum of Squared Errors was 7.77 and the Root Mean Squared Error was 0.217. Figure 2 compares the observed and predicted fish biomass values time series, for the different data points considered, showing good agreement.

Fig. 2. Comparison between recorded and modelled fish biomass (in  $\mbox{kg/km}^2).$ 

According to our results fuzzy modelling improved the multiple linear regression approach in describing the variation of fish biomass according with the variables considered. Biologically, bottom temperature, bottom salinity and water depth should be considered as principal constrains in the biomass carrying capacity of demersal environment. Furthermore, fish and crustaceans dependence may be explained either in terms of predator-prey relationships or in terms of environmental niche siilarities.

Fuzzy modelling shows potential for the fisheries domain, but its predictability must be demonstrated with further studies.

#### Abstract

The present study describes variations in biological and ecological features of sand smelt in three different ecosystems (fresh, brackish and saline-marine waters). Otolith analysis indicated that lifespan was three years in all study areas. Length-at-age data showed that sand smelt grew better in Ömerli Reservoir rather than in Homa Lagoon and İzmir Bay. Life history variables were relatively similar, although the spawning duration was more extended and GSI higher in Ömerli Reservoir. Differences in growth and life history traits of sand smelt from different water bodies could be attributed to variation in environmental factors.

Keywords : Fishes, Reproduction, Growth, Lagoons.

The sand smelt , *Atherina boyeri* (Risso 1810), is a small, short-lived, euryhaline teleost fish of faunistic importance in coastal, estuarine and lagoon habitats, salt marshes, and, inland waters, forming large local populations. Sand smelt fisheries are among the most common and important in the Mediterranean countries and represent one of the main fishing resources. In Turkey, even though this species is not consumed by people, it is exported to some Mediterranean countries. However, there is no information about its environmental biology in Turkish waters. In this study, we provide basic information about some biological parameters of sand smelt for the fresh, brackish and marine waters from Turkey, which will be useful for its management.

Sand smelt were collected from Ömerli Reservoir (Anatolian part of Istanbul), Homa Lagoon (İzmir), and İzmir Bay using gill-nets, beach-seines and trawls between September 2003 and August 2004. In the laboratory, the fish were measured for total length (TL) to the nearest 1 mm and for wet body weight (TW) to the nearest 0.1 g. Sex was determined by visual examination of the gonad either by naked eye for larger fish or with the aid of a lens (x16) for smaller fish. Gonad weight (GW) was measured to the nearest 0.001 g. Age was determined from the otoliths. The gonadosomatic index (GSI) was calculated as: GSI = (GW/TW) x 100. The overall ratio of males to females was examined with the chi-square ( $\chi^2$ ) test. Mean length-at-maturity was calculated using non-linear regression [1].

A total of 378 individuals from Ömerli Reservoir, 605 individuals from Homa lagoon, and 966 individuals from İzmir Bay were caught. Otolith analysis indicated that maximum age was three years old from all study areas. Minimum length was 2.4 cm in İzmir Bay and 12.9 cm in Ömerli Reservoir (Fig. 1). GSI of sand smelt peaked between April and July in Homa lagoon and İzmir Bay. However, this period was a bit longer in Ömerli Reservoir which extended to September. The length at first maturity was 4.1 cm, 4.6 cm and 5.1 cm for Ömerli Reservoir, Homa Lagoon and İzmir Bay, respectively. Corresponding ages were 1 year for the three areas. The male:female ratio was 1:12.5 for Ömerli Reservoir, 1:1.28 for Homa Lagoon and 1:1.96 for İzmir Bay which deviated statistically from 1:1 (P<0.0001).

In the three studied areas, the life cycle of sand smelt was short, with only three age groups being evident. This is in agreement with the general pattern observed in most other sand smelt populations previously studied throughout their distribution range [2, 3]. [4] showed that sand smelt can adapt its life history and morphology to environmental conditions with a trend to reduced growth and length-age data along an oceaniccoastal-estuarine-freshwater habitat range. However, this trend has been conversely occurred in the present study. Length-at-age data showed that sand smelt grew better in Ömerli Reservoir rather than Homa Lagoon and İzmir Bay. A positive effect of temperature and food on growth of fish has been well documented. However, temperature regimes are quite similar in these locations and had probably no considerable impact on growth differences. We suggest that the presence of large sand smelt in Ömerli Reservoir is attributed to the lack of large predatory fishes in the reservoir and to the lack of fishing which is prohibited by local authorities throughout the year.

Life history variables were relatively similar, with some slight differences, namely extended spawning and higher GSI in Ömerli Reservoir. This may be ascribed to phenotypic adaptation to the environment with an increase in reproductive effort with increasing environmental variability. Since the Ömerli Reservoir is used as a source of drinking water for the İstanbul metropolitan area, an average of 872,000 m<sup>3</sup> water per day is discharged from the reservoir which leads to very unstable water level. Furthermore, algicide (copper sulphate) treatments are applied to the reservoir to decrease cyanobacterial blooms, which influence water quality negatively and cause severe fish kills. High dominance of females to males in the reservoir supported this suggestion.

Fig. 1. Length-at-age data for Atherina boyeri from Ömerli Reservoir, Homa Lagoon and İzmir Bay.

#### Abstract

*Compsonema saxicola* (Kuckuck) Kuckuck (Phaeophyceae, Scytosiphonaceae) is reported for the first time in the Aegean Sea (Turkey). It was collected growing as an epiphyte in the midlittoral zone (-0,5 m) from Ayvalik (eastern Aegean Sea, Turkey) and identified with its usual distromatic base. Only unilocular sporangia were observed. *Keywords : Aegean Sea, Algae.* 

#### Introduction

The genus *Compsonema* was established by Kuckuck [1] and *Compsonema gracile* Kuckuck [= *Compsonema minutum* (C. Agardh) Kuckuck] is the type species of the genus. *Compsonema saxicola* has been first described as " *Myrionema saxicola* ?" from Helgoland in the North Sea [2], and it was subsequently transferred to the genus *Compsonema* [3]. *C. saxicola* (Kuckuck) Kuckuck has been reported from the Adriatic Sea and from the Gulf of Trieste (northern Adriatic, Italy) in the Mediterranean Sea till now.

The genus *Compsonema* has been assigned to the Ectocarpaceae [3], the Myrionemataceae [4], and more recently to the Scytosiphonaceae [5, 6]. The justification for placing this genus in the Scytosiphonaceae is based upon evidence form culture studies that demonstrate it to be a phase in the life history of *Petalonia* or *Scytosiphon* [5, 6]. *Compsonema minitum* shows two features which are characteristic for the Scytosiphonales [5]:

1. The presence of a single large lobed chloroplast per cell with a large pyrenoid in a pyrenoid sac.

2. A partly parenchymatous prostrate system morphologically similar to the knot filaments in the comparable thallus parts of *Scytosiphon* and *Petalonia*.

#### Material and Methods

*Compsonema saxicola* was collected in the midlittoral zone, as an epiphytic on *Chaetomorpha aerea* (Dillwyn) Kützing from Ayvalik (Aegean Sea, Turkey) in February 2005 and was preserved in 4% Formaldehyde in seawater. The identification of the this alga was made according to the accounts in Kuckuck [2], and Fletcher [4].

#### Results

Compsonema Kuckuck 1899: 58

Compsonema saxicola (Kuckuck) Kuckuck 1953: 343

(Myrionema saxicola Kuckuck 1897: 381)

Thalli were epiphytic on *Chaetomorpha aerea* (Dillwyn) Kützing, 0,5 mm diameter, spherical and dark brown. In a squash preparation the thallus is seen to consist of a distromatic basal layer (Fig 1a). Phaeophycean hairs, unilocular sporangia and erect filaments arise from the basal cells. The erect filaments are simple, uniseriate, up to 10-15 cells long, the cells 7-11  $\mu$ m long, 8-10  $\mu$ m broad, and each cell contains one plate-like chloroplast with one pyrenoid. Unilocular sporangia are common, oval, 35-40 x 20-25  $\mu$ m, borne directly from the basal cells, sessile or 1-celled stalks (Fig 1b). Plurilocular sporangia are unknown in this species. The plants were observed occurring at a water temperature of 10 °C.

*Compsonema saxicola* has been reported from the Helgoland, England and Ireland, Scandinavia, the Azores, Italy and the Aegean Sea coast of Turkey (this paper).

#### Discussion

*Compsonema saxicola* was characterized as being lithophilic or saxicolous. But Turkish plants were determined as epiphytic on *Chaetomorpha aerea* in the midlittoral zone.

It has been showed a connection between a minute *Scytosiphon* (*Scytosiphon pygmaeus* Reinke) with *Compsonema sporangiiferum* Setchell *et* Gardner and *Streblonema anomalum* Setchell *et* Gardner. It has been reported that the Atlantic *Compsonema saxicola* is very similar to the Pacific *Compsonema sporangiiferum*. *C. sporangiiferum* was reported first time as epiphytic on *Nereocystis luetkeana* (Mertens) Postels *et* Ruprecht from Neah Bay (Washington, USA). *C. saxicola* was studied in culture by P.M.

Pedersen (unpubl.) and he reported that a connection with a parenchymatous, erect phase was not shown.

*Compsonema saxicola* is probably a summer annual, and it was recorded from April to October from England and Ireland [4]. It has been reported that the erect thalli were poorly developed in culture but were recognisable as like *Petalonina* or *Scytosiphon* [4]. It was also called that the environmental conditions played role, particularly temperature and photoregime in the relationship between the *Compsonema* microthalli and the erect macrothalli and *Compsonema*-like thalli showed maximum development in warm temperature/long day conditions.

Fig. 1. *Compsonema saxicola*. a) Distromatic basal layer; b) nilocular sporangia and erect filaments.

# CONTRIBUTIONS TO SPECIES KNOWLEDGE OF AMPELISCA GENUS AT THE BLACK SEA ROMANIAN LITTORAL

Adrian Teaca \* and Marian-Traian Gomoiu

1National Institute of Geology and GeoEcology - GeoEcoMar, Constanta Branch, 304 Mamaia Bvd., RO-900581 Constanta, Romania -

adrianxteaca@yahoo.com

# Abstract

Based on the detailed analysis of a huge material collected on the sedimentary bottoms (1-25 m depths) from the Romanian continental shelf during the period 2005-2006, the authors establish, for the first time in the Black Sea, the presence of the amphipod *Ampelisca sarsi*. The paper brings some arguments, which prove the presence on the shallow sedimentary bottoms of the Romanian shelf, of the species *A. sarsi*, which probably had been incorrectly identified before (unfortunately, checking material was not possible, due to the absence of any amphipod collections in the past decades).

Keywords : Crustacea, Biodiversity, Black Sea.

In the latter half of the 20th century the Black Sea benthos fauna was relatively well studied, considering particularly the spreading and abundance of populations. With rare exceptions, the issues of systematics were in the background, at that time researchers making use of the few existing identification books, taking the information from the predecessors and keeping the species nomenclature. This situation requires the revision of almost all groups of organisms in the Black Sea. The case analysed in this paper refers to the crustacean amphipod genus *Ampelisca*.

Ampeliscidae represents the genus prevailing in the benthic communities dwelling the sedimentary substrata from the temperate region up to the polar one. In the Black Sea, four species were identified: *Ampelisca diadema*, A. (*aff. spinipes*) [1], *A. pseudospinimana* (Turkish littoral) and *A. brevicornis* (Bulgarian littoral). The presence of the *A. diadema* was signalled for the majority of sectors, the rest of species having a strictly limited distribution. The high numerical abundance of the genus populations in the Black Sea, comparable with that of the populations formed by similar species living the European seas, as well as its spreading up to the oxic/anoxic zone, compensates for its reduced diversity.

Analysing some *Ampelisca specimens* from the shallow Romanian waters and comparing the results with the data of the literature, a few differences regarding the external morphologic features were observed: form of cephalic extremity, length and number of articles of AI, form of telson, presence and disposition of setae on the surface of each lobe.

It was established that all the more than 1 000 individuals collected in the Romanian littoral inshore waters (1 to 25 m depths), pertained to the *Ampelisca sarsi* (Chevreux, 1888), not to *Ampelisca diadema* as it had been quoted before.

A simple analysis of the species shows important differences comparatively with the classic species quoted at the Romanian littoral - *A. diadema*. The main elements, differentiating the two species are (Table 1) [2].

Tab. 1. Identifications elements of the species A. diadema and A. sarsi.

| Identification features                     | Ampelisca diadema                                                                                    | Ampelisca sarsi                                                                                                                                                     |

| Telson (female)                             | Elongated, devoid setae<br>on dorsal surface with 4<br>pairs of distal and<br>subdistal small spines | Triangular with 2-3 simple<br>small setae on the surface of<br>each lobe, 2 pairs of<br>plumose setae disposed<br>lateral-basal and 1 distal<br>spine for each lobe |

However, some external morphologic features of the individuals from the northern sector in front of the Danube Delta and Constanta - Eforie Nord present a few differences comparatively with the species described for the Mediterranean Sea. The individuals collected from the southern sector (Mangalia) totally correspond to the classic description, without evident morphologic differences. The differences identified at the individuals collected in Sf.Gheorghe - Constanta and Eforie Nord areas consist in: variation in number of flagellum articles from antenna I (5-8); presence of different number (among 2 and 4 pairs) of setae and distal and subdistal spines of telson comparatively with only 1 of the Mediterranean species; existence of minor differences between morphology of uropod U3 of female and male (both sexes have plumose setae); both female and male

have always 2 pairs of plumose setae on lateral-basal part of the telson, and 2-3 pairs simple setae on dorsal surface (Fig. 1).

Fig. 1. Morphologic variation of telson at *Ampelisca sarsi* (a - female (f) from Mediterranean Sea [2]; b - female for Romanian southern sector (Mangalia); c, d - female and male (m) for Romanian northern sector (Sf.Gheorghe - Constanta) (original).

The issue of replacement of *A. diadema* with *A. sarsi* described for the Romanian marine waters seems to be very difficult, remaining still an open issue. Our explanation is that either the species was incorrectly determined for NW sector of the Black Sea or a gradual replacement of one species with another one occurred along the last decades. Taking into consideration the references, in the NW Black Sea, the actual presence of *A. diadema* in the benthic biocoenosis is constant. The co-habitation of the two species in mixed populations might be possible, which has to be checked in future. Recently, the analysis of samples collected from 60 m depths bottoms at the Romanian shelf has led to the identification of *A. sarsi* at these depths too, while *A. diadema* was absent.

Thus the presence of the species in NW Black Sea has to be very carefully checked both for the Ukrainian and Bulgarian littorals. The absolute dominance of on a large area of the Romanian shelf represents an element, which gives birth to the following remarks: 1. the difficulty of quick reorganization of the genus in NW Black Sea; 2. an incorrect identification of the amphipod species; 3. the uncertainty of being a new species introduced into the Black Sea and 4. necessity for more attention paid to taxonomy/systematics of benthic species.

Acknowledgement: We gratefully acknowledge Mrs. D. Bellan - Santini's invaluable support in checking our material and confirming the identification of *A. sarsi* in the Black Sea.

# FECUNDITY OF RED MULLET (*MULLUS BARBATUS* L., 1758) ALONG THE TURKISH COASTS OF THE MEDITERRANEAN SEA

Eyup Mumtaz Tirasin \*, Aydin Unluoglu and Bulent Cihangir

Dokuz Eylul University, Institute of Marine Sciences and TechnologyIzmir-Turkiye - mumtaz.tirasin@deu.edu.tr

## Abstract

A total of 194 red mullets, *Mullus barbatus*, were sampled for fecundity studies by bottom-trawl along the Turkish coasts of the North Aegean Sea during Summer 1991 and Spring 1992 and of the Northern Levant Sea in Spring 1992. The mean batch fecundity was 7023 eggs in summer and 7960 eggs in spring for the North Aegean Sea. The mean fecundity estimates were higher in the Northern Levant Sea, being 11180 and 13000 eggs for the western and eastern regions, respectively.

Keywords : Aegean Sea, Eastern Mediterranean, Levantine Basin, Reproduction.

## Introduction

Red mullet (*Mullus barbatus*, Linnaeus 1758) (Pisces Mullidae) is one of the most valuable demersal fish species in the Mediterranean trawl fishery. Therefore, its biology and population dynamics have been widely studied in several regions of the Mediterranean Sea. However, previous investigations concerning the reproduction characteristics of the red mullet are limited, and only one study [1] provides information about its fecundity in Turkish coasts.

The main objective of this study is to present data on the fecundity of red mullet in the Mediterranean Turkish waters (North Aegean and Northern Levantine Seas).

#### Material and Methods

A total of 194 red mullet specimens with matured ovaries were used for fecundity estimation in this study. These fish were selected from the random subsamples of red mullets caught during the bottom trawl surveys conducted with R/V *K. Piri Reis* along the Turkish coasts of the North Aegean Sea in Summer 1991 and Spring 1992, and the Northern Levantine Sea in Spring 1992.

The fork length (mm) and total body weight (g) of each fish were measured on board, and gonad weight (g) and fecundity estimations were done in the laboratory.

Batch fecundity was determined using the hydrated oocyte method [2]. The relationship between batch fecundity and fish fork length (mm) was based on the function of  $Y=a10^{bX}$ , where the dependent variable (Y) is the batch fecundity and the predictor (X) is the fork length. This function was transformed to a linear form by taking logarithms, i.e.  $log_{10}(Y)=log_{10}a+bX$ . The linear regression analysis was used to fit this relationship to the data [3]. ANCOVA was also carried out to detect possible spatial differences in the values of the slopes b. Batch fecundity was divided by the ovary free weight of female fish in order to estimate relative fecundity (eggs/g). ANOVA was used to check if mean relative fecundity values differed spatially [3].

#### Results and Discussion

The fork length of the specimens caught ranged from 94 to 220 mm and the mean fecundity calculated was 7030 eggs in the North Aegean Sea during summer. A higher mean fecundity (7960 eggs) was found for the same region in spring. The mean fecundity estimates were 11180 and 13000 eggs for North-western and North-eastern Levantine Sea, respectively. The results of the regression analyses are given in Table 1. These analyses showed that batch fecundity increased with fork length. Larger red mullets have a significantly higher annual fecundity (per unit body weight) than younger ones. The slopes of the regression lines (all b values) were homogenous (according to the ANCOVA results). ANOVA and Tukey's HSD test showed that mean batch fecundity was significantly higher in the North-eastern Levantine Sea than in other areas. According to the results of ANOVA and Tukey's HSD test, there was a significant (P<0.05) difference in mean relative fecundities in the North Aegean Sea in Summer 1991 and Spring 1992 (Table 1). The mean relative fecundity was also significantly (P<0.05) higher in the North Aegean Sea in Spring 1992 than those estimated for the Northern Levant Sea (Table 1).

Tab. 1. Results of regression analyses by sampling area in Summer 1991 and Spring 1992. Here, n, min and max denote numbers of fish used in the analyses, and minimum, and maximum fork lengths, respectively. Estimated mean batch fecundities (BF) and their standard deviations (SD), and mean relative fecundities (RF) and their standard deviations (SD) are also given.

# STRUCTURE ET ORGANISATION DES MACROINVERTEBRÉS DE LA LAGUNE NORD DE TUNIS (TUNISIE)

Sabiha Tlig-Zouari \*, Thouraya Mami and Fadhila Maamouri

Laboratoire de Biologie, d'Ecologie et de Parasitologie. Faculté des Sciences de Tunis, Tunisie - SZouari.T@fst.rnu.tn

# Résumé

L'étude des maroinvertébrés benthiques de la lagune nord de Tunis fait apparaître des peuplements prospectés qui dénotent d'une diversification spécifique et une régression notable des espèces indicatrices de forte pollution. Les facteurs hydrodynamiques (marée, courant ...) et édaphiques (pollution) paraissent dominants dans l'organisation et la répartition de cette macrofaune. *Mots clès : Zoobenthos, Biodiversity, Lagoons.* 

Situé à l'est de la capitale, le lac nord de Tunis a été sujet à une forte perturbation anthropique. Pour remédier à cet état critique, le lac a été restauré dont le but d'améliorer son hydrologie et sa sédimentologie. Cette étude a pour objectif la caractérisation et la détermination de l'organisation des peuplements macrobenthiques du lac après son aménagement.

Cinq stations de la lagune nord de Tunis (A1, A2, B, C1 et C2) ont été échantillonnées saisonièrement entre novembre 1997 et novembre 1998. Les prélèvements ont été réalisés au moyen d'un quadrat de 0.5 m de côté et de 0.2 m de long. Ils ont été triés à l'aide d'un tamis de 1mm de vide de maille, fixés dans une solution de formol salée à 10% et identifiés jusqu'à l'espèce puis dénombrés.

La classification hiérarchique ascendante et l'analyse factorielle des correspondances ont été effectuées à partir de l'abondance moyenne de chaque espèce sur les quatre relevés saisonniers.

L'ensemble des relevés permet de recenser 90 espèces de macroinvertébrés qui se répartissent en six taxons zoologiques (Mollusques, Crustacés, Cnidaires, Annélides et Ascidiacés) avec une nette prédominance numérique des Mollusques.

La comparaison de la valeur estimée de la richesse spécifique à celle trouvée par Zaouali et Baeten [1] avant l'aménagement du lac, suggère que le nombre d'espèces dans la lagune a largement doublé et que certaines espèces ont disparu telles que les espèces de Polychètes opportunistes. Toutefois la dominance des espèces tolérantes à l'excès de matières organiques constatée dans cette lagune, semble traduire un certain déséquilibre de ce biotope.

Le regroupement des stations sur la base de la distance euclidienne en fonction de leurs abondances macrozoobenthiques (Fig. 1), permet de repérer trois secteurs lagunaires. Le premier secteur comporte la station B, et le second couvre le secteur sud; il est constitué des stations C1 et C2. Enfin, un troisième secteur rassemble les autres stations (A1 et A2).

Fig. 1. Classification ascendante et hiérarchique des stations (B, C1, C2, A1 et A2 : stations).

Concernant l'AFC appliquée à ces prélèvements, nous retenons le plan factoriel F1xF2 (Fig.2). Le pourcentage d'inertie du premier axe F1 est de 47.1 % et celui du second F2 est de 28.8 %, soit 75.5 % au total. L'axe F1 oppose la station A2 à la station C1. Il paraît exprimer les variations horizontales du facteur hydrodynamique. L'identification du second axe F2 permet de séparer la station A2, à substrat sablovaseux, pauvre en matières organiques, de la station B pourvue d'un substrat vaseux noir, très riche en matières organiques. Cet axe semble exprimer une zonation selon les facteurs édaphiques notamment la pollution organique.

Cette analyse révèle une répartition différentielle des espèces macrozoobenthiques en fonction à la fois des facteurs hydrodynamiques et édaphiques qui sont eux-mêmes en relation avec d'autres facteurs environnementaux (climatiques, hydrologiques, profondeurâĂę). Ainsi, Les stations étudiées forment trois groupes, le premier est formé par les stations A1 et A2, le second par la station B et le troisième par les stations C1 et C2.

Fig. 2. Plan F1/F2 de l'analyse factorielle des correspondances (AFC) (A1, A2, B, C1, C2: stations).

# STOMACH CONTENT OF HARBOUR PORPOISES (*PHOCOENA PHOCOENA*) FROM THE TURKISH WESTERN BLACK SEA IN SPRING AND EARLY SUMMER

Arda M. Tonay \*, Ayhan Dede, Ayaka A. Öztürk and Bayram Öztürk

Istanbul University, Faculty of Fisheries, Marine Biology Dept. Ordu Cad. No:200, Laleli 34480, Istanbul, Turkey / Turkish Marine Research Foundation (TUDAV), P.Box: 10 Beykoz 81650, Istanbul. - atonay@istanbul.edu.tr

## Abstract

The study was based on stomach content from 42 harbour porpoises bycaught or stranded between April to June in 2002 and 2003, on the Turkish western Black Sea coast. Seven fish species were identified. Sprat and whiting were the most important fish species in the diet by frequency of occurrence (64.1% and 23.6%, respectively). Besides fishes, crustaceans, pieces of algae, molluscs, bivalves, sand and plastic debris were also recorded.

Keywords : Cetacea, Diet, Black Sea, Plastics.

#### Introduction

There are three cetacean species living in the Black Sea, namely, bottlenose dolphin (Tur s iops truncatus), short-beaked common dolphin ( Delphinus delphis) and harbour porpoise (Phocoena phocoena). One of the important threats to these cetaceans, especially harbour porpoises, is bycatch in turbot fisheries in the Black Sea. The Turkish western Black Sea traditionally includes fishing grounds for turbots, Psetta maxima, P.m.maeotica and Scoptalmus maeoticus, which have high economic value. Many harbour porpoises and bottlenose dolphins die as the result of incidental catch in turbot and sole fishing nets in April, May and June [1-4]. Understanding feeding habits is one of the key factors in considering the protection measures for cetaceans. There have been some studies on the stomach contents of Black Sea cetaceans complited by [5]; but few on the Turkish coast [3]. The aim of the study is to identify food components of the spring diets of the Black Sea harbour porpoises on the Turkish coast as basic information to elaborate proper protection measures for the Black Sea cetaceans.

#### Materials and Methods

A total of 42 stomachs of harbour porpoise (33 female, nine male) were analyzed. Forty individuals were bycaught in turbot nets and two individuals were found stranded, in April - June in 2002 and 2003, in the western coast of Turkey [4, 6]. All stomach compartments were examined and stored in a freezer at -20 °C. Samples were thawed later; the contents removed, washed and sieved in a  $200\mu$  mesh size sieve and stored in 70% ethanol. Prey remains consisted principally of otoliths and bones of fish and rostrum and other body parts of crustaceans, which were identified using reference materials and published guides [7-8].

#### Results and Discussion

Food remains were found in 90.4% of the stomachs but only one individual contained decomposed fish remains. The stomach contents of the 42 porpoises included 3304 otoliths, of which 1935 (>1mm) were identified. These were from seven fish species, which were sprat ( S. sprattus), whiting (M. merlangus euxinus), sole (Solea (spp.)), gobies (Gobiidae (spp.), European hake (M. merluccius), anchovy (E. encrasicolus) and red mullet (M. barbatus) (Fig.1). Remains of 26 crustacean individuals (nine Crangonidae (spp.), seven Decapoda (spp.), seven Crustacea (spp.), three Caridae (spp.)) were also found in six stomachs, while the fish remains were found in 88,1%. Meanwhile, in another five stomachs, plastic debris was found. Pieces of algae, molluscs, bivalves and sand were also recorded. The debris in one of the bycaught individual (female, 130cm) stomach consisted of plastic bags and sheeting with dry weight of 40,9 g. Ingestion of plastic or other marine debris has been documented for 26 species of odontocetes and this is the fourth reported case of plastic ingestion by a harbour porpoise according to [9]. Benthic fish including whiting, and gobies; and pelagic schooling fishes such as sprat and anchovy, composed the basic diet of harbour porpoises in the Black Sea [5], [3]. Protection measures for harbour porpoises in the Black Sea, therefore, should be elaborated taking such information into consideration.

#### Acknowledgments

We thank Dr.B.Topaloglu who identified crustacean, Dr.S.Karakulak, Dr.M.Oral, Dr.Ç.Keskin for otolith reference material, M.Kececi and SUFSAK students who helped in lab. works, turbot fishermen for their help in collecting specimens.

# STOMACH CONTENTS OF BYCAUGHT HARBOUR PORPOISES (*PHOCOENA PHOCOENA*) FROM THE MARMARA SEA

Arda M. Tonay \*, Ayhan Dede and Ayaka A. Öztürk

Istanbul University, Faculty of Fisheries, Marine Biology Dept. Ordu Cad. No:200, Laleli 34480, Istanbul, Turkey / Turkish Marine Research Foundation (TUDAV), PK 10 Beykoz 81650, Istanbul, Turkey. - atonay@istanbul.edu.tr

## Abstract

The study was based on stomach content of four harbour porpoises bycaught in the coastal fishery in 2004 and 2006, on the Marmara Sea coast. Three fish species, horse mackerel (*Trachurus trachurus*), sprat (*Sprattus sprattus*) and gobies (*Gobiidae* sp.) were identified. Horse mackerel and sprat were the most important fish species in their diet. *Keywords : Cetacea, Diet, Marmara Sea.* 

## Introduction

The Turkish Straits System (TSS), namely the Istanbul Strait (Bosphorus), the Marmara Sea and the Canakkale Strait (Dardanelles), constitute a biological corridor for dolphins as well as for pelagic fish between the Black Sea and Mediterranean Sea [1]. In the Marmara Sea, three cetacean species; bottlenose dolphin (*Tursiops truncatus*), short-beaked common dolphin (*Delphinus delphis*) and harbour porpoise (*Phocoena phocoena*), are known to occur. Harbour porpoise strandings have been reported from the TSS [2]. The aim of the study is to identify food components of harbour porpoises, as the first information on their feeding preference in the Marmara Sea.

#### Materials and Methods

Three porpoises were bycaught in the bottom gillnets for whiting and the trammel net for soles, one nautical mile off Yalova in 2004 and 2006 (Fig. 1). The fourth porpoise was found floating at sea by the fishermen and had clear net marks on it. All stomach compartments of individuals were examined. The contents were removed, washed and sieved in a  $200\mu$  mesh size sieve and stored in 70% ethanol. Prey remains consisted principally of otoliths and bones of fish which were identified using reference materials and published guidebook [3].

Fig. 1. Location of Yalova where the bycatch of harbour porpoises occurred

#### Results

The stomach contents of three porpoises included 153 otoliths, of which 148 (>1mm) were identified. These were from three fish species, which were horse mackerel (*Trachurus trachurus*), sprat (*Sprattus sprattus*) and gobies (*Gobiidae* sp.) (Table 1). In the stomach of porpoise no.1, half-decomposed horse mackerels (15 individuals) were found, but in the stomach of porpoise no.4, only a fish vertebra and crustacean body parts were found.

#### Discussion

Benthic fish, such as whiting, European hake and gobies, and pelagic schooling fish, such as sprat and anchovy, composed basic diet of harbour porpoises in the Black Sea [4], [5]. In this study, a very few species were found to be prey species which may be due to the small number of samples. However, it was documented for the first time that the porpoises do feed on horse mackerels in the Marmara Sea. Horse mackerels had not been found as prey species for the porpoises in this basin, although they are widely distributed in the Black Sea as well. Harbour porpoises in the Marmara Sea may conflict with coastal fisheries because they compete for the same resources, such as horse mackerels.

The occurrence of the harbour porpoise was first described as "sometimes" in the Marmara Sea and "very rare" in the Mediterranean by [6]. In the TSS three cetacean species were observed at most in April and October [7]. However, due to the heavy marine traffic and other ecological stress in the Istanbul Strait, their migration does not occur regularly [1]. In the two surveys of cetaceans in the TSS in 1997 and 1998 using line transect methods, no porpoise was observed [8]. A few harbour porpoises have been recorded in the northern Aegean Sea; their genetic signatures and small size suggest that these individuals originated from the Black Sea [9]. Resident populations of harbour porpoises have not yet been determined in the Marmara Sea. In this respect, these bycatch cases off Yalova in spring and autumn, can be considered as the result of the porpoise movements although it rarely occurs at present between the TSS and Black Sea. More specimens and detailed studies are needed for better understanding of the occurrence of the harbour porpoises in the Marmara Sea.

### Acknowledgement

We thank Mert Kececi for his help in the field and laboratory work, fisherman Ertuğrul Say from Yalova for his help in collecting specimens and IDO for transportation of the specimens.

# INVESTIGATION ON THE MACROZOOBENTHIC INVERTEBRATE FAUNA IN THE NORTH AEGEAN SEA

Bülent Topaloğlu

Istanbul University, Fisheries Faculty. Ordu Cad. No.200 Laleli-Istanbul & Turkish Marine Research Foundation. P Box:10 Beykoz-Istanbul - topalbl@istanbul.edu.tr

## Abstract

Macrozoobenthic invertebrates were collected by bottom trawl at 13 stations in Thirteen locations off the Turkish coasts of the North Aegean Sea. A total of 9561 specimens were identified to 61 taxa. *Stichopus regalis* was present in 11 of the stations, *Penaeus kerathurus* and *Parapenaeus longirostris* were both common and abundant. *Keywords : Aegean Sea, Biodiversity, Zoobenthos.* 

Introduction

At the North Aegean Sea the thermophilic fauna of the Mediterranean Sea meets psychrophilic fauna of Black Sea origin [1]. Knowledge of the Aegean Sea is comparatively scarce [2]. Some of the earliest studies of the Mediterranean marine biota were carried off the Turkish Aegean coast by Forbes (1848), Colombo (1885) and Ostroumoff (1896) [3]. However, most studies in the Aegean Sea were limited to particular taxa, Gastropoda [4], teuthofauna [5] and sponges [6][7]. The aim of this study was to understand the vertical and geographical distribution of the macrozoobenthic invertebrate fauna off the Turkish Aegean coast.

## Materials and Method

Thirteen stations spread between Edremit Bay and Saros Bay, at depths between 40 and 480 m, were sampled by bottom trawl between 1-19 August 2001. Stations 1, 3, 6, 9, 12 and 13 were deeper than 300 m; stations 4, 5 and 12 between 100 - 300 m and 2, 7, 8 and 10 less than 100 m deep (see Fig 2). Each sample was counted and weighed after the identification. The abundance, presence and dominance were calculated. The abundance (A) is the mean number of the individuals from the total number of samples; presence (P) the number of observations of a species from the total number of samples, e.g. a "P" value of 11 indicates 11 stations. Dominance (D) is the proportion of the total number of one species to the total number of all organisms.

Fig. 1. The number of specimens in the various groups sampled from the stations in the North Aegean Sea.

#### Result and Discussion

A total of 9561 specimens were identified to 61 taxa. *Stichopus regalis* (Cuvier, 1817) was present in 11 of the 13 stations. *Penaeus kerathurus* (Forskål, 1775) has the highest dominance (55.726 %) and abundance (409.85) with 5328 specimens. *Parapenaeus longirostris* (Lucas, 1846) was present in 8 stations; abundance 87.15 and dominance 11,850 %. Crustaceans were the most presence and abundant group. Similar result was given by [1]. The specimens were mostly from stations 3 and 10 which were around 250-300 m deep. The highest values of species diversity were found in the deep water (250 m to 400 m) stations 3, 6, 9, 11 and 13. All groups were sampled at stations 2 and 8, 40-45 m deep. According to our data, the most abundant groups, crustaceans and mollusks, were sampled from deep water with the most abundant specimens (*P. kerathurus* and *P. longirostris*), but all groups were present in shallow waters (see

Fig.1). As a result, the species diversity was higher in shallow water than deep water and the species abundances were higher in the bottom water than the upper layer in the North Aegean Sea.

Fig. 2. The sampling stations.

# LUNAR CYCLES OF OTOLITH GROWTH IN THE JUVENILE SILVER SCABBARDFISH ( $L\!EPIDOPUS$ CAUDATUS)

Michele Torre \* and Argyris Kallianiotis

Fisheries Research Institute, National Agricultural Foundation, 64007, Nea Peramos, Greece - fri@otenet.gr

# Abstract

Otolith analysis was performed on the silver scabbardfish (*Lepidopus caudatus*) in the northern Aegean Sea in order to examine whether the growth zones that appeared between the nuclear area and the otolith edge in fish aged less than a year old, are related to the lunar cycle. The number of these zones ranged between 1 and 13 and was highly correlated with fish length. The periodicity of the zone formation was attributed to the lunar cycle. This hypothesis was validated by comparing the assigned birth of each fish to the spawning of adult population.

Keywords : Aegean Sea, Teleostei, Growth, Deep Waters, Fish Behaviour.

#### Introduction

The silver scabbardfish, *Lepidopus caudatus*, is a benthopelagic species living along the continental shelf and upper slope. It is a schooling species that lives close to the bottom during the day and migrates into midwater at night [1]. Growth analysis on the northern Aegean population of the species using otolith reading revealed that, in fish up to one year old, a series of opaque and translucent zones appear between the nuclear area and the otolith edge (Torre *et al.*, unpublished data) (Figure 1). The aim of the present work is to examine whether these zones are related to the lunar cycle.

Fig. 1. Translucent zones checked in 0+ specimen of the silver scabbard-fish (*Lepidopus caudatus*) in the northern Aegean Sea.

#### Materials and methods.

A total of 370 otolith of fish up to 1 yr old (TL range: 85-700 mm; mean TL=  $487.5\pm12.54$  mm) were seasonally sampled (summer 2003-summer 2005) with bottom trawling. Otoliths were observed under a light microscope. The number of translucent zones, their distances from the otolith nucleus, and otolith radius were recorded.

#### Results and discussion

The number of growth zones checked, varied between 1 and 13 and a highly significant linear correlation between the number of translucent zones (N) and otolith radius (OR) was observed (N = 7.94 OR - 0.94; R<sup>2</sup>=0.97, n=370, p<0.01). The fact that in 1 yr old fish the number of growth zones was 13 suggested that growth zones followed a lunar periodicity (13 cycle x 28 days = 364 days  $\approx$  one year). Thus, for each specimen, a date of birth was assigned. The peaks of birth (summer and autumn-winter) coincided with the reproductive peaks of the species in the area (Torre *et al.*, unpublished data) and hence indirectly validated the ageing method.

Accordingly, the number of translucent zones recorded, was age transformed (month) to formulate an age-length key. Total length at age data were statistically analyzed using non-linear regression analysis. The data were best fitted by the logistic model ( $R^2 = 0.87$ , Figure 2): TL = La(1/(1+exp(-r(t-a)))) where TL is the total length (mm), La the asymptotic length (in mm), t the age (in months), r the growth coefficient (in months<sup>-1</sup>) and a is a parameter (in months) equivalent to the age at 1/2 La. The parameters computed were:  $La = 702.19 \pm 43.28$  mm (p<0.01),  $a=7.33\pm0.41$  months (p<0.01),  $r=0.34\pm0.04$  months<sup>-1</sup> (p<0.01).

The growth of the otolith daily increments is slower during the full moon in deep water species following the same daily migratory behavior [2, 3]. This is probably caused by the possible dispersion of zooplankton during full moon [2]. Euphausiid crustaceans are the main prey of the silver scabbard fish [4] and their diel vertical migration may be influenced by moonlight [5]. Assuming that the silver scabbardfish may also be a nocturnal feeder, changes in prey availability related to the lunar cycle, may influence its feeding activity and consequently its growth rate. Hence, the lunar cycle may influence the growth patterns of the silver scabbardfish otolith.

Further studies on the daily feeding and migratory behavior of the silver scabbardfish coupled with otolith microstructure analysis may clarify this hypothesis. Moreover, the possibility of detecting lunar phases by otolith reading instead of using the time consuming daily increment analysis may be an useful tool in ageing of fish.

Fig. 2. Logistic model applied to total length (TL, mm) at age (months) data for silver scabbardfish (*Lepidopus caudatus*) in the northern Aegean Sea.

# DISTRIBUTION OF DEMERSAL FISHES IN THE NORTH AEGEAN SEA, GREECE

Michele Torre \*, Romain Fageot , Alice Khayati and Argyris Kallianiotis

Fisheries Research Institute, National Agricultural Foundation, 64007, Nea Peramos, Greece - fri@otenet.gr

## Abstract

The summer demersal fish density was assessed at 64 stations in the northern Aegean Sea sampled using a bottom trawl (1996-2001). Five high density regions were observed with the biomass density presenting a north/south and an inshore/offshore gradient. The biomass variability was explained by the mixing of the prevailing water masses, the water circulation of the northern Aegean Sea and the upwelling systems.

Keywords : Aegean Sea, Demersal, Fishes, Crustacea.

#### Introduction

The northern Aegean Sea is an area of complex bathymetry with an extended continental shelf. Although the landings are dominated by small pelagic fish, some demersal fish species (e.g. the European hake, *Merluccius merluccius*) constitute a significant part of the commercial catch in the area. The overall biomass of demersal fishes in the northern Aegean Sea has never been evaluated. The aim of the present work is to assess the demersal fish distribution and their biomass in the northern Aegean Sea and to explain the parameters that may are responsible for such variability.

## Materials and methods

The summer fish species density was calculated using the swept area method based on data from 64 stations of the northern Aegean Sea. Sampling was performed using a bottom trawl during the Mediterranean International Trawling Survey (MEDITS) program between 1996 and 2001 [1]. The duration of each haul was 30 or 60 min, depending on the sampling depth and the vessel speed was kept constant during hauling (at 3 knots). The gear used was the same for each haul (GOC 73) with a codend stretched mesh size of 20 mm and a vertical mouth opening of about 2 m. The swept area method is based on the analogy between the sampled area (estimated by the trawl opening, the speed and the duration of each haul) and the entire stock area [2]. The fish density was estimated by simply dividing the weight (kg) of fish caught in each haul by the sampled area (km<sup>2</sup>). No error estimates are available for these calculations.

Sea surface and bottom temperatures ( $^{\circ}$ C) were recorded *in situ*. MapInfo Professional 8.0 was used to show the fish biomass in the area and principal component analysis (PCA) to determine the factors (sea surface and bottom temperature, depth, longitude, latitude, cephalopod and crustacean biomass) that better explained the fish distribution variability.

Fig. 1. Average demersal fishes density in the North Aegean showing demersal resources high density spots (MEDITS 1996-2001 data). TS : Thracian Sea, TG : Thermaikos Gulf, EG : Evoikos Gulf, TI : Thassos Island, SI : Sporades Islands, EI : Evoia Island, LI : Lesvos Island, CI : Chios Island.

#### Results

The biomass density presented a north/south and an inshore/offshore gradient with the coastal regions being richer in terms of biomass than the open sea ones, as it has been previously pointed out for zooplankton [3]. We observed 5 high-density regions persistent over the 5 years (Fig. 1): Thracian Sea (TS), Thermaikos Gulf (TG), South of Chios Island (CI), Evoikos Gulf (EG) and the area 25 km west of Lesvos Island (LI). The PCA showed that there was a correlation between fish biomass and crustacean biomass, explaining 30.14% of the system's variance. No other correlations were found.

#### Discussion

Three main areas were previously distinguished in the northern Aegean Sea based on their particular environmental conditions [4]: TG, TS and central Aegean Sea. These areas are also highlighted in this study, with TG and TS being biomass-rich areas. TG and TS are shallow areas influenced by the less saline and nutrient-rich riverine input and the Black Sea water [5]. These water and nutrients fluxes tend to explain the biomass abundance and the north/south gradient. EG is a particularly deep (about 500 m) with the lowest bottom water temperature in the entire northern Aegean Sea. Yet, it is a productive area, exhibiting high fish biomass which remains unexplained.

The zone located to the west of LI belongs to the generally biomasspoor central Aegean and yet shows a high fish biomass. An upwelling/downwelling system [6] that brings nutrient-rich water offshore may explain this phenomenon. The west CI high density area may be also due to Ekman transport leading to water mixing [6]. The Ekman transport and the subsequent upwelling/downwelling is greatly related to the northerly winds blowing during the summer in the Aegean Sea and, to a large extent, is seasonally confined. Hence, the overall demersal fish distribution pattern refers to summer conditions only.

# Abstract

The present work examines the size specific distribution of anchovy and sardine in the Aegean Sea (Eastern Mediterranean basin) during early summer. Data from pelagic trawl hauls, multivariate methods, certain satellite environmental data and area topographic characteristics were used in order to identify the parameters that could discriminate the spatial distribution of the juveniles and the adults of both species *Keywords : Aegean Sea, Eastern Mediterranean, Pelagic.* 

## Introduction

Considering the general lack of information on the size related distribution of small pelagic fish in the Eastern Mediterranean basin, we examined the spatial changes in the length frequency distribution of anchovy and sardine populations, in the main fishing grounds of Aegean Sea, during June. Catch data from pelagic hauls were used and multivariate methods were applied separately for anchovy and sardine, in order to examine the classification of the pelagic trawl hauls in respect to fish size. Furthermore, certain satellite environmental data and area topographic characteristics were used to identify the parameters that could discriminate the resulting size-related groups.

#### Materials and methods

Data on catches from 132 pelagic hauls of 6 research surveys (1998-2006) on board the R/VPHILIA carried out in Aegean Sea during June, were analyzed in order to explore the spatial changes in the size distribution of anchovy (data from 99 hauls) and sardine (data from 78 hauls). Mean total length and fish abundance per hour and 0.5 cm length class were estimated for each haul. This weighted length frequency distribution was analyzed with the non metric Multi Dimensional Scaling (MDS) using a Bray-Curtis similarity matrix, in order to identify haul groups based on fish size.

Fig. 1. MDS results for sardine. Juveniles: hauls with mean length of the catch <110mm; Adults: hauls with mean length of the catch >110mm.

In order to determine if the groups defined by the MDS could be distinguished in terms of certain environmental characteristics a stepwise backward Discriminant Function analysis (DFA) was applied. The F-statistic was used to test the significance of the group centroid differences [1]. Satellite and topographic data were used. The satellite data (mean weekly values of sea surface temperature-SST in °C, chlorophyll-a CHLA in mg/m<sup>3</sup>, sea surface salinity-SSS, sea level anomaly-SLA in cm, photosynthetic active radiation-PAR in Ein/m<sup>2</sup>/day) were estimated by GIS techniques [2]. Regarding topographic data, the study area was divided into 6 sub areas and the Enclosure Index (EI) as well as the size of each sub-area (in  $\rm Km^2$ ) were estimated as described in [3], in order to take into account the peculiar topography of the Aegean Sea that is consisted of variable sized, open as well as semi-enclosed areas.

Tab. 1. DFA results for anchovy and sardine. EI: Enclosure index, SST: Sea surface temperature, CHLA: Chlorophyll-a, PAR: photosynthetic active radiation, SLA: sea level anomaly.

|         | Varia-<br>bles            | Wilks'<br>λ | p-<br>value | Correct<br>assignments |
|---------|---------------------------|-------------|-------------|------------------------|
| Anchovy | EI<br>SST<br>CHLA         | 0.83        | 0.000       | 81.82%                 |
| Sardine | SLA<br>CHLA<br>SST<br>PAR | 0.83        | 0.009       | 73.08%                 |

### Results and Discussion

The MDS analysis showed that hauls characterized by mean length less than 110 mm for both species were mainly grouped together indicating groups of juveniles and adult individuals (Fig.1). This length is close to the size of first maturity for both anchovy and sardine in the Aegean Sea [4]. Table 1 shows the results of the DFA analysis on the environmentalvariables used. The differences between the two groups were in all cases highly significant as shown by the Wilks' statistic and its correspondent F-statistic. The high percentages of correct assignments of hauls to the groups (>73%) indicated satisfactory discrimination between adults and juveniles (Table 1). DFA revealed that theparameters, mostly responsible for the spatial separation of the juveniles and the adults were EI, SST and CHLA regarding anchovy andS ST, CHLA, PAR and SLA regarding sardine (Table 1). These preliminary results indicate that juveniles and adults of both anchovy and sardine are spatially separated which seems to be related to certain environmental parameters. The use of data from additional areas and years will further highlight the habitat characteristics of juveniles and adults. This information could be coupled with GIS techniques for mapping the potential habitat of juveniles and adults.

# DEMERSAL-PELAGIC RATIO IN GREEK FISH LANDINGS (1964-2003)

Athanassios C. Tsikliras \* and Konstantinos I. Stergiou

Department of Zoology, School of Biology, Aristotle University of Thessaloniki, UP Box 134, GR 54 124, Thessaloniki, Greece; Tel.: 0030 2310 998268 - atsik@bio.auth.gr

## Abstract

The demersal/pelagic (D/P) ratio was assessed in different Greek fishing regions for the period 1964-2003. In eastern/southern Aegean region and in western/central Aegean and Ionian region, the D/P ratio decreased significantly (P<0.05) during 1964-2003. In contrast, in the northern Aegean such a trend was present only for the period 1990-2003. These trends indicate that fisheries in these regions are increasingly relying on the smaller, short-lived pelagic fishes.

Keywords : Aegean Sea, Demersal, Pelagic, Fisheries, Ionian Sea.

### Introduction

The annual landings of the Greek commercial fishing fleet have been routinely recorded since 1964 by the National Statistical Service of Greece (NSSG) for 16 fishing subareas [1]. Landings data refer to the legal and reported large- and small-scale fisheries, excluding recreational or sport fishing.

The aim of the present work was to assess the demersal/pelagic ratio (D/P) in groups of fishing subareas based on their fish landings composition for the period 1982-2003. The D/P ratio is used in fisheries science as an indication of the effect of fishing on marine ecosystems [2].

#### Materials and methods

Non-parametric multidimensional scaling (NMDS) using the Bray-Curtis similarity measure was applied to the average (1982-2003) landings of 66 per species (or groups of species) for each Greek fishing subarea. NMDS was used to identify groups of fishing subareas having similar landings composition. Stress values <0.15 indicate a good representation of data in two dimensions [3]. Consequently, we estimated the D/P ratio, for the groups of subareas indicated by NMDS, for the period 1964-2003. Demersal and pelagic species were defined based on FishBase (www.fishbase.org).

#### Results and discussion

The application of NMDS revealed the existence of three groups (Figure 1): (A) the northern Aegean subareas 13 and 14, including the Pagassitikos Gulf, subarea 11; (B) the Ionian (subareas 3, 4, 5 and 6) and western/central Aegean (subareas 8, 9, 10 and 12); and (C) the eastern/southern Aegean subareas (7, 15, 16, 17 and 18). This grouping was also confirmed by cluster analysis (results not shown). The two dominant pelagic and demersal species per group are shown in Figure 1.

Fig. 1. NMDS of Bray-Curtis similarities from standardised mean catch data per species (1964-2003) showing the 16 Greek fishing subareas [for the location see figure 3 in (1)] assembled in three groups. The dominant pelagic (P) and demersal (D) taxa landed in each area are also shown.

The mean D/P ratio differed with group of subareas (ANOVA, P<0.05; A:  $0.364\pm0.001$ ; B:  $0.848\pm0.004$ ; C:  $2.27\pm0.014$ ), being higher for southern Aegean, thus indicating the predominance of demersal species in this region when compared to the northern Aegean the landings of which are dominated (>45%) by anchovy and sardine. The D/P ratio declined

significantly with time in the eastern/southern Aegean and in the western/central Aegean and Ionian Sea group (C and B respectively: Figure 2), a fact showing that fisheries in these areas are increasingly relying on the smaller, short-lived fishes from the lower part of marine food webs because the demersal stocks are depleted and the large pelagic ones are either declining or remain stable. Although the D/P showed no significant trend with time in the northern Aegean Sea for the entire period, it declined significantly (P<0.05) for the 1990-2003 period (Figure 2: bottom line, black circles).

Fig. 2. The D/P ratio for Greek landings (1964-2003) in the three groups of subareas shown in figure 1. Regression for Group A refers to the 1990-2003 period.

# THERMAL THRESHOLD OF THE ONSET OF MATURATION IN CLUPEID FISHES USING QUOTIENT ANALYSIS

Athanassios C. Tsikliras

Department of Zoology, School of Biology, Aristotle University of Thessaloniki, UP Box 134, GR 54124, Thessaloniki, Greece -

atsik@bio.auth.gr

# Abstract

The quotient rule analysis was applied to assess the preferred ranges of sea surface temperature for sardine (*Sardina pilchardus*) and round sardinella (*Sardinella aurita*) spawning which was associated with temperatures  $<16^{\circ}$  C for the former and  $>21.5^{\circ}$  C for the latter. *Keywords : Spawning, Fishes, Temperature, Aegean Sea.* 

## Introduction

The psychrophilous European sardine (*Sardina pilchardus*) and the thermophilous round sardinella (*Sardinella aurita*) are the most important, in terms of biomass landed, clupeid fishes in the Aegean Sea. Despite the close taxonomic relationship, they exhibit different reproductive strategy in the Mediterranean Sea with the European sardine spawning over an extended period during the winter (see [1] and references therein) and round sardinella spawning over a relatively short period during the summer (see [2] and references therein). The aim of the present work is to assess the thermal threshold which determines the onset of gonadal maturation using an empirical method and the two clupeid fishes as case studies.

#### Materials and methods

Samples were collected monthly onboard the northern Aegean purse seine commercial fleet for the period September 2000-August 2002. Sea surface temperature was measured using a CTD probe. The annual reproductive allocation index (ARA), which describes the relative size of gonads and is used as an indicator of reproductive activity was calculated monthly based on the gonad and somatic weights [3].

A quotient-rule analysis [4] was applied to assess the preferred ranges of sea surface temperature for sardine and round sardinella spawning. For each species, the ARA value corresponding to each class was expressed as a percentage of the total ARA values added together (% ARA) and was divided by the percentage frequency of occurrence of each class (% SST) giving the quotient values (Q) for each temperature class [4]: Q= (%ARA)/(%SST). Quotient values >1 indicate preference to a specific range of variable, while those <1 indicate avoidance of the specific class [4]. Quotient curves were generated from smoothed (using a 6-point running mean) quotient values and were plotted against variables.

#### Results and discussion

The quotient curve plots for sardine (Figure 1) and round sardinella (Figure 2) showed their preferred ranges of SST. The quotient values >1 that are indicative of the onset of reproductive activity, were associated with temperatures >21.5 °C for round sardinella, and with temperatures <16 °C for sardine. The results coincide with the reported onset of gonad maturation for the two species at the northern Aegean Sea. Round sardinella has been reported to start spawning in May/June at temperatures exceeding 20 °C. Similarly the European sardine spawns between October and March, i.e., the beginning of gonad maturation occurs at around 16-17 °C.

Fig. 1. Quotient curves for European sardine (*Sardina pilchardus*) annual reproductive allocation (ARA) with sea surface temperature (SST, °C). Note the reverse order of x-axis data.

This method is of high importance in fisheries management because it allows a quick pre-estimation of reproductive activity for species whose spawning is largely depended on environmental and/or climatic factors [2, 5]. However, this method needs to be tested for other species and variables to ensure its efficiency in predicting the onset of spawning based on environmental data.

Fig. 2. Quotient curves for round sardinella (*Sardinella aurita*) annual reproductive allocation (ARA) with sea surface temperature (SST, °C).

## Abstract

The shallow-water fish assemblage from Prapratna Bay was sampled with a small beach seine at 4-h intervals over 24-h periods between April 2003 and March 2004. A total of 51802 individuals from 58 species (55983,27 g) were caught. The dominant species (*Boops boops*, *Atherina boyeri*, *Sardina pilchardus* and *Sarpa salpa*) were caught in consistently higher numbers and biomass in different times of the diel period. At the assemblage level, generally more species were caught during daytime wheraeas a larger number of individuals and biomass were caught during night.

Keywords : Fishes, Biodiversity, Adriatic Sea.

#### Introduction

Coastal shallow-water areas are important feeding and nursery grounds for many fish species. In these areas there is usually a distinct periodicity to the catch rate over the 24 h period [1]. In part, this reflects net avoidance, as fish can see the net in daytime and avoid it [1,2]. This can also be due to real changes in the abundance and structure of the fish assemblage. Diel changes in assemblage structure, which are superimposed on the seasonal one could have a profound effect on the perception of a fish assemblage [2]. The present study provides data on the diel changes in catches of shallow-water fish community in the Prapratna Bay, southern Adriatic Sea.

### Material and methods

Monthly samples were collected with a small beach seine (mesh size 8 mm in outer wings and 4 mm at the bag end, knot to knot) between April 2003 and March 2004, every 4-h over a 24-h period (daily samples were taken at 08.00, 12.00, 16.00h; night samples at 20.00, 24.00, and 04.00h) in the Prapratna Bay, southern Adriatic Sea (N  $42^{\circ}$  48' 58.1"; E  $17^{\circ}$  40' 50.6"). Sampling depth ranged from 2.5 to 0 m. The substratum is clean sandy bottom sporadically overgrown by *Cymodocea nodosa* beds. Collected material was kept on ice and returned to the laboratory for identification. Species were identified according to [3]. Data were analysed using PRIMER [4]. Data were transformed for presence/absence and the Bray-Curtis similarity matrix was used to generate a 2-dimensional plot with the non-metric multidimensional scaling (nMDS) technique.

#### Results

Over the sampling period a total of 51802 individuals and 55983.27 g of fishes, belonging to 24 families and 58 species, were caught. The dominant species with respect to both numbers (57.21%) and weight (49.90%) were Boops boops. Except in April, the greater numbers of species were caught during night and there was also a significant higher number of individuals (p=0.002) and biomass (p=0.031) during night. Boops boops (57.21%), Atherina boyeri (19.70%), Sardina pilchardus (6.82%) and Sarpa salpa (6.60%) made a significant contibution to the overall number of individuals (92.48%) or biomass (70.56%). With respect to both numbers of individuals and biomass Boops boops, Pagellus acarne, Sarpa salpa, Atherina boyeri had higher catches during night and Mullus barbatus during day. The other species did not show any strong diurnal or nocturnal tendency in catches. Community parameters fluctuated during the diel period and was higher during the daytime. Results of the ANOSIM test for the two-way crossed analysis showed that there was significant difference in species assemblages among seasons ( $\rho_{av}$ =0.118, P=0.017), but there was no significant difference in those catches between day and night. The nMDS plot showed that there is a clearly visible overlapping of the day and night samples (Figure 1).

#### Discussion

Diel fluctuations in fish communities are a summation of the diel fluctuations of the component species [2]. Over the diel cycle in the Prapratna Bay, there were fluctuations in both number of individuals and number of species. The dominant species were either primarly diurnal or nocturnal and it is the relative abundance of these species in each period which determines the assemblage structure during day or night. The greater number of species caught at night was similar to that of other studies [5]. However, the greater number of individuals and biomass caught during the night in the Prapratna Bay differs from that in the Azores [2]. Differences in catches between day and night can have a profound effect on the perception of a fish community and it is apparent that a full description of an asemblage or assemblages within an area must incorporate both time periods. The Prapratna Bay fish assemblage is typical of many marine fish assemblages with relatively few species constituting the majority of individuals and biomass [2,5]. In general, the fish assemblage at Prapratna Bay were dominated by juveniles. One might expect that an assemblage with such a high proportion of juveniles may be a nursery area. Shallowwaters are often utilised as nursery areas as they provide suitable food, shelter and reduction in predation [1,2,5].

## Abstract

Analysis of literature information and the examination of decapod collections permitted the creation of updated checklists of the decapod species from Cyprus, the south Turkish coast, the Aegean and the Black Seas. These checklists are presented and the decapod faunas of these areas are compared in order to assess the gradient of decapod diversity from Cyprus towards the Black Sea. As it results from this study, there is a decrease in the number of lessepsian decapod species from the south Turkish coast towards the Black Sea, implying an attenuation of the lessepsian immigratory current in this direction.

Keywords : Decapoda, Aegean Sea, Black Sea, Eastern Mediterranean.

#### Introduction

There is a significant body of literature providing information on the decapod fauna of the Eastern Mediterranean [reviewed by 1]. The decapod fauna of this area is also enriched with lessepsian immigrants and with Atlantic tropical species that enter the Mediterranean Sea through the Straits of Gibraltar [2].

The aim of the present study is to provide updated checklists and information on the diversity of the decapod faunas of Cyprus, the south Turkish coast, the Aegean and the Black Seas, and assess the gradient of decapod diversity along these certain areas.

## Materials and Methods

Based on a detailed review of the relevant literature and the examination of large collections of decapods, collected by different kinds of gears, detailed checklists of the decapod species were created for Cyprus, the south Turkish coast, the Aegean Sea and the Black Sea.

#### Results and Discussion

Figure 1 demonstrates the distribution of the decapod species number in the certain territorial areas of the Eastern Mediterranean and the Black Sea. Based on Figure 1, data on the Mediterranean water circulation [3] and geographical aspects, the following considerations can be made:

Cyprus (145 decapod species, 6 of these are lessepsian immigrants): In respect of the Cypriot coasts, the number of decapod species is slightly lower to that reported from the south coast of Turkey. Furthermore, the number of lessepsian decapod species is significantly lower in relation to that reported from the south Turkish coast, although Cyprus is located closer to the Suez Canal. This could be mainly attributed to: a) the reduced sampling effort in this area and b) the fact that the Cypriot coasts are considerably distant from the neighboring continental Asian coasts and are surrounded by very deep waters, which possibly prohibit the lessepsian decapod species to reach this area.

South Turkish coast (152 decapod species, 28 of these are lessepsian immigrants): The number of known decapod species is slightly higher than that of Cyprus. Moreover, the known lessepsian decapod species number in this area is much lower than the respective total Mediterranean number (43). This implies an attenuation of the lessepsian immigratory current in this area.

Aegean Sea (263 decapod species, 12 of these are lessepsian immigrants): The total decapod species number of this region is the highest among the studied areas. This could be possibly attributed to the high diversity and complexity of habitats of the Aegean Sea but also to the more intensive sampling effort that has been carried out in this area. The number of lessepsian decapod species is much lower than that from the south Turk-ish coast, indicating a further attenuation of the lessepsian immigratory current in the Aegean Sea, mainly due to the different hydrographic conditions prevailing in these two regions (e.g., the wider ranges of temperature and salinity of the Aegean Sea).

Black Sea (36 decapod species): The Black Sea demonstrated the lowest species number among the studied areas. This should be mainly attributed to the peculiar oceanographic conditions prevailing in this region, especially the low salinities and temperatures [4]. As it results from the present study no lessepsian decapod species have reached the Black Sea.

Fig. 1. Known decapod species number in the certain geographical areas of the eastern Mediterranean and the Black Sea. The black part of each column represents the number of lessepsian decapod species known from the certain area. The arrow indicates the movement of the lessepsian decapod species and its width in each area is proportional to the lessepsian species number that has reached this region. At the area of the Suez Canal, the number 43 represents the total number of lessepsian decapod species reported so far from the Mediterranean. CY, Cyprus; ST, South Turkish coast; AS, Aegean Sea; BS, Black Sea.

# LENGTH AND GROWTH PARAMETERS OF SCALDFISH (*ARNOGLOSSUS LATERNA* (WALBAUM, 1792)) IN IZMIR BAY, AEGEAN SEA

D. Uckun Ilhan , S. Akalin , O. Ozaydin , Z. Tosunoglu , S. Leblebici \*, E. Uluturk Ege University, Faculty of Fisheries, 35100, Bornova, Izmir, Turkey - dilek.uckun@ege.edu.tr

## Abstract

Length frequency distribution and growth parameters of the scaldfish (*Arnoglossus laterna* (Walbaum, 1792)) were investigated based on samples collected monthly in Izmir Bay (Aegean Sea) between January 2005-May 2006. Fork length and total weight ranged from 4.5 to 14.9 cm and from 0.68 to 24.53 g respectively. The length-weight relationships were W=0.0081\*L<sup>2.986</sup>, W=0.0093\*L<sup>2.925</sup> and W=0.0087\*L<sup>2.949</sup>, and the von Bertalanffy growth parameters were  $L_{\infty}$ =16.34, 14.07 and 16.70 cm; k=0.388, 0.212 and 0.392 t<sub>0</sub>=0.502, 0.980 and 0.494 for females, males and sexes combined, respectively.

Keywords : Aegean Sea, Fishes, Growth.

## Introduction

The scaldfish, *Arnoglossus laterna*, is a small bothid flatfish whose geographical distribution extends from the Black Sea and the Mediterranean along the west coast of Europe to Norway [6]. It is a bentic species which extends from the shallow sublittoral zone down to about 200 m. The biology of scaldfish was investigated by Gibson and Ezzi [3] on the west coast of Scotland. Deniel [2] studied its growth in Brittany. Karakulak et al. [4] and Çiçek et al. [1] examined its length-weight relationship in Northeastern Mediterranean and Aegean Sea, respectively. The present study provides preliminary information on the biology of scaldfish in Izmir Bay.

### Materials and Methods

A total of 1274 specimens were caught during trawl surveys carried out monthly between January 2005 and May 2006 in Izmir Bay. Individuals were measured in mm (fork length, FL), and weighed to the nearest 0.01 g (total weight, W), and dissected in the laboratory. Sex and maturity stages were determined macroscopically. von Bertallanfy growth parameters  $L_{\infty}$  and k were estimated by analyzing monthly length frequencies with the ELEFAN I routine incorporated in the FISAT II Software. to was estimated using the empirical equation of Pauly (7) for growth fitting; Log ( $-t_0$ ) = (0.03922) - 0.2752 logL $\infty$ -1.038 log k. The length-weight equation, W=a.L<sup>b</sup>, was estimated [8], where W is the total weight (g), L is the total length (cm), and a and b are the regression coefficients. Growth performance index (logk +  $2log_{\infty}$ ) values were computed with FISAT II software.

#### Results and discussion

The sex composition for the 1274 specimens sampled was 25.31% females, 43.42% males and 31.27% undetermined sex. Females ranged from 6.0 to 14.9 cm in size and from 4.8 to 13.5 g in weight. Males ranged from 4.8 to 13.5 cm in length and from 0.78 to 22.88 g. The most abundant size class was 8 cm and 9 cm for females and males, respectively (Figure 1).

Fig. 1. Montly length frequency distributions of scaldfish in Izmir Bay.

The von Bertalanffy growth parameters for females, males and combined sexes were:  $L_{\infty}$ = 16.34 cm, 14.07 cm and 16.70 cm; k= 0.388, 0.212 and 0.392 year<sup>-1</sup>, t<sub>0</sub>=0.502, 0.980 and 0.494 years. The length-weight reationships were: W=0.0081\*L<sup>2.986</sup>, W=0.0093\*L<sup>2.925</sup> and W=0.0087\*L<sup>2.949</sup>, for females, males and sexes combined respectively. Positive allometric growth was observed in all cases. The growth performance index was 2.015, 1.623 and 2.039 for females, males and sexes combined, respectively.

Length-weight relationships for different studies are shown in Table 1. The b values in the present study are lower than those in Italian waters.

Tab. 1. Length - weight relationship coefficients of scaldfish in different localities.

| Т                       |                                           | 877 | 0.0087     | 2.949 | 0.980 |

N, number of specimens; a, intercept of the relationship; b, slope of the relationship; r, corelation coefficient.

The  $L_{\infty}$  values were 16.34 cm and 14.07 cm for females and males. For the West Coast of Brittany Deniel [2] calculated  $L_{\infty}$  values as 15.8 and 15.2 cm. When we compare the growth performance index values estimated in the present study with those from other studies, our data (2.015 and 1.623) are lower than those reported by Deniel [2] (2.322 and 2.377).

## Abstract

Diel variability in bottom trawl catches carried out by R/V K. Piri Reis during two 24-h surveys conducted in 1-2 and 30 September 1999 in the Edremit Bay (North-eastern Aegean Sea) were analysed. Maximum total catch was observed in the early morning and tended to decrease progressively towards the night period in 1-2 September 1999. While small variations were observed in total catch rate during the day, the minimum catch was observed at midnight in 30 September 1999.

Keywords : Trawl Surveys, Fish Behaviour, Aegean Sea.

Trawl surveys are used worldwide to estimate the abundance of demersal fish species [1]. Efficiency of trawl surveys depends on the ability of the gear to catch the available fish and further, the availability of target species to the trawl [2]. The occurrence and distribution pattern of a species in a given habitat depend on factors such as food availability, salinity, temperature, time of the day, and light intensity. These factors may change throughout a 24-h period [3]. Consequently, studying diurnal variation in bottom trawl catches, allow us to understand behavioural ecology of demersal organisms and also to estimate the abundance more accurately. This is the first study to examine diel variation in the bottom trawl catches from the Eastern Aegean Sea.

Trawl catch data were collected with R/V K. Piri Reis during two 24-h surveys conducted in 1-2 and 30 September 1999 in the Edremit Bay (North-eastern Aegean Sea). This particular area has been closed for commercial trawlers since 1995. In each survey, a total of 8 trawls were hauled consecutively in the same area with 3 h intervals at depths from 40 to 80 m. Trawl duration was 20 min but standardised to 1 h for subsequent calculations and evaluations.

Hake, *Merluccius merluccius*, red mullet, *Mullus barbatus*, and poor cod, *Trisopterus luscus capelanus*, were the dominant fish species in most of the trawl compositions. They were also the main target fishes for the demersal trawl fishery in the region.

A total of 46 species were sampled during 1-2 September 1999. Hake (20.7%, mean: 5.8 kg/h, min: 1.3 kg/h, max: 10.3 kg/h and SD: 3.14 kg/h), red mullet (11.5%, mean: 3.2 kg/h, min: 0.4 kg/h, max: 6.0 kg/h and SD: 2.35 kg/h), and poor cod (7.05%, mean :1.96 kg/h, min: 0.91 kg/h, max: 3.47 kg/h and SD: 0.85 kg/h) constituted 39.2% of the total catch during the 24 h sampling survey period. Total catch rate varied between 8 and 56 kg/h. Maximum total catch rate was observed in the early morning and tended to decrease progressively towards the night period (Fig 1).

Fig. 1. Diel variations in catch rates on 1-2 September 1999.

In 30 September, 50 species were caught in the sampling area. Hake (32.9%, mean: 21.6 kg/h, min: 11.3 kg/h, max: 29.7 kg/h and SD: 5.56 kg/h, red mullet (13.5%, mean: 8.9 kg/h, min: 4.4 kg/h, max: 15.9 kg/h

and SD: 2.35 kg/h), and poor cod (5.1 %, mean: 3.3 kg/h, min: 1.9 kg/h, max: 5.5 kg/h and SD: 1.11 kg/h) constituted 51.5% of the total catch. Total catch rate was higher than the previous sampling and ranged between 31 and 80 kg/h. Small variations were observed in the total catch rate during the day period (Fig 2). A similar distributional pattern was also determined for the dominant fishes, especially for hake.

30 September 1999

Fig. 2. Diel variations in catch rates on 30 September 1999.

# Abstract

Monthly changes in zooplankton abundance, biomass and taxonomic composition off Sinop (southern Black Sea, Turkey) were studied during January 2003-December 2004. Cladocerans, the appendicularian, the chaetognath and copepod *Centropages ponticus* dominated the autumn and summer communities, whereas meroplankton and the other copepod species were more pronounced in winter and spring months. Copepods were the most abundant zooplankton group in 2003, whereas *Noctiluca scintillans* was the most dominant species in 2004.

Keywords : Black Sea, Zooplankton, Biomass.

Zooplankton is the principal trophic link between primary production and higher trophic levels, (i.e. in many cases the fish), and hence studying their abundance and distribution is important [1]. In the southern Black Sea, there are only a few published studies about distribution of zooplankton population, and regular annual studies only made after the year 1990. In comparison with the other basins in the Black Sea, even less work has been devoted to the plankton of Sinop region [3]. This study aims to evaluate seasonal mesozooplankton structure of the southern Black Sea.

The sampling station  $(35^{\circ} \ 09' \ 32"E-42^{\circ} \ 00' \ 21"N)$ , a mile off-shore off Sinop (southern Black Sea, Turkey) having a 50 m bottom depth, was sampled monthly from January 2003 (except August 2003) to December 2004. The sampling of the zooplankton was carried out from 50 to 0 m (surface) for vertical tows using plankton net (50 cm diameter mouth opening and 210 mm mesh size) with the "Arast Irma" research vessel. The samples were preserved with borax buffered formalin solution (final concentration 4%). The analyses of samples were carried out using sub-samples with a Stempel pipette. The results were then averaged and extrapolated to the whole sample. Biomass transformations were based on wet individual weights [2].

In the present study, the annual total zooplankton ranging between was 4800 - 204 500 ind.m<sup>-2</sup> in 2003 and 13 300 - 198 900 ind.m<sup>-2</sup> in 2004. In terms of either in abundance and biomass the highest values were recorded in February, April, September and November 2003; May and August 2004. Zooplankton biomass showed a clear peak in May 2004, mostly due to the dinoflagellate *Noctiluca scintilans*.

Copepods (maximum: 172 200 ind.  $m^{-2}$ ) of annual abundance was the dominant group in 2003. *N. scintillans* was the most abundant of zooplankton group with a share of 49.6% (max: 172 000 ind.  $m^{-2}$ ) in 2004. All mentioned groups exhibited clear seasonality. This was especially apparent for cladocerans and appendicularian; which occurred in autumn, and for meroplankton, which were more abundant during spring months. *S. setosa* showed a summer-autumn distribution which closely coincided with the pattern of appendicularian and cladocerans. Amongst cladocerans, *Penilia avirostris* was dominant during summer and early autumn.

In this study, six copepods species were identified. Surprisingly, there were no *Acartia tonsa* in subsamples. *Acartia clausi* (65% in 2003 and 43% in 2004) was the most dominant copepod which was followed *Pseudocalanus elongatus* by in two years. *Acartia clausi* showed its remarkable existence in November 2003 and August 2004. *Calanus euxinus*, *P. elongatus*, *Oithona similis* and *Paracalanus parvus* was more pronounced cold months and *Centropages ponticus* was distinct summer and early autumn.

In this study, we observed that there was no significant alterations between the annual temperature mean changes within 2003-2004 (P>0.05). This situation reflected stable composition biomass and abundance of zooplankton between the years. Except Appendicularian, there were no statistically significant differences in abundance of different mesozooplankton groups between two consecutive years. It is especially interesting to note the dramatic decline in the abundance of all zooplankton groups in the period of peak *Noctiluca*. Same situation was observed by Unal (2002). We expect that these results will have importance in explaining oscillations in plantivorous fish catches from the region.

# DENDROPOMA PETRAEUM (MONTEROSATO, 1884): A MEDITERRANEAN SPECIES COMPLEX BASED ON REPRODUCTIVE CHARACTERISTICS?

Sima Usvyatsov

Israel Oceanographic and Limnological Research. Shikmona, P.O.B. 8030, Haifa 31080, Israel - simau@ocean.org.il

# Abstract

The reproductive characteristics of the northern Israeli population of the Mediterranean endemic reef-building gastropod *Dendropoma petraeum* were examined. The species is apparently gonochoristic, with a peak of gonad activity from October to May. In June only hatching was observed. Histological examination revealed hermaphroditism and males with parasitic infestation. The characteristics studied (female/male ratio, gonad activity period, size and number of egg capsules and number of eggs per capsule) are markedly different from those reported from Spain.

Keywords : Endemism, Gastropods, Levantine Basin, Reproduction.

The reef-building vermetid *Dendropoma petraeum* (Monterosato, 1884), a species endemic to the Mediterranean Sea, forms dense aggregations along the northern shores of Israel. These reefs protect the shoreline from erosion by waves and support a high biodiversity community [1]. During the 1960s and 1970s living *Dendropoma* mollusks constituted 30% of the reefs [1], whereas current estimation is 1% for most of the sites (Galil, unpublished). We set out to continue and expand prior research on the reproductive period of the mollusks and their fecundity.

A total of 285 specimens of *D. petraeum* were collected in Shikmona  $(32^{\circ}49'N, 34^{\circ}57'E)$  from January 2003 to May 2004, in monthly or bimonthly intervals. The samples were divided according to their reproductive stages: resting phase, maturation, active mature and degenerating gonad.

900 egg capsules were harvested in April and June 2003 and analyzed for size, number of embryos/eggs and the developmental stages of the embryos.

Of the 285 mollusks collected, 152 were females, 106 - males, 22 were unidentifiable and 5 were hermaphrodites with developed gonads of both sexes (Fig. 1). In 7 females captured sperm mass was identified within the mantle cavity. In 12 males it was observed that the retained spermatozoa degenerated to dense balls within the testes, half of them were parasitized. Mature males were found from October to May, mature females from December to May. In June no gonad activity was observed, though embryo maturation continued within the female mantle cavity. The resting phase lasted from late June to September, with the gonads degenerating, and histological sex recognition impossible.

Fig. 1. A hermaphroditic gonad, showing oocytes (A) and spermatozoa (B).

Mean capsule size in April 2003 was  $0.91 \times 0.7$  mm, in June 2003 -  $0.99 \times 0.74$  mm. Up to 17 egg capsules per female were recorded (mean=4.67), containing a maximum of 10 eggs/embryos (mean=2.3), see example in Fig. 2. In April the capsules contained pre-hatchlings (24% of embryos), veligers (24%), trochophores (31%) and ova (21%). By comparison, in June the pre-hatchlings constituted 93% of the embryos, veligers - 6%, trochophores - 3% and no ova were observed. The data indicate a single period of reproductive activity. Gonad maturation in males and females began simultaneously. Males matured earlier than the females, since oogenesis proceeds slower than spermatogenesis. We recorded larger capsules, more eggs/embryos per capsule and less capsules brooded simultaneously than described for the Spanish population of *D. petraeum* [2]. Moreover, the female/male ratio is lower and the repro-

ductive period in Israel, though of same duration, began in October rather than March. The temperature difference between Israel and Spain may be offered as an explanation. However, these findings also strengthen the hypothesis of a genetic difference between the two populations, reported in [3].

## Abstract

The spatial variation in population density of the edible ascidian *Microcosmus sabatieri* Roule, 1885 was studied in the Dodecanese complex (south Aegean). Sampling included the random collection of specimens during a 50 min dive with SCUBA apparatus. Mean population density was  $156 \pm 53$  individuals/20-min. Additionally we examined its genetic polymorphism using RAPD markers. Data imply high genetic diversity between populations with a rather complex clustering of a southeastern to northwestern pattern in the Aegean Sea. Thus, its fishery should be treated as complicated stocks, which respond independently to exploitation. *Keywords : Aegean Sea, Genetics, Population Dynamics, Stock Assessment.* 

#### Introduction

Ascidians are among the most important members of the benthic assemblages in the Mediterranean Sea. *Microcosmus sabatieri* Roule, 1885 is an endemic species known from Adriatic and Western Mediterranean basin. It is an edible and of commercial interest species in many Mediterranean areas. However, few data exist on its population structure and even fewer in the South Aegean [1]. This study presents preliminary data on spatial variation of its population density in South Aegean, where it has been traditionally harvested. We also determined its genetic structure using RAPD fingerprinting [2]. The results were used to investigate the differentiation between six Aegean populations and provide information to assist management and conservation on this marine species. No studies on genetic structure of the species in question are available in the bibliography.

Fig. 1. Spatial population density of *M. sabatieri* over nine sampling sites in the Dodecanese complex.

#### Materials and Methods

In the south Aegean, overall sampling of 1,513 specimens was carried out with SCUBA diving at nine coastal stations (Fig. 1), at depths between 20 and 60 m in September 2005. Specimens of M. sabatieri were randomly collected during a 50 min dive and counted in the field with a tapeline to the nearest mm (total length of the tunic and maximum diameter of the tunic). Population density was estimated as the number of individuals collected per 20 min dive (N/20-min). The null hypothesis of no significant differences in the mean length (or diameter) of M. sabatieri specimens among stations was tested with one-way ANOVA, after an initial logarithmic transformation of the data to meet the assumption of the analysis. Seventy eight (78) samples from Astypalea Island along with 28 from Trikeri (central Aegean), 61 from Platanias (central Aegean), 20 from A. Nikolaos (central Aegean) and 27 from Maliakos Gulf (central Aegean) were used for the genetic screening. Eight RAPD primer markers were found to produce well-amplified and reproducible electrophoretic bands. In total 22 loci were observed and scored. Genetic statistical indeces were calculated according to [2].

#### Results and Discussion

Mean population density, over all sites, was  $156 \pm 53$  individuals/20-min. Increased stocks were found at three stations (St1, St3, St8), while at St4 and St7 few specimens were caught (Fig. 1). One-way ANOVA showed significant spatial differences on mean tunic length (F=9.82 p<0.05) and diameter (F=10.99 p<0.05). Both characters varied in a similar way, showing maximum values at St4 and St6 and minimum at St2. Large sized specimens were also caught from St1, St3 and St5, while the specimens from St7, St8 and St9 were smaller, for both dimensions. Total  $H_e$ =0.499 was higher, but not statistically significant, than  $H_o=0.311$ , implying a heterozygote deficit on the sampled populations. Total  $F_{IS}$ =0.492 was high enough and statistically significant on the  $P_{99}$  criterion, indicating a possible presence of local sub-populations. Studied populations either do not follow Hardy-Weinberg law, or are not yet in genetic equilibrium, so there is evidence to reject random mating within them. Total  $F_{ST}$ =0.286was high enough and pairwise  $F_{ST}$  values were statistically significant for all populations at all loci on the  $P_{99}$  criterion. Data imply high genetic diversity among populations, since a quite low  $N_m$ =0.046 migrants per generation, was observed. Furthermore, one could observe a rather complex, but not statistically significant, clustering pattern of southeastern to northwestern populations in the Aegean Sea, by using the stepwise method [3]. Even if fishing pressure becomes intensive, natural stocks of *M. sabatieri* tend to recolonize the substratum from deeper populations; in any case its high local population diversity is preserved.

# EVALUATION OF THE PERFORMANCE OF FISHERY INDICATORS IN THE AEGEAN SEA

Vassiliki Vassilopoulou \* and John Haralabous

Hellenic Centre for Marine Research, Hellenikon 16777, Athens, Greece - celia@ath.hcmr.gr

## Abstract

Fishery indicators were calculated from data derived through a monitoring program of trawl catches from 1995 till 2005 in the Aegean Sea. Size-based indicators were highly correlated with each other and with the mean trophic level of the demersal assemblages of the study area. Mean trophic level seemed to constitute a useful indicator since it offered powerful detection of existing trends with sampling sizes of a relatively smaller time interval.

Keywords : Bio-indicators, Fisheries, Demersal, Eastern Mediterranean.

Trawlers have dramatic effects on the ecosystem including physical damage to the seabed and the degradation of associated communities, the overfishing of demersal resources, and the changes in the structure and functioning of marine ecosystems derived from the depletion of populations and the huge amount of by-catches and associated discards. In the Mediterranean, bottom-trawling fisheries are essentially multi-species, carried out in a wide range of depths and affecting different bottoms and communities. Moreover, the large number of landing harbours makes it difficult to gather long and reliable series of trawl fisheries data, which are necessary for the development of appropriate indicators contributing to track the impact of trawling on the ecosystem. In this study we discuss the performance of fishery indicators calculated from data derived through a monitoring program of observers recording catches on-board commercial trawlers during an eleven years period in the Aegean Sea. The aim is to evaluate which are more powerful in detecting trends on the state of demersal fish assemblages in eastern Mediterranean waters, being thus more useful for monitoring community/ecosystem changes.

From 1995 to 2005, on a seasonal basis, observers on-board commercial trawlers followed fishing operations and recorded data from hauls in the central Aegean Sea, considered to be among the most important fishing grounds for trawl fisheries in Greece. In a representative sample from each haul, the various species were sorted out, the number of individuals per species and their total weight were noted, while total length of each individual was also recorded. Based on these data three of the so-called size-based indicators, i.e. the mean length, the mean weight, as well as the mean maximum length of the Aegean demersal assemblages, were calculated in each haul. Then, the mean trophic levels were estimated by assigning trophic levels to individuals of the various species on the basis of their length, using relationships between length and trophic level as determined by [1]. Finally, Hill's first and second diversity numbers (i.e. N1 and N2: [2]) were used as overall measures of species diversity, as they are less sensitive to the dominant species and to the sampling effort. The overall performance of the indicators was evaluated through correlation analysis and power analysis [3].

Tab. 1. Pearson correlation coefficients between all indices' time series in the Aegean Sea.

\*\*. Correlation is significant at the 0.01 level (2-tailed).

\* Correlation is significant at the 0.05 level (2-tailed).

From Table 1 it is obvious that most indicators are positively correlated to each other. Highly significant positive correlations existed between the various pairs of size-based indicators, as well as between the mean trophic level and each of the size indicators. For powerful detection of a relatively small ecosystem change (<5% of the mean value of the series) a sample exceeding 20 years is needed for all indicators calculated in the present study except for the mean trophic level; the latter appeared to offer powerful detection of possible trends with sampling sizes covering smaller time intervals (Fig. 1). It should be noted, however, that no single tropho-dynamic indicator can track the complexity of the possible changes in fisheries and ecosystems and any change must be interpreted in the light of other complementary indicators. In fact, the present study based on data of a rather limited spatio-temporal coverage could be considered as indicative and has a preliminary role, while the clarification of the observed patterns will be derived only through long-term retrospective analyses, which would also allow correct interpretation of possible trends.

Fig. 1. Power versus sample size (in years) of all indicators' time series in the Aegean Sea. The hypotheses tested a detection of a linear trend (in terms of absolute value of slope)  $\leq 5\%$  of the mean value of the series.

# OYSTER TRANSFERS: A MAJOR VECTOR FOR MACROPHYTE INTRODUCTIONS

Marc Verlaque <sup>1</sup> \*, Charles François Boudouresque <sup>1</sup> and Frédéric Mineur <sup>2</sup>

<sup>1</sup> UMR 6540, COM - Luminy, 13288 Marseille, France - verlaque@com.univ-mrs.fr

<sup>2</sup> Queen's University ofBelfast, Belfast, U.K.

# Abstract

Oyster transfers, as a vector of primary introduction and secondary dispersal of exotic macrophytes, were assessed on the basis of (i) two major French aquaculture sites: the Thau Lagoon and the Arcachon Basin; (ii) a bibliographical analysis of 34 Mediterranean coastal lagoons; and (iii) an experimental simulation of oyster transfers. The resultsconfirmed the tremendous efficiency of the vector. The oyster trade is by far the main vector of macrophyte introduction into the Mediterranean Sea, ranking above the shipping and the opening of the Suez Canal.

Keywords : Algae, Aquaculture, Lagoons, Strait Of Messina.

#### Introduction

Transfers of oysters for aquaculture purposes (both importation from exotic areas and livestock transfer between basins; i.e. primary and secondary vectors) have resulted in the introduction of a number of pathogens, parasites and pests [1]. Elton argued that 'The greatest agency of all that spreads marine animals to new quarters of the world must be the business of oyster culture' [2]. 46 % of the exotic marine species in northern Europe and 20 % in Australia probably arrived via oyster imports [3]. However according to [4], shellfish transfers rank below shipping (hull fouling and ballast waters) for the introduction of species. As a part of the European ALIENS program, we investigated the shellfish transfer vector (http://www.uniovi.es/ecologia/aliens/E-aliens.htm).

#### Results

In the Mediterranean, Crassostrea gigas production is wholly dependent on spat or adult importation. In France, massive importations from the northern Pacific occurred during the 1970s. Nowadays, only the spat produced in the NE Atlantic is authorized, but livestock transfers between basins frequently occur to ensure an optimum growth.

In the Thau Lagoon (Mediterranean), 25 % (57 taxa) of the total number of macrophyte species were identified as introduced. Introduction by shipping, via the harbour of Sète, is likely for only a few species. 89% of taxa may originate from the northern Pacific, introduced either directly via importation or indirectly via shellfish transfers (fixed on oysters, mussels, clams and the packing materials) from other aquaculture basins.

In the Arcachon Basin (NE Atlantic), 19 exotic macrophytes were identified [5]. Oyster transfers to and from the other European basins regularly occur [6]. Again, with the exception of the oldest introductions for which shipping cannot be ruled out as a vector, shellfish transfer and the Pacific appear as the most probable vector and origin, respectively, for introduction.

In the 34 Mediterranean coastal lagoons we studied, 67 exotic macrophytes (78% from the Pacific and 94% via shellfish transfer) have been reported, with the lowest number  $(1 - 2 \tan a)$  in the lagoons without aquaculture facilities, and the highest in the major aquaculture basins: Mar Piccolo (10 taxa), Salses-Leucate (11 taxa), Venice (25 taxa) and Thau (57 taxa).

The experimental simulation of transfer showed that oyster shells cleaned out (visually without epibionts) can still bear a high diversity of viable native and exotic macrophyte propagules (41 and 16 taxa, respectively). The abundance of propagules may be due to the fact that after cleaning, the oysters are re-immersed for two weeks before each transfer.

#### Discussion and conclusion

The ALIEN program has evidenced oyster transfer as the most efficient vector for macrophyte introduction into the Mediterranean. In addition, our census probably represents only the tip of the iceberg because the exotic cryptic species and gene introductions from remote populations are very difficult to detect. The conditions of livestock transfers appear as very favorable for the survival of the organisms with fewer constraints hindering the introduction than for the other vectors (hull fouling, ballast waters, Suez Canal) [7]. Within Europe, large amounts of shellfish are being transported from one basin to another and the European authorities even encourage this practice [1]. However, the inadequacy of current legislation is such that these transfers still result into species introductions. The adoption of comprehensive guidelines for preventing the introductions [8,9].

Guidelines to reduce the unintentional introductions by shellfish aquaculture.

- Awareness of farmers concerning the risks associated with uncontrolled importation has to be increased.

- Aquaculture has to be based on native, local stock whenever possible. Imports and transfers of livestock have to be minimized, thoroughly inspected, and quarantined for an appropriate observation period.

- Special attention has to be paid during aquaculture trials with new exotic species (even with livestock from hatcheries).

- Non-native livestock for introduction has to be produced in hatcheries.

- Live products destined for consumption, processing, and aquarium or display must not be placed into the natural environment.

- In the case of livestock transfers (including interregional ones), decontamination processes and/or quarantine as proposed by ICES have to be followed.

- Efficient treatments (e.g. hot-seawater for oysters) to avoid introduction or secondary dispersal of exotic or native species have to be carried out prior to each transfer, i.e., after the period of re-immersion preceding the transfer, and have to be repeated on arrival.

# THECOSOME PTEROPOD ON THE BOKA KOTORSKA BAY (SOUTHERN ADRIATIC)

Vera Vukanić

Laboratory of Zooplankton Ecology, 85330 Kotor, Montenegro; Faculty for Applied Ecology, Singidunum University, Bul. Kralja Aleksandra 79, 11000 Belgrade, Serbia - v\_vukanic@yahoo.com

# Abstract

Thecosome pteropods were collected monthly since 2003 at seven stations with different hydrographic characteristics at Boka Kotorska Bay in Southern Adriatic. At the same time the basic ecological parameters were measured. This paper presents the first data on thecosome pteropods in Boka Kotorska Bay. We recorded 7 species: *Cymbulia peroni* Lamarck, *Creseis acicula* Rang, *Creseis virgula* (Rang), *Limacina inflata* d'Orbigny, *Limacina bulimoides* d'Orbigny, *Pneumodermopsis conephora* Pruvot-Fol i *Atlanta helicinoides* Souleyet. *Keywords : Adriatic Sea, Zooplankton.* 

### Introduction

Thecosome pteropods were not previously studied at Boka Kotorska Bay, so the data presented in this paper are the first for this group in this biotope. [5] in epipelagial, at two stations 3NM and 10NM in front of entrance to Boka Kotorska Bay, recorded 6 species with the percent participation of 0.63% in total zooplankton. [3] cites 10 species and their percent participation in eastern coastal waters of Adriatic. The dominant species was Creseis acicula with participation of 94.3% in total the cosome pteropod fauna for the studied period. [1] in the vicinity of Dubrovnik recorded 12 species, while in mid January Limacina inflata, Creseis virgula and Creseis acicula had more than 85% of participation in total pteropod fauna. [2] recorded 10 species of the cosome pteropods in waters of deep Southern Adriatic during the yearly cycle of 1993/94, with a great abundance in April 1993 and June 1994 in euphotic zone (0m-100m), matching the large concentration of Chl a. The pteropods seem to be characterized by great variability; they may appear in large numbers in plankton or completely disappear [4].

#### Material and Methods

Our observations were based on the analysis of zooplankton samples collected monthly during 2003 on three shallow stations near the seafood farming areas (P-M, P-O and P-IBM) and 4 stations in the middle of each bay within Boka Kotorska Bay (P-1, P-2, P-3, P-4 or Kotor, Risan, Tivat and Hercegnovi bays, respectively). Zooplankton was collected with Nansen net (100 and 150 microns). In the same time, other factors were measured: T  $^{\circ}$ C, Sal psu, pH, O<sub>2</sub>, transparency by Secchi plate, color of the sea with Forel scale I-XXI. Zooplankton samples were used to determine presence and abundance of the cosome pteropod in all research stations.

## Results and Discussion

The studies have shown that Boka Kotorska Bay is a specific biotope in the southeastern part of Adriatic. That specificity is caused not only by the geographic position but also by special biotic and abiotic environmental factors. Living conditions at Boka Kotorska Bay are very different than those at the open sea. The basic ecological factors (temperature, salinity and density) are under a strong influence of hydrometeorological conditions, which are specific and susceptible to numerous local changes. This has an important role impacting life histories and distribution of organisms. Boka Kotorska Bay shows characteristics of a shallow closed sea at the eastern coastline of Adriatic. At one hand it is influenced by influx of fresh water from surrounding mainland (coastal rivulets and springs at the sea bottom), and on the other hand it is under impact of open sea which is indicated by hydrographic and planktological data. According to the collected data and citations by other authors, Boka Kotorska Bay is not a homogenous area in thermal sense. The maximal temperatures were recorded in July and minimal in January. Data on salinity clearly indicate the strong influence of influx of fresh water, especially in the surface layer and in shallow habitats along the shore.

Thecosome pteropods were not previously studied at Boka Kotorska Bay, so the data presented in this paper are the first for this group in this biotope. We have recorded 7 species: *Cymbulia peroni, Creseis acicula, Creseis virgula, Limacina inflata, Limacina bulimoides, Pneumodermopsis conephora* and *Atlanta helicinoides*.

*Limacina inflata* d'Orbigny was the most abundant, with maximums in April and July. It was recorded throughout the year at all the stations, and its percent participation in the group was 70.6%.

*Limacina bulimoides* d'Orbigny is represented at all the stations throughout the year, and its percent participation in the group was 27.1%. Abundance maximum was recorded only in July.

*Limacina inflata* and *Limacina bulimoides* are the most abundant species of the cosome pteropods during the study at Boka Kotorska Bay, and their percent participation in the group is 97.7%.

*Cymbulia peroni* Lamarck was recorded in vicinity of the Institute (P-IBM) at Bay of Kotor in May, as several specimens. *Creseis acicula* Rang, known as a species appearing in warmer period of the year, was not very abundant in the study year, and its participation in total pteropod fauna was 1%. *Creseis acicula* is the commonest pteropod and at the same time one of the commonest species of Adriatic Sea [3].

Following species were recorded sporadically, in insignificant numbers or as single individuals: *Creseis virgula* (Rang), *Pneumodermopsis conephora* Pruvot-Fol and *Atlanta helicinoides* Souleyet.

Percent participation of the cosome pteropods when compared to other groups of zooplankton was: at Bay of Kotor 0,08%, at Bay of Risan 0,39%, at Bay of Tivat 0,94% and at Bay of Herceg Novi 1,15%.

The regularity observed in horizontal distribution of the cosome pteropods was in increase in number of species and biomass longitudinally from the inner waters of the Bay (Bay of Risan and Bay of Kotor) toward the outer stations under the direct influence from the open sea (Bay of Tivat and Bay of Herceg Novi).

## Abstract

Based on the correlation between cetacean distribution patterns and oceanographic features, this paper opens discussions about possibilities to define multidimensional pelagic habitats in order to link these discussions to the ongoing debate about the efficiency of Marine Protected Areas as a tool for conservation, and proposes ways to proceed towards marine biodiversity conservation. *Keywords : Cetacea, Biodiversity, Food Webs, Pelagic.* 

The effectiveness of the IWC pelagic protected areas for whales has been recently questioned by Gerber et al. [1]. On the basis of existing knowledge about marine protected areas and cetacean biology, they point out four main limitations: arbitrary boundaries, narrow focus, lack of an adaptive population design and needs for baseline. The multidimensional nature of the problems related to marine environment protection needs a multidimensional approach to be understood and solved [2]. The typical solution in the ocean governance is to establish boundaries, mainly from legal perspective, because the clarity of boundaries would improve governance. Unfortunately, from an ecological point of view, this is a frustrating task due to the high variability of the omni-directional relationships among ocean habitats, species, land and atmosphere. These aspects are enhanced in the pelagic environment because its stability can be evaluated only through long term global scale measures of its dynamic structured habitats.

One possible solution could be to identify one or more species which food web can summing up the results of all the derived effects from the natural and anthropic induced variability of the pelagic environment. Obviously this group of species have to be long living, high-level predators, high biomass consumers with high energy budget needs: cetaceans seems to be the most suitable group of marine organism for this purpose. To evaluate this hypothesis, the relatively small pelagic domain of the Mediterranean Sea because of its oceanographic features, large cetacean populations and strong human impact, could be a reliable test to establish dynamic pelagic protected areas for several reasons.

The total area of the Mediterranean is more than  $3.000.000 \text{ km}^2$  (including the Black Sea). Because of the limited extension of the continental slope, the pelagic domain covers about 70%, corresponding to 96% of the total water volume. The Mediterranean Sea is a mid-latitude partially enclosed sea but, even if semi-isolated, can be considered an oceanic system. Processes which are fundamental to the general circulation of the world ocean also occur within the Mediterranean, identically or by analogous mechanisms.

The Mediterranean Sea exchanges water, salt, heat and other properties with the North Atlantic Ocean, which is known to play an important role in the global thermohaline circulation. The effects encompass the Atlantic, Southern, Indian, and Pacific Oceans [3], thus the salty water of Mediterranean origin may affect water formation processes and even the stability of the global thermohaline equilibrium state. The picture of the Mediterranean general circulation which is now depicting is complex, even if the Atlantic water jet is the main basin scale feature, from Gibraltar to the Levantine, with its instabilities, bifurcations, and multiple pathways, also cold wind stress, intermediate heat fluxes and other hydrodynamic movements, due to freshwater income and to evaporation loss, contribute to the general circulation pattern [4].

Too rough generalisations on oligotrophy of this flow affected the general believe on the trophic potential of the Mediterranean Sea: nevertheless the presence and abundance of large predators such as cetaceans drives to reconsider the oligotrophy paradigm [5]. Rather recently the classic scheme of marine food webs has been revised and the role of microorganisms has been reconsidered under various aspects: CO2, organic into inorganic, but also as food when they aggregate as rods or in a synergetic action with jelly macroplancton through the water column [6]. Now it is recognised that in some oligotrophic sea bacteria can constitute 70-80% of the biomass.

The abundance of cetaceans in the pelagic Mediterranean incites other consideration related to upper trophic levels than the primary production, particularly about the timing of the energy turn over through the biomass formation and transportation from the surface to the deep bottoms and vice-versa. Hundred thousands tonnes per year of euphausid krill can be consumed by the Mediterranean fin whales and ten thousands tonnes of various pelagic and bathy-pelagic cephalopods are eaten by odontocetes. Thus new ideas about the trophic potential of the pelagic ecosystem have to be developed not only to explain the top predator biomass but also the prey biomass formation and turnover in a relatively short time period.

The bottom morphology and hydrodynamic features of the Mediterranean Sea explain the organic matter flow from the coastal zone to the pelagic one, from the surface to the bottom and from deep waters to the entire water column, but the reasons why the energy flow through the biomass formation is so fast have, in turn, to be sought within the food webs. Mediterranean cetaceans show various degrees of prey selection but, in general, the most abundant species, such as striped dolphin and fin whale, seem to be rather opportunistic, they fully exploit this potential, moving and concentrate time by time where food is abundant. Nevertheless their opportunism has to be better defined because all the Mediterranean cetaceans, with the only exceptions of bottle-nose dolphin (Tursiops truncatus) and common dolphin ( Delphinus delphis), feed on short living species such as ammoniacal cephalopods (Histioteuthis), myctophids ( Diaphus) and glass shrimps (Pasiphaea) moving from the bathyal grounds up to the surface [7]. The effect of the very fast biomass formation by these prey on the energy flow is enhanced through the space by the amplitude of their daily vertical migrations.

These factors affecting the cetacean distribution patterns can be relatively well defined, but are not constant on the time-space domain, as is generally believed. Not always and not everywhere the crossing over of strong temperature gradient (frontal zone) and depth or bottom morphology (slope gradient, canyons, sea-mounts) determine the prey presence and abundance, but when this happens the cetaceans are there, as indicators of a past or actual particular oceanographic and biological condition. Based on the above, to define ephemeral pelagic habitats suitable for protection could be more efficient for conservation than permanent Marine Protected Areas and a way to proceed towards marine biodiversity conservation.

## Abstract

Saurida undosquamis and Synodus saurus had ripe gonads all year round. The spawning season of S. undosquamis is from April to September. For S. saurus, the spawning season is from March to October. Keywords : Demersal, Eastern Mediterranean, Fishes, Spawning.

The lizardfish, *Saurida undosquamis* (Richardson, 1848) has a wide Indo-Pacific distribution from Japan and the Philippines through the Indian Ocean to the Red Sea [1]. The first report in the Turkish Seas was by Kosswing (1951) [2]. *Synodus saurus* (Linnaeus, 1758) occurs in Madeira, the Canaries, Cape Verde, the Mediterranean, and off the Moroccan coast. In the western Atlantic, it is known from Bermuda through the Bahamas and Lesser Antilles (the Leeward Islands) [3]. The objective of this research is to study the spawning season of these two species of lizardfish in Antalya Bay on the eastern Mediterranean coast of Turkey.

Fishes from the present study were randomly collected from the fish markets, bazaars and fishing port of Antalya on a monthly basis between April 2002 and August 2003, but some samples were obtained from the small fishing boats fishing by gillnets/longline due to the bottom trawl being forbidden in Antalya Bay from April to August. Length measurements were made by considering fork length (FL) and a 1 mm. sensitivity fish measuring ruler was used. Also scales with 0,1 g and 0,01 g. sensitiveness were used in measuring whole body weight (W) and the gonads. Sex was established by macroscopic examination of gonads. To determine the spawning season a gonadosomatic index (GSI=(gonad weight (GW)/ (the total fish weight (TW)-GW))\*100) was calculated [3]. Temperatures of sea water values were obtained from the Republic of Turkey Ministry of Environment and Forestry and the Turkish State Meteorological Service. Of the total of 738 specimens of S. undosquamis that were dissected. 437 (59%) were females and 301 (41%) were males. In S. saurus 230 (42%) out of 546 sexed specimens were females and 316 (58%) were males. The spawning season of both species as indicated by the year-round GSI is long [Figure 1].

Fig. 1. Gonadosomatic index (GSI) variation of *S. undosquamis* and *S. saurus* during sampling period, with temperature of sea water

The lizardfish had ripe gonads during the sampling period. The maximum values of GSI of *S. undosquamis* were found between April and September. For *S. saurus*, the maximum values of GSI were determined between March and October.In the present study, the spawning of *S. undosquamis* and *S. saurus* was affected negatively during winter when the temperature decreased in the Mediterranean, although both species had ripe gonads throughout the year [see figure 1]. The intensity of spawning in each month during the sampling period showed that most *S. undosquamis* spawn between April and September. The monthly gonado somatic index

of *S. saurus* revealed that most of this species spawn between March and October. For *S. undosquamis*, the results of this study are similar to the results of many studies about the spawning season [1, 2, 4, 5, 6, 7]. Golani (1993) reported that the spawning season of *S. saurus* was from February to August on the Mediterranean coast of Israel. Sousa et al. (2003) found that the most intensive reproduction period of *S. saurus* was during Spring and Summer in the Azores, and this species had an asynchronous posture. The results of these studies are similar to the results of our study.

# LONG TERM TRENDS IN THE DISTRIBUTION OF *MNEMIOPSIS LEIDYI*, AGASSIZ 1865, IN THE SEA OF MARMARA

Ahsen Yuksek \*, Erdoğan Okuş , I. Noyan Yilmaz and Nazli Demirel

Institute of Marine sciences and Management, Istanbul University, Muskule Sok. No:1, 34116, Vefa, Istanbul, Turkey -

ayuksek@istanbul.edu.tr

## Abstract

The distribution of *Mnemiopsis leidyi* Agassiz, 1865 in the Sea of Marmara was examined in 1995-2006. It has been observed that biomass and abundance of *M. leidyi* decreased sharply at the end of the decade. *Keywords : Sea Of Marmara, Zooplankton, Ctenophora.* 

The ctenophore *Mnemiopsis leidyi* Agassiz, 1865 was introduced to the Black Sea in ballast waters in the early 1980s [1] and adversely affected the Sea of Marmara ecosystem [2]. This study investigated the long term distribution of *M. leidyi* in the Sea of Marmara. Samples were collected at 63 stations in the Sea of Marmara between 1995 and 2005, using a Nansen closing net (1 m diameter, 500  $\mu$ m mesh) vertically. At the end of each tow, the ctenophores were sorted, counted and their volume measured using an Imhoff cone. *Mnemiopsis leidyi* was considered the main reason for the collapse of Black Sea ecosystem in mid 1980s. Its distribution decreased significantly in the years 1995-2005 (Fig. 1). The monthly biomass and average volume of individuals increases in July and reaches its highest values in September (Fig. 1). The number of large individuals was higher in October and November (Fig. 1). The species distribution is usually limited to the upper water layer of the Sea of Marmara.

Fig. 1. A) Abundance and biomass distribution of *M. leidyi* in different years; B) Monthly changes in biomass and average individual volume of M. leidyi.

The highest density was found around Istanbul Strait, Dardanelles and Erdek Bay in 1995. However, in 1996 high densities were observed through the basin (Fig. 2). The stocks decreased significantly in 2000s and they were mostly confined to north part of the basin. The highest frequencies were observed between 1995 and 1997. Significant decrease in abundance and frequency was detected in the end of August 2000, and decreased further to less than %5 in 2005. Values decreased more than 300 times between March 1996 and March 2006 (Fig. 1, 2). Additionally abundance of *M. leidyi* decreased 73 times between December 1996 and December 2006 (Fig. 2).

Fig. 2. Distribution of M. Leidyi per unit area in different years.

The sharp collapse in demersal fish stocks in the Sea of Marmara in 1994 has been associated with enormous increase of M. *leidyi* [3]. Mesozooplankton and ichthyoplankton was adversely affected [2]. Eggs of the planktivorous anchovy were at the lowest levels in 1994 [4]. It has been also noted that the abundance and number of ichthyoplankton species increased rapidly following the sharp decline in M. *leidyi* density [4].

# MONTHLY SIZE FREQUENCY DISTRIBUTION OF *MNEMIOPSIS LEIDYI* AGASSIZ, 1865 IN THE SEA OF MARMARA

Ahsen Yuksek \*, Erdoğan Okuş , I. Noyan Yilmaz and Nazli Demirel

Institute of Marine Sciences and Management Istanbul University, Muskule Sok. No:1, 34116, Vefa, Istanbul, Turkey -

ayuksek@istanbul.edu.tr

## Abstract

This study has been performed monthly at two stations in the Northern Sea of Marmara between 1997 and 1998. Results showed that abundance and biomass of *Mnemiopsis leidyi* Agassiz, 1865 increased in summer. The size frequency data indicated that small individuals were abundant through out the year, while highest increase has been observed in July-September, when water temperature was higher. *Keywords : Ctenophora, Sea Of Marmara, Biomass.* 

Gelatinous macrozooplankton constitute a common group of marine ecosystem. Rapid augmentation of gelatinous macrozooplankton with selective feeding [1] decreases zooplankton stocks and this interruption of food chain influence fish stocks [2]. Drastic effects of *M. leidyi* invasion have been observed at the Sea of Marmara [3]. Present study examined recruitment of *M. leidyi* abundance and biomass in relation to water temperature at the Sea of Marmara.

Vertical plankton samples were collected monthly from the upper and intermediate layers, using a Nansen closing net (1 m diameter, 500  $\mu$ m mesh). The haul depth has been chosen by examining the salinity and temperature profiles recorded by a CTD system prior to the sampling. Species were immediately sorted, counted and volume of each species was measured by an Imhoff cone.

Average individual volume (AIV) and abundance of *Mnemiopsis leidyi* in relation to water temperature indicated that AIV is reduced in warm periods while abundance increased. In cold periods a reverse structure has been observed (Figure 1, 2).

Fig. 1. Monthly changes on abundance and biomass of *M. leidyi* in relation to water temperature.

Although smaller individuals were abundant through the year, highest percentage of small individuals (0.1-0.5 ml) in samples was detected in September (47.8 %), when water temperature was the highest. Second recruitment period started in July in smaller magnitude. Another important observation is the increase in the number of large individuals prior to the months of population increase. Frequency of individuals between 3-8 ml particularly increased during these periods and the largest individual (48 ml) was detected in August 1997 (Figure 2).

Results point out that recruitment occurred in 18-25 °C water temperature in sampling area. According to periodical data, abundance of *M. leidyi* peaked in July and September (Figure 1, 2). Another important characteristic of 1997 is the lack of its predator (*Beroe ovata*) in the ecosystem.

*M. leidyi* abundance was higher in the upper layer in 1997. Highest abundance has been detected in September 1997 (127.4 ind.m<sup>-2</sup>) and water temperature at 5 m was ~20 °C. Although abundance increased at the intermediate layer despite of low water temperature at the upper layer,

during warm periods (17-27  $^{\circ}$ C) upper layer values were higher than the intermediate layer. This situation can be explained with reduced stocks in upper layer and some changes in ecological conditions such as increase in predators or decrease in zooplankton biomass.

Fig. 2. Monthly size frequency distribution of M. leidyi.

## Résumé

La présente étude a porté sur l'expérimentation d'un appareil acoustique, pour dissuader le grand dauphin *Tursiops truncatus* de s'approcher des senneurs lors des opérations de pêche. Elle porte aussi sur une analyse économique pour évaluer l'impact de cette interaction sur la pêcherie en question. Cette expérimentation a été réalisée au niveau de la zone sud-ouest de la Mer d'Alboran, pendant les mois d'avril, mai et juin 2005. Les principaux résultats montrent une réduction des attaques sur les filets de pêche que ce soit en nombre ou en intensité ; l'efficacité de l'appareil a été jugée significative à près de 90%. L'utilisation de ce répulsif acoustique dans les mêmes conditions d'expérimentation, permettrait de réduire les pertes en Valeur Ajoutée, évaluées actuellement à18%, à un niveau de 1,8% seulement. *Mots clès : Acoustics, Alboran Sea, Cetacea, Fisheries.* 

## Introduction

Les interactions entre les pêcheries et les cétacés sont reportées dans toutes les régions méditerranéennes[1]. Au Maroc, ce phénomène cause un sérieux problème pour les pêcheurs à la senne (150 unités de pêche) ; ces derniers subissent une réduction de leurs revenus, à la suite de l'endommagement des filets de pêche par le grand dauphin *Tursiops truncatus* qui cherche la prédation du poisson capturé [2]. Ce problème qui est devenu de plus en plus fréquent, risque de pousser les pêcheurs à la lumière des actions néfastes envers ce cétacé [2]. De ce fait, et à la lumière des recommandations de certains Organismes Régionaux (AC-COBAMS) qui conviennent que la solution à ce problème se trouve en grande partie dans l'utilisation saine de l'acoustique, l'Institut National de Recherche Halieutique (Maroc) a appuyé cette étude qui porte sur l'expérimentation d'un appareil acoustique répulsif désignée par (HIS), et sur l'évaluation technique et économique du niveau d'interaction.

#### Matériel et méthodes

La zone d'étude se situe entre le détroit de Gibraltar et Oued Laou (sudouest de la mer d'Alboran), connue par les niveaux élevés des attaques du grand dauphin sur les filets des senneurs [2]. La mise à essai du HIS s'est déroulée du 27 avril au 15 juin 2005. Le dispositif expérimental comprend d'une part, 3 senneurs équipés en appareils répulsifs, et d'autre part, 40 senneurs témoins non équipés. Les ondes acoustiques émisent par les HIS(s) ont une portée de plus de 250 m à la ronde, un niveau sonore de 155 dB et un niveau de fréquence allant de 5 à 160 KHz. L'efficacité de l'appareil a été évaluée en comparant les résultats obtenus pour chacun des deux groupes de senneurs, moyennant la formule suivante Efficacité =  $[1-(Frq_e*I_e)/Frq_ne*I_{ne})]*100$ , avec Frq: fréquence des opérations de pêche positives attaquées par le cétacé ; I : intensité des attaques exprimée en nombre de ramendeurs employés pour réparer les filets ; e : senneurs avec HIS ; ne : senneurs sans HIS. Les résultats obtenus ont été validés statistiquement avec un seuil de signification de 0.05. L'évaluation économique de l'utilisation de ce répulsif, a été faite par la Méthode du Budget Partiel qui a mis en considération les pertes avec et sans utilisation de l'appareil ; Les pertes économiques prises en compte dans cette étude sont la réduction des captures en valeur, les charges suplémentaires de réparation et d'amortissement des filets de pêche, et le manque à gagner issu de la réduction de l'activité de pêche.

### Résultats et discussion

Les opérations de pêche positives, réalisées sans utilisation du HIS, ont connu dans 15 % des cas, des attaques du grand dauphin sur les filets de pêche, alors que les bateaux équipés en HIS ont enregistré seulement une fréquence des attaques de l'ordre de 4,6% (Figure 1); la Méthode Exacte de Fisher conclue que cette différence est significative.

Par ailleurs, le nombre de ramendeurs employés pour réparer les filets endomagés, est moins important pour les bateaux équipés (2 ramendeurs) que pour ceux qui ne le sont pas (6 ramendeurs) (Figure 2); le Test de Student confirme cette différence, et donc, on peut considérer que l'utilisation du HIS réduit significativement l'intensité des attaques.

La combinaison entre la fréquence et l'intensité des attaques pour les deux groupes de bateaux, nous donne une efficacité du HIS de l'ordre de 90%.

Fig. 1. Fréquence des opérations de pêche attaquées par le grand dauphin.

À l'échelle économique, ce phénomène d'interaction engendre une perte économique globale -pour l'ensemble des senneurs durant la période d'étude- de l'ordre de 167.400 Euros, équivalents à une réduction en Valeur Ajoutée de près de18%. Dans la considération des résultats obtenus lors de notre étude (90% d'efficacité), l'utilisation du HIS permettrait de récupérer un manque à gagner de près de 158.100 Euros. Conclusion

L'utilisation du HIS pour limiter l'interaction entre le grand dauphin et la pêche à la senne au sud-ouest de l'Alboran, a montré des résultats très encourageants, avec une efficacité de près de 90%. Cependant, il est un peu tôt pour préconiser l'utilisation de ce répulsif acoustique. En effet, l'appareil n'a pu être expérimenté que durant une courte durée et en une période de l'année, et nous ne pouvons être sûrs de la non adaptation du mammifère aux ondes émises, qu'après une longue durée d'observation. Par ailleurs, des études sont vivement sollicitées, afin d'évaluer l'impact réel des ondes émises par les HIS(s) sur la conservation des cétacés et sur l'écosystème marin en général.

## Résumé

Les observations faites au niveau de l'espace médiolittoral de substrat dur, aussi bien à Zarzis (sud tunisien) qu'à Tripoli (Libye), nous ont permis de mettre en évidence des biocénoses d'installation récente typiques des littoraux de la mer Rouge et de la zone nord ouest de l'Afrique.

Mots clès : Species Introduction, Western Mediterranean, Coastal Systems.

Cinq espèces nouvelles pour les eaux libyennes et tunisiennes dont 3 nouvelles pour les eaux méditerranéennes ont été récoltées en nombre important sur substrat rocheux dans la zone intertidale proche des installations portuaires de Zarzis (Tunisie) et Tripoli (Libye).

## Espèces sessiles et/ou peu mobiles

La première est une patelle qui est présente, à la fois, sur les quais du port de commerce de Zarzis et sur des roches proches de la zone portuaire de Tripoli. Les individus récoltés ont des tailles allant de 17 à 29 mm à Tripoli et de 20 à 29 mm à Zarzis. Leur observation a permis de les classer dans la famille des Nucellidae et de les identifier en tant que Cellana radiata radiata (Born, 1778) synonyme de Cellana rota Gmelin, 1791. Cette espèce (Fig. 1), largement répandue dans tout le Pacifique, a été signalée en Méditerranée orientale en 1961 sur les côtes israéliennes, elle a, depuis, été mentionnée en Egypte (1994) et en Grèce, 1999 [1]. Sa présence, en quantité abondante à quelques 300 km de distance au niveau de la grande et petite Syrte montrerait qu'elle s'est, ces dernières années, très bien acclimatée dans les eaux de la Méditerranée méridionale. La seconde espèce est un polyplacophore. Elle n'a été trouvée qu'à Tripoli. Les individus récoltés sont de taille allant de 33 à 47 mm. Leur observation a permis de les identifier en tant qu' Acanthopleura gemmata (de Blainville, 1825) synonymes Acanthopleura vaillanti de Rochebrune, 1882 et Acanthopleura haddoni Winckworth, 1927. Cette espèce, largement répandue dans tout le Pacifique, n'a pas, jusqu'à aujourd'hui, été signalée en Méditerranée, la citation la plus proche étant faite en mer Rouge dans le golfe d'Aqaba par Hullings [2]. La troisième espèce est une balane. Comme Acanthopleura gemmata cette espèce nouvelle en Méditerranée, n'a été trouvée que dans la seule zone de Tripoli. Les individus récoltés mesurent entre 9 et 32 mm à la base. Ils appartiennent à l'espèce d'origine indo-pacifique Tetraclita squamosa rufotincta Pilsbry, 1916.

Fig. 1. *Cellana radiata radiata*, à gauche, spécimen de Zarzis, au centre et à droite, spécimen de Tripoli.

#### Espèces mobiles

La première est une ophiure indo pacifique appartenant au genre *Ophiocoma*. *Ophiocoma scolopendrina* (Lamarck, 1816) présente dans le golfe d'Aqaba [3] n'a jamais été signalée en Méditerranée (Fig2a). Nous ne l'avons trouvé (diamètre du disque des oscillant entre 17 à 21 mm) que dans la région portuaire de Tripoli. La seconde, présente à la fois à Tripoli et à Zarzis, est le crabe Grapsidae *Plagusia tuberculata* Lamarck, 1818 (Fig. 2b). Les individus récoltés mesurent entre 12 et 22 mm (largeur du bouclier thoracique). Cette espèce, considérée à ce jour comme très rare avec une seule signalisation en 1981 au Liban [4], a donc trouvé, en Méditerranée méridionale, un biotope nettement favorable à son installation.

Fig. 2. a) Ophiocoma scolopendrina, Tripoli; b) Plagusia tuberculata, Zarzis.

L'ensemble des observations faites à Tripoli et à Zarzis met bien en évidence le rôle fortement "colonisateur" des espèces originaires du Pacifique dans cette partie méridionale de la Méditerranée et la "tropicalisation" du milieu ambiant se traduisant par une synergie dans la dynamique d'installation des peuplements littoraux.

# Abstract

*Sardinella aurita* eggs and larvae were investigated in the Tunis Gulf by four seasonal surveys from the summer 2002 to the spring 2003. This species spawns mainly in summer, when the sea surface temperature  $(25.5^{\circ}C)$  and the water stratification were maximal. In this period, eggs were concentrated in the south of Zembra Island and in the west of the Gulf. However, the larvae were concentrated in the centre of the Gulf and in the north of Cape Fartas.

Keywords : Temperature, Spawning, Ichthyoplankton.

#### Introduction

Sardinella aurita is the second most important small pelagic species in Tunisian waters. Indeed, it represents 17.5% (16 000 t) of the small pelagic exploitable biomass [1]. In spite of the fishery importance of the species, there is no information on its early life stage in Tunisian waters. Indeed, this work investigated Sardinella aurita egg and larval distributions in the Tunis Gulf in relation to hydrographical conditions.

#### Material and Methods

Four ichthyoplankton surveys were conducted in the Tunis Gulf, one in each season: summer (August 2002), autumn (October 2002), winter (February 2003) and spring (April 2003). Samples were taken on a grid of 29 stations. Temperature and salinity was measured at each station. CTD profiles were obtained using a Sea-Bird911+. Plankton samples were taken by oblique tows with a 60 cm mouth diameter Bongo gear, fitted with nets of 335  $\mu$ m mesh size and a HydroBios flowmeter. Following each tow, the plankton samples were preserved in 4% formaldehyde solution.

#### Results and Discussion

In summer, the sea surface temperature (SST) ranged between 25.1 and  $26.2^{\circ}$ C with an average of  $25.5^{\circ}$ C. A patch of warmer waters was detected near Cape Sidi Bou Said. Column water was stratified and the thermocline was localized between the depths 25 and 45 m. Autumn distribution showed some heterogeneity. The patch of the relatively colder water (20°C) was found near Cape Sidi Bou Said and the patch of warmer waters (22.6°C) was in the south-west of Zembra Island. In winter, surface waters were cold with an average of  $13.4^{\circ}$ C. The heterogeneity was important and the spatial difference was around  $4.2^{\circ}$ C. Between the winter and spring (16.1°C) there was a light enhancement of temperature equal to  $2.7^{\circ}$ C.

Sardinella aurita eggs were found in the Tunis Gulf only in summer and autumn with average abundances 35 eggs/10 m<sup>2</sup> and 2 eggs/10 m<sup>2</sup>, respectively. In the main spawning period (summer), the highest abundances (221 eggs/10 m<sup>2</sup>) were obtained in the south of Zembra Island (fig. 1) that extend to the north of Cape Fartas and in the west of the Gulf (116 eggs/10 m<sup>2</sup>). We note that no eggs were collected in the Bay and in the western coasts. In autumn, only low abundances were localised from Cape Sidi Bou Said to Majreda mouth, in the north of the Gulf and the north of Cape Fartas.

The larvae were most abundant in summer (27 larvae/10 m<sup>2</sup>). In this season, the highest concentrations (118 larvae/10 m<sup>2</sup>) were in the north of Cape Fartas and the centre of the Gulf. In autumn, low abundances were localised in the north of Cape Fartas to the north of the Gulf and near Sidi Daoud. However, in winter high abundance (117 larvae/10 m<sup>2</sup>) was found in the south of Majreda mouth.

In conclusion, there is no significant spatial correlation between the distributions of eggs and larvae and SST. However, our results agree with the studies in the Mediterranean [2, 3] that this species spawns mainly in summer, with maximal SST and water stratification.

# RESEARCHES ON UPPER INFRALITTORAL ALGAE SOUTH OF GOKOVA SPECIALLY PROTECTED AREA

Sibel Zeki \*, Ahsen Yuksek and Erdogan Okus

Institute of Marine Sciences and Management, Department of Physical Oceanography and Marine Biology, University of Istanbul,

Turkey - sibelzeki@yahoo.com

# Abstract

In the present study the species composition and biomass of upper infralittoral macroalgal communities in the south part of Gokova Specially Protected Area, were studied. Thirty macroalgal species were identified in the study area. The mean biomass per station was  $2641,65 \pm 2023,30$  gram/m<sup>2</sup>.

Keywords : Algae, Biomass, Aegean Sea.

## Introduction

Marine macroalgae, better known as seaweeds, are classified according to their pigmentation into brown (Heterokontophyta), red (Rhodophyta), and green (Chlorophyta) seaweeds. They are widely used as food, as ingredients in cosmetics and fertilizers, and in hydrocolloid production (e.g. agar and alginate). Seaweeds are of ecological importance because they assist in supplying oxygen to the sea and act as one of the primary producers in the marine food chain. Some seaweeds have the capacity to remove heavy metals from the water and can potentially be used in biomonitoring and in the bioremediation of such pollutants. Seaweeds also possess excellent survival strategies to withstand the many environmental stresses that they are exposed to. For all these reasons, together with their unique life-cycle and physiology, seaweeds are interesting study subjects [1].

#### Material and Method

The study was carried out in the south of the Gokova Bay (Aegean Sea, Turkey). Sampling was done randomly at 24 stations in 20 June - 5 July 2005. Samples were collected at upper infralittoral zone (0,3-0,5m) by scraping off all attached vegetation within 25x25 cm quadrate. At each station two quadrates were taken. Samples, fixed in 4% formaldehyde seawater solutions, were sorted in laboratory for both taxa identification and biomass determinations. Wet weight of each macroalgal species was calculated.

## Results and Discussion

A total of 30 taxa were identified including 14 Rhodophyta (*Florideophyceae*), 11 Heterokontophyta (*Phaeophyceae*) and 5 Chlorophyta (*Ulvophyceae*) (Table 1).

Tab. 1. List of species, their mean biomass  $\pm$  standard deviation (expressed as wet weight).

| Wrangelia penicillata (C. Agardh) C. Agardh                                 | 0,80                           | 3,90    |  |  |

*Cystoseira* and *Dictyota* were the genera with the highest number of taxa. Among these species, three brown algal species (*Cystoseira corniculata* (Turner) Zanardini, *Cystoseira elegans* Sauvageau and *Cystoseira amentacea* var. *stricta* Montagne) exhibited the highest mean biomass values. The maen number of species per stations was  $6 \pm 3,8$ .

In the upper infralittoral zone (0-1m depth) of the Mediterranean coasts, the species of the genus *Cystoseira* are usually the dominant element of the benthic vegetation on unpolluted hard substratum [2]. In this study, it's clear that *Cystoseira* spp. communities have a significant distribution in the Gokova Specially Protected Area and they support a rich associated flora on hard substrata. Among the 30 species *Cystoseira amentacea* var. *stricta* Montagne (Figure 1) has been listed as a protected species in "Protocol concerning Specially Protected Areas and Biological Diversity in the Mediterranean" and this have a great importance for protection and conservation of natural habitats in Gokova Specially Protected Area.

Fig. 1. Cystoseira amentacea var. stricta Montagne.

#### Acknowledgements

This study is part of the Marine Biological Diversity Assessment of Gökova Specially Protected Area project. We commemorate the deceased Prof. Dr. Erdogan OKUS.

## Abstract

In this study, the biomass of the deep-water pink shrimp (*Parapenaeus longirostris*), which was commercially caught with bottom trawl and beam trawl nets in the Marmara Sea, in 2001-2002, was estimated by depth and season. The average biomass per unit area was higher for the beam trawl than the bottom trawl. Comparisons with previous studies showed that its biomass has increased in the last decade in the Marmara Sea.

Keywords : Crustacea, Biomass, Sea Of Marmara.

#### Introduction

Shrimp is the most abundant species in the benthic fauna of the Marmara Sea. Currently in Turkey, 72% of the shrimp production is providing from the shrimp stocks in this sea. In Turkey, shrimp fishing increased since the beginning of the 1980's and catches increased to a maximum of 8380 t in 1989 [1]. However, catches decreased below to 1000 t in the beginning of the 1990's because of the increase in the fishing effort and illegal trawl fisheries. The decreasing catch was consistent with the results of the study on the biomass, which was carried out by JICA (1993) in 1991-1992 [2].

### Materials and Methods

This study was carried out in five stations at depths of 20 to 200 m. Sampling was carried out seasonally (autumn, winter, spring and summer) in 2001-2002. Samples were collected by commercial fishing vessels. Bottom trawl and beam trawl were used for sampling. The head-rope lengths of the bottom trawl and the beam trawl nets were 37 and 6 m, respectively. Each trawl was equipped with 20 mm mesh size (knot to knot) at the codend. Trawling duration (per haul) was limited to one hour. Trawling speed was 2.4-2.7 knots for the bottom trawl and 1.5-1.8 knots for the beam trawl. Biomass estimation were calculated with the swept area method "per stratum" [3]. The catchability coefficient was considered as q=1 for the trawl net. The head rope mouth opening ratio was considered 0.5 for the bottom trawl and 1 for the beam trawl [4].

#### Results and Discussion

In total, 43 samplings for the bottom trawl and 50 samplings for the beam trawl were carried out during the survey period. The average biomass per unit area of deep-water pink shrimp obtained from the bottom trawl and the beam trawl nets were estimated as  $229.8\pm57.3$  kg/km<sup>2</sup> and  $409.3\pm152.1$  kg/km<sup>2</sup>, respectively. The maximum average biomass was estimated for the winter and at the 50-100 m depth zone for both fishing gears (Fig. 1). The differences between winter and the remaining seasons may be the result of migration and thermocline layer changes [5].

Fig. 1. Biomass distribution of *P. longirostris* estimated by bottom trawl and beam trawl nets according to depth and season.

By comparing the two gears according to the average biomass per unit area, it became apparent that the beam trawl was more advantageous. The biomass of *P.longirostris* has increased slightly since the mid-1990's in the Marmara Sea (Fig. 2). In the ealry 1990's, the average biomass of trawling at depths 20-100 m was 88.9 kg/km<sup>2</sup>[2], however, in the mid-

1990's it was 127.3 kg/km<sup>2</sup>[6]. These two previous studies were carried out in the same ground and depth and used the swept area method for the calculation of the average biomass. In this study the average biomass was 172.1 $\pm$ 44.3 kg/km<sup>2</sup>. There are many factors that can be related with such a linear increase in the *Plongirostris* biomass: (a) the short population doubling time, (b) the fact that spawning takes place twice a year, and (c) the recruitment age of +1 yr [7]. Better oceanographic conditions which occurred in the Marmara and Black Seas in recent years might have also played an important role in the increase of the deep-water pink shrimp stocks during the last decade [1, 6].

# ANNUAL VARIATIONS OF ZOOPLANKTON BIOMASS AND ABUNDANCE IN MERSIN BAY (NE MEDITERRANEAN SEA)

Arife Zenginer \* and Sengul Besiktepe

Institute of Marine Sciences, Middle East Technical University - arife@ims.metu.edu.tr

# Abstract

Annual changes in zooplankton abundance, biomass and group composition were studied monthly at a coastal (20m) and an open (200m) stations between December 2004 and January 2006 in Mersin Bay, NE Mediterranean Sea. Zooplankton biomass and abundance were determined for four size fractions: 112-200, 200-500, 500-1000 and >1000  $\mu$ m. Surface seston chlorophyll-a, lipid, protein and carbohydrate concentrations were also measured. Zooplankton abundance was correlated with chlorophyll in the coastal station (p<0.05). Significant correlation was observed between total zooplankton biomass and total particulate organic matter (p<0.01) in coastal station. *Keywords : Biomass, Zooplankton, Eastern Mediterranean*.

## Introduction

The Eastern Mediterranean Sea is an oligotrophic sea with poor nutrient concentration leading to low plankton biomass and production ([1]). Zooplanktonic organisms play a key role in the pelagic food web by controlling phytoplankton production and shaping pelagic ecosystems ([2]). Studying zooplankton communities are especially important for understanding the functioning of coastal ecosystems because of both land and ocean based environmental factors ([3]). The aim of the study is to provide information on the zooplankton annual cycle in relation to the influence of environmental parameters on them.

### Material and Methods

Zooplankton sampling were carried out monthly at two stations; one representing coastal (36°33'58N, 34°15'68E; 20m depth) and the other representing open waters (36°26'N, 34°21'E; 200m depth) characteristics, from December 2004 to January 2006 in Mersin Bay, NE Mediterranean Sea. Samples were collected with Nansen net (70 cm mouth diameter with 112  $\mu$ m mesh) and fractionated into 112-200, 200-500, 500-1000 and >1000 $\mu$ m size groups for biomass (dry weight) estimation and major taxonomic group identification. Zooplankton samples were preserved in 5% borax-buffered formaldehyde for quantitative taxonomic analyses. Temperature and salinity profiles were obtained with a CTD-probe. Surface seawater samples were collected with niskin bottles for chlorophyll-a, lipid, protein and carbohydrate measurements. Correlates with zooplankton parameters.

## Results and Discussion

Very low chlorophyll concentrations in the open station (0.02-0.35  $\mu g$  $L^{-1}$ ) can be compared with those observed in the NW Levantine Sea  $(0,10-0,47 \ \mu g \ L^{-1},[4])$ . Chlorophyll maximum occured in spring and autumn for both stations. Highest chlorophyll-a concentration  $(2.5 \mu g$  $L^{-1}$ ) were observed in March at coastal station due to the input of Lamas River nearby. Total particulate organic matter (POM) (sum of total lipid, protein and carbohydrate) varied from 42.1  $\mu$ g L<sup>-1</sup> (in January) to 1082  $\mu$ g L<sup>-1</sup> (in March) and 53.7  $\mu$ g L<sup>-1</sup> (in January) to 246  $\mu$ g L<sup>-1</sup>(in May) in coastal and open station, respectively. Total POM decreases with increasing distance from the coast which then reflects the spatial pattern of phytoplankton biomass and zooplankton biomass ([5]). Mediterranean zooplankton is characterized by two abundance maxima: one in late winter or early spring and a second peak in autumn ([6], [7]) as shown in the figure 1. Average zooplankton abundance in coastal station was about ten times more abundant than the open station throughout the year. 112-200 and 200-500  $\mu$ m size groups were the dominant groups in the coastal station and only the 112-200  $\mu$ m size group in the open station. Copepods were the main group in total zooplankton abundance; 65% of the coastal zooplanktonic groups and 76% of the open station within the year, thus this group plays an important role in the annual changes of zooplankton. After copepods, crustacea nauplii and appendicularia were the dominant groups both in the coastal and open stations. Throughout the year, average zooplankton biomass in coastal station was about nine times higher than the open station. Highest biomass was observed in June at coastal station, and in November at open station. 200-500 $\mu$ m size group constituted the majority of the average zooplankton biomass in coastal station within the year, on the other hand open station is constituted by >1000 $\mu$ m size group. Zooplankton abundance was correlated with chlorophyll in the coastal station (p<0.05) and significant correlation was observed between

total zooplankton biomass and total particulate organic matter (p<0.01) in coastal station. Acknowledgement The present study was supported by METU-BAP-2005-07-01-01 project. We would like to thank to Doruk Yilmaz for his assistance in biochemical composition of particulate organic matter measurements and to Dr. Dilek Ediger for helping in chlorophyll-a measurements.

# BIOMETRIC CHARACTERISTICS OF EUROPEAN GLASS EEL DURING THE MIGRATION SEASON ALONG THE WESTERN GREEK COAST

S. Zompola<sup>1</sup>\*, G. Ioannou<sup>2</sup>, C. Koutsikopoulos<sup>1</sup> and Y. Cladas<sup>2</sup>

<sup>1</sup> Laboratory of Zoology, Department of Biology, University of Patras, 26500 Patra, Greece - szobola@upatras.gr

<sup>2</sup> Department of Aquaculture and Fisheries, T.E.I of Epirus, 46100 Igoumenitsa, Greece

# Abstract

Biometric characteristics and developmental stages of glass eels (*Anguilla anguilla* L., 1758) collected from November 1999 to March 2000 were studied in two areas along the western part of Greece (Ionian Sea). Despite the fact that glass eel size from Greek coast was smaller compared to those reported for the Atlantic zone, similar temporal changes in the pigmentation stages of the glass eels were observed.

Keywords : Biometrics, Ionian Sea, Migration, Pigments.

#### Introduction

European eel is a species of great economical and ecological importance for the west coasts of Atlantic Ocean and the Mediterranean Sea. Glass eels are harvested during their mass migration into European rivers for either direct consumption or aquaculture purposes. Glass eel migration dynamics in the E. Mediterranean coast has scarcely been described [1].

#### Materials and Methods

Glass eels were collected from November 1999 to March 2000 at the marsh of Sagiada near the mouth of Kalamas river  $(39^{\circ}37'500 \text{ N} \text{ and } 20^{\circ}11'200 \text{ E})$  and at the mouth of Alfios river  $(37^{\circ}36'500 \text{ N} \text{ and } 21^{\circ}26'300 \text{ E})$  using fyke nets (total length 1.35 m, mouth 40 cm wide, mesh 1.5 mm). Fyke nets were installed at noon, mouth oriented downstream and withdrawn the following morning. Glass eels were daily collected, weighed and afterwards transported for rearing experiments. Total length and weight were measured on freshly caught individuals once per week. Pigmentation stages were identified as defined in [2, 3].

Fig. 1. Mean monthly total length and body weight of glass eels. Vertical bars indicate standard errors.

#### Results and Discussion

The seasonal changes in mean total length and weight of glass eels are presented in Fig. 1. Glass eels (mean length±sd: 5.92±0.29 cm; mean weight±sd: 0.177±0.036 g) seem to be smaller compared to those reported for the W. Mediterranean region [4] and for the Atlantic coast [5]. This smaller mean size of glass eels could be linked to the prevailing oligotrophic conditions in the Mediterranean Sea. The observed sizes of transparent glass eels VB stage (mean length±sd: 5.88±0.29 cm; mean weight±sd: 0.181±0.036 g) seem also to be smaller than those of the Atlantic coast [5, 6]. There were no marked differences in the mean weight of the glass eels from the two areas (Mann-Whitney test, U=671261, p>0.05) but differences were detected in mean glass eel length (t-test, t=4.59, p<0.05) with mean length of glass eels collected from the Sagiada marsh being slight greater than those in the Alfios river. A significant decreasing trend in mean weight of glass eels from Sagiada with season was observed (ANOVA, F=55.99, p<0.05, r<sup>2</sup>=0.95). The decreasing trend in mean weight with advancing season is consistent with previous studies in W. Mediterranean [4] and the Atlantic coast [6]. A progressive increase in the proportion of advanced stages through the season was also observed (Fig. 2). In the Sagiada marsh, the level of glass eels pigmentation changed significantly over the season (contingency table:  $X^2$ =85.39, p<0.05). Similar results were observed for glass eels of the Alfios river (contingency table: X<sup>2</sup>=203.15, p<0.05). Such seasonal changes in the pigmentation have been also pointed out for the European Atlantic coast [6].

# REPRODUCTIVE CYCLE OF THE SPHYRAENA CHRYSOTAENIA FROM THE GULF OF GABES (TUNISIA)

Rim Zouari-Ktari<sup>1</sup>\*, Mohamed-Nejmeddine Bradai<sup>1</sup>, Mohamed Ghorbel<sup>1</sup> and Abderrahmen Bouain<sup>2</sup> <sup>1</sup> National institute of Marines Sciences and Technologies (INSTM), Center of Sfax, P.B. 1035, 3018 Sfax, Tunisia. - riminstm@yahoo.fr <sup>2</sup> Faculté des Sciences de Sfax B.P 802. Sfax 3018, Tunisia

# Abstract

Reproduction of *Sphyraena chrysotaenia* from the Gulf of Gabès was investigated. Monthly variation of gonadosomatic index (GSI %) and hepathosomatic index (HSI %) revealed that the species reproduces between May and November and spawning takes place between August and November.

Keywords : Fishes, Gulf Of Gabes, Migrant Species, Reproduction.

#### Introduction

The lesspsian fish species *Sphyraena chrysotaenia* was observed for the first time in Tunisia in December 2002 when it was fished by bottom trawlers in the Gulf of Gabès [1]. Since then, it became relatively abundant but its landing were irregular. This species found new feeding habitats and adapted to new areas. This study provides data on its reproductive period.

#### Material and Methods

Biological data was collected monthly from 955 specimens purchased from commercial catches made in the Gulf of Gabes between August 2003 and February 2005. Total length (TL) in the nearest 1 mm and total weight (W) in the nearest 0.01g were recorded for each specimen. The sex of all individual was determined by macroscopic examination of the gonads of mature specimens but microscopic examination was used for differentiating sex in juveniles. Gonads and liver were weighted (Wg and Wf respectively) with an accuracy of 0.01 g. Mean monthly gonado-somatic (GSI) and the hepato-somatic indices (HSI) were calculated for all sexually identified specimens (GSI = 100 Wg/W and HSI = 100 Wf/W).

## Results and Discussion

It is well known that the gonads in fish show a seasonal variation which might vary within the same species in different geographic localities in response to environmental factors which affect the physiological activity of the fish [2]. The GSI of Sphyraena chrysotaenia attained a maximum in July for males (4.691) and in August for females (11.199), followed by a rapid decrease in September following egg deposition (Fig. 1). The female GSI was higher than that of males; but both displayed nearly the same cyclic trend during the period of study. From December to April, the GSI reached the lowest average values in both sexes. Reproduction is concentrated in May and October and spawning took place between August and November with fish in spawning condition only being observed during this period. This is confirmed by an examination of the ovaries and the GSI for each female: by October, 70% of the females had terminated their reproduction, and by November the reproduction was completed. Similarly, in the Egyptian Sea the breeding season extends from May to October with analysis of the monthly distribution stages.

The HSI for females, during the more intensive reproduction period, increased with GSI with a peak in July and started to decrease in August when GSI was highest, suggesting that the liver had a weight loss, which may indicate the mobilisation of hepatic reserves for oocytes maturation. For males, HSI peaked during September, suggesting that liver reserves may not be used in the final maturation stages [3].

Fig. 1. Monthly variations in the gonadosomatic index and hepatosomatic index for female and male *Sphyraena chrysotaenia* in the Gulf of Gabès.

# CARACTÉRISTIQUES BIOMÉTRIQUES DE *STEPHANOLEPIS DIASPROS* (FRASER-BRûNNER, 1940) (POISSON TELEOSTEEN) DES CÔTES DU GOLFE DE GABÈS

Rim Zouari-Ktari<sup>1</sup>\*, Mohamed-Nejmeddine Bradai<sup>1</sup>, Mohamed Ghorbel<sup>1</sup> and Abderrahmen Bouain<sup>2</sup>

<sup>1</sup> Institut National des Sciences et Technologies de la Mer (INSTM), Centre de Sfax, B.P. 1035, 3018 Sfax, Tunisie. - riminstm@yahoo.fr <sup>2</sup> Faculté des Sciences de Sfax B.P 802. Sfax 3018 Tunisie.

## Résumé

La morphologie de *Stephanolepis diaspros* du golfe de Gabès a été décrite par 10 caractères métriques et 5 caractères méristiques. L'accroissement des différentes parties du corps montre une forte corrélation avec la longueur totale. La relation taille-masse montre une allomètrie minorante.

Mots clès : Biometrics, Gulf Of Gabes, Fishes, Eastern Mediterranean.

#### Introduction

*Stephanolepis diaspros*, immigrant de la Mer Rouge et du Golfe d'Arabie via le canal de Suez, est la première espèce lessepsienne apparue en Tunisie. Elle a été signalée dans le Golfe de Gabès en 1966 [1]. Cette espèce démérsale dans les eaux littorales et récifales des mers tropicales et tempérées chaudes, est devenue très abondante sur nos côtes. Nous nous intéressons dans ce travail à la description de la morphologie de cette espèce et au suivi de la croissance massique et la croissance relative des différentes parties de son corps.

#### Matériel et méthodes

Les relevés biométriques ont été réalisés à 0,01 mm prés sur un échantillon de 328 individus de *S. diaspros* de longueur totale (LT) comprise entre 4,8 et 22,4 cm collectés durant la période allant de mai 2003 jusqu'au juillet 2005.

Pour l'étude de la croissance massique, nous avons examiné 1030 spécimens de longueurs totales comprises entre 3,7 et 23,7 cm. Pour chaque spécimen, et après la détermination du sexe, nous avons relevé la masse totale (M) au centième de gramme le plus proche.

A partir de ces mensurations, nous avons estimé la croissance relative de différentes parties du corps par une fonction de la forme  $y = ax^b$ , où y = longueur du caractère considéré, x = LT (longueur de référence) ; a et b sont des constantes. Ces dernières sont estimées par la méthode des moindres carrés. Nous avons estimé aussi la croissance pondérale par une fonction de type puissance:  $M = a LT^b$ ; où b exprime le taux de croissance. Pour apprécier le degré d'allomètrie entre les deux variables, nous avons comparé les valeurs du coefficient d'allomètrie "b "à 1 pour les caractères métriques et à 3 pour la relation taille-masse en appliquant le test "t "de Student à 5%.

#### Résultats et discussions

La première nageoire dorsale de *S. diaspros* consiste en une forte épine barbelée située au-dessus de la moitié postérieure de l'ÅŞil. Le nombre de rayons mous de la deuxième dorsale varie de 28 à 32 avec une moyenne de 30,3 et un mode situé au niveau de 31. Le deuxième rayon mou de cette nageoire dorsale est toujours prolongé chez les mâles. Le nombre des rayons mous à l'anale varie entre 28 et 31 avec une moyenne de 29,5 et un mode au niveau de 30. La nageoire pectorale, courte, est constituée de 12 à 13 rayons mous avec une moyenne de 12,82 et un mode de 13, alors que le nombre des rayons ramifiés de la nageoire caudale est 12 (Tableau 1).

Le nombre total des branchiospines varie entre 17 et 30 avec une moyenne de 22 et un mode situé au niveau de 24. Malgré ces grandes variations, nous n'avons pu montrer aucune corrélation entre le nombre de branchiospines et la longueur du poisson.

Les résultats de l'analyse de l'allomètrie des différents caractères métriques de *S. diaspros* par rapport à la longueur totale sont consignés dans le tableau 2.

L'analyse des relations taille-masse du poisson plein chez les deux sexes séparés et confondus de *S. diaspros* nous permet de constater que les valeurs du taux de croissance "b "sont inférieurs à 3 (2,7892 pour les 2 sexes confondu; 2,8184 pour les femelles et 2,7849 pour les males) et les coefficients de corrélations "R "sont proches de 1. Les deux variables sont donc bien corrélées et l'allomètrie est donc minorante. Ceci est prouvé par le test "t "de Student au seuil de 0,05 qui ne montre aucune différence significative chez les deux sexes séparés et confondus.

Ces résultats sont totalement différents de ceux des côtes turques [2] où l'allomètrie est majorante (b= 3,186). Toutefois, cette étude a porté sur un faible échantillonnage (207 spécimens) et une marge faible de longueur totale (7,1 <LT <13).

# Abstract

The age and growth of European hake was undertaken for the Moroccan Mediterranean and the Gibraltar Strait regions. The comparison of the von Bertalanffy growth parameters in both regions and between regions, showed significant differences between males and females for all three growth parameters.

Keywords : Demersal, Growth, Strait Of Gibraltar.

## Introduction

The European hake, *Merluccius merluccius*, L.1758, is a species with a high commercial value. The present study focused on the comparison of the precision of age determination and the growth of this species between the Mediterrranean and the Strait of Gibraltar regions by the use of a multivariate analysis.

#### Material and Methods

The area of study covered the hake fisheries off the Mediterranean and the Strait of Gibraltar regions of Morocco. The Mediterranean region extends from Algeria borders to Tangier; while the Gibraltar Strait region, contiguous to the latter, extends from Tangier to Larache.

The samples used in this study were collected by using a stratified random sampling of hake captures carried out in 2004 and 2006 surveys in the Mediterranean region, and in 2004 and 2005, from monthly commercial landings of trawlers in the Gibraltar strait region at the fish auction of Larache.

Samples of 510 individuals, ranging in size between 10 and 60 cm total length, were sexed, measured for total length to the nearest centimeter and weighted with a precision of 0.1 g. For age determination, 10 sagittal otoliths by length class of 1 cm, were removed, washed, viewed whole and sectioned, with a magnification of 50x. Each otolith was read three times. The standard deviation and the Percentage of Agreement between age-readings were calculated for whole and sectioned otoliths [1]. Age readings were analysed with a spreadsheet developed by Guus Eltink [2]. The von Bertalanffy growth parameters using sectioned otoliths were estimated by region, separately for males and females using the length-age keys established by using FISHPARM program [3]. Hotlling's  $T^2$ test [4], was used to compare growth parameters between male and females in each region and between the two regions for each sex separately.

#### Results and discussion

In both regions, high Percentage of Agreement, between the age-readings (over 89% for whole otoliths versus 100% for sectioned ones), was observed for young individuals; but as fish got older for both regions, the distinction of age rings became hard to distinguish, especially for whole otoliths due to their overlappings; thus, for older individuals, the Percent Agreement underwent a sharp decrease (49% and 67% respectively for whole and sectioned otoliths); while the standard deviation increased from 0.33 to 0.72 and 0.57 respectively for whole and sectioned otoliths. These results indicate that age determined by using whole otoliths is underestimated especially for old individuals.

Tab. 1. Von Bertalanffy growth parameters with standard errors (SE) for hake by sex and region; n is the sample size.

| Region           | Sex    | n   | Loo    | SE    | K     | SE   | to     | SE   |
|------------------|--------|-----|--------|-------|-------|------|--------|------|
| Mediterroneon    | male   | 236 | 64.10  | 21.95 | 0.167 | 0.01 | 0.299  | 0.05 |
| weutenanean      | female | 248 | 81.57  | 26.19 | 0.124 | 0.01 | 0.195  | 0.06 |
| Gibraltar Strait | male   | 238 | 78.49  | 40.62 | 0.106 | 0.10 | -0.418 | 1.20 |
|                  | female | 244 | 102.35 | 50.50 | 0.075 | 0.06 | -0.756 | 1.00 |

Von Bertalanffy growth parameters were calculated by region, separately for males and females (Table 1). In both regions, significant differences between males and females were found for all three growth parameters (Hotlling's T<sup>2</sup>tests, P <0.001); females grew faster and on average were larger than males of the same age in both regions. The study showed for the Gibraltar Strait region a slightly higher asymptotic length (L $\infty$ ), for females. Similar comparisons were made between regions for each sex separately. For each sex, all three growth parameters were significantly different between the Mediterranean and the Strait of Gibraltar regions (Hotlling's  $T^2$  test, P<0.001).

The data in our study confirmed that females grow faster than males for both regions, as found in a previous study [5].

Growth rates of fish can be affected by many factors including differences in the seasonality of spawning, environmental factors (temperature), amount of food, and genetics [6].

# Abstract

A study on gear interaction in hake fisheries was carried out in the Moroccan Mediterranean and the Gibraltar Strait regions. The trawl landings in both regions were composed mainly of immature specimens while longliners were targeting only mature individuals. *Keywords : Demersal, Stock Assessment, Analytical Methods, Western Mediterranean, Strait Of Gibraltar.* 

## Introduction

The European hake, *Merluccius merluccius*, L. 1758 constitutes a species of high commercial value for the Moroccan demersal fishery. This work focused on the study in both regions of gear interactions in hake fisheries using an analytical model.

tion of von Bertalanffy while holding the other parameters constant, the variation of the yield per recruit is particularly important with a reduction of asymptotic length (L $\infty$ ), and K of 20 %. The simultaneous variation of M and F generated an almost negligible variation of the estimate of yield per recruit.

#### Material and Methods

The data used in this study were samples, collected by length category, using a stratified random sampling of hake captures. The sampling was carried out in the 2004 and 2006 surveys in the Mediterranean region, and in 2004 and 2005, from monthly commercial landings of trawlers and longliners in the Gibraltar Strait region.

The samples were weighted and all individuals were measured to the nearest centimeter for total length (TL). A subsample was then chosen, and each fish was measured to the nearest cm and then weighted with a precision of 0.1 g. Otoliths were removed, washed and sectioned for age determination. The von Bertalanffy growth parameters were calculated (sexes combined), using the Fishparm program [1]. The length-weight relationship parameters (a and b), were obtained by linear regression. The natural mortality (M) was estimated based on [2].

The length distributions of the samples were raised to the catches of the vessels and that of the month, and then extrapolated to the species annual catches made in each region.

The annual length distribution by region was then used to estimate the fishing mortality parameters (F) for each region using the linearized catch curve method [3]. The parameters obtained by region are given in Table 1.

Tab. 1. Biological parameters of hake with value (Val.), and standard error (SE):  $L\infty$  (cm), K (per year),  $t_0$  (year), are von Bertalanffy growth parameters. Length-weight relation parameters: a and b (slope); M and F are natural and fishing mortality; n is the sample size.

| Region                | n   |       | (m    | ,    | ĸ    | 4     | 0    | 1      |      | b     | М    | F    |
|-----------------------|-----|-------|-------|------|------|-------|------|--------|------|-------|------|------|
| Medit.                |     | val   | SE    | val  | SE   | val.  | SE   | val    | val. | SE    | val  | val  |
|                       | 484 | \$1.1 | 23.47 | 0.12 | 0.01 | 0.19  | 0.04 | 0.0053 | 3.04 | 0.003 | 0.19 | 0.43 |
| Strait of<br>Gibralta | 482 | 93.1  | 46.11 | 0.09 | 0.09 | -0.37 | 1.10 | 0.0041 | 3.20 | 0.011 | 0.31 | 0.39 |

A yield par recruit analysis by region was then applied to the average pseudocohort 2004-2006, using VIT [4]. An analysis of sensitivities to the errors related individually to all parameters of the model was also performed.

#### Results and Discussion

For both regions, the analysis of annual length-frequency distributions showed that the landings of the trawlers were mainly composed of specimens of sizes ranging between 14 and 36 cm, while the landings of longliners were essentially composed of individuals with length from 25 to 58 cm (Fig.1). The fishing mortality (F) in both regions, was higher for juveniles (14-24 cm), exploited exclusively by trawlers (Fig. 1). Longliners targeted only mature individuals of sizes higher than 40 cm (maximum for the size of 52 cm). Similar studies on hake [5] show that the high level of trawling effort causes growth overfishing.

From a study of sensitivity to the errors related individually to all parameters of the model, it appeared that the estimates of yield per recruit and the biomass are very sensitive to the variation of the slope of the length-weight relationship (b). With a simultaneous variation of parameters of the equa-

Fig. 1. Length frequency distribution (%) and fishing mortality (F) with length for hake fishery in the Mediterranean (a) and Gibraltar Strait region (b).

#### Abstract

In the summer of 2004 the invasive green alga *Caulerpa racemosa* var. *cylindracea* was found in N.P. Mljet in the area of Great Lake which is a unique marine ecosystem. Eradication was conducted with the aim to slow down the algae spread. Manual eradication methods were used such as covering with plastic foil or collecting by underwater suction pump. In two years period the area covered by alga was significantly reduced.

Keywords : Adriatic Sea, Algae.

#### Introduction

The invasive green alga Caulerpa racemosa var. cylindracea was observed in the Mediterranean Sea for the first time in 1991 in Libya. In a period of 20 years it expanded to almost all regions of the Mediterranean [1]. First record in the Adriatic Sea was in September 2000 in Croatia [2]. Predominantly spreading by current, till the end of 2006 there is more than 50 locations recorded [3, not published data]. In July 2004, the alga was found in Channel Soline in N.P. Mljet between 0.5 and 4 m deep, affecting around 150 m of coastline (Fig 1.). Channel Soline connects open water and two sea lakes which are a unique marine ecosystem. Additional colony of the alga was found just outside of the channel in Gonoturska cove. In September 2004 the alga was found in Grate Lake between 8 and 14 m deep, affecting around 150 m of coastline, just a few meters from the greatest Mediterranean colony of Cladocora caespitosa reef. To protect lakes and the reef of Cladocora caespitosa, eradication of the alga was conducted in channel Soline and in Grate Lake. Colony in Gonoturska cove has affected 600 m of coastline and developed from 1 till 30 m deep. Therefore it was too large for eradication.

Fig. 1. Locations of *Caulerpa racemosa* var. *cylindracea* in National park Mljet. Data of covered area (Cvd), affected area (Aff) and affected coast-line (AffCl) on the first observation.

#### Material and methods

Cartography of location Soline and Grate Lakes was made on 2.5 m wide transects. All detected colonies were eradicated by covering with black plastic foil, by sucking with underwater suction pumps or by manual collecting of small thalli. Plastic foils were left at the bottom for at least 6 months. Applied methods were developed during previous eradication of *Caulerpa taxifolia* [4]. Eradications were made in the beginning and near the end of the vegetative season of the alga (Tab. 1).

#### Results and discussion

Eradication of the *Caulerpa racemosa* var. *cylindracea* colonies was exceptionally difficult. Small fragments are usually invisible until stolon reaches length of 10 - 20 cm. Due to constant eradication efforts number of colonies and covered area was significantly reduced (Tab. 1). *Caulerpa racemosa* var. *cylindracea* is an exceptionally invasive species. Its erad-

ication is difficult due to small fragments, successful reproduction and fast growing thalli. Therefore it was decided by croatian scientists that eradication has to be done in the areas of high biological value but only if the colonies are small, as in the case of Great Lake. Eradication of the alga in Channel Soline and Great Lake can not be done in full due to extensive colony in Gonoturska Cove from where the new fragments or zygotes are carried into Channel Soline and Great Lake. If we allow the alga to spread easily, it would occupy Great Lake, the unique marine ecosystem and destroy the greatest Mediterranean *Cladocora caespitosa* reef. With eradication we can slow down its spreading and protect Great Lake ecosystem. In the mean time, scientist should find global method for algae control, e.g. biological control.

NATURAL AND HUMAN-INDUCED ENVIRONMENTAL CHANGES IN THE LAND-SEA INTERFACE OF THE IONIAN SEA - THE LAMINATED SEDIMENTARY RECORD OF LAKE BUTRINTI (ALBANIA)

Daniel Ariztegui¹*, Jean-Marc Robbiani¹ and Flavio S. Anselmetti²

¹ Earth Sciences Section, University of Geneva, 13 Rue des Maraichers, 1205 Geneva, Switzerland - daniel.ariztegui@terre.unige.ch ² Geological Institute ETHZ, Universitätsstrasse 16, 8092 Zürich, Switzerland

Abstract

Lake Butrinti, located in the Ionian Sea shore of southwestern Albania, contains laminated sediments reflecting regional environmental history. A sedimentological and geochemical dataset combined with an excellent chronology indicate that these lacustrine sediments are recording not only changes in Mediterranean climate but also historic anthropogenic and tectonic events affecting the region during the last 260 years.

Keywords : Ionian Sea, Coastal Systems, Global Change, Eutrophication, Geochemistry.

Coastal areas in the Mediterranean realm provide ideal archives of past and present natural and human-induced environmental changes along the land-sea interface. Lake Butrinti, located in southwestern Albania near the Greek border, is a lacustrine archive containing a perfectly laminated sedimentary succession reflecting regional environmental history [1]. On its shore, the antique city of Butrinti, an UNESCO world heritage site, is a unique archaeological example representing a microcosm of Mediterranean history from the archaic Greek until the Venetian cultures providing an unusual source of continuous documentary data. In addition, a meteorological station located in Corfu -relatively close to the lakeprovides instrumental data to calibrate the modern response of the lake system to the most recent changes in climate (e. g., precipitation). Our results indicate furthermore that the lake system is responding not only to changes in Mediterranean climate and historical anthropogenic impact on the catchment but that it is also sensitive to the documented regional seismic activity.

Water column data and a first set of sedimentary cores were recovered in summer 2000 within the framework of an Albanian-Swiss cooperative project. Physical properties (density, sonic velocity and magnetic susceptibility) allowed the correlation of a set of sedimentary cores throughout the basin. The recovered cores with a maximum length of 2 m consist of a continuously laminated sequence covering the last 260 years as confirmed by Cs-137 isotopes. Each annual lamina is composed of three characteristic layers. One layer consists of authigenic carbonates, a classical source of lacustrine chemostratigraphy in hard water lakes and one of the best paleoenvironmental archives. The dominant climate of the region is typically Mediterranean combining dry and hot summers with cold and wet winters. This seasonality provides ideal conditions to promote the precipitation of carbonates in the water column that are in turn preserved in the sediments as fine laminae. The microstratigraphical analyses of the sequence using a wide range of techniques such as SEM, X-ray microfluorescence and X-ray diffraction showed distinctive sediment types and a variable composition and morphology of the authigenic carbonates. Next to the carbonate laminae, the varves are composed of layers with organic-rich biogenic constituents and of dominantly detrital particles, respectively.

These results together with C and O stable isotopes in both authigenic carbonates and organic matter, as well as bulk organic matter pyrolysis, have been used to reconstruct the climatic and anthropic influence on Lake Butrinti sediments. They revealed a hypereutrophication trend increasing towards the end of the 20th century and a decadal cyclicity in the varves thickness that might be partially controlled by the North Atlantic Oscillation (NAO) and/or ENSO-like phenomena. Additionally, a comparison of distinctive and well-dated turbidites with historically recorded seismic events indicate that earthquakes may have triggered their formation. Supplementary field investigations, however, are still needed to confirm the influence of these frequent tectonics events in the Balkanic region on the formation of the mass-wasting deposits.

Further retrieving of long cores in Lake Butrinti will provide a potentially varved section of environmental change punctuated by historic anthropogenic impact, covering the late Holocene period on a decadal and even annual scale. In particular the construction of a few-km long channel, already initiated during the ancient Greeks and maintained during Roman and later periods, connected the antique City of Butrinti and the lake to

the Mediterranean Sea. This sedimentary archive, hence, might also offer new insights into linking coastal lacustrine deposits and the Mediterranean system.

Acknowledgments

We thank E. Xhemo from the Geological Research Institute, Tirana, Albania, and W. Finger, Zürich, Switzerland, for introducing us to Lake Butrinti and helping with logistics. Sedimentary cores were retrieved by A. Gilli, M. Lehmann and E. Xhemo. Stable isotopes analyses and Cs-137 activities were measured by S. Bernasconi (ETH Zürich) and J.- L. Loizeau (Institute Forel, Geneva), respectively.

SUSAK ISLAND (NORTH ADRIATIC SEA): POSSIBLE PROTECTED MARINE AREA

Milvana Arko-Pijevac¹*, Marin Kirinčić¹, Marcelo Kovačić¹ and Cedomir Benac² ¹ Natural History Museum Rijeka, Lorenzov prolaz 1, 51000 Rijeka, Croatia - milvana@prirodoslovni.com ² University of Rijeka, Faculty of Civil Engineering, V.Cara Emina 5, 51000 Rijeka, Croatia

Abstract

The program encompasses environmental research of the submarine zone of Susak Island (Kvarner bay of the Northern Adriatic Sea), with the aim of proposing the establishment of a protected area. The submarine zone of Susak Island should be proposed as a protected area for the following reasons: the morphogenesis and geological composition of Susak island and the shallow surrounding submarine plateau are unique among the islands of the Northern Adriatic Sea; 3 biocenoses, 4 floral species and 15 invertebrate species found are, according to the Mediterranean Action Plan, of conservation interest; this area is surrounded by sea-grass *Posidonia oceanica* community; the submarine zone of Susak Island complements geographically previously proposed marine protected areas in the Kvarner region. *Keywords : Adriatic Sea, Biodiversity, Geomorphology, Marine Parks*.

Susak Island is situated in the open sea of the Kvarner area, to the west of the Cres-Lošinj archipelago. There are no published data about the benthic communities of Susak Island local waters. Only summarized data about the flora and fauna for the Cres-Lošinj archipelago, which includes Susak Island, were published [1].

Methodology

Biological researches of this area were carried out in the period from 6 -12 October, 2006. The research of benthic biocenoses was carried out by using the method of direct observation and photodocumentation by means of SCUBA-diving equipment. On the basis of field notes and material analyses we determined the benthic communities according to standard classification [2]. The decapod crustaceans were researched by direct underwater visual examination and caught by special baited traps during day and night time. The composition of the fish assemblage was investigated by using the visual census method.

Geology of investigated area

Susak Island has a relatively low-lying irregular shape with NW-SE orientation. The surface of the island is 3.76 km^2 . A relatively flat loess plateau bordered by steep slopes around the greater part of the island is the characteristic feature of Susak. The Quaternary loess and loess-like sediments with maximum thickness of 90 m cover Upper Cretaceous limestones [3]. Limestone bedrock is partially visible on the coast. Shallow and narrow submarine plateau has depth range between 5 and 15 m. Steep submarine slopes are situated along the north-eastern and south-western coast of Susak Island. These submerged relief forms separate the narrow submarine plateau from almost flat sea bottom at the depth of 40 to 50 m. The shallow submarine plateau around the island is mostly covered by sand, and silty sand prevails on deeper sea bottom [4].

Results and discussion

A total of 6 hardbed biocenoses were determined: the biocenosis of upper mediolittoral rock, biocenosis of lower mediolittoral rock, biocenosis of infralittoral algae, precoralligenous aspect of a coralligenous biocenosis, coralligenous biocenosis and biocenosis of semi-dark caves. Furthermore, two biocenoses of movable bottoms were determined: the biocenosis of the Posidonia oceanica meadows and the biocenosis of littoral detritic bottom. The island of Susak is surrounded by sea-grass community of Posidonia oceanica, which appears on sandy seabed at the depths of 1 to 25 m. Communities of infralittoral algae are mostly limited to the narrow zone of rocky bottom up to 2 m deep, where, due to the pronounced sea dynamics, the algae of low taluses predominate. The biocenosis of semi dark caves, precoralligenous aspect of a coraligenous biocenosis and facies with Eunicella cavolinii of the coralligenous biocenosis were mostly observed at the steep rocky bottom of the south-eastern side of Susak Island. In the area of investigation 62 species of macroflora (Cyanophyta 1, Rhodophyta 35, Phaeophyta 13, Chlorophyta 11, Angiospermae 2) and 218 species of macrofauna (Porifera 24, Cnidaria 21, Placophora 2, Gastropoda 12, Bivalvia 23, Cephalopoda 2, Echiura 1, Sipuncula 1, Polychaeta 9, Crustacea 36, Bryozoa 8, Echinodermata 14, Tunicata 6, Pisces 55) were determined. Three biocenoses, 4 floral species, 6 species of Porifera, 1 species of Echinodermata, 4 species of Mollusca and 3 species of Crustacea found are, according to the Mediterranean Action Plan, of conservation interest. The characteristics of the benthic communities of the Susak submarine area differ from benthic communities of other previously investigated submarine areas whose aim is establishing protected areas in the Kvarner region (the Islands Ćutin mali and Ćutin Veli, the Kostrena municipality aquatorium and the Prvić, Grgur and Goli islands) [5, 6, 7]. While the most important feature of benthic communities of the Susak submarine area are well developed meadows of Posidonia oceanica, the most important value of other investigated areas are well developed biocenoses of hard bottom (biocenosis of upper mediolittoral rock, association with Nemalion helminthoides; biocenosis of lower mediolittoral rock, association with Lithophyllum tortuosum; biocenosis of infralitoral algae, associations with Cystoseira spp.; coraligenous biocenosis, facieses with gorgonarians (Eunicella cavolinii, Paramuricea clavata) [5, 6, 7]. The submarine zone of Susak Island should be proposed for a protected area for the following reasons: 1) Due to its morphology and geological fabric, Susak island and the surrounding shallow submarine plateau is unique among the islands of the Northern Adriatic Sea channel zone; 2) The present limited research revealed 3 biocenoses, 4 floral species and 15 invertebrate species that are, according to the Mediterranean Action Plan, of conservation interest. It could be expected that future more extensive researches would increase the known biodiversity and conservation interest of this area: 3) The submarine zone of Susak island is unique among the islands of the Northern Adriatic Sea by the wide spread of Posidonia oceanica meadows, a community of particular conservation interest; 4) This area, with its position in the open Northern Adriatic Sea (west of the Cres-Lošinj archipelago), complements previously researched marine zones in the Kvarner area with the aim of proposing the establishment a protected area. The other previously investigated and possibly protected areas are situated in the channel zone of Kvarner area: Ćutin veli and Ćuti mali islands in Kvarnerić aquatorium, near the eastern coast of Cres Island and Prvić, Grgur and Goli islands are situated in Velebit Channel, and Konstrena area, which is near the northeastern coast of Rijeka Bay.

Résumé

L'article présente quelques résultats des analyses de matière organique vivante et non-vivante particulaire de long des côtes roumanines de la mer Noire de Sulina à Copstinesti, en avril 2006. La matière organique particulaire (MOP) du Danube présente des valeurs en δ^{13} C et δ^{15} N plus faibles que la MOP de l'eau de mer de surface. La signature en isotopes stables du fleuve influence d'une manière significative celle de la MOP marine et le zooplancton dont nous avons identifié 24 espèces. Leur densité varie entre 241 ind m⁻³ et 101024 ind m⁻³. Les espèces caractéristiques pour la zone étudiée sont: *Synchaeta littoralis, Asplanchna priodonta* et *Acartia clausi. Mots clès : Black Sea, Coastal Waters, Organic Matter, Zooplankton.*

Les zones côtières à proximité de l'embouchure des grands fleuves se rangent parmi les écosystèmes les plus productifs de la planète.

L'eau des bras Sulina et Sfantu Gheorghe du Danube , ainsi que l'eau de surface (0-10 et 20-30 m de profondeur) de la mer le long des côtes roumaines, a été filtrée sur des filtres GF/F pour l'analyse de la matière organique particulaire (MOP) [1], ainsi que pour les analyses des isotopes stables δ^{15} N et δ^{13} C. L'analyse des signatures de ces isotopes a été effectuée par spectrométrie de masse isotopique en flot continu à combustion assistée par un analyseur élémentaire au Scottish Crop Research Institute (U.K.) selon les techniques usuelles [2].

Nous avons collecté les échantillons quantitatifs de zooplancton dans la colonne 10-0 m avec un filet à traction verticale de maille de 90 μ . Nous avons fait le tri et l'identification taxonomique des organismes, conditionnés avec du formaldéhyde (4%), à l'aide d'un stéréomicroscope Nikon SMZ-2T et d'un microscope Nikon E 200. Les données de densité (D) sont exprimées en nombre d'exemplaires rapportés à un mètre cube d'eau (ex·m⁻³).

Nous avons fait l'échantillonnage en avril (12-17.04.2006) de Sulina à Costinesti. Les paramètres physico-chimiques de l'eau marine (tableau 1) présentent des valeurs normales pour la saison vernale [3].

Tab. 1. Conditions physico-chimiques des eaux côtières de la mer Noire dans la zone d'échantillonnage (12-17.04.2006)

Station	Coord géogra	lonnées phiques	Isobathe (m)	Temp. (°C)	Salinité (psu)	O_2 (mg•l ⁻¹)	Matériel organique (g•m ⁻³)
Sulina Bara	N 45.08	E 29.45	15	12.5	7.7	9.87	85.25 écart type 3.53
Sulina	N 45.08	E 29.47	21	12.7	7.6	9.93	43.80 écart type 1.78
Sf. Gheorghe	N 44.55	E 29.48	20	13.6	6.9	10.13	28.82 écart type 2.54
Zăton	N 44.45	E 29.50	42	14.1	12.9	9.91	3.73 écart type 0.58
Constanta 1	N 44.09	E 28.42	16	11.0	11.5	17.24	2.07 écart type 0.28
Constanta 2	N 44.06	E 28.42	24	9.4	11.3	13.52	-
Agigea 1	N 44.06	E 28.40	17	9.9	9.5	10.06	S.=).
Agigea 2	N 44.05	E 28.42	25.6	8.5	15.2	10.38	
Ef. Nord 1	N 44.04	E 28.43	29	8.4	15.2	10.53	-
Ef. Nord 2	N 44.03	E 28.40	17.5	8.6	15.3	10.32	-
Costinesti	N 43.56	E 28.40	20	7.5	16.7	10.45	-

L'importance des deux facteurs étudiés (site et profondeur) sur la signature en isotopes stables de la matière en suspension a été estimée par des analyses de variance (ANOVA). La MOP du Danube ($\delta^{15}N =$ 4.08+2.20%, $\delta^{13}C = -27.34+1.46\%$ o) présente une signature différente sur les deux bras étudiés (F = 10.10, p = 0.000). Le bras Sf.Gheorghe qui a un débit plus important au printemps présente une signature plus élevée en $\delta^{13}C$ et plus faible en $\delta^{15}N$ que le bras Sulina. La MOP de l'eau marine de surface présente des valeurs en $\delta^{15}N$ (6.64+2.27%o) et $\delta^{13}C$ (-24.36+2.14%o) plus élevées que celles de la MOP du Danube. L'influence du Danube diminue de la côte vers le large et de Nord vers le Sud des côtes roumaines. Elle est plus st plus importante au printemps, en période de crue du fleuve, qu'en automne [2].

Le printemps 2006, dans les eaux côtières roumaines nous avons identifié 24 espèces (12.5% méroplanctoniques et 87.5% holoplanctoniques), les especes d'eaux douces ayant une grande importance (37.5%). Les valeurs de densite sont comprise entre 241 ex·m⁻³à Sf.Gheorghe et 101024 ex·m⁻³ à Eforie Nord 2. Des densités remarquables ont été constatées dans les stations Constanta 2 (22356 ex \cdot m⁻³) et Agigea 2 (58544 ex \cdot m⁻³). Selon les valeurs de l'indice de signifiance écologique, *Synchaeta littoralis* et *Asplanchna priodonta*, suivis par *Acartia clausi*, sont les espèces caractéristiques de la communauté zooplanctonique étudiée [tableau 2].

En conclusion, la MOP du Danube influence fortement les eaux marines et les communautés planctoniques des côtes roumaines. Le zooplancton vernal, est dominé par les éléments fluviatiles apportés par les eaux danubiennes, par les eaux très eutrophes des enceintes portuaires, ou encore par les effluents de la station touristique Eforie Nord qui sont à l'origine de l'augmentation de la densité du zooplancton.

Abstract

In the framework of this study, microfauna (foraminifers, ostracods) and microflora (charophytes, diatoms) of some of the salt lakes located on the Aegean coasts of Turkey were investigated. In total, 43 sediment samples were collected from various salt lakes (Büyük Kemikli Cape, Gallipoli Peninsula; Diremin and Dalyan, Biga Peninsula; Gökçeada Island). Physicochemical measurements, such as temperature, pH and salinity were also recorded in order to compare the marine and hypersaline foraminifera and ostracod faunas and the related environmental conditions.

Keywords : Aegean Sea, Foraminifera, Diatoms, Sediments.

Sediment samples from several of the saltpans and salt lakes located on the Turkish Aegean coastline were analysed (Fig. 1). In total, 31 benthic foraminifera and 13 ostracod species were recorded. Five samples also included three species of Charophytes. Four diatom species were observed only in one of the samples. Morphological anomalies were observed in the benthic foraminifera species. In the framework of this study, the foraminiferal composition typical of the marine environment is compared with that of the lagoon environments, characterized by high salinity during summer.

Fig. 1. Map showing the saltpans and salt lakes sampled.

Marine microfauna of the Northeastern Aegean Sea have been investigated in detail [1, 2, 3, 4, 5, 6, 7, 8]. The species composition differed considerably among sampling sites: 163 foraminifera species have been identified in the Gulf of Saros, 104 foraminifera species around Gokceada Island, 58 foraminifera and 24 ostracod species around Bozcaada Island, 44 foraminifera species around Mitillini Island, 160 foraminifera species in the Gokceada-Bozcaada-Canakkale triangle and 101 species of foraminifera in Gulf of Edremit. In a study concerning the 27 samples from Izmir ÇamaltıSaltpan, due to hypersaline environment (45-52 psu), a different but not much diverse foraminifera-ostracod-mollusc fauna have been identified. Besides, several twin and triplet, as well as morphological aberrant forms of *Ammonia tepida* Cushman have been observed.

In the 43 samples analysed, the most abundant species observed comprised *Adelosina carinata-striata* Wiesner, *A. mediterranensis* (Le Calvez, J. and Y.), *Quinqueloculina disparilis* d'Orbigny, *Quinqueloculina seminula* (Linné), *Nonion depressulum* (Walker and Jacob), *Ammonia compacta* Hofker, *A. tepida* Cushman, *Elphidium complanatum* (d'Orbigny), and *E. crispum* (Linné). The two most dominant species were found to be *N*.

depressulum (Walker and Jacob) and *A. tepida* Cushman. The ostracod species most frequently observed were *Cyprideis torosa*, *Eucypris virens*, *Cypridopsis vidua*, and *Loxoconcha elliptica*. *C. torasa* and *L. elliptica* are known to be freshwater species [9].

Brackish and freshwater species of charophytes were also found in the samples. But the presence of the genus *Lamprothamnium* indicates special ecological conditions. The diatom species observed in one sample belong to the Family Cocconeidaceae Kützing.

Abstract

The degree of Fe, Zn, Cu, Pb and Cd contamination in the coastal section of the Evros River Delta, Northern Aegean Sea was assessed using water, sediment and the macroalga *Ulva rigida* analysis. Zinc, Cu and Pb levels in the water exceeded the European Environmental Quality Standards (EQSs) of waterborne contamination in estuaries and mainly Cu and Pb sediment contents the baseline levels in estuarine sediments. Metal levels in *U. rigida* indicate that the study area was rich mainly in bioavailable Cu and Fe. *Keywords : Estuaries, Metals, Bio-accumulation, Algae.*

Introduction

One of the most important estuarine areas in Southern Europe, owing to its notable natural history and recreational interest, is that of Evros River, Northern Aegean Sea. Although the Evros Delta is protected as a wetland of international value according to the RAMSAR convention and despite the fact that considerable amounts of metals originated from human polluting activities enter Evros River over almost its entire catchment area, no information on metal contamination in the coastal section of the Evros Delta is essentially available. The use of bioindicators is the most employed method in the assessment of metal contamination in coastal environments; among the organisms most used is the green seaweed *Ulva rigida* C. Agardh ([1],[2] etc.). This study aims to assess the degree of Fe, Zn, Cu, Pb and Cd contamination in the coastal section of the Evros River Delta using *U. rigida*, and supplementary water and sediment, analysis.

Materials and Methods

Metal concentrations in water, surface sediments and *U. rigida* were measured seasonally in the coastal section of the Evros River Delta at four stations located at increasing distance from the estuary of the major branch of Evros River, using flame AAS or graphite furnace AAS with Deuterium background correction.

Results and Discussion

Mean Zn, Cu and Pb levels in the water (63.3, 9.8 and 31.5 μ g l⁻¹, respectively) exceeded, whereas those of Fe and Cd (501 and 0.95 μg 1^{-1} , respectively) did not, the European Environmental Quality Standards (EQSs) of waterborne contamination in estuaries (<40 μ g l⁻¹, <5.0 μ g l^{-1} , <25 µg l^{-1} , <1.0 mg l^{-1} and <5.0 µg l^{-1} , respectively). A comparison of metal concentrations in surface sediments of the coastal section of the Evros Delta (Fe: 19270-31310 $\mu g~g^{-1}$ DW; Zn: 68.7-247.0 μg g⁻¹ DW; Cu: 58.7-710.0 μg g⁻¹ DW; Pb: 66.0-219.4 μg g⁻¹ DW; Cd: 0.2-1.6 μ g g⁻¹ DW) with those of several Greek estuaries ([3], [4], etc.) and baseline levels in estuarine sediments (Zn: <100 μ g g⁻¹ DW; Cu: approx. 10 μ g g⁻¹ DW; Pb: approx. 25 μ g g⁻¹ DW; Cd: approx. 0.2 μ g g⁻¹ DW)([5]) reveals that the coastal area near the mouth of the major branch of Evros River shows some degree of contamination with Zn and Cd and overall the coastal section of the Evros Delta with Cu. Pb and Fe. Mean Fe and Cu levels in U. rigida at the study area (Fe: 2994 μ g g⁻ DW; Cu: 22.4 μ g g⁻¹ DW) are among the highest and mean Zn, Pb and Cd ones (Zn: 61.0 μ g g⁻¹ DW; Pb: 6.1 μ g g⁻¹ DW; Cd: 1.1 μ g g^{-1} DW) in the range of concentrations previously reported for the same species at other coastal areas (Fe: 73.58-4300 μ g g⁻¹ DW; Zn: 6-594 $\mu g g^{-1}$ DW; Cu: 1.1-29 $\mu g g^{-1}$ DW; Pb: 0.51-29.8 $\mu g g^{-1}$ DW; Cd: 0.01-2.5 μ g g⁻¹ DW;), some of which are recipients of domestic and industrial wastes (Thermaikos Gulf, central part of Venice lagoon) ([2], [6], [7], [8], [9], etc.). The above suggest a high bioavailability mainly of Fe and Cu in the coastal section of the Evros Delta.

Abstract

Lead concentrations were measured in column, sediments and dominant macrophyte, macroinvertbrate and fish species of a coastal lagoon (Monolimni Lagoon, Northern Aegean). Sediments had the highest Pb contents. *Ruppia maritima* roots, compared to other anatomic plant parts, accumulated higher Pb loads, while this angiosperm leaves contained similar Pb signatures with the green seaweed *Ulva rigida*. Soft tissues of the bivalve *Abra ovata* showed the highest Pb loads among invertebrates. Lead concentrations in whole body of gobies and muscle tissues of mullets were generally lower than those within invertebrates.

Keywords : Metals, Bio-accumulation, Phanerogams, Zoobenthos, Lagoons.

Introduction

Anthropogenic input of heavy metals to coastal lagoons is a potentially serious problem. Nevertheless, scientific knowledge concerning the biological fate and effects of heavy metals in coastal lagoons is limited. This study aims to determine and compare lead concentrations in basic abiotic and biotic components of the ecosystem of a relatively enclosed, macrophyte based Mediterranean lagoon (Monolimni Lagoon, Northern Aegean).

Materials and Methods

Samples of water, surface sediments and biota were collected seasonally from the innermost section of Monolimni Lagoon, where a *Ruppia maritima* meadow occurred. *Ruppia maritima*, the dominant macroalga (*Ulva rigida*), the dominant macroinvertebrates (*Ventrosia maritima*, *Abra ovata*, *Hediste diversicolor*, *Corophium orientale*, *Gammarus aequicauda* and *Crangon crangon*) and the dominant fish species (*Knipowitschia caucasica*, *Mugil cephalus* and *Liza aurata*) were used for analysis; in particular, three anatomic parts of *R. maritima* (roots, rhizomes plus stems, leaves), soft tissues of *A. ovata*, muscle tissues of mullets and whole tissues of the rest species. Lead concentrations were measured using graphite furnace AAS (Perkin-Elmer 4100) with Deuterium background correction.

Results and Discussion

Amounts of Pb obviously reached Monolomni Lagoon; mean dissolved Pb concentrations (25.1 μ g l⁻¹) exceeded the European Environmental Quality Standards of waterborne contamination in estuaries (<25 μ g l⁻¹) and mean Pb contents in sediments (99.1 μ g g⁻¹ dry wt) the baseline Pb levels in estuarine sediments (about 25 μ g g⁻¹ dry wt) ([1]). Lead contents in sediments were significantly higher than those in the biotic components (Mann-Whitney's U-test, p<0.05 or 0.01), reflecting the low bioavailability of this element from sediments. Lead concentrations in *R. maritima* roots (mean 35.7 μ g g⁻¹ dry wt) were markedly higher than those in the other plant parts (p<0.05 or 0.01). This can be explained by the comparatively high sediment metal burden; it may also suggest a high abundance of binding sites in roots and a low or no acropetal Pb translocation ([2], etc.). Leaves and rhizomes plus stems showed similar Pb signatures (10.9-11.5 μ g g⁻¹ dry wt; p>0.05). Lead concentrations in R. maritima leaves did not significantly differ to those in U. rigida (6.9 $\mu g g^{-1}$ dry wt), despite the differences in morphology and physiology. Soft tissues of the deposit-feeding bivalve A.ovata had the highest Pb contents (mean 52.7 $\mu g g^{-1}$ dry wt) among invertebrates, followed by the primarily deposit-feeding polychaete H. diversicolor and the selective deposit-feeding amphipod C. orientale (15.2-10.2 μ g g⁻¹ dry wt), the epifaunal herbivore amphipod G. aequicauda and the selective depositfeeding mudsnail *V. maritima* (5.2-3.4 μ g g⁻¹ dry wt), and finally the epibenthic shrimp *C. crangon* (0.5 μ g g⁻¹ dry wt), that feeds preying on invertebrates (p<0.05). This pattern may mainly reflect interspecific differences in rates of Pb uptake from sediments, since this metal was substantially accumulated in sediments and, being a non-essential one, is taken up by organisms in relation to its environmental levels ([3]). Lead concentrations in fish were generally lower than those within macroinvertebrates. Muscle tissues of both mullets, M. cephalus and L. aurata, showed similar Pb contents (mean 0.8-1.0 μ g g⁻¹ dry wt; p>0.05), probably owing to similar ecological characteristics. Lead contents in mullet

muscles did not significantly differ (p>0.05) to those in the whole body of the goby *K. caucasica* (1.5 μ g g⁻¹ dry wt) despite in fish muscle tissues low metal accumulation generally occurs ([4],etc.).

GÖLMARMARA LAKE (EASTERN AEGEAN REGION): LATE HOLOCENE ENVIRONMENTAL CHANGES

Ozlem Bulkan Yesiladali¹*, M. Namik Yalcin¹, Heinz Wilkes² and Lisa Doner³

¹ Istanbul University, Department of Geological Engineering, Avcılar, Istanbul, Turkey - bulkan@istanbul.edu.tr

Abstract

Gölmarmara Lake's sedimentary record has been investigated by multi-disciplinary approaches, to define environmental and climatic changes during Late Holocene in Eastern Aegean Region. For this purpose two 1.5m long cores were taken from two different depocenters of the Gölmarmara Lake. Along the cores different intervals were distinguished based on lithological, sedimentological properties, type and amount of organic matter and carbon isotopic composition of organic matter. These variations were than used to reconstruct the Late Holocene evolution of the lake system.

Keywords : Organic Matter, Sedimentation, Aegean Sea.

It's known that, even unremarkable changes in climatic, hydrologic, tectonic, volcanic processes are recorded in lake sediments. Although there are a number of recent lake systems in Western Turkey, only a few of them are studied in detail, to investigate this kind of paleo-environmental and paleo-climatic changes during Holocene. One of the less studied lake systems is the Gölmarmara Lake (Manisa). Formation age of the Marmara Lake is reported as Holocene [1], but its exact age is not determined by analytical investigations, yet. It is known that a number of old lake basins, close to the study area (around Salihli-Akhisar-Izmir), existed between Neogene and late Pliocene/late Pleistocene time period. Comparison of the Gölmarmara Lake system with these old lake systems will be one of the most useful approaches not only to understand past (Cenozoic) environmental and climatic conditions, but also to define probable changes of them at recent future in Eastern Aegean Region.

To investigate paleo-climatic and environmental changes during Holocene in Eastern Aegean Region, two different depocenters of the lake were cored by hammer coring techniques. These two cores are approximately 1.5m long and one of them (H3) is taken from the western depocenter of the lake and the other (H5) is from the eastern depocenter. Preliminary analytical result of the H3 core will be presented in detail.

Interpretation of the analytical results indicated that there are two different intervals along the H3 core (Fig. 1).

Fig. 1. The type, amount and carbon isotopic composition variations of organic matter along the H3 core.

First one is 0-115cm interval, which contains relatively high amount of (TOC: 1.4%-3.7%), mixed (HI: 82-315 mg HC/ g TOC) organic matter. The second is 115-150cm interval, which is characterized by less

amount of (TOC: $\leq 0.5\%$), terrestrial (HI: 40-80 mg HC/ g TOC) organic matter. These intervals are also identified by carbon isotopic composition of organic matter and macroscopic investigations such as lithology and sedimentological properties. These variations are interpreted that the sedimentary sequence of 115-150cm is affected by oxidation processes whereas the interval above is deposited in a shallow lake environment. Furthermore variations in mineralogical composition, amount and type of organic matter will be discussed both in terms of environmental changes in the lake system and also of external effects such as climate, tectonics and hydrology.

THE EROSIONAL RETREAT OF THE ITALIAN COASTLINE AND ITS MEASUREMENT BY GIS TECHNOLOGY

Nicola Calda and Renzo Valloni *

Department of Earth Sciences, University of Parma, Area delle Scienze, 43100 Parma, Italy - renzo.valloni@unipr.it

Abstract

At the beginning of the 21st century one third of Italian beaches is subjected to erosion. The reconstruction of the historical trends of the coastline and the monitoring of actual variations is strongly facilitated by GIS technology. The adopted procedure is based on the overlay of two georeferenced time-sepatated images, the digitization of the two coastlines, the color distinction of areas subjected to shoreline retreat and advancement and the linear and areal measurement of coastal change.

Keywords : Beach, Erosion, Gis, Tyrrhenian Sea, Adriatic Sea.

Coastline erosion

From mid 20th century the stability of the Italian shoreline is increasingly deteriorating. In the literature two important surveys on Italian beaches stand out. The first, known as *De Marchi Report* [1] provides the national picture in the year 1968 with 600 km of eroding beaches. The second known as *CNR Atlas of the Italian Beaches* (1997) depicts the stretches of eroding beaches totalling ca 1000 km [2].

Shoreline erosion is caused by both natural and anthropogenic factors. Among natural factors subsidence may be very important especially in the northeast; the wave climate, affected by increasing storminess, is also important. Anthropogenic factors are frequently overwhelming, converging towards the reduction of river sediment transport to the coast.

Definitions

The measurement of the variation of the physical position of the coastline based on the comparison of dated maps of airphotos is a common practice. The measured change however says nothing of what happened between the considered time-frames; actually the rate of coastal retreat or advancement cannot be measured and may also vary as a consequence of coastal defence interventions.

The coastline is the expression of a dynamic equilibrium; its position in time indicates: *Retreat* (erosion) or *Advancement* in case of migration towards the mainland or the sea, respectively.

Lenght of the coastal stretch (km): Linear development of the coastline measured on the younger image of the couplet; the front of morphologically stable river-mouths is not measured.

Maximum retreat or advancement (m): Straight-line measurement of the distance between the two coastlines made on the transept of maximum migration.

Land surface balance (sqkm): Surface difference between the advancing and retreating portion of the considered coastal stretch. The coastal area increase or decrease is indicated by the positive and negative signs, respectively.

GIS Measurements

This research revealed that the most severe retreat of the Italian coastline is found at the tip of major deltas. This is caused by the wave exposed delta front protrusion and the concomitant reduction of river sediment flux.

The rivers and their respective drainage areas are: Arno (9.116 sqkm), Tevere (17.369), Liri-Garigliano-Volturno (11.326), Po (71.057), Adige (11.981) and Tagliamento (2.871). The analysis of airphotos of the indicated time interval using the ESRI ARC-GIS software provided the following results.

Tyrrhenian Sea - Arno delta, Tevere delta, Garigliano and Volturno delta Duration, time interval (yr) 37, 1959-96 45, 1950-96 39, 1957-96 Lenght of coastal stretch (km) 18.2 33.0 38.5 Retreating shoreline (km) 10.1 (55.5%) 13,8 (41.8%) 17.0 (44.2%) Maximum retreat (m) 273 232 712 Land surface balance (sqkm) -0.76 nc -0.63

Adriatic Sea - Po delta, Adige delta, Tagliamento delta Duration, time interval (yr) 51, 1945-96 33, 1963-96 45, 1951-96 Lenght of coastal stretch (km) 71.6 10.9 16.6 Retreating shoreline (km) 37.6 (52.5%) 5.1 (46.8%) 8.7 (52.4%) Maximum retreat (m) 1466 233 341 Land surface balance (sqkm) -7.19 nc

LE COMPLEXE LAGUNAIRE DE NADOR (LITTORAL MÉDITERRANÉEN ORIENTAL, MAROC): FONCTIONNEMENT - CONTRÔLE NATUREL ET PROVOQUE - ÉVOLUTION

Naima Hamoumi

Faculté des Sciences, Université Mohammed V- Agdal, Rabat, Maroc - naimahamoumi@yahoo.fr

Résumé

L'étude de toutes les composantes de l'écosystème lagunaire de Nador (masse d'eau, sédiments, microfaune) ainsi que ses domaines physiographiques et son bassin versant, complétée par les données historiques, a permis de comprendre son mode de genèse et de fonctionnement et de mettre en évidence des évolutions d'ordre spatial et temporel à une échelle saisonnière et à l'échelle du millénaire. Ces évolutions sont liées à des facteurs naturels qui peuvent être interdépendants ou agir de concert et à des facteurs anthropiques. L'analyse de l'impact des facteurs naturels a également permis de prédire sept scenarii d'évolution future de cet écosystème. *Mots clès : Lagoons, Coastal Systems, Western Mediterranean, Time Series.*

Introduction

La lagune de Nador (Fig. 1), présente un intérêt particulier, aussi bien sur le plan écologique, que sur le plan socio-économique, il était donc intéressant de connaître son fonctionnement et sa morphodynamique. Pour ce faire, une nouvelle démarche a été appliquée pour la première fois dans le cadre du projet COLASU. Elle intègre, d'une part, l'étude de toutes les composantes de l'écosystème lagunaire (masse d'eau, sédiments, microfaune) et d'autre part, celle de tous ses domaines physiographiques et de son bassin versant (dans ce volume). De plus, elle fait intervenir des disciplines et des techniques variées: étude morphostructurale, géomorphologie, étude de la qualité de l'eau, sédimentologie, écologie, télédétection et SIG, couplés à un suivi de l'état de l'environnement.

Fig. 1. Situation de la lagune de Nador.

Fonctionnement et organisation la lagune

La corrélation des milieux identifiés: milieux sédimentaire, milieux écologiques et zones hydrologiques et hydrochimiques (dans ce volume), a permis de reconstituer les zones dynamiques de la lagune, de suivre leurs répartitions spatiales pour l'actuel (hiver 2003, été 2004) et pour une période ancienne, estimée à 1000 - 1200 ans BP d'après les datations de Mahjoubi [1] et de préciser le contrôle naturel et anthropique. Cinq zones ont été ainsi reconnues pour l'actuel: la passe et ses alentours proches (zone I), la bordure interne de l'île barrière (zone II), la partie centrale de la lagune (zone III), les extrémités NW et SE (zone IV), la partie nord de la bordure continentale (zone V) et la partie sud de la bordure continentale (zone VI). L'impact saisonnier n'entraîne pas de modification dans l'organisation de la lagune, seule la bordure sud de la zone III subit un changement de son milieu écologique. Cependant, il y a 1000 à 1200 ans BP, le fonctionnement de la lagune était différent du fait de la position de sa limite continentale qui coïncidait avec la limite continentale actuelle du marais salant de Taouima et de celle de la passe qui était au niveau du double tombolo. Les zones dynamiques I, III, V, VI et II, existaient déjà , mais la zone II se limitait à la partie nord de la bordure interne de l'île barrière, la partie sud de cette bordure correspondait à une zone plus confinée (Zone IIa). De plus, à l'emplacement de la zone IV actuelle, se développait une zone où l'influence marine était plus importante (Zone IVa). Enfin, la bordure continentale sud actuelle correspondait à la marge de la partie centrale de la lagune (Zone VIa).

Contrôle naturel et anthropique et scenarii d'évolution futurs La lagune de Nador résulte de la transformation d'une baie comme le montre le MNT et l'analyse morphostructurale. Sa genèse et son évolution ont été contrôlées par la tectonique et le climat. La tectonique contrôle la morphologie du littoral et constitue le moteur : de la subsidence, des mouvements de failles entre les différentes unités de l'île barrière, qui induisent l'ouverture des passes et du tectono eustatisme. Le climat global est à l'origine des mouvements glacioeustatiques durant le Quaternaire, il détermine également le climat local qui contrôle les apports sédimentaires, l'hydrologie côtière, la géomorphologie et la morphodynamique. Il y a 1000 à 1200 ans BP, cet écosystème correspondait déjà à une lagune de type restreinte avec une île barrière étroite et rectiligne de type microtidal. Le changement enregistré dans son mode de fonctionnement depuis cette époque, est lié essentiellement à des évolutions géomorphologiques. Son fonctionnement actuel n'a pas changé depuis quelques années comme le montre les travaux précédents [2, 3 et références citées dans ce volume] et sa profondeur ne varie que durant les périodes d'ensablement de la passe, du fait de la prédominance du taux de subsidence sur celui des apports sédimentaires [1]. Cependant, son équilibre actuel est menacé par les activités anthropiques qui se sont accrues et diversifiées ces dernières décennies. L'impact de la pollution continentale affecte la qualité de l'eau ainsi que la biodiversité et la densité de la microfaune, l'aménagement de la passe engendre des problèmes d'érosion et d'engraissement du littoral et favorise l'ensablement de la lagune, enfin, le comblement artificiel de l'extrémité NW accentue les processus de confinement [4]. L'analyse de l'impact des facteurs naturels identifiés, permet également de prédire sept scenarii d'évolutions futures faisant intervenir : la tectonique (exhaussement ou affaissement de la lagune ou mouvements verticaux et /ou décrochants au niveau de l'île barrière), le volcanisme, les variations eustatiques ou leur interaction.

INFLUENCE DES APPORTS D'EAU SUR LA VARIATION DE LA SALINITÉ DANS LA LAGUNE DE L'ICHKEUL (TUNISIE SEPTENTRIONALE)

Besma Chaouachi¹*, Abdessalem Shili² and Oum Kalthoum Ben Hassine¹

¹ Faculté des Sciences de Tunis, Tunisie - Besma.Chaouachi@fsb.rnu.tn

² Institut National Agronomique de Tunisie.

Résumé

Les salinités des eaux de la lagune de l'Ichkeul sont influencées par l'évaporation et par les apports d'eaux d'origine marine ou continentale. Les fluctuations des salinités ont été très importantes durant la période d'étude (1992-1996) avec des valeurs comprises entre 6,2 psu et 73,5 psu. L'augmentation des salinités peut être expliquée par les variations hydroclimatiques et par les aménagements hydrauliques. *Mots clès : Hydrology, Lagoons, Salinity.*

La lagune de l'Ichkeul était tributaire d'un grand réseau hydrographique qui l'alimentait en eau douce (figure 1). Cependant, les barrages construits sur les principaux oueds qui se déversent dans la lagune ont réduit les apports d'eau douce. Durant la période d'étude (janvier 1992-août 1996), les relevés ont intéressé le sens du courant de l'oued Tinja, noté quotidiennement à la station de Sidi Hassoun et la salinité de l'eau, relevée en moyenne tous les mois dans une station centrale de la lagune.

L'observation du courant de l'oued Tinja nous a permis de distinguer une période de courant entrant continu dans la lagune de l'Ichkeul qui reçoit des apports d'eau marine, une période de courant sortant continu de la lagune de l'Ichkeul qui déverse son surplus en eau douce dans la lagune de Bizerte et une période d'alternance. La date et la durée de ces périodes influencent les migrations des poissons euryhalins comme les muges et les anguilles (juvéniles vers la lagune et adultes vers la mer) qui se font en contre courant. Les salinités des eaux ont considérablement varié entre un minimum de 6,2 psu relevé en février 1993 et un maximum de 73,5 psu enregistré en septembre 1995 (figure 2). Les fluctuations ont été observées à l'échelle saisonnière et annuelle.

Fig. 1. Situation de la lagune de l'Ichkeul.

En effet, durant l'année 1993, les salinités ont été comprises entre 6,2 psu et 38,3 psu avec une moyenne annuelle de 19,5 psu. Pour les deux années 1994 et 1995, relativement sèches, les salinités ont fluctué respectivement entre 24,0 psu et 67,0 psu avec une moyenne annuelle de 41,2 psu pour la première année et entre 40,2 psu et 73,5 psu avec une moyenne annuelle de 54.6 psu pour la seconde. Ces valeurs élevées expliquent la disparition des herbiers à Potamogeton pectinatus, principale source de nourriture pour les oiseaux aquatiques. D'une manière générale, les salinités les plus basses sont observées à la fin de l'hiver et au printemps (février 1993 et 1994 et avril 1995). Elles augmentent ensuite progressivement pour atteindre un maximum en automne (octobre 1993, septembre 1994 et 1995). Les salinités mesurées durant la période d'étude sont nettement supérieures à celles relevées les années précédant notre travail [1, 2, 3]. Cette augmentation peut être expliquée par les variations climatiques mais également par la réduction des apports en eau douce. En effet, la mise en eau des barrages de Joumine (en 1984), de Ghezala (en 1988) et de Sejnane (en 1994) a réduit les apports par les affluents de la lagune et a entraîné par conséquent une élévation des salinités des eaux.

Le suivi régulier du sens du courant et de la salinité des eaux, bons in-

dicateurs des capacités trophiques de la lagune nous a permis d'analyser certaines variabilités surtout avant la mise en service de l'écluse. Celle-ci, construite sur l'oued Tinja, est un aménagement compensatoire destiné à régulariser et à contrôler les échanges entre le plan d'eau de l'Ichkeul et la lagune de Bizerte.

Fig. 2. Evolution saisonnière de la salinité des eaux dans la lagune de l'Ichkeul (janvier 1992-août 1996).

Résumé

La variation saisonnière des apports d'eau dans la lagune de l'Ichkeul préserve sa richesse faunistique et floristique. La pluviosité annuelle moyenne est de 609 mm. Le niveau moyen est de 0,23 m NGT avec un maximum de 0,91 m NGT. L'évolution saisonnière des précipitations et du niveau de l'eau montre une bonne concordance entre les maximums et les minimums enregistrés. Les dates d'établissement des courants continus sont tributaires du niveau de l'eau dans la lagune. Mots clès : Coastal Systems, Lagoons.

La lagune de l'Ichkeul communique indirectement avec la mer Méditerranée par l'intermédiaire de la lagune de Bizerte à laquelle elle est reliée par l'oued Tinja. Elle est alimentée en eau douce par les pluies arrosant directement le plan d'eau et les eaux drainées par son bassin versant. Pendant la saison pluvieuse, les oueds se déversent dans la lagune et entraînent l'élévation de son niveau. En période sèche, en revanche, l'absence d'apports d'eau douce et la forte évaporation engendrent un abaissement du niveau de l'eau. L'alternance saisonnière caractéristique du niveau et de la salinité préserve la diversité et la richesse de l'écosystème et maintient tout autour de la lagune un système de marais recherché par les oiseaux migrateurs. Cependant, trois barrages ont été édifiés sur les principaux affluents de l'Ichkeul et trois autres sont en cours. Ces ouvrages ont réduit les apports d'eau douce alimentant la lagune. L'écluse construite sur l'oued Tinja, est un aménagement compensatoire destiné à contrôler les échanges avec la mer.

La présente étude décrit les fluctuations saisonnières du niveau de l'eau et des précipitations durant cinq années hydrologiques (septembre 1991-août 1996). Le niveau de l'eau de la lagune de l'Ichkeul a été relevé au moins toutes les semaines à l'échelle I de Sidi Hassoun, Tinja. Le sens du courant a été noté quotidiennement sur l'oued Tinja. La quantité de précipitations fournie par l'Institut National de la Météorologie (INM) a été relevée à la station de Sidi Hassoun.

La pluviosité annuelle moyenne calculée pour la période d'étude est de 609 mm. La saison pluvieuse s'étend du mois d'octobre au mois d'avril. Les fluctuations du niveau de l'eau dans la lagune de l'Ichkeul suivent de près les variations de la pluviométrie (Figure 1).

Fig. 1. Relation entre les précipitations (en mm, données INM) et le niveau de l'eau (en m NGT : Nivellement Général du Territoire) dans la lagune de l'Ichkeul ï£; l'échelle I de Sidi Hassoun (septembre 1991-août 1996).

Le niveau moyen de la lagune est de 0,23 m NGT. La variabilité saisonnière du niveau montre que le maximum peut varier de facon importante (0,27 à 0,91 m NGT) alors que minimum est peu fluctuant (-0,04 m et 0,11 m NGT). Il existe une bonne corrélation entre la hauteur maximale et la pluviométrie durant la saison humide. La relation est nettement améliorée en utilisant la pluviométrie moyenne calculée sur l'ensemble des stations du bassin versant de la lagune. Les précipitations de l'automne (septembre, octobre et novembre) et du printemps (mars, avril-mai) donnent une idée sur l'inversion du sens du courant dans l'oued Tinja (Tableau 1). Au cours de la période d'étude, le courant s'est établi définitivement dans le sens Ichkeul-Bizerte pour un niveau compris entre 0,23 m NGT et 0,40 m NGT. Par contre, il s'est maintenu dans le sens Bizerte-Ichkeul pour un niveau variant de 0,01 m NGT à 0,14 m NGT. Ces résultats confirment les

observations antérieures [1].

Les alternances saisonnières caractéristiques risquent d'être perturbées en raison de la restriction des apports en eau douce. Une bonne gestion de l'écluse permet de maintenir le bon fonctionnement écologique de cet écosystème lagunaire.

Tab. 1. Dates d'inversion du courant de l'oued Tinja (1991-1996).

Années	Vers la lag	une de Bizerte	Vers la lagune de l'Ichkeul		
hydrologiques	Pluviométrie de l'automne	Date du début du courant continu	Pluviométrie du printemps	Date du début du courant continu

A DOWNSCALING EXPERIMENT FOR THE LAGOON OF VENICE. TESTING POTENTIAL IMPACTS OF CHANGES IN PRECIPITATION TEMPORAL PATTERN ON BIOGEOCHEMICAL PROPRIETIES

Gianpiero Cossarini *, Simone Libralato, Stefano Salon and Cosimo Solidoro

Dept. of Oceanography - Ist. Naz. di Oceanografia e di Geofisica Sperimentale, Borgo Grotta Gigante 42/c; 34010 Sgonico, (TS) - Italy gcossarini@ogs.trieste.it

Abstract

A downscaling approach adopting a transport-biogeochemical model coupled with statistical and regional climate model data has been used to assess potential effects of nutrient loads variations, induced by climate changes, on the water quality of Venice lagoon. Results provide evidence of impact of possible regional effects of global climate change: the strengthening of seasonal dynamics - drier summer and rainier autumn - will produce a decrement of productivity of the ecosystem.

Keywords : Adriatic Sea, Lagoons, Global Change, Coastal Models, Geochemical Cycles.

Introduction - Nutrient loadings are among the most influential forcing in coastal and estuarine ecosystems. Climatic changes can induce variations of precipitation patterns and might substantially modify river runoff and nutrient loading both in terms of amount and timing thus affecting water quality of coastal ecosystems. This is one of the less studied effects of climatic changes because of difficulties in describing these cascading changes [1]. This study aims at assessing the potential impact of changes on seasonal precipitation pattern on biogeochemical proprieties in the lagoon of Venice, where spatial distributions and time variability of biogeochemical proprieties are clearly influenced by river runoff and lagoon-sea exchanges [2]. We implemented a downscaling experiment, represented in Fig. 1, which involves four components: a regional climate model providing inputs for two statistical models that gave boundary conditions for a coupled transport-biogeochemical model of the lagoon. The hierarchy of models was used to hindcast present climate and to explore two possible future scenarios.

Fig. 1. Downscaling approach used in our study. domain of the RegCM (modified from [3], upper panel), statistical models (grey circles), TDM (lower panel). The superimposed box indicates the area of interest.

Models - We use the output of a Regional Climate model, RegCM [3], extracting high-resolved meteo data for the drainage basin of the Venice lagoon (Fig. 1). RegCM provided three multidecadal data sets, relative to a present-day climate (1961-1990, RF), and two future scenarios (2071-2100, A2 and B2) [4]. Output of RF run for the area of interest was validated against several climatologies. A statistical logarithmic regression model between annual nutrient loads and observed precipitation was calibrated using historical data and was used to provided annual loads from RegCM output. A climatological annual evolution of nutrients and phytoplankton concentrations at the lagoon-sea boundaries data was modulated according to seasonal precipitation of RegCM output and a regression model based on historical data. Finally a coupled transportbiogeochemical model (TDM) [5] was used to simulate trophodynamics in the lagoon. The model state variables are inorganic nutrients, phytoplankton and zooplankton concentrations and N, C and P contents in detritus and in sediment. Transport is described in term of pure turbulent diffusion, inhomogeneous and anisotropic diffusion tensors parametrize the tidal mixing. Model boundaries are taken from the two statistical models and directly from RegCM output for meteorological conditions. The TDM model, corroborated using experimental data of 2001-2003 period, showed a good performance when simulating very different conditions of both rainy and dry years.

scenarios, A2 and B2, show both a strengthening of the seasonal dynamics, resulting in more precipitation during the rainy season (autumn) and in less precipitation during the dry season (summer) with respect to the present-day situation (RF). The impact of these variations on biogeochemical proprieties was assessed comparing the present-day TDM run RF-forced, with TDM A2 and B2-forced scenarios. The comparison is summarized in Table 1. Changes of the rain regime implied a seasonal variation of nutrient loads characterized by a mean decrease in spring and summer (more intense in A2 than in B2), and an increase in winter and autumn. As a consequence, the mean level of DIN (sum of NH4 and NOx) during winter and autumn was higher in future scenarios than in the present-day run. Such a surplus of nutrients was not utilised in the system and resulted in an increase of nutrients export to Adriatic Sea in A2 and B2 scenarios. In spring and summer the decrease of nutrient loads implied a decrease of nutrient concentrations in the system. Under A2 scenario such reduction caused a widespread decrease in the productivity of system. The number of years characterized by very dry summer increased of about 20% with respect to the RF run.In B2 scenario, the decrement of nutrient content did affect neither mean seasonal phytoplankton biomass nor primary production, but had a strong impact on secondary production, that decreased by 10% during summer (Table 1).

Tab. 1. Seasonal means of RF run (first 4 rows). The other groups of rows report the comparisons (percentage variation) between A2, B2 and RF.

		Input N	DIN	Phytopl.	Prim. Prod.	Sec. Prod.	Export

	AUT	+8%	+7%	+1%	+2%	+3%	+7%
	WIN	+15%	+12%	0%	0%	+2%	+14%
20	SPR	-1%	+4%	0%	+3%	+5%	+7%
	SUM	-6%	-10%	0%	-3%	-10%	-5%
	AUT	.04/	1.20(00/	. 40/	1.01/	01(

Conclusions - Climate predictions showed a strengthening of seasonal dynamics and the decrease of summer precipitation would affect biogeochemical proprieties of the systems: and a productivity reduction of the system would be expected. Such an effect was amplified and more easily recognized in the higher trophic level of the ecosystem.

PLANNING OF MARINE PROTECTED AREAS: USEFUL ELEMENTS TO IDENTIFY THE MOST RELEVANT SCUBA-DIVING SITES

Taira Di Nora , Sabrina Agnesi *, Giulia Mo and Leonardo Tunesi

Central Institute for Marine Research (ICRAM), via di Casalotti 300, 00166 Rome (Italy) - s.agnesi@icram.org

Abstract

Recreational scuba diving is a relevant activity for the success of marine protected areas (MPAs). The case-study of the proposed MPA of Rdum Majjiesa and Ras ir-Raheb (NW Malta) illustrates the key-elements that should be considered in the definition of the scuba-diving attractive sites map, which is an important component for the planning of coastal MPAs. *Keywords : Coastal Management, Marine Parks, Mapping.*

Recreational scuba diving is a relevant activity for the success of marine protected areas (MPAs); it allows visitors to appreciate the effects of protection on marine biota, and can financially support MPAs [1] though it needs to guarantee a sustainable use of the marine environment. For these reasons the planning of new coastal MPAs should take into account the collection of data useful for the future management of scuba activities in the framework of the wider MPA management scheme.

The Italian Central Institute for Marine Research elaborated a zoning proposal [2] and a management plan for the marine area of Rdum Majjiesa and Ras ir-Raheb (NW Malta) (fig.1).

Tab. 1. Matrix applied to calculate intensity values

TOTAL	18	17	19	14	16

The activity, conducted in 2002-2004 and coordinated by the Regional Activity Center for Specially Protected Areas, involved the collection and analysis of environmental and socio-economic data, including recreational scuba diving activities. The present paper centers on the relevant aspects that were considered in the identification process of the most important recreational scuba diving sites. The study area was previously known to host some diving activities but no data was available to determine scubadiving site locations. For this reason, information collected from local experts was used in the preliminary identification and description of the interesting diving sites. The identified zones were implemented in a Geographical Information System (GIS) and reselected using bathymetry and geomorphologic spatial data (layers) derived from previous studies. The bathymetry was used to identify stretches of seafloor with scuba-diving depth ranges, while the geomorphology was used to reselect the specific seafloor typologies that are of interest for diving: screes and vertical or terraced rock walls. Each resulting sector was classified through the main environmental features (variables) which influence diving site selection as identified in previous studies [3]. The variables considered were: geomorphology, spectacular seascapes (shallows, caves etc.); benthos, highly aesthetic benthic species (i.e. Paramuricea clavata, Corallum rubrum); abundance, high specimen density (i.e. shoal of fishes); diversity, species number; size, large specimens; uncommon species, rare/relevant species; visibility, water transparency; access, simplicity in reaching the dive site. Each variable was given an intensity value (importance of the variable for each sector) on a 3 level scale: 0, none; 1, low; 2, medium; 3, high. Five sectors (a, b, c, d, e) were identified and classified (tab. 1).

Figure 1 shows the distribution of the relevant sites classified according to the main environmental features that are attractive for scuba diving.

Fig. 1. Map of the relevant sites for recreational scuba diving

The approach considers the key-elements (main environmental aspects) which determine diver preference, through a standardised evaluation of the dive site potentials. Such baseline data are necessary for the development of economic recreational activities to be conducted in compliance with the MPA aims. The rendering of this type of data, in a specific layer and through a GIS, represents a scientific approach that can support an MPA's zoning and planning process, both when scuba diving activities are already existing and need to be managed (through the construction of a layer representing actual site use) or when they are yet to be promoted and developed (through the construction of a layer illustrating the potential attractive sites). The authors are grateful to Prof. P. Schembri and Dr. K. Pirrotta for their support in data collection.

RADIOECOLOGICAL SENSITIVITY PROJECT ON THE FRENCH MEDITERRANEAN COASTAL ENVIRONMENT

Céline Duffa *, Catherine Mercat-Rommens and Hervé Thebault

Institut de Radioprotection et Sûreté Nucléaire, DEI/SESURE/LERCM, Port du Brégaillon, Base Ifremer, 83507 La Seyne sur Mer,

France - celine.duffa@irsn.fr

Abstract

The radioecological sensitivity of Mediterranean French coasts is evaluated in order to propose a forecasting system usable as decision support in case of accidental nuclear release in the marine environment. Radioecological sensitivity is defined as the result of the combination of physical, biological, socio-economical and radioecological parameters (related to radionuclide specificities). A resulting sensitivity index is then attributed for a given zone.

Keywords : Coastal Management, Radionuclides.

Introduction

The impact of an hypothetical marine radioactive pollution on man and his environment depends on the extent and type of pollution, but also on the polluted environment itself. The economical, toxicological or health repercussions will vary according to the characteristics of the polluted environment and its human use. The marine stage of the Radioecological Sensitivity project (SENSIB project), brought by the French Institute for Radioprotection and Nuclear Safety with funding of the French Agency Environment and Energy Management [1], aims to create standardized tools which make it possible to represent and to compare with the same scale the sensitivity of various coastal environments. This concept will be first dedicated to the French Mediterranean coasts.

Method

The marine radioecological sensitivity is defined as the sensitivity of a coastal environment subject to a radioactive contamination. Sensibility refers to the capacity of a given environment to exhibit significant changes concerning various possible indicators: activity concentration, radionuclide stock or flux. This sensitivity is determined by the relationship between the ecosystem intrinsic characteristics (physical or biological), the radioecological parameters (dependant of the concerned radionuclide) and the socio-economical resources.

These three natures of criteria produce several sensitivity factors, which are studied in the project. The ecosystem characteristics concern geomorphic data, sedimentary type, biological resources and eventually the presence of rare species. The radioecological parameters include dilution coefficient, concentration factors expressing the transfer to biological species, partitioning coefficients (Kd), sedimentary migration rate. The socio-economical criteria refer to professional or recreational activities (fisheries, beaches), resource extraction locations (water intake, aquaculture, etc.) and management areas like ecological reserves.

Values are attributed to these factors regarding their efficiency to increase or decrease the final sensibility indicator. The attributed values can be binary (0/1) or entire values comprised between 0 and 10. Their combination results in a sensitivity index, comparable to the ESI (Environmental Sensitivity Index) previously developed in the United States [2]. This indexation requires the attribution of a weight relative to each factor as regards to the others. This weighting depends both on involved radionuclide and on sensitivity chosen indicator. It is evaluated by sensitivity analysis and by expert judgement.

Hence, environmental sensitivity will be calculated by adding the value of each factor weighted by its contribution. The higher is the number, the more sensitive is the environment.

Finally, resulting sensitivity maps are set up using a management subsystem based on geographical information system (GIS). Similar kind of results, i.e. environmental sensitivity mapping, are often used to characterize oil-spill coastal impact [3] and for coastal integrated management [4] [5] [6]. Such maps allow comparisons of environments as regards their sensitivity. The working scale (country, local...) is important as it determines the level of knowledge that is required when assessing ecosystem and human-use data.

Conclusion

In post-accidental situation, the coupling of sensitivity maps with risk maps (based on radionuclides source term knowledge and marine dispersion modelling) might give localisation of vulnerable coastal areas (Figure 1).

A first application of the radioecological marine sensitivity concept will be carried out on Toulon bay area. This area has already been partially studied from ecological, economical and radioecological points of view. Local sediments have been partially characterized [7]. This area is biologically rich with important beds of *Posidonia oceanica*, shellfish fields, spawning grounds, and different protected areas. Human-uses and economic pressure are also important: fishery, aquaculture and tourism especially. These data are still to be completed and updated, and will be used to characterize and evaluate the global radioecological sensitivity of this area.

AN INTERACTIVE DECISION SUPPORT SYSTEM FOR MANAGEMENT OF THE NILE DELTA SHORELINE OF EGYPT

Ahmed Abdel Hamid El-Gindy 1 *, Omran Frehy 2 and Esam Deebes 2

¹ Oceanography Department, Faculty of Science, Alexandria University, Alexandria, Egypt - aelgindy45@yahoo.com ² Coastal Research Institute, 15 El Pharaana St., 21514, El Shallalat, Alexandria, Egypt

Abstract

The Egyptian Mediterranean Coasts in the south of Levantine basin is suffering from coastal erosion and accretion. Inspite of availability of data and information after measurements and models applications, its management still not advanced. This paper presents an effort done for using GIS application as a tool for making information available to decision makers. Data used are taken by field mesurements, Remote sensing and model applications to estimate the variables affecting shore processes, waves and currents. Keywords : Coastal Management, Gis.

Remote sensing and linked database-geographic information system (GIS) have been combined to build an interactive decision support system to better manage the Nile delta coast of Egypt, 140 km long. This computerbased system is designed to support decision makers and planners to deal with beach protection, human infringements, dune, mining, water pollution, over fishing, beach restoration, archeological sites, set-back line, sedimentation in estuarine, lagoon inlet and navigation channels of the delta harbors. Acting in parallel with these issues are possible consequences and proposed adaptation of relative sea-level rise in the non-protected low-lying coastal areas.

The designed DSS is computer-based system for storing, manipulating, analyzing and displaying spatial and non-spatial coastal data at individual coastal stretch. It enables one to compare a large number of maps employing carefully geo-referenced data. Data collected in this system are essentially based on historic data-base comes from the Coastal Research Institute of Egypt and spanned the last two decades in addition to modeling results obtained in the present study [1-6]. This system enables users to automatically update and revise stored data. The designed system is build using visual basic language and consists of four subsystems:

(1) Collection of data and information such as beach profile surveys, grain size distribution of beach and seabed sediment, water circulation, bathymetry, coastal structures, measurements of wave, hydrographic conditions (Salinity, Temperature, Turbidity and pH), wind, current, and tide. Spatial maps obtained from satellite images and topographic charts are incorporated. This subsystem provides the user interface, operation modules, and the view subsystems with data and set of procedures to complete their functions.

(2) The mathematical operations subsystems are a set of procedures (modules), these modules applied on the system of data collection to obtain the results, which can be displayed through the view subsystem. These operations enable a user to calculate sediment volume change trends, sediment budget and rate of shoreline changes for a particular beach. Further, statistical analysis can be manipulated for waves, current, tide and other related parameters such as wave energy, beach slope, breaker heights on beaches, beach face slope, morphodynamic classification of beaches, and swash runup elevations on beaches induced by storm waves, depth of closure and sediment transport rates.

(3) User interface tool manages interactions between the three linked subsystems. The user interface subsystem has the windows manager, which contains all possibilities and operations to help the user to get the information or results.

(4) The system provides an environment, view subsystem, for displaying geographic reference layers such as illustrations, maps as well as tabulated data. A view is simply a user visible representation of the results and information (database).

The system provide the following assistances to decision-makers and planners:

1- Basic facilities for the manipulation, analysis, retrieval, distribution and storage of coastal related information as well as additional remotely sensed or other thematic information;

2- Technical assistance to outline shoreline management plans;

3-Design data to numerical models required to design protective projects;

4- Baseline data for any future EIA studies;

5- Temporal and spatial information on coastal changes, which will meet the immediate needs of authorities and other user groups; and Mapping positions of set-back distance along the delta coastline.

HOLOCENE SANDY BARRIER EVOLUTION AS INDICATED THROUGH LAGOONAL SEDIMENTARY INFILL. THE EXAMPLE OF THE THAU LAGOON-AND-BARRIER SYSTEM (WESTERN GULF OF LIONS, MEDITERRANEAN SEA, FRANCE)

P. Ferrer¹ *, B. Tessier², M. Benabdellouahed², R. Certain¹, J.-P. Barusseau¹

¹ LEGEM, University of Perpignan, 52 avenue Paul Alduy, 66860 Perpignan Cedex, France - pierre.ferrer@univ-perp.fr ² UMR CNRS 6143 M2C, University of Caen, 2-4 rue des tilleuls, 14000 Caen, France

Abstract

As soon as a littoral barrier begins to construct, isolating progressively a lagoon, the sedimentary infill of the later can start and be potentially preserved. The different stages of a barrier construction and evolution can be thus analyzed by studying the sedimentary record preserved into the lagoon. Such a study has been performed, using very high resolution seismic data and sediment cores, into the Thau lagoon (SE France) that forms during the Holocene transgression. Two main sedimentary units above the rocky basement have been defined into the infilling. U1 corresponds probably to remnants of pre-Holocene continental facies, U2, which constitutes the main part of the infill, represents the Holocene infill. The detailed analysis of U2 allows to reconstruct the palaeogeographic evolution of the lagoon-barrier system during the last stages of the Holocene transgression. *Keywords : Lagoons, Seismics, Gulf Of Lions.*

The Mediterranean coastline is characterized by numerous lagoons that are separated and protected from the sea by sandy barriers (also called lides) resulting from a process of above regularization by usage [1]. These

lidos) resulting from a process of shore regularization by waves [1]. These lagoon/lido systems have been formed during the Holocene transgression and more precisely during the late Holocene period when sea-level rise slow down. Since they are protected from high energy open marine hydrodynamics, the lagoons are the most favorable areas to preserve into their sedimentary infilling, the different stages of construction of the beach barrier and adjacent shoreface that are usually subject to heavy wave reworking.

The Thau lagoon is one of these Mediterranean lagoons. It is located along the shore of the western Gulf of Lions (Languedoc-Roussillon, France) and belongs to a lagoon system that develops from the Rhone delta to the Spanish border. It is the largest and deepest lagoon. In order to study the sedimentary infill of the Thau lagoon, a very high resolution seismic survey has been performed. In addition, some cores have been collected for lithology analysis and ^{14}C dating.

Three main seismic units have been recognized, U0 representing the rocky substratum, U1 and U2 forming together the sedimentary infill of the lagoon [2] (Figure). U0 is represented by tilted, locally folded, reflectors interpreted as Pliocene to Miocene formations. The upper limit of U0 is an erosional surface corresponding to the bottom of the lagoon basin. The basal unit of the infill, U1, is acoustically transparent, locally chaotic, and rests discordantly on U0. Its thickness is variable, from 0 to about 6 m. It is mainly developed where the substratum is the deepest and tends to shape the erosional top surface of U0. U1 has not been reached by coring and its origin is uncertain. It probably corresponds to the very early stage of the lagoon infill, either of continental or marine origin. U2 constitutes the main unit of the sedimentary infill and reaches locally about 15 m in thickness. It rests discordantly on U0, and concordantly on U1. Its upper surface is the lagoon sediment bottom. U2 displays a general aggrading configuration and consists in an alternation of high amplitude and continuous parallel reflectors, and low amplitude, poorly continuous reflectors. U2 can be divided in two sub-units, SU2-1 and SU2-2. SU2-2 is generally concordant on SU2-1, especially where U2 is the thicker, toward the center of the lagoon. On topographic highs of the basement, SU2-2 rests discordantly on SU2-1. A marked unconformity between the 2 sub-units is also observed on the seaward edge of the lagoon, i.e. on the landward face of the present-day lido (Figure). This unconformity is assumed to indicate a probably important landward shift of the barrier.

Thus, as recorded by the lagoon infill through the seismic data, two main stages of construction of the littoral barrier seem to have occurred, a significant retrogradational event having arised between stage 1 (SU2-1) and stage 2 (SU2-2). During each of the stages, seismic facies evidences alternations of period of respectively low energy (high amplitude continuous reflectors) and high energy (low amplitude discontinuous reflectors) deposition that could be related to more or less protected configuration of the lagoon, and thus to the barrier state of stability. Cores collected in SU2-2 are composed of successive sequences consisting of thick shelly layer passing upward to organic rich clayey layer. The process that could explain this sediment alternation is not fully understood but is probably due to change in biological productivity and thus could be related to climate fluctuation. However the link between such changes in sedimentation,

seismic facies, and barrier dynamic cannot be clearly established at the present state of the study.

In terms of chronology, ¹⁴C AMS analyses are in course. However, we assume that the beginning of the lagoonal infill, coeval with the initiation of barrier construction has occurred when sea-level lowed down, and reached almost its present-day level, i.e. around 6.000 B.P. We assume as well that the barrier retrogradational event recorded into the lagoon infill between SU2-1 and SU2-2 could be dated around 2000 B.P. Indeed, previous studies have demonstrated that the regional coastline has severely retreated since Classical times as a result of a drastic decrease in sediment supply [3]. In that hypothesis, the successive sequences preserved into the lagoon infill could represent the record of millennial to multicentennial time-scale climatic cycles that would have controlled sediment supply and the barrier morphodynamic.

Abstract

Excesses of radium and ²²²Rn have been found in cove waters of a karstic area in Minorca (Balearic Islands) pointing out the existence of submarine groundwater discharge. Visible springs actually supply enriched groundwater while sediment does not seem to contribute to the Ra balance. The SGD flux has been estimated to be around 5 cm/d by applying a two endmember mixing model. *Keywords : Coastal Waters, Radionuclides, Geochemistry, Western Mediterranean, Coastal Management.*

Minorca (Balearic Islands), as most of the Mediterranean islands, has limited water reserves that are intensively exploited for the demographic pressure. Minorca is divided in two geological settings: an impermeable area in the north and a permeable band constituting the most important aquifer in the south. This area is characterized by an inclined plain towards the sea, crossed by deep precipices that end into small and narrow coves. This aquifer is composed of miocenic materials highly degraded by erosion and karstification processes. The aquifer supplies up to 90% of the extracted water and from the hydrological balance the submarine groundwater discharge (SGD) is estimated to be up to 38 hm³/yr [1]. This may stand for an input of nutrients to the sea that, in certain circumstances, can induce the proliferation of algae. The present study has been carried out in the Alcalfar cove with an extension of 1.74 Ha.

The Ra quartet (223,224,226,228 Ra) has been proposed as a useful tool to estimate SGD in several environments [2; 3; 4]. The strategy for using Ra isotopes in SGD studies is based on the fact that Ra is greatly enriched in groundwater relative to coastal waters (1-2 orders of magnitude) [5]. It is largely particle-bound in fresh water but desorbs from particles in contact with salty water, so adopting a conservative behavior once released in sea water. In order to determine the SGD, a total of 36 samples were collected from seawater, submarine springs, wells and drive points. The short-lived isotopes, 223 Ra and 224 Ra, where measured with alpha delayed coincidence counting [6], while concentrations of 226 Ra and 228 Ra were determined by gamma spectrometry. In order to complete the series of data, 222 Rn was measured in some samples using a commercial RAD 7 detector.

Groundwater discharges from several visible points along the cove and forms a several mm film above surficial seawater. Concentrations of Ra isotopes in spring samples showed an enrichment in comparison with seawater samples (two orders of maginitud for the ²²⁴Ra). The radiumactivities in cove surficial waters versus salinity pointed out a Ra dilution process taking place when mixing with seawater. On the other hand, cove water samples collected at 10 cm above the sediment presented salinities comparable to the open sea stations and ²²²Rn at bottom waters showed lower concentrations, indicating no detectable groundwater is flowing out through the sediment and thus supporting the idea of the submarine karstic springs as the sole groundwater inputs. A two endmember mixing model between spring and open sea waters has been built to estimate the groundwater fraction in cove waters. An average groundwater fraction of about 30% is obtained when using the radium isotopes distribution. This is translated in an approximate SGD flux of 5 cm/d when considering the width of the cove water's fresh layer and the residence time of the water as obtained from the short-lived Ra isotopes distribution.

Abstract

Spatial distribution and seasonal variability of surface active substances (SAS) and nutrients were studied and correlated for the Northern Adriatic Sea in the period from February 2001 to October 2002.

Keywords : Adriatic Sea, Organic Matter, Po Delta, Surfactants, Eutrophication.

Dissolved organic matter in the sea is an important pool of carbon in the global carbon cycling [1]. Alarge fraction of OM has surface-active properties [2]. The Northern Adriatic Sea is the most productive region in the Mediterranean Sea. The most important source of the nutrients in the region is the Po River and the winter overturn of regenerated nutrients from the bottom layer [3]. As the SAS in the Northern Adriatic are highly dependent on the phytoplankton community production [4]. In this work we aimed to correlate SAS concentration with different nutrients. SAS were determined by phase-sensitive alternating current voltammetry by in-phase measurements using o-nitrophenol as an electrochemical probe [5]. Nutrients (nitrate-NO3, nitrite-NO2, ammonium-NH4, orthophosphate-PO4 and orthosilicate -SiO4) were analyzed by widely used oceanographic methods. Concentration of SAS was correlated separately with the concentrations of different nutrients. The analysis was performed for the two stations 101 and 107 that were representative for the marine system that is under the direct influence of the Po River discharge, and oppositely the system that is rarely influenced by Po River waters, respectively, at water column lavers; 0.5, 5, 10, 20, 30 m and bottom. Temporal distributions of SAS for bottom and surface water for two Stations 107 and 101 are presentedin the Fig. 1.

Fig. 1. The variations of SAS for the eastern Station 107 and western Station 101.

The concentration of SAS of the region varied from 0.042 to 0.145 mg/dm⁻³ equiv. T-X-100. The lower values were observed in February for all water column. The highest SAS values were recorded in surface layer during warm period of the years. In Fig. 2 are presented average concentrations of nutrients for the presented stations and investigated period. Nutrients concentrations were the most variable in low salinity surface water. Bottom layer experienced relatively higher values of all nutrients. Lower values of all nutrients concentrations in the water column were observed at Station 107 as compared to Station 101. Correlation between SAS and certain nutrient concentrations revealed that only statistically relevant correlation was found between SAS and nitrites at Station 107 and depths 0.5 to 20 m (R = -0.51, -0.65, -0.57 and -0.68). Found correlation is negative that might be expected as SAS pool is mainly increasing from nutrients pool. Although statistically irrelevant it is worth mentioning that correlation of SAS with orthophosphate and orthosilicate was mainly found to be negative. Low correlation might be explained with few facts. Northern Adriatic is oligo- to eutrophic region, especially on the westernpart, represented by Station 101. Therefore, phytoplankton was not limited by the nutrients. Also, phytoplankton activity is dynamic and dependant on many factors.

Fig. 2. Average nutrient concentrations for for the eastern Station 107 and western Station 101.

GEOARCHEOLOGIE DU PORT ANTIQUE DE ROME : PREMIERS RESULTATS PALEOENVIRONNEMENTAUX

Jean-Philippe Goiran, Hervé Tronchère * and Carole Ognard

UMR CNRS 5133, Maison de l'Orient et de la Méditerranée, 7 rue Raulin, 69007 Lyon, France - jean-philippe.goiran@mom.fr

Résumé

Au I^{er} siècle ap. J.C. l'empereur Claude construit un port pour Rome sur le littoral du delta du Tibre. Au II^e siècle ap. J.C. Trajan complète le dispositif en construisant son port hexagonal. Une étude géoarchéologique par carottages a été effectuée sur ce site. Les premiers résultats permettent de progresser dans deux directions : 1. La configuration préportuaire : il apparaît que Claude et par la suite Trajan ont tiré parti de la paléo-embouchure du Tibre pour bâtir leurs bassins. 2. Le fonctionnement du port lui-même : le port de Claude était muni d'une double entrée, générant un courant dans le bassin afin de limiter l'ensablement. *Mots clès : Coastal Engineering, Deltas, Geomorphology, Stratigraphy, Western Mediterranean.*

La ville d'Ostie est fondée au milieu du IV^e siècle av. J.C. à l'embouchure du Tibre afin de servir d'avant port à la ville de Rome. Mais ce port fluvial se révèle rapidement peu fonctionnel en raison des forts courants et de la mobilité des bancs sableux d'embouchure, ne permettant pas d'approvisionner suffisamment Rome en blé [1]. Le port de Pouzzoles, près de Naples, redevient alors le principal port nourricier [2].

Au I^{er} siècle ap. J.C. l'empereur Claude fait construire un véritable port pour Rome sur le littoral du delta du Tibre à 3 km au nord d'Ostie. Au II^e siècle ap. J.C. Trajan complète le dispositif en construisant son port fermé hexagonal.

Quelles raisons ont poussé ces 2 empereurs à construire successivement ces deux ports ? Quels étaient le cours du Tibre et la configuration du rivage dans l'Antiquité ? Par où se faisait l'entrée des navires dans le port de Claude ? Sur quelles bases les moles ont-ils été construits ? Quel était le niveau marin, quelle était la profondeur dans le port et quels types de navires pouvaient y accoster ?

Telles sont les questions auxquelles la communauté scientifique essaye de répondre par l'étude des textes et les fouilles archéologiques ponctuelles depuis la Renaissance.

En raison de l'ampleur du périmètre archéologique, de l'omniprésence de la nappe phréatique, de la rapide progradation du delta qui a entrainé l'enfouissement des structures portuaires sous les sédiments [3] et de la construction de l'aéroport sur le site, la méthode d'analyse stratigraphique par carottages nous a paru particulièrement indiquée.

1) L'étude stratigraphique montre 3 séquences sédimentaires distinctes : fluviale, marine et portuaire. La base de l'unité se compose de sédiments fluviaux du Tibre. La transition fluvio-marine brutale, positionnée à -8 m, est datée de 3100 BP. La présence de sédiments marins si récents (IX^e siècle av. J.C) et si profonds implique une défluviation du Tibre et un envahissement de son embouchure par la mer. L'unité sus-jacente est typique d'un environnement portuaire vaseux.

Autrement dit, sous le port antique se trouve la trace de l'ancienne embouchure du Tibre qui se jetait alors en mer selon une orientation est-ouest, beaucoup plus rectiligne qu'aujourd'hui. Au IX^e siècle av. J.C. le fleuve a connu une défluviation qui lui a fait prendre une direction sud avant de reprendre la direction ouest pour déboucher dans la mer, là où sera fondée 5 siècles plus tard la cité d'Ostie sur la rive gauche du méandre [4]. Ces résultats permettent d'affirmer que Claude et surtout Trajan ont utilisé l'ancienne embouchure du Tibre pour faciliter l'implantation de leurs bassins portuaires.

2) Quant à la position géographique de l'entrée des navires dans le port de Claude, la première hypothèse, émise dès le XVI^e siècle, implique une ouverture plein ouest encadrée par deux moles enveloppants construits en partie en domaine offshore [2]. La seconde hypothèse, proposée au XX^e siècle, se base sur la présence, à l'ouest, d'un long cordon sableux formé par les sédiments du Tibre. Cet obstacle naturel contraint une configuration portuaire avec une ouverture au nord [5].

Les principaux carottages ont été réalisés le long du mole nord de Claude. Dans son secteur ouest, la stratigraphie indique non pas un cordon dunaire sur lequel serait venu s'appuyer le mole, mais au contraire, des sédiments marins sur 9 mètres d'épaisseur. Le mole a donc été construit en domaine offshore. Une carotte réalisée dans le mole montre que ses fondations, composées d'éléments grossiers et de pouzzolane, descendent jusqu'a -7 m de profondeur et reposent sur les sédiments marins. Une telle assise amène à reconsidérer la façon dont les ingénieurs ont conçu le port de Claude et de façon plus générale les ports à cette époque.

A l'opposé, les carottages réalisés dans le secteur est du mole montrent

une accumulation de 1.5 m de sédiments marins. La base de ces sédiments a été datée du II^e siècle ap. J.C. Il y avait bien une communication avec le domaine marin mais de faible profondeur. Il s'agissait probablement d'une entrée secondaire, plus tardive, destinée aux navires de faible tirant d'eau. Le port de Claude était donc muni d'une double entrée et les deux hypothèses de départ n'étaient donc pas antinomiques. Cette double entrée devait générer un courant dans le bassin afin de limiter l'ensablement.

Ces premiers résultats géoarchéologiques permettent de faire progresser nos connaissances sur l'histoire des ports et indirectement celle de la navigation antique.

CONTRÔLE ET ÉVOLUTION DES MILIEUX DE SÉDIMENTATION DE LA LAGUNE DE NADOR (LITTORAL MÉDITERRANÉEN ORIENTAL, MAROC)

N. Hamoumi, M. Chafik *, M.A. Hazim, R. Kharbaoui, L. Terhzaz, A. Hourimeche, A. Louaya Faculté des Sciences, Université Mohammed V- Agdal, Rabat, Maroc - naimahamoumi@yahoo.fr

Résumé

L'étude sédimentologique des dépôts intra lagunaires et extra lagunaires (embouchures des oueds) prélevés dans la lagune de Nador (littoral méditerranéen oriental, Maroc) au cours de trois campagnes d'échantillonnage (hiver 2003, été 2004 et hiver 2005), a permis d'identifier les milieux de sédimentation et de suivre leur évolution spatiale pour la période actuelle (Hiver 2003, été 2004 et hiver 2005) et pour une période ancienne estimée à 1000 à 1200 ans BP. Elle a également permis de préciser les sources d'apport, les processus de transport et les facteurs (climat, contexte géologique de l'arrière pays, morphologie et taille de lagune, position de la passe et activités anthropiques), qui contrôlent les faciès ainsi que la répartition et l'évolution des milieux de sédimentation. *Mots clès : Lagoons, Coastal Systems, Western Mediterranean, Sedimentation.*

Introduction

La lagune de Nador (Fig. 1) a fait l'objet d'un certain nombre d'études sédimentologiques [1-5], cependant, dans le cadre du projet COLASU, il était nécessaire disposer de données sédimentologiques récentes et contemporaines de celles de la masse d'eau et de la microfaune (dans ce volume). Ce travail a porté sur l'analyse stratonomique, l'étude granulométrique, la calcimétrie et l'étude minéralogique aux RX (roche totale et minéraux argileux) de 146 carottes (20 à 50 cm) et 146 échantillons de sédiments superficiels prélevés dans les dépôts intra lagunaires et extra lagunaires (embouchures des oueds) lors de trois campagnes d'échantillonnage (hiver 2003, été 2004, hiver 2005).

Fig. 1. Situation de la lagune de Nador.

Les milieux de sédimentation: caractérisation, évolution et contrôle La reconstitution des faciès sédimentaires a permis d'identifier les milieux de sédimentation et de suivre leur évolution spatiale pour la période

actuelle (sommet des carottes de l'hiver 2003, l'été 2004 et l'hiver 2005) et pour une période ancienne 1000 à 1200 ans BP (base des carottes de l'Hiver 2003), estimée d'après les datations effectuées par Mahjoubi [4]. Cinq milieux de sédimentation ont été ainsi reconnus pour la période actuelle.

- La bordure interne de l'île barrière (milieu sédimentaire SI), caractérisée par des sables moyens bien classés et une fraction importante de rudites (galets et fragments de bioclastes), des teneurs élevées en carbonates (26.,5 à 53 %) et l'abondance de feldspaths, de quartz et de minéraux argileux où domine l'illite.

- La partie centrale de la lagune (milieu sédimentaire SII) caractérisée par des sables moyens moyennement à bien classés, des teneurs moyennes en carbonates (26%) et la dominance des feldspaths, de l'illite et de l'aragonite (parmi les minéraux accessoires).

- La bordure continentale (milieu sédimentaire SIII) caractérisée par une prédominance des lutites et des sables mal classés, ainsi que par de faibles teneurs en carbonates (5.3 à 26.5 %) et une prédominance du quartz, de l'illite et de la kaolinite.

- Les extrémités NW et SE de la lagune (milieu sédimentaire SIV), caractérisées par : la prédominance des lutites mais également par l'abondance des rudites au niveau de l'Attalayun, des sables mal à moyennement classés, de faibles teneurs en carbonates (sauf dans la bordure marine), l'abondance de quartz et de minéraux argileux et la présence de minéraux accessoires: gypse, halite, aragonite, hématite et pyrite.

- Les embouchures des oueds (milieu sédimentaire SV) caractérisées par des graviers et des sables mal classés, de faibles teneurs en carbonates (5 à 15 %), la prédominance du quartz et des feldspaths, ainsi que la présence de dolomite, d'hématite, d'illite et de kaolinite.

La comparaison saisonnière a montré que en dehors d'une élévation importante de la quantité des lutites au niveau de la bordure continentale (SIII) pendant l'été, les autres milieux ne montrent aucune évolution significative entre la saison d'hiver et la saison d'été. Cependant, la comparaison des milieux sédimentaires actuels avec ceux de la période ancienne, a mis en évidence l'existence d'une influence marine dans l'extrémité NW (SIV à Ben Ensar) et le Nord de la partie centrale (SII) ainsi que des conditions de confinement au niveau de l'extrémité SE (SIV à Kariat Arekmane), il y a 1000 à 1200 ans BP. Cette évolution confirme les résultats de l'étude écologique (dans ce volume) qui ont montré que la passe était située à cette époque à l'emplacement du double tombolo.

La composition des sédiments reflète une alimentation par des processus de transport variés (écoulements à travers la passe, vagues de tempêtes, émissaires à écoulements torrentiels, ruissellements, vents et écoulements gravitaires) et à partir de sources intra bassin (faune lagunaire, minerais d'épigenèse) et de sources extra bassin (sédiments marins et produits de l'érosion des formations géologiques et des sols du bassin versant, de la bordure continentale et de l'île barrière). Par ailleurs, les faciès ainsi que la répartition et l'évolution des milieux sédimentaires, traduisent un contrôle par le climat, le contexte géologique de l'arrière pays, la morphologie et la taille de lagune, la position de la passe et enfin les activités anthropiques qui accentuent le confinement des extrémités NE et SW.

Résumé

La circulation saisonnière de la lagune de Nador, située en mer Méditerranée marocaine, a été appréhendée à l'aide du modèle hydrodynamique MIKE3-HD. La lagune est classifiée comme étant une lagune de type étouffé et sa circulation est principalement régie par les vents dominants qui sont, sur la période 1991-2001, de secteurs W, NE et ENE. La circulation moyenne de surface de la lagune est présentée ainsi à partir de ces différents champs de vents.

Mots clès : Alboran Sea, Coastal Processes, Lagoons, Coastal Models.

Introduction

La lagune de Nador, située sur la façade méditerranéenne marocaine entre le Cap des Trois Fourches et le Cap de l'Eau, présente un grand intérêt socio-économique pour la région où s'exercent différents types d'activités, notamment celles liées à la pêche artisanale. Cette lagune a fait l'objet de diverses études visant la compréhension du fonctionnement de son écosystème [1-3] mais celles relatives à son hydrodynamisme sont très peu nombreuses [4-6]. L'objectif de cette étude est de présenter la circulation saisonnière de la lagune élaborée par modèle numérique.

Matériel et méthodes

La circulation tridimensionnelle des eaux de la lagune de Nador a été étudiée à l'aide du modèle hydrodynamique MIKE3-HD, calibré et validé sur la période d'automne 2001 [4, 6]. Les vents utilisés dans cette étude pour le forçage du modèle, sont des vents moyens journaliers observés sur la période 1991-2001 [7]; la circulation saisonnière de la lagune est ainsi appréhendée à partir de ces différents champs de vent.

Résultats

La lagune est classifiée comme étant une lagune de type étouffé [4, 6] et sa circulation est principalement régie par les vents [4-6]. Les vents moyens observés sur la période 1991-2001 sont dominants de secteur W durant les mois de novembre, décembre et janvier, et leurs intensités moyennes varient entre 3.8 à 4.4 m.s⁻¹. Ils sont de secteur NE durant les mois de mars, septembre et octobre, avec des intensités moyennes variant entre 4.6 à 5.3 m.s⁻¹. Les vents les plus intenses sont de secteur ENE d'intensités moyennes variant entre 4.6 à 6.2 m.s⁻¹ et dominent pratiquement en février et entre avril à août [6]. Compte tenu de ces différentes configurations des champs de vent, la circulation moyenne de surface de la lagune de Nador va présenter quelques similarités durant les saisons étudiées.

ÉVOLUTION DE LA QUALITÉ DES EAUX DE LA LAGUNE DE NADOR (LITTORAL MÉDITERRANÉEN **ORIENTAL, MAROC) DURANT LA PÉRIODE 2003-2005**

Nissrine Iouzzi, Mohamed Magoua, Loubna Terhzaz * and Naima Hamoumi

Laboratoire Océanologie et Géodynamique des Bassins sédimentaires, Département de Géologie, Faculté des Sciences, Université Mohammed V- Agdal, Rabat, Maroc - loubnater@yahoo.fr

Résumé

L'étude de la qualité des eaux de la lagune de Nador (littoral méditerranéen oriental, Maroc) a porté sur l'évaluation et le suivi des paramètres physico chimiques, des éléments nutritifs et de la matière en suspension des eaux lagunaires (de surface et du fond) et extra lagunaires (émissaires de la bordure continentale), pour les périodes : hiver 2003, été 2003, été 2004 et hiver 2005. Elle a permis de distinguer quatre zones hydrologiques et hydrochimiques dans la lagune, de connaître l'évolution spatio-temporelle des paramètres étudiés et enfin de mettre en évidence une importante dégradation de la qualité de l'eau dans les extrémités NE et SW et la bordure continentale de la lagune qui est engendrée par les activités anthropiques.

Mots clès : Lagoons, Hydrology, Western Mediterranean, Coastal Systems.

Introduction

La lagune de Nador (Fig. 1) a fait l'objet de plusieurs suivis concernant l'hydrologie et l'hydrochimie [1-5], du fait de son intérêt pour l'aquaculture et la pêche. Cependant, il était nécessaire de disposer de données récentes sur la qualité des eaux dans le cadre du projet COLASU. Pour ce faire, un suivi des paramètres physico chimiques, des éléments nutritifs et de la matière en suspension des eaux lagunaires (de surface et du fond) et extra lagunaires (émissaires de la bordure continentale), a été réalisé durant les périodes : hiver 2003, été 2003, été 2004 et hiver 2005, en collaboration avec l'Institut National de Recherches Halieutiques. Les résultats obtenus ont permis de distinguer quatre zones hydrologiques et hydrochimiques dans la lagune et de connaître l'évolution de la qualité de l'eau.

Fig. 1. Les zones hydrologiques et hydrochimiques de la lagune de Nador.

Les zones hydrologiques et hydrochimiques de la lagune

- La zone 1 correspond aux extrémités Nord Ouest (Beni Enzar) et Sud Est (Kariat Arekmane) de la lagune, elle se caractérise par des valeurs de pH élevées et de fortes concentrations en éléments nutritifs qui sont en relation avec un confinement important et la pression anthropique.

- La zone 2 correspond ï£; la passe, elle se caractérise par des paramètres physico chimiques proches de ceux de la mer Méditerranée, des concentrations faibles en éléments nutritifs et un hydrodynamisme énergétique. Elle est contrôlée essentiellement par les facteurs naturels.

- La zone 3 correspond ï£; la partie centrale de la lagune, elle se caractérise par les valeurs les plus faibles de pH (6,8 ï£; 7,92), des concentrations faibles en éléments nutritifs et une faible circulation. Elle est contrôlée par les facteurs naturels.

- - La zone 4 correspond ï£; la bordure continentale entre Nador et oued El Bachir, elle se caractérise par un pH généralement très basique, des teneurs élevées en éléments nutritifs et une turbulence liée aux décharges fluviatiles. Elle est sous l'influence continentale et la pression anthropique.

Evolution de la qualité de l'eau

Les résultats indiquent une importante dégradation de la qualité de l'eau, en particulier dans les extrémités NE et SW ainsi que la bordure continentale durant la période d'étude et par rapport aux données des études antérieures réalisées durant une période où la passe dont la largeur ne dépassait pas 100m, était le siège d'un ensablement. Cette évolution est d'autant plus inquiétante que actuellement, la largeur de la passe (300m), permet une alimentation en eaux marines plus importante.

- Les valeurs du pH varient de (6 - 8) en hiver ï£; (7 - 10) en été et au niveau de Kariat Arekmane, les mesures indiquent une augmentation considérable entre 2003 et 2005, avec un maximum de 9,21 durant l'été 2004 et une alcalinisation importante par rapport aux données des études antérieures, en particulier dans les zones soumises ï£; un stress anthropique très important.

- Les mesures de l'oxygène dissous varient de 6.3 ï£; 8.73 mg/l avec des valeurs maximum au niveau de la passe et du canal d'irrigation. Elles indiquent une diminution par rapport aux données antérieures qui traduit un confinement général.

- Les concentrations en éléments nutritifs montrent une diminution durant la période d'étude de : 0.004 ï£; 0.1 µmol/l pour l'ammoniac, 37 μ mol/ pour les nitrites, 0.1 ï£; 12.3 μ mol pour les nitrates et 0.2 ï£; 8.44 μ mol pour le phosphore qui pourrait être expliquée par une consommation excessive par le phytoplancton. Mais, elles ont augmenté de manière significative par rapport aux données antérieures du fait de l'impact de l'aquaculture.

Les résultats ont également mis en évidence :

- une augmentation de la matière en suspension, en particulier durant l'été 2004 où elle atteint des valeurs de 0,38 ï£; 0,52 mg/l, en relation avec l'augmentation des rejets urbains, le sapement de la bordure continentale et le développement excessif du phytoplancton,

- une augmentation de la température de 11° durant la période d'étude et de 6° ï£; 7° par rapport aux données antérieures,

- des valeurs de la salinité qui varient en moyenne entre 35 et 38 g/l en hiver, et 38 ï£; 40 g/l en été, mais qui restent proches des données antérieures.

Abstract

Three oceanographic cruises were conducted to determine the seasonal and spatial variability of the water column characteristics along the coastal zone of western Thracian Sea, under the variable influence of Nestos River discharge rates. *Keywords : Estuaries, Coastal Waters, River Input.*

Introduction

Nestos River flows for 230 km through Bulgarian and Greek territory before emptying in Thracian Sea. The mean annual discharge for the period 1966-1990 was measured to 37 m³/s, ranging below 10 m³/s (August) and 150 m³/s (February). The coastal area of River Nestos outflow is influenced by the cooler and fresher Black Sea Water (BSW), which moves cyclonically along the Thracian Sea [1]. The present study aims at describing the level of riverine influence in the distribution of nutrients, chlorophyll and suspended matter along the coastal zone near the Nestos River mouth.

Materials and Methods

Three hydrographic cruises were conducted during March, May and August 2006 for the collection of water quality data from 24 stations, commencing 20 km upstream of the river's outflow, following its route and covering the broader river plume area. Sampling cruises took place during high (84.8 m³/s in March 2006), intermediate (59.0 m³/s in May 2006) and reduced (21.0 m³/s in August 2006) river flows. Temperature, salinity, conductivity and density were recorded using a Seabird SBE-19plus CTD. Water samples were collected from the surface and the bottom layer of the water column for the determination of nutrients according to [2] and chlorophyll-a according to [3] method. Finally, meteorological data were obtained from Chryssoupolis Airport located 10 km from the river mouth.

Fig. 1. Surface salinity spatial distribution during (a) high and (b) intermediate river flow.

Results and Discussion

Explicit T-S diagrams were used to define the level of background salinity corresponding to the limit between BSW and river plume water, and thus estimate the freshwater volume of the river plume area [1], which was calculated at 176×10^6 , 172×10^6 and 13×10^6 m³ for March, May and August, respectively. Nestos River dissolved inorganic nitrogen (DIN) loads were calculated at 116.1, 70.9 and 29.4 tones per month for the increased, intermediate and reduced flow conditions, respectively. Similarly,

dissolved inorganic phosphorus (DIP) loads were assessed at 16.7, 21.0 and 3.2 tones per month, for the increased, intermediate and reduced flow conditions, respectively. River plume nutrient concentrations, integrated over the entire freshwater layer, showed that the total DIN content reached 29.6 tones in March 2006, reduced to 5.6 tones in May 2006 and dropped further to 0.4 tones in August 2006. Similarly, the total DIP pool within the propagating river plume water was estimated at 4.5 tones, 4.4 tones and 0.03 tones, respectively. Plume dynamics were mostly governed by the strong geostrophic and tidal currents, enhanced in the Nestos River mouth area due to the presence of Thassos Passage, a narrow canal connecting Kavala Gulf with North Aegean Sea [4]. Atmospheric forcing seems to play a secondary role in plume expansion. Maximum plume surface expansion was observed in May, due to limited vertical mixing (Figure. 1).

Nutrient stoichiometric ratios within the plume depicted nitrogen limitation during March and May, and phosphorus limitation at the distant stations of the coastal zone, under low flow conditions. Nutrients spatial distribution presented an inverse linear relation to salinity, indicating the conservative mixing behavior under high (DIN: R^2 = 0.96, DIP: R^2 = 0.87 and Si: R^2 =0.94) and intermediate (DIN: R^2 = 0.92, DIP: R^2 = 0.89 and Si: R^2 =0.92) flow rates, while weaker correlations prevailed in August (DIN: R^2 = 0.04, DIP: R^2 = 0.13 and Si: R^2 =0.30) due to the limited nutrient fluxes.

NUTRIENT DISTRIBUTION IN THE MEDITERRANEAN COAST OF TURKEY

Asli Kaymakçi Başaran * and Özdemir Egemen

Ege University, Faculty of Fisheries, Dept.of Hydrobiology, 35100 Bornova-Izmir, Türkiye - asli.basaran@ege.edu.tr

Abstract

In this study, seawater samples were collected during September 2005 at 50 points in the eastern and western part of Mediterranean coast of Turkey and analyzed for nutrients, temperature and salinity. The concentrations of nutrient changed between nd-1.60 μ g/L for NO₂-N; nd-7.95 μ g/L for NO₃-N; nd- 25.93 μ g/L for NH₄-N; nd-4.68 μ g/L for PO₄-P; and 0.42-91.09 μ g/L for Reactive Si. The results are compared with data obtained from previous studies.

Keywords : Eastern Mediterranean, Pollution.

Introduction

The coastal zone of the Mediterranean Sea is of considerable socioeconomic importance for Turkey, since it supports large scale tourism, fishing and port activities. Discharge of industrial, agricultural and domestic activities, which are the main sources of nutrients, flow to the Mediterranean Sea. Terrestrial phosphate input into the Mediterranean Sea has been increasing considerably since 1960 [1]. The eastern Mediterranean including Turkish coasts has oligotrophic conditions due to the lack of freshwater input and physical characteristics of water masses [2]. The objective of this study is to determine the nutrient distributions in the Mediterranean coast of Turkey. The results are also compared with the previous studies.

Material and Methods

The study (within the framework of the Project 104Y065 supported by TÜBITAK) was carried out at 50 stations during one month period between 12 September - 7 October 2005. Map of sampling locations are given in Figure 1.

Fig. 1. Map of sampling stations

Surface water temperature and salinity were measured during the sampling cruise with a SCT meter (YSI model). Water samples for nutrient determinations were collected at surface waters in 1000ml polyethylene bottles and then immediately frozen. Samples were kept continuously in deep freeze (-20 °C) until analysis. Sample analyses were generally carried out within one week of the completion of the cruise. Nutrients were measured spectrophotometrically [3].

Results and Discussion

Nutrient distribution is associated with physico-chemical dynamics (temperature, salinity, etc.) of the sea. In this study, the sea surface temperature ranged from 21.4° C to 31.4° C in September. The salinity changed between 13.3-39.4 ppt; low salinities are observed near freshwater input (Station 39). Table 1 summarizes the nitrate, nitrite, ammonium nitrogen, phosphate phosphorus, reac. silicate, salinity and temperature data for the 50 stations all of which the water depth is approximately between 1 and 2 meters. Mean values with the standard error and previous studies are given.

Nutrients (especially nitrite, ammonium, phosphate) concentrations are extremely high at station 15 in the Mersin Bay where the fertilizer, chemistry textile industrial wastes are discharged. Maximum peak in silicate and nitrate concentration took place at station 39 located in Beymelek Lagoon in Antalya owing to the freshwater input. Dissolved inorganic nutrients were generally low in Northeastern Mediterranean Sea [4, 5, 6]. Especially phosphate phosphorus, found below or near detection limit, is considered to be the limiting nutrient in Mediterranean Sea [7].

Tab. 1. Minimum, maximum and mean values together standard	error	of
physico-chemical characteristics and nutrients in Mediterranean	coast	of
Turkey and previous study (range values)		

Variables	Min.	Max.	Mean±SE	Northeastern Mediterranean [4]	Iskenderun Bay [5]	Cilician Basin [6]
Temperature (°C)	21.4	31.0	27.09±0.28	14	15.9-29.0	-
Salinity (ppt)	13.3	39.4	37.34±0.68		38.0-39.2	-
NO2-N (µgat/L)	nd	1.60	0.16±0.03		20	123
NO ₃ -N (µgat/L)	nd	7.95	0.86±0.22	0.05-6.0	0.31-1.63	0.16-0.31
NH4-N(µgat/L)	nd	25.93	1.33±0.52			-
PO ₄ -P (µgat/L)	nd	4.68	0.42±0.15	0.01-0.24	0.08-0.60	0.02-0.03
Reac.Si (µgat/L)	0.42	91.09	10.97±2.16	1.0-11.0	0.5-2.7	0.95-1.2

In conclusion, although the land-based activities (agriculture, industry, tourism) on the Mediterranean region of Turkey has brought increased phosphate and nitrate inputs to the Mediterranean Sea, this coast is not eutrophicated due to the physical characteristics related to the different water masses.

STABLE ISOTOPIC TRACERS (DELTA13C AND DELTA15N) OF RIVERINE INPUTS INTO THE GULF OF LIONS: RESULTS FROM A ONE-YEAR SURVEY

Philippe Kerhervé and Anna Sanchez-Vidal *

CEFREM, UMR-CNRS 5110, Université de Perpignan, 52 av. P. Alduy, 66860 Perpignan - anna.sanchez@univ-perp.fr

Abstract

Continental margins are regions that receive and store high amounts of organic carbon and nitrogen introduced by a variety of terrestrial and marine sources. This sedimentary material represents a complex mixture of biogenic substances with variable biological reactivity. Therefore, a good understanding of the biogeochemical processes requires an accurate estimation on the origin of this detrital material. Stable C and N isotopes are used in this study to define the signature of the terrestrial source and the accuracy consists of the integration of spatial (six different rivers) and temporal (season and flash-flood event) variations. Keywords : Gulf Of Lions, Organic Matter.

Continental margins are dynamic sedimentary environments that receive and store high amounts of organic carbon (OC) and nitrogen (N) introduced by a variety of terrestrial and marine sources. Rivers, termed as "arteries of continents", provide the major pathways for the input of terrestrial organic matter to marine sediments. In addition, riverine inputs are unidirectional fluxes affected by numerous natural factors such as precipitations, mean temperatures and morphology of the draining basin, as well as by anthropogenic factors such as agricultural, industrial and urban uses.

Freshwater inputs from rivers play a major role in the Mediterranean Sea since they enhance significantly the primary productivity and play a major role in the balance of water inputs through the Strait of Gibraltar. However, the actual water discharge of rivers into the entire Mediterranean Sea is estimated to be about 330 km³ yr⁻¹ [1], which is only 55% of the value at the beginning of the 20th century. The sediment fluxes into the Mediterranean have also markedly dropped of an estimated 70% to less than 200 Mt yr^{-1} , because of the massive construction of water reservoirs.

The Gulf of Lions is a key area of the Mediterranean Sea since it receives the Rhone river discharge, the largest river input into the Mediterranean Sea in terms of liquid and solid fluxes. Also, the Rhone river is an exception to the general temporal trend of Mediterranean rivers as its average runoff seems to remain at constant levels. The Gulf of Lions receives also numerous small Mediterranean coastal rivers such as the Tet, Agly, Aude, Orb and Herault rivers (Figure 1). Due to the strong seasonal contrast of climate, the hydrological regime of these small Mediterranean rivers is quite particular compared to other regions. The difference between low and high water discharge in drainage basins of 1.000 to 10.000 km², which is quite typical for Mediterranean rivers, is frequently about one order of magnitude greater than for rivers in non-Mediterranean basins, as the Rhone river [2]. Therefore, the impact of storms on river discharge is largely enhanced in the Mediterranean terrestrial basins where the mountains are adjacent to the shore and where storm frequency is high.

Fig. 1. Location of the sampling sites (circles) on six rivers (Tet, Agly, Aude, Orb, Herault, Rhone) flowing into the Gulf of Lions (NW Mediterranean Sea).

The aim of this study is to perform for the first time a one-year survey on the quality of the riverine particulate organic material discharging into the

Gulf of Lions. Carbon and nitrogen stable isotopes (δ 13C and δ 15N) are used to trace this terrestrial source. Variations of the carbon isotopic ratio in organic matter result mainly from the type of autotrophic species and from the intensity of degradation processes. Regarding nitrogen, isotopic changes in an aquatic ecosystem are mainly explained by the dynamics of inorganic nitrogen compounds and more particularly in rivers, by the intensity of the denitrification process related to waste water treatments in urban areas.

The use of stable isotopes on suspended material will allow us to determine the spatial variations of the terrestrial inputs into the Gulf of Lions and to check if there is a difference in the nature of the organic material discharged by coastal Mediterranean rivers (Tet, Agly, Aude, Orb, Herault) and the Rhone river. We will also determine the temporal variations of these terrestrial inputs into the Gulf of Lions, in order to know if there are seasonal organic material changes in all rivers and how organic matter change during flash flood events.

This survey benefits from the network of sampling stations framed in the ORME (Observatoire de Recherche Méditerranéen sur l'Environnement) programme. Riverine suspended material is monthly and simultaneously collected in the six selected rivers to determine the particulate load and analyze the OC and N contents and the isotopic ratio δ 13C and δ 15N. The study of short-term variations during a flash flood event is carried out on the Tet river, which is equipped with an automatic sampling station.

This integration of spatial and temporal variations of the riverine sources in the Gulf of Lions will improve our knowledge on the functioning of this terrestrial sources and will, therefore, allow us to trace accurately this source into the marine coastal system.

REGULATION ON SHIPS NAVIGATION TO REDUCE RISK OF MARINE ACCIDENTS IN FAVOUR OF MARINE AND COASTAL ECOSYSTEMS ON THE AEGEAN COASTS IN TURKEY

Cem Orkun Kiraç 1 * and Harun Güçlüsoy 2

¹ Underwater Research Society-Mediterranean Seal Research Group (SAD-AFAG), Ankara, Turkey - afag_ankara@yahoo.com ² Institute of Marine Sciences and Technology, Dokuz Eylül University, Izmir, Turkey

Abstract

A regulation on ships navigation was put into force in order to reduce risk of marine accidents after a ship grounding on Çavuş Island, SW Turkey. Following the regulation established in February 2001, certain type and size ships are obliged to navigate out of ecologically sensitive marine and coastal areas in Ayvalik, Foça and Bodrum Peninsula on the Aegean coasts of Turkey. *Keywords : Coastal Management, Conservation, Pollution, Aegean Sea, Water Transport.*

Introduction

Oil pollution by ship accidents require clean-up when spilled oil comprises persistent oils such as crude oil, fuel oil, heavy diesel oil and lubricating oil [1]. SAD-AFAG completed a field study on endangered Mediterranean monk seals Monachus monachus and habitats on the Bodrum Peninsula in 1996 [2] while, interestingly, a heavy but local oil spill was identified on rocky cliffs of Çavuş Island by the first author during the implementation of this project. A sample from the pollution was analyzed by the Ministry of Environment (MoE) who confirmed the pollution was origin of both aliphatic and aromatic hydrocarbons [3]. According to witnesses, a coaster grounded on NW coasts of Çavuş Island in the summer of 1996 and pollution occured by an oil spill from the ship, possibly bilge comprising high density and aged lubricating oils in a few hundred tons quantity, which seriously affected coasts of Çavuş Island and Gümüşlük, a tourist attraction village at 2nm. distance. The fact that Çavuş Island holds important monk seal caves in whole Bodrum Peninsula with surrounding 21 islands & islets [2] forced SAD-AFAG to take action for an oil spill clean-up operation to save marine and coastal ecosystem with special emphasis to endangered monk seals in the area.

Methods

SAD-AFAG, the Friends of Bodrum Society and the MoE have completely cleaned both the oil sludge floating on the sea surface & inside a cave and cliffs & cobble beach on Çavuş Island. 137 tons of oil sludge was collected via labor intensive cleaning methods and dumped into a suitable terrestrial dumping site in 1997 [4]. After clean-up was completed, SAD-AFAG deemed necessary to bring a permanent solution to reduce the risk of further marine accidents. First an analysis was made among SAD-AFAG members and a gap was identified on environmental safety; there was no regulation to let ships avoid to navigate in the narrow waterways near coasts where also biological diversity is rich and/or endangered species inhabit. Therefore, SAD-AFAG proposed Undersecretariat for Maritime Affairs (UMA), the competent maritime authority, to regulate the navigation of ships prohibiting routing through coastal waters between mainland and adjacent islands on Ayvalik, Foça and Bodrum Peninsula in 08.02.1999.

Results

The proposal of SAD-AFAG was thoroughly examined by UMA comparing similar and successful examples in the world. After having the opinions from the relevant organizations, it was finally evaluated affirmatively and the Navigation, Hydrography and Oceanography Dept. (NHOD) announced the new regulation on "areas to be avoided by ships". According to this regulation, *navigation is prohibited within the indicated bounded areas for cargo vessels greater than 300 GRT and all vessels carrying dangerous goods in order to avoid risk of pollution and damage to environment. This interprets that navigation between the mainland and adjacent islands in Ayvalik, Foça and Bodrum Peninsula marine areas is restricted for the purpose of protecting marine life with special emphasis to endangered monk seals and their habitats. It was published in the NHOD's journal Denizcilere Ilanlar (Announcements to Mariners) in 10.02.2001 [5] and the marine areas to be avoided by ships were plotted onto the relevant navigation charts.*

Discussion

Maritime traffic increased %169 in 2004 compared to 1970 worldwide and trend is increasing [6]. In spite of all measures taken, marine incidents shall continue to happen, however, precautionary actions such as understanding the risks and designing the navigational regulations in certain ecologically sensitive marine zones shall reduce the risk of marine incidents. Basic navigational regulations, Traffic Separation Schemes (TSS), Vessel Traffic Management and Information Systems (VTMIS) and Automatic Identification System (AIS) are effective tools. In the maritime areas given in this article, the application of "areas to be avoided by ships", as a basic navigational regulation, is unique in its category in Turkey and no ship accidents resulting in oil pollution happened in these marine areas since the regulation was in effect in 2001.

Fig. 1. The marine areas where regulation is applied on Aegean Sea coasts of Turkey (inset) and the marine area to be avoided by ships indicated with the dotted line at Bodrum Peninsula.

A METHODOLOGY FOR ASSESSING THE CURRENT STATE AND FUTURE TRENDS IN COASTAL AREAS: THE CASE OF KALLONI BAY, LESVOS, GREECE

Dimitra Kitsiou * and Maria N. Kostopoulou

Department of Marine Sciences, University of the Aegean, University Hill, 81100 Mytilene, Lesvos, Greece - dkit@aegean.gr

Abstract

In this paper, a methodology is presented for assessing the current state and future trends in coastal areas which are important prerequisites for the implementation of appropriate management schemes. The methodology is based on the integration of Geographical Information Systems and multiple criteria choice methods. A case study is carried out in the coastal area of Kalloni Bay on the island of Lesvos (Greece) where multiple activities take place causing an urgent need for the application of proper management policies. *Keywords : Coastal Management, Coastal Systems, Gis, Eastern Mediterranean.*

Introduction

Under the legislation of the European Union, the sustainable development of coastal zones is a main priority. To achieve this priority, long-term economic, environmental and social information data has to be analyzed for gaining a better understanding of coastal areas and designing appropriate management plans [1]. Therefore, decision-making in coastal areas involves collaboration among various disciplines related to environmental and socio-economic issues. Geographical Information Systems play a significant role in that field, since they provide a powerful framework where detailed spatial databases can be developed and integrated with appropriate methodologies and models [2]. In this paper, multi-dimensional evaluation and ranking of coastal areas using a set of selected criteria and based on the combination of multiple criteria choice methods and Geographical Information Systems (GIS) was carried out.

Description of the study area

The Bay of Kalloni is a deep coastal embayment at the south-western part of the island of Lesvos with a surface of 110 km^2 . The watershed is limited by steep mountainous formations. Several small settlements and villages are located around the Bay. The area has remained rural and the total population accounts approximately 12.808 inhabitants [3]. During the last 15 years the development of a confined area in Kalloni settlement as a tourist site has been the key factor controlling the economic development of the region. Until now, activities in the area are based on occasional schemes ignoring any sustainable development.

Methodology and analysis results

In this study, a methodology was developed for assessing the current state of the coastal ecosystem of Kalloni Bay and evaluating its future trends towards different aspects of development. The catchment area was divided into five management zones (Z1 to Z5) with a high degree of homogeneity regarding their socio-economic and environmental characteristics. Assessment of the state of each zone was carried out based on selected criteria. The methodology involved combination of GIS with multiple criteria choice methods. The principle of multiple criteria evaluation choice methods is the classification / ranking of alternative choice possibilities on the basis of various criteria. In this study, the regime multiple criteria choice method was applied [4]. In Fig. 1, the division of the study area into five management zones is illustrated.

Fig. 1. Division of the study area into five management zones.

The criteria used for the evaluation of the current state of each zone and the comparison among zones, are the following: C1: Natural and cultural resources, C2: Exploitation of resources, C3: Protection of ecosystems, C4: State of pollution, C5: Population, C6: Quality of life, C7: Human

potential, C8: Primary sector, C9: Secondary sector, C10: Tertiary sector. The analysis was carried out by considering three objectives regarding development: Agricultural, Tourism and Sustainable Tourism. Subsequently, the regime multiple criteria choice method was applied twice for each objective: (a) No weights were assigned to the criteria as they were considered of equal importance. (b) Priorities were assigned to the criteria for representing their degree of importance. It should be noted here that some criteria were given negative values; those represent cost criteria, since the lower their value, the better for the considered objective. The rankings of the zones for each objective are shown in Table 1. Zones Z4 and Z1 are ranked at high levels for all the objectives, since well developed infrastructures are available in these zones. Z3 is always ranked in low levels which can be attributed mainly to the lack of infrastructures. Z2 is more orientated to agricultural development and less to tourism development. Furthermore, the potential for touristic development is better when considering sustainable approaches. Z5 is ranked in better place concerning Tourism and Sustainable Tourism compared to Agriculture, since natural land overwhelms agricultural land. Finally, an important feature is that the zones ranked in lower levels are characterized by a serious shrink of the local population.

Tab. 1. Ranking of the five zones for all the objectives under examination.

		2	Ranking						
Objective	1	2	3	4	5				
Agriculture	No weights	Z1	Z4	Z2	Z3	Z5			
	Weights	Z1	Z4	Z2	Z3	Z5			
Tourism	No weights	Z4	Z1	Z5	Z2	Z3			
	Weights	Z4	Z1	Z5	Z2	Z3			
Sustainable	No weights	Z4	Z1	Z5	Z3	Z2			
Tourism	Weights	Z4	Z1	Z5	Z2	Z3			

Conclusions

The ranking of coastal zones could be useful to coastal decision-makers for assessing their current state, indicating the ones where specific initiatives should be undertaken and evaluating their potential for development in accordance with specific objectives. Finally, the possibility of assigning priorities to the criteria is important, since it allows the reflectance of different viewpoints to be examined.

THREE-DIMENSIONAL MODEL FOR THE SIMULATION OF SUSPENDED MATTER PELAGIC-BENTHIC EXCHANGES IN COASTAL WATERS

Katerina Kombiadou¹*, Yannis Krestenitis¹ and Chryssanthi Antoniadou²

¹ Department of Civil Engineering, Aristotle University of Thessaloniki, Thessaloniki, Greece - kobiadou@civil.auth.gr

² Department of Zoology, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract

A three-dimensional model has been formulated for the description of fine matter exchanges between sea-column and benthos in the coastal environment. The physical processes affecting the properties and the propagation of a sedimentary plume, embodied in the model, include coagulation-deflocculation, the effects of stratification and ambient density to the vertical propagation and the density of the sedimentary plume, settling and deposition on the seabed, self-weight consolidation of deposited particles and erosion of the bed. The usability of benthic ascidia as biological filters was investigated by the exploitation of *in situ* and laboratory experiments. *Keywords : Aegean Sea, Coastal Models, Coastal Processes.*

Introduction

The mathematical model [1] is based on the tracer method and thus describes the sediments entering the marine environment as particles each representing particular mass of matter. Every particle bears personal information in the form of indicators that express the total of the mass that composes the particle, which may however differ between the various particles included in the simulation, enabling the tracing of changes in the characteristic properties of the sediments with time. The physical processes affecting the properties and the propagation of the sedimentary plume embodied in the model include flocculation, settling, deposition, consolidation, resuspension and erosion of the bed.

Description of the mathematical model

The movement of each particle under the influence of coastal currents is analyzed into a deterministic part that expresses advection, controlled by the local fluid velocity and the settling rate of the particles and a stochastic that accounts for the random Brownian motion of the particles. Changes of the characteristic diameter of the cohesive aggregates due to coagulation and deflocculation processes are defined applying the simplified flocculation model. The effect of ambient density to the density of the particle is calculated in relation to the porosity of the cohesive aggregate and the density of the primary particle. These properties are used for the determination of the settling velocity of each particle applying Stoke's law for cohesive sediments. When a particle reaches the bed the shear stress conditions determine the possibility of the particle to deposit and the beginning of self-weight consolidation during which the critical stress for resuspension of the material increases with time the particle remains in deposition. After the completion of the process the particle is considered to be part of the seabed.

The sources of sedimentary particles that can be included are various, among which rivers, aeolian transported matter and erosion of the seabed. Input parameters of the model are hydrodynamic and physical parameters data that include values of seawater velocities, salinity and temperature.

Application of the model for the simulation of the efficacy of benthic ascidia as biological filters

The model has been applied for the investigation of the applicability of benthic ascidia as biological filters. Specifically the model described has been properly adapted so as to mathematically express the filtration of marine water by the ascidia and the removal of suspended material from the water column.

For this purpose the findings of a research program carried out in the gulf of Thermaikos (NW Aegean) for the potential of the ascidia *Styela Plicata* [2] were put to use. Dense ascidia populations were found in the SW gulf, which is the area of application for both the *in situ* [2] and the mathematical experiments. The average filtration efficacy of the ascidia e_{filt} was determined experimentally to be 40%, whereas the length of the ascidia from *in situ* measurements was of an average of 6cm. These parameters were put to use as loss-terms of particle mass in conditions a particle approaches the ascidia populations in their detection distance (d_{det}) [3]. Namely the possibility of absorption P_{ab} of a particle in suspension at a distance z_b from the bed is considered to be zero if $z_b < d_{det}$ and 1 otherwise. The time considered for the assimilation of the particulate matter by the ascidia (t_{ass}) was found to be 2hrs, period during which the absorbed particle is excluded from the calculations. Following full assimilation (t >t_{ass}) the particle reenters the flow with reduced mass (m_p):

$m_p = (1 - e_{filt}) m_{in}$

where m_{in} is the initial particle mass.

The results from the mathematical experiments conducted in the area fully support the findings of the laboratory experiments performed regarding the applicability of benthic ascidia as biological filters, since the efficacy in removing suspended matter from the water-column has reached satisfying percentages.

PRINCIPAL COMPONENT ANALYSIS PHYSICO-CHEMICAL AND BIOLOGICAL PARAMETERS IN THE INNER PART OF BOKA KOTORSKA BAY

Sladjana Krivokapic *, Zivko Stankovic and Nenad Vuksanovic

Department of Biology, Faculty of Science, University of Montenegro, Cetinjski put bb., 81000 Podgorica, Montenegro -

sladjana69@yahoo.com

Abstract

In the period from September 2003 to August 2004, physico-chemical and biological parameters (phytoplankton abundance and chlorophylla) were analysed at five sampling locations in the inner part of the Boka Kotorska Bay. Principal component analysis showed the greatest interaction between chlorophyll *a* and silicates then follows its interaction with nitrites and phosphates in the first group of data. In the second group of data a great interaction between temperature and nitrites was present as well as between transparency and salinity. *Keywords : Adriatic Sea, Eutrophication.*

Introduction

The Boka Kotorska Bay is located in the south eastern part of the Adriatic Sea, comprising a part of the Montenegrin coast. The ecological studies of seawater at the Montenegrin coast, conducted in different seasons between 1995 and 2005 [1], showed that the problem of anthropogenic eutrophication increased. The results of Principal Component Analysis (PCA) carried out using physical, chemical and biological parameters in the inner part of the Boka Kotorska Bay (Adriatic Sea) are presented in this paper.

Materials and Methods

Seawater samples were taken on a monthly basis from September 2003 to August 2004 from five sites in the inner part of the Boka Kotorska Bay. Temperature, salinity and oxygen concentration were measured *in situ* by the use of an oxygen meter. Turbidity was determined with a Secchi disk. Nutrients were estimated by standard methods [2]. Chlorophyll *a* concentration was calculated according to Jeffrey et al. [3]. Abundance of phytoplankton was calculated according to Utermöhl [4]. Statistics 7 was used for statistical analyses of data. Biplot for the studied elements was obtained by using S-Plus statistical programme.

Results and discussion

Principal Component Analysis (PCA) was carried out by the use of physical, chemical and biological data from the inner part of the Boka Kotorska Bay (Fig. 1).

Fig. 1. Biplot of studied physico-chemical and biological parameters at explored sites in the inner part of the Boka Kotorska Bay.

In daily date results of Perez-Ruzafa et al. [5], the relationship between chlorophyll a with nutrients is negative, disagree with traditional models, and suggest that phytoplankton controls nutrient concentration. In the researches of Weckström et al. [6], a great negative correlation between silicates and salinity was expected because the rivers are the main external

sources of silicate in the coastal waters of Finland and that can be accepted as explanation for the data obtained for the Boka Kotorska Bay. Also, great interaction and correlation between chlorophyll a and silicates point out to the statements of Kristianses & Hoell [7], that silicon is an important element in still insufficiently known mechanism of harmful algal bloom. It is possible that the input of nutrients by rain in spring and autumn was the main cause of increased abundance of phytoplankton and chlorophyll a during these researches, while temperature was not a limiting factor that is in concord with the model of Dugdale & Goering [8].While in the investigations of Dorgham et al. [9] the salinity was determined as an important factor in relation to the concentration of chlorophyll a, in this study the relationship between them is negative. A permanent monitoring has to be organized for a better understanding of the interaction between physico-chemical and biological parameters that influence the process of eutrophication in the Boka Kotorska Bay.

THE DISTRIBUTION AND MOBILITY OF IRON IN COASTAL SEDIMENTS COVERED WITH CYANOBACTERIA MATS

Manos Ladakis *, Manos Dassenakis , Christos Belias and Michael Scoullos

University of Athens, Dept of Chemistry, Lab. of Environmental ChemistryPanepistimioupolis 157 71 Athens, GREECE - eladakis@in.gr

Abstract

In coastal marine environments with shallow, warm and calm waters, it is sometimes possible to observe the presence of organosedimentary structures (algal mats). The aim of this work was the study of the distribution and mobility of Fe among the main layers of coastal algal mats in a closed bay at Anavissos, on the coast of the Saronikos Gulf. Small sediment cores were collected and separated to three discrete layers. The trace metals of each layer were extracted according to the BCR sequential extraction method. The main results of the study are: a) The labile forms of Fe are mostly associated with organic compounds and sulfides and b) Fe tends to accumulate in the anoxic layer of the sediment.

Keywords : Algae, Anoxia, Metals, Sediments.

In coastal marine environments with shallow, warm and calm waters, it is sometimes possible to observe the presence of organosedimentary structures, which are produced by sediment trapping, binding and /or precipitation as a result of the growth and metabolic activity of microorganisms, principally cyanobacteria [1].

The aim of this work was the study of the distribution and mobility of various forms of Fe, in the main layers of coastal cyanobacteria mats that have been observed in some Greek coastal areas.

The area under research is a closed bay at Anavissos on the coast of the Saronikos Gulf, 50 Km away from Athens, with an area of about 20,000 square meters. This area has ideal conditions for the development of such formations [2]: A line of beachrocks shuts the bay's entrance, obstructing the water's renewal. At the shallow bottom of the cove (max. depth of about 0.6 meters) a layer of green algae with a thickness of 0.2 - 2 mm is observed, which extends throughout the bottom of the bay [3].

Sediment cores about 10 cm long, were collected seasonally from one point inside the bay that is partly covered with seawater for a course of one year. The cores were separated in three layers that were freezedried and sieved through 0.25 mm sieves: a) the upper one, 0.2 - 2 mm thick, which includes the cyanobacterial mat; b) the middle one, up to 5 cm thick, of dark colour, which is anoxic and has the characteristic odour of hydrogen sulfide; c) the third one, about 5 cm thick, of brown colour, which represents the background sediment. According to the BCR sequential extraction procedure the trace metals were separated in four fractions: Fraction A: metals connected to small inorganic particles and carbonates; fraction B: metals connected to oxides/hydroxides of Mn and Fe; fraction C: metals connected to organic compounds and sulfides; fraction D: metals strongly bound in the alumino-silicate lattice. A Flame Atomic Absorption apparatus equipped with Sample Introduction Pump System and D₂ lamp for the background signal correction was used for the determination of Fe. The contents of all layers of the sediment in the various fractions of Fe are presented in table 1.

Tab. 1. The content of the sediment in Fe (in mg/Kg)

Fraction	Summer 2000	Autumn 2000	Winter 2001	Spring 2001
	Sur	face layer		
A	0.091	0.049	0.050	0.114
в	0.788	0.721	0.230	0.260
С	0.693	1.54	0.526	0.826
D	13.1	11.9	17.5	18.2
	An	oxic layer		
A	0.152	0.185	0.072	0.075
в	0.532 0.577 0.356		0.356	0.253
С	1.43	1.55	1.74	0.981
D	12.7	14.3	17.6	11.5
294	Back	ground layer	1945-20.03	
A	0.040		0.055	
в	0.139		0.190	
С	0.353		0.637	
D	12.6		16.4	

According to that table, 90% of Fe in the surface layer, 88% of Fe in the anoxic layer and 95% of Fe in the background layer is strongly bound in the sediment's crystalline grid. The second most abundant form of Fe in all sediment's layers is the one associated with organic compounds and

sulfides and represents 61%, 72% and 70% of all labile forms in the surface, anoxic and background layers respectively. On the other hand, the less abundant form of Fe is the one connected to small inorganic particles and carbonates as it represents 5 -7 % of its labile forms. About half of the labile forms of Fe accumulate in the anoxic layer of the sediment. In order to explain the distribution of Fe among the sediment's layers we tried to extract the ratio $[Fe^{+3}]/[Fe^{+2}]$ in the porewater as the mobility of Fe is dependent on its oxidizing level. After theoretical calculations we found out that this ratio is a function of the oxygen concentration (PO₂), pH, temperature (T), E_o (of the reaction Fe⁺³ + e⁻ à Fe⁺²; here is 0.770) and the number of electrons moved (n; here is 1). Thus, $\log([Fe^{+3}]/[Fe^{+2}]) =$ f(PO₂, pH, T, Eo, n). When applying the physicochemical measurements that we carried out in the anoxic sediment's porewater (pH = 6.8, T = 293 °K, PO₂ = 0.01 (anoxia), n = 1 and $E_o = 0.770$) we found out that $\log([Fe^{+3}]/[Fe^{+2}] = 0.2$, meaning that considerable amounts of Fe⁺² are present in the porewater. Cyanobacteria that extend through the surface of the sediment uptake inorganic Fe and convert it into organic Fe. After their death, organic Fe is gradually buried in the anoxic layer and converted again into inorganic Fe. A part of the Fe^{+3} is reduced to Fe^{+2} due to the anoxic conditions and partly converted into FeS. As Fe^{+2} is more labile than Fe^{+3} , a part of it can reach the surface via porewater, be oxidized into Fe⁺³ and then be recycled. Figure 1 presents the cycle of Fe in this particular ecosystem.

DÉTERMINATION DES ZONES POTENTIELLEMENT AQUACOLES EN OFFSHORE PAR TÉLÉDÉTECTION ET SYSTÈMES D' INFORMATION GÉOGRAPHIQUES (SIG) : CAS DE LA BAIE DE M' DIQ AU NORD OUEST MÉDITERRANÉEN MAROCAIN.

Résumé

La télédétection et les SIG ont été conjugués dans ce travail pour déterminer les sites aquacoles dans la baie de M'diq. Une image multi bande du capteur TM de Landsat datant du 28 mars 1998 a servi de base: la circulation des eaux, la répartition de la chlorophylle et l'état de la pollution du littoral ont été cartographiés. Les données physicochimiques in situ issues d'une campagne de prospection (juillet 1997) ainsi que celles extraites de l'image ont été intégrées dans un SIG en mode vectoriel. Les fonctionnalités du SIG ont permis la détermination des zones potentiellement aquacoles du loup et de la daurade en cages flottantes et des huîtres, moules et coquilles Saint Jacques en filières.

Mots clès : Aquaculture, Remote Sensing, Swath Mapping, Western Mediterranean.

Le développement de l'aquaculture se heurte de plus en plus à des contraintes environnementales : sites non propices, indisponibilité et non renouvellement des eaux, concurrences avec d'autres utilisations, etc. Le choix des sites en offshore permet de contourner ces problèmes. Pour se faire, les méthodes traditionnelles ne permettent pas une vue synoptique ; de plus, certains paramètres connaissent des changements liés aux fluctuations de la marée, du vent et des décharges d'eau douce.

L'utilisation conjuguée de la télédétection et des SIG permet d'explorer les nouveaux sites aquacoles potentiels [1]. En effet, les données satellitaires sont adaptées à l'échelle marine et fournissent des scènes synoptiques des étendues marines ; de plus, elles sont dotées d'une richesse en informations inhérentes à l'eau puisque le passage des valeurs radiométriques aux grandeurs thématiques se fait aisément à l'aide d'algorithmes et de modèles mathématiques pré-établis [2, 3].

La baie de M'diq, située au Nord ouest méditerranéen marocain, et seule région du Maroc présentant un intérêt pour l'investissement en aquaculture offshore, a été sélectionnée. Le processus d'intégration des données dans un SIG a permis de construire une base de données qui renseigne sur les conditions environnementales de la baie. L'information intégrée en mode vectoriel comprend d'une part des données satellitaires extraites de l'image Landsat TM [4] datant du 28 mars 1998 (fournie par le Centre Royal de Télédétection Spatiale) et couvrant la circulation des eaux, la répartition de la chlorophylle et l'état de la pollution des eaux, et d'autre part, des données physicochimiques mesurées in situ issues lors d'une campagne de prospection du 6 au 21 juillet 1997 dont la température, la salinité, les nitrates, les phosphates, l'ammonium et les matières en suspension [5]. La bathymétrie et la nature des fonds ont été tirées d'un précédent travail dans la région [6].

L'analyse spatiale a permis de réaliser deux fonctions principales : croisements et requêtes. Le processus de croisement des couches thématiques initiales consiste d'abord à établir les croisements primaires suivants : profondeur + types de fonds, salinité + température, MES + oxygène dissous, nitrates + nitrites, ammonium + phosphates et pollutions + chlorophylle. Les croisements secondaires combinent les primaires deux à deux et ainsi de suite jusqu'à la couche finale. On obtient ainsi une couverture dont la taille des attributs englobe tous les paramètres de la base des données.

L'application des requêtes relevant des exigences de la daurade, du loup, des huîtres, des moules et de la coquille Saint Jacques [7] donne directement les résultats escomptés. La figure 1 représente les zones potentielles aquacoles résultantes de l'analyse spatiale des couches thématiques initiales concernant les poissons en cages flottantes et les coquillages en filières.

Considérant les faibles différences des limites de tolérance des espèces vis-à-vis des conditions environnementales [6], il s'est avéré judicieux de procéder à trois regroupements des espèces : daurade et loup, moules et huîtres, et enfin coquille Saint Jacques ; cette dernière a été écartée des autres coquillages, car elle ne supporte pas les hautes teneurs en turbidité. Les zones révélées comme potentielles pour l'aquaculture en offshore montrent bien que la baie de M'diq est apte à l'élevage des espèces étudiées. Les plages de variation des paramètres physicochimiques ne présente aucun obstacle pour la survie des espèces en période estivale. Pour la profondeur, contrainte plutôt technique, l'emplacement des zones sélectionnées comme favorables sont comprises entre les isobathes 10 et 50 m, cette dernière a été choisie comme profondeur maximale vue que la stabilité des structures requiert une installation coûteuset au-delà de cette

profondeur. La turbidité est le seul facteur déterminant dans le choix des sites vu le déversement de deux oueds dans la baie.

La force du courant dans la baie varie de 10 à 70 cm/s au Nord et de 2 à 5 cm/s au Sud [5]. En comparant avec les valeurs limites prescrites, la partie sud de la baie pourrait être favorabsle à la conchyliculture [8]. Alors que la pisciculture en cages ne souffre pas de l'hydrodynamisme de la baie. Les résultats obtenus ne sont qu'une analyse concrète des potentialités aquacoles de la baie en période estivale, la fiabilité définitive des résultats ne peut être acquise qu'après avoir fait la même analyse en période hivernale.

Fig. 1. Zones potentielles pour l élevage de la daurade et du loup en cage (A), de la coquille Saint-Jacques en filières (B), et des moules et des huîtres en filières (C) au niveau de la baie de Mdiq (Maroc).

Abstract

Physicochemical parameters and nutrient concentrations were measured during 13 monthly samplings in the water and 4 seasonal samplings in the sediment at Eratino Lagoon, northern Greece. Salinity data were utilized for freshwater content and discharge determination. Lagoon-open sea interactions were assessed through direct monitoring and budget calculations. An integrated lagoon biogeochemical model was developed to describe nutrient cycling and transformation.

Keywords : Lagoons, Sediments, Phosphorus.

Introduction

Eratino is a shallow (mean depth: 0.5 m) coastal lagoon located in northern Greece with a surface area of about 3.5 km^2 . It is part of a coastal lagoon system, with a total area of 1,700 ha, located at the western part of Nestos River Delta. The lagoon is supplied with freshwater by a small stream (2 km long), draining agricultural land, and communicates with the nearby Kavala Gulf by a tidal channel. Tidal elevation at the lagoon's mouth ranges between 0.14 and 0.39 m [1, 2]. The present study provides a preliminary approach aiming towards the estimation of nutrients influx, the determination of flushing and exchange with the adjacent sea, and the understanding of nutrients cycling inside the lagoon.

Materials and methods

Overall 13 sampling cruises were conducted between August 2005 and August 2006. Water temperature, salinity, pH and dissolved oxygen content were measured in situ at 10 stations inside the lagoon, using portable instrumentation. Nutrients (N-NO₂, N-NO₃, N-NH₄, P-PO₄, Si-SiO₂), chlorophyll-a and total suspended solids were determined at each site [3, 4]. Sediment samples were collected seasonally using a box-corer sampler at 5 stations, to determine nitrates, total Kjeldahl nitrogen (TKN) and total phosphorus content (TP) [3]. Salinity data were used for the freshwater content and discharge estimation [5], while flushing and exchange dynamics were considered from previous monitoring efforts [1]. A lagoon biogeochemical box model was developed [6], and the present dataset were imported for preliminary runs. The model simulates the temporal variability of nutrients (nitrates, ammonium, phosphates, silicates), phytoplankton, zooplankton, detritus (nitrogen, phosphorus and silica), dissolved oxygen and benthic nutrients (nitrogen, phosphorus and silica).

Results and discussion

Sampling sites were classified in three groups (tidal, lagoon, freshwater) according to the factors driving their water quality. The temporal variability of the in situ measurements in the water column, as well as the results from the chemical analyses of the water and sediment samples is presented in Table 1. Salinity depicts inversely proportional relations with nutrient concentrations along the main lagoon axis, although the spatial and temporal variability of sediment nutrient concentrations do not follow a similar pattern. Preliminary model runs evaluate the rates of phytoplankton grazing and mortality, heterotrophs excretion, detritus mineralization and nutrients uptake, along with benthic mineralization, absorption and denitrification.

IMPACTS OF CLIMATE CHANGE ON THE FRESH WATER FLUXES TO THE MEDITERRANEAN SEA: CASE STUDY OF COASTAL RIVERS IN LANGUEDOC-ROUSSILLON AREA (SOUTH-EAST OF FRANCE)

Franck Lespinas *, Wolfgang Ludwig and Serge Heussner

Centre de Formation et de Recherche sur l'Environnement Marin - Université de Perpignan - 52, avenue Paul Alduy 66860 PERPIGNAN - franck.lespinas@univ-perp.fr

Abstract

Languedoc-Roussillon area experimented a high temperature increase during the spring and summer seasons for the period 1965-2004, but no clear evolution for the precipitation. Increase of the associated water loss by evaporation explains partly the general decrease of discharge in the rivers limited to this area and therefore their contribution less important to the fresh water fluxes to the Mediterranean Sea. *Keywords : Gulf Of Lions, Hydrology, Time Series.*

This study was initiated by the recent analyses reported by IPCC (Intergovernmental Panel on Climate Change) about the past, actual and future evolution of bioclimatic conditions on Earth and the observed/excepted consequences on the water cycle. Among recent studies relating to the ongoing climate change context, those pertaining to the Mediterranean area have revealed evidence of a reinforcement of dryness conditions over the recent period [1-3]. This evolution is the result of a couple effect of a high annual temperature increase in the whole basin and a decrease of precipitation observed mainly during the winter months in some countries (Italy, Greece and Maghreb states). These studies also suggest that western Mediterranean basin is presumably more affected by the ongoing Global Change than the others land-sea areas.

As a consequence of these preliminary results, a comprehensive dataset related to the hydroclimatic conditions and atmospheric dynamic patterns has been collected for the Languedoc-Roussillon area for the period 1965-2004. Climatic data were collected from a network of 44 and 117 stations measuring temperature and precipitation respectively (fig. 1). These climatic parameters were spatially interpolated and averaged for 15 subcatchments whose hydrologic data were equally acquired. Main objective of this work was to study possible recent changes of evolution of climatic conditions presumably related to the ongoing Global Change and its consequences on the hydrology of rivers limited to the studied area. These latter are considered typical to Mediterranean basins, that are characterized by a great interannual variability of discharge and occurrence of severe flash-floods. Statistical analysis performed on time series of hydroclimatic data allowed us to study trends and links between surface hydrologic conditions and climatic variability. An attempt to explain origin of the climatic variability and its recent evolution was investigated from correlation analysis between the observed climatic parameters and related to the atmospheric circulation NCEP data.

This study revealed an annual temperature increase of about 1.5° for the entire studied area during the considered period. Temperature increase was the most important for the spring and summer seasons and negligible during the others seasons indicating that annual thermal amplitude has recently significantly increased in this area. Annual precipitation didn't show clear evolution but some catchments (Orb and Herault) experimented a slight shift in the intra-annual precipitation distribution. Increase of pressure conditions over the Mediterranean area for the period 1965-2004 seems to explain mainly the important temperature increase during most months. Furthermore, high positive phases of NAO index during the wintry months explain partly the observed precipitation decrease during this season for the Orb and Herault catchments.

As a consequence of this recent climatic evolution probably added with human activities influence, most of discharge series showed a general trend to a decreasing of available water resource in Languedoc-Roussillon area, especially during the spring and summer seasons. Correlation analyses showed statistically significant link between temperature and discharge series for the summer season, which underlines role of the increasing water loss due to the temperature increase during this season.

Accounting future climate conditions predicted by most of Global Circulation Models, this study also revealed consistent evolution of the observed past and predicted future conditions for temperature. This is not clearly the case for precipitation, which can be partly explained by the great interannual variability of this parameter in the studied area.

Abstract

The Inner Catalan river basins (NW Mediterranean) have been analysed from two different perspectives. The first analysis deals with the long-term hydrological evolution of the studied watersheds and its relation with global and regional climatic factors. The second analysis integrates the available sediment load data with lithologic, climatic, land-use, and geomorphic parameters in order to develop a reliable model of river influx under natural and human impacted conditions. This second analysis is reinforced by a similar study involving other 79 Mediterranean river basins.

Keywords : Gis, Hydrology, River Input.

Introduction

The pressure over fluvial systems is especially intense in the Mediterranean region mainly due to the rising human population and the agricultural needs. Mediterranean rivers are not only important as fresh-water sources, but also as nutrient and sediment suppliers to the marine environment. A significant scientific effort is underway to understand the hydrological and sedimentary behavior of Mediterranean rivers in order to ensure their sustainability and that of the Mediterranean Sea and its shorelines.

Catalonia is in the western part of the NW Mediterranean Basin. As in many other Mediterranean regions, fluvial solid discharge has not been regularly and historically monitored. The challenge is, therefore, to achieve a reliable model of river input under natural and human impacted conditions.

Analysis of long-term hydrological and climatic time series

Long-term water discharge (Q) data series have been gathered from the Catalan watersheds, 10 fluvial systems ranging between 70 and $5,000 \text{ km}^2$. Various global datasets compiled into a GIS allowed extracting lithologic, climatic, land-use, and geomorphic parameters for each watershed.

Q was essentially homogeneous in the Catalan rivers along the 20^{th} century, with slightly increasing or decreasing long-term trends. Mean values for all rivers ranged from 0.3 to 11 m³/s. Precipitation (P) decreased in all the watersheds at a rate of about 0.33 mm/yr, while temperature (T) increased nearly 0.02° C/yr. This is in agreement with the mean P and T trends on the NW Mediterranean Basin, although in Catalonia these climatic changes are larger in land than above the sea. However, these P drop and T rise do not directly translate into river flow reduction.

Hydrological periodicity has been also analysed. A negative relationship between the Q data series and the NAO index has been observed, i.e. maximum discharge events often fit with the most negative NAO values, and vice versa. The frequency and magnitude of droughts (flow below the 15^{th} percentile) and floods (flow exceeding more than 10 times the average Q) were very irregular during the last decades, a period during which most of the Catalan watersheds showed a slight increase in the magnitude of these extreme events.

Sediment load analysis: From the Catalan to the Mediterranean case Total suspended sediment (TSS) field data from the Catalan basins are limited to 6 years of punctual uneven measurements. The recorded values (average 9-209 mg/l equivalent to 0.4-15 t/km²yr) show that sediment flux is relatively low in Catalan rivers compared with other Mediterranean rivers [1].

River regulation in the form of dam construction and water extraction concentrates in 2 of the 10 studied basins. Residence times on reservoirs range from one day to more than one year, causing variable impacts on sediment transport. 10 over the existing 16 dams retain more than 90% of the suspended material. The overflow rate indicates that only 4 dams allow bypassing medium silt sized sediment.

All the parameters collected from the Catalan basins were used to develop a TSS multiple regression model (R^2 =0.87) that involved Q, slope, the Fournier index, the percentage of agricultural land, and the percentage of outcropping hard rocks. We also compiled all the available Mediterranean natural (before human regulation) water and solid discharge values and the same lithologic, climatic, land-use, and geomorphic parameters used

for the Catalan case in order to analyse a larger number of Mediterranean rivers on the same basis and compare the resulting models. 79 Mediterranean river basins ranging from 300 to 90,000 km² were considered. The highest correlation indexes (r>0.6) are found between Q, P and 1/T, while TSS is best correlated with the inverse of the basin area and with the percentage of outcropping sedimentary rocks. The best multiple regression models between TSS and the available parameters come to light after classifying river basins by their temperature-precipitation relationship, obtaining 4 sets of rivers with significative regression models (R²=0.42-0.99) based on slope, basin area, P, T, lithology and land-use. Our first results show that most of the Catalan rivers are part of the driest Mediterranean groups whose sediment flux depends largely on terrain characteristics such as lithology, land-use and slope.

MORPHODYNAMIQUE ET EVOLUTION GEOMORPHOLOGIQUE DU COMPLEXE LAGUNAIRE DE NADOR (LITTORAL MÉDITERRANÉEN ORIENTAL, MAROC)

Abdelkrim Louaya and Naima Hamoumi *

Faculté des Sciences, Université Mohammed V- Agdal, Rabat, Maroc - naimahamoumi@yahoo.fr

Résumé

L'étude géomorphologique détaillée du complexe lagunaire de Nador et de son arrière pays (littoral méditerranéen oriental Maroc) a été réalisée en intégrant pour la première fois : l'analyse des images satellites, l'analyse morphostructurale, l'étude de terrain, les données historiques et l'outil informatique. Elle a permis de réaliser une carte morphostructurale, une carte géomorphologique et un MNT continent/ lagune/plate-forme et de préciser le cadre géomorphologique et géodynamique régional, en particulier, l'extension du bassin versant et les facteurs qui ont contrôlé la genèse et le mode d'évolution du complexe lagunaire. Elle a également permis de préciser la morphodynamique et l'évolution morphologique du complexe lagunaire de Nador.

Mots clès : Lagoons, Coastal Systems, Geomorphology, Western Mediterranean.

Introduction

L'étude géomorphologique détaillée du complexe lagunaire de Nador (littoral méditerranéen oriental Maroc) et de son arrière pays (Fig. 1) a été réalisée dans le cadre du projet COLASU en intégrant pour la première fois : l'analyse des images satellites (Landsat MSS., 1975 ; Landsat TM ,1986, 1988, 1993 et Landsat +ETM, 2000, 2005), l'analyse morphostructurale, l'étude de terrain, les résultats de l'interprétation des photos aériennes au 1/20000 [1, 2], les données historiques et l'outil informatique. En plus, de l'établissement d'une carte morphostructurale et d'une carte géomorphologique, ce travail a permis de préciser le cadre géomorphologique et géodynamique régional ainsi que la morphodynamique et l'évolution géomorphologique du complexe lagunaire.

Fig. 1. Situation de la lagune de Nador.

Cadre géomorphologique et géodynamique régional

Les résultats obtenus ont permis d'identifier les failles (N-S, E-W, NE-SW et NW-SE) ayant servi de moteur à la tectonique et à la subsidence qui sont à l'origine de la genèse et du contrôle de l'évolution de la lagune de Nador. Par ailleurs, la réalisation d'un modèle numérique de terrain (MNT) continent/ lagune/plate-forme a permis d'aboutir à des conclusions essentielles pour la compréhension du contexte géomorphologique et géodynamique de la zone d'étude.

- Les chaînons montagneux encadrant la lagune s'organisent selon des alignements qui dessinent un V ouvert vers la mer. Cette disposition explique à la fois l'origine multi sources des apports qui alimentent la plaine de Bou Areg et son caractère subsident.

- La lagune montre une intégration morphologique logique dans la géométrique continentale générale de la région. Elle correspond au point de convergence topographique principal de ce secteur.

- L'île barrière correspond à une discontinuité géomorphologique entre le compartiment continent-lagune et la plate forme continentale. Cette discontinuité prolonge la faille de direction WNW-ESE, qui est à l'origine de l'exhaussement des barres de calcarénites ayant servi d'île barrière lors de la genèse de la lagune.

- La limite du bassin versant de la lagune correspond au ressaut topographique qui sépare la plaine du Gareb et la plaine de Bou Areg. L'île barrière est constituée par quatre unités morpho- sédimentaires limitées par des accidents : N-S, N 70 et N 45 (dont le jeu peut être vertical ou décrochant). L'extension des deux unités centrales est différente de celle proposée antérieurement [2, 3]. La position de la passe a changé plusieurs fois au cours de l'histoire de la lagune. En 1975, la passe était située au niveau du delta relique de Oulad Zahra. La passe qui a fonctionné il y a 1000 à 1200 ans a évolué en tombolo simple entre 1975 et 1993 puis en double tombolo. La passe située entre l'extrémité SE de l'île barrière et la Tour Restinga dont l'ouverture est liée à un mouvement de failles a été comblée par des flèches azoviennes dont la progradation se poursuit actuellement comme cela est attesté par les images satellites de 1975 à 2005. La superficie des extrémités de la lagune a enregistré une diminution depuis 1975 du fait du comblement artificiel de l'extrémité NW pour les besoins de la construction du port de Beni Ensar et de la progradation d'une flèche sédimentaire dans l'extrémité SE. Cependant, la profondeur de la lagune n'a pas changé comme cela est démontré par les mesures bathymétriques effectuées au cours de la campagne d'hiver 2003, qui indiquent pour la zone centrale, la même profondeur (7.5 m) que la carte bathymétrique de l'Institut hydrographique de Cadix, réalisée en 1951. Dans la bordure continentale, les deltas des émissaires enregistrent un engraissement progressif depuis 1975, alors que les trottoirs subissent des sapements fréquents.

A METHODOLOGICAL APPROACH TO STUDY THE ENVIRONMENTAL IMPACT OF OIL AND GAS OFFSHORE PLATFORMS

C. Maggi, B. Trabucco *, M. Mannozzi, L. Manfra, M. Gabellini, R. Di Mento, O. Nonnis, C. Virno Lamberti, A.M.

Cicero

ICRAM - Via di CAsalotti, 300 - 00166 Roma - b.trabucco@icram.org

Abstract

The Central Institute for Marine Research (ICRAM) deals with a monitoring of the eventual environmental impact of the offshore platform activities. Specific monitoring programmes concern the discharge of the Produced Formation Water (PFW) into the sea, the installation operations of platforms and the existence of the offshore structures themselves. In this work we describe the methodological approach for the offshore monitoring used by ICRAM since more than five years.

Keywords : Adriatic Sea, Monitoring.

The oil and gas industry is truly global, with operations conducted in every corner of the world. In Italy there are about 1200 productive wells and 124 offshore platforms, whose 112 in the Adriatic Sea. Oil and gas exploration and production operations have the potential for a variety of impact on the environment. This potential impact may be avoided, minimized and mitigated, through proper tools of environmental monitoring. In particular, with regards to the aquatic environment, the principal problems are linked to the installation of the offshore structure and then to waste streams of drilling fluids, cuttings, well treatment chemicals and produced formation water (PFW). Since 2000 the Central Institute for Marine Research has been carrying on national monitoring plans concerning the environmental impact both of the PFW discharge into the sea and of the installation operations and existence of platforms in the Adriatic Sea, according to national and international protection policies and legislation [1-4].

Our methodological approach matches information on physical, chemical and biotic variables in order to give the best description of the environmental quality status by means of an integrated approach [5]. Through an appropriate sampling strategy we monitor selected chemical and physical variables of water column and sediment, studying the effects on biota and spatial-temporal trend of the eventual alteration that could occur [6-7].

The perforation activities, by the discharge of the water-based drilling fluids and cuttings, and the positioning of a permanent structure may cause effective changes of the chemical quality and physical characteristics of sediment; moreover perturbations on the sea-bottom geomorphology and on the marine living communities could occur. During the offshore production phase water is produced along with oil and gas. This water is called Produced Formation Water (PFW). The PFW discharge impact on marine ecosystem is highly dependent on its quantity, its quality, the characteristics of the receiving environment and dispersion processes.

The extent of the impact can only be judged through specific monitoring activities. The following parameters have been selected for the environmental investigations.

Parameters to investigate Matrix

PFW

Parameter: BTEX, total mineral oil, aliphatic hydrocarbons, PAHs, phenols, metals, total nitrogen, sulphurs, sulphorate compounds, suspended matter, total organic carbon, nutrients, ecotoxicological assays *Water column*

Parameter: current, temperature, pH, salinity, trasmittance, dissolved oxygen, chlorophyll *a*, nutrients, total nitrogen, total sulphurs, particulate matter, BTEX, total mineral oil, metals, aliphatic hydrocarbons, phenols, ecotoxicological assays

Sediment

Parameter: grain size, % water, metals, PAHs, PCBs, organotin compounds, total nitrogen, sulphorate compounds, total mineral oil, total organic carbon, aliphatic hydrocarbons, phenols, BTEX, ecotoxicological assays, macrozoobenthic soft-bottom community analysis *Biota*

Parameter: fish assemblages analysis, bioaccumulation analysis on *M. galloprovincialis*

Sea bottom

Parameter: bathymetry and morphology

The investigations on water column, sediment and biota matrices allow to study, thus highlighting, the natural features of the marine environment

and then the changes due to the PFW discharge into the sea and to the presence of the offshore structure.

Chemical analysis is known to permit to identify and quantify different single compounds responsible for the environmental contamination, so to give a measure of pollution. Nevertheless, since the chemical approach alone can not provide information about the possible toxicity of bio-available pollutants, it should always be associated to biotic investigations [8]. The monitoring of chemical-physical characteristics of water and sed-iment, together with ecotoxicological assays, bioaccumulation analyses, macrozoobenthic soft-bottom community structure and fish assemblages study, let to provide the necessary information for assessing the actual spatial and temporal perturbations occurring in the marine ecosystem. Moreover, the acoustic investigations can also allow to map the alterations and to supply the background information necessary for a correct planning of sampling activities and represent the basis for a long-term monitoring study.

The methodological approach presented in this paper is the result of more than five years of experience, gained by ICRAM in the drawing up of the monitoring projects, the performance of the analytical methodologies and the carrying on the monitoring activities. This kind of studies allow us to collect integrated data in order to provide environmental information particularly useful for the public administration and decision makers for the protection of the marine ecosystem.

EVALUATING THE IMPACT OF CIVIL WORKS ON WATER FLOW IN THE INLETS OF THE VENETIAN LAGOON

Isaac Mancero-Mosquera¹*, Miroslav Gačić¹ and Andrea Mazzoldi²

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Borgo Grotta Gigante 42/C; 34010 Sgonico (TS) Italy. -

imancero@ogs.trieste.it

² Istituto di Scienze Marine - C.N.R. Venice, Italy

Abstract

Local fishermen in the Venetian lagoon reported an increase in the currents velocities at Chioggia inlet. A deeper insight into ADCP records revealed an increase in the flow energy even though the average remains statistically unchanged. Also a significant change in the relationship between vertically averaged current time-series and water flux rate has been detected directly connected with the reduction of cross-sectional area due to civil works carried out inside Chioggia inlet.

Keywords : Currents, Lagoons, Time Series.

Long-term monitoring has been going on in the inlets of the Venetian lagoon within the framework of CORILA project to study variability of water exchange at different time scales between the lagoon and the open sea. Current measurements have been carried out with bottom mounted ADCP (Acoustic Doppler Current Profiler) since June 2001 in Lido and Malamocco inlets and since February 2002 in Chioggia inlet.

Since the Italian government approved major works in order to prevent the flooding of the city (locally called "Acqua Alta") this record has become essential in order to study possible changes in the dynamics due to civil works carried out. Previous analysis have revealed a highly tidal driven flow with 95% of the energy due to astronomical signal [1], [2]; an other property is the high polarisation along the channels with more than 99% of energy in the principal axe at each channel.

Commenting of local fishermen about changes in the velocity of currents in Chioggia became evident by the end of 2005. Also minor precision in the tidal predictions based on the bottom-mounted ADCP was noticed. Once failures at instrumental level were discarded, Principal Component Analysis (PCA) and Harmonic Analysis (HA) were applied to currents time series on a monthly basis to obtain series of estimates of main HA parameters as well as energies, maxima and minima currents.

Fig. 1. Standard deviation of vertically averaged time-series of currents in the inlets of the Venetian lagoon with the major civil interventions indicated: 1.- Begining of works. 2.- Barrier under the sea surface. 3.- Barrier start emerging. 4.- Ending of works. 5.- Construction of navigation lock. 6.- Finishing of navigation lock.

Statistic tests yielded no detectable change in the mean currents values, but a gradual increase of velocity maxima and minima has been found in Chioggia since late 2004. This indicates an increase in the variability as apparent in the Figure 1. Also estimates of magnitudes of K1, M2 and S2 tidal constituents denoted an increase in Chioggia, which is connected also with the velocities reported by the fishermen. However, the average remains statistically unchanged so an increase in the energy follows as a consequence.

Chronology of major civil interventions is also shown in the Figure 1

including wave-breaking barriers and navigation lock. In Malamocco constructions are outside of the inlet while they are inner in Chioggia. Moreover, the cross-sectional area has decreased in Chioggia by about 18% causing the increasing of currents magnitudes even though they are the same in average. Thinning of channel changed also the linear relationship between water transport (Q_T) and the vertically averaged velocity (V), which was used as a predictor in the estimation of water flux rates. While this relationship was $Q_T = 4969.2V - 159.61$ with $R^2 = 0.9808$, now it is $Q_T = 4023V - 18.07$ with R²=0.9940. So, higher velocity is required in order to produce the same water transport. The transport, which is mainly astronomically driven, tends to be steady. Additional studies are necessary to complete the picture of impact of civil interventions in the water exchange rate.

PHYSICAL PROPERTIES AND NUTRIENT DYNAMICS IN COASTAL WATERS OF SOUTH TYRRHENIAN SEA (CAMPANIA REGION)

Francesca Margiotta *, Ciro Chiaese , Augusto Passarelli and Vincenzo Saggiomo Zoological Station A. Dohrn - Villa Comunale 80121 Naples, Italy - margiot@szn.it

Abstract

Seven coastal sites along the Campania Region (Southern Tyrrhenian Sea) were sampled biweekly from June 2001 till May 2005 for physical and chemical properties. As expected due to very different riverine and anthropic influences, notable differences in hydrographical and chemical properties occurred but still common patterns in temperature, salinity and nutrients were observed. *Keywords : Coastal Systems, Tyrrhenian Sea, Monitoring.*

Introduction

The coastal zone is one of the most valuable areas of Earth from a human perspective. More than half population resides within 100km from the coast and this proportion is expected to increase in the future. Large perturbations related to human activities on land have contributed to severe degradation of water quality and alterations of marine food webs and community structure. Trying to evaluate the response of coastal waters to human perturbations and climate changes is the challenge of the worldwide monitoring coastal water programs. This study is conducted in the framework of the Italian monitoring coastal ecosystems project. The physical properties and the nutrient dynamics of seven sampling sites, distributed along the coasts of the Campania Region (South Tyrrhenian Sea), were analysed. The stations differ for their environmental conditions from strongly eutrophic (influence of large urbanized areas, proximity of river outlets) to oligotrophic (in a Marine Protected Area).

Materials and Methods

The sampling was carried out biweekly from June 2001 till May 2005. Temperature and salinity profiles were acquired by a SBE 19 Plus of Sea - Bird Electronics. Nutrient analyses of surface samples were performed with a TECHNICON II autoanalyser.

Results

Temperature profiles showed a clear seasonal pattern (thermal stratification during summer and winter mixing) and a strong interannual variability. In winter, a progressive temperature decrease was observed in all the sampling stations. The minimum temperature, integrated over the water column, was 1.4° C lower in 2005 as compared to the 2002 value. Highest temperatures were recorded in the surface layers in summer 2003 (28.4 \pm 0.5 °C). Due to freshwater inputs, local hydrodynamic conditions and water column depth, salinity showed a pronounced spatial variability. The lowest salinities were recorded in the proximity of rivers and the highest occurred in the Marine Protected Area. Despite the very different properties observed, a decrease in salt content was noticed in all the sampling sites during the spring - summer period from 2001 till 2004.

Nutrient concentrations showed a very wide range of variability. The average concentrations of dissolved inorganic nitrogen (TIN) were two orders of magnitude greater in polluted areas (e.g. 18.3 μ M off the Volturno River as compared to the Marine Protected Area 0.5μ M). Each sampling site presented a specific N:P ratio. This ratio was higher than the Redfield value [1] near the river mouths (>40), close to the typical western Mediterranean ratio [2, 3] near the city of Naples (18), and lower for the Marine Protected Area (10). However, the N:P ratio always presented a bimodal distribution strongly linked to seasonality. The minimum values were recorded in the period from May to September, mainly due to a relevant decrease in TIN. Phosphates, total phosphorous and total nitrogen did not show a clear seasonal signal.

Discussion

The sampling sites presented different hydrographical and chemical properties related to their environmental conditions. In particular, the northern part of the Campania coastal area resulted more influenced by human activities. Despite these strong differences, common patterns in temperature, salinity and nutrients were observed. The different N:P ratios in summer and in winter was opposite to that observed in the western Mediterranean open waters (Dyfamed time-series station) [4]. However, a preliminary analysis suggests that the different phytoplankton communities (prymnesiophytes in Dyfamed, diatoms in Campania coastal waters) might explain these differences in nutrient dynamics.

DEFINITION AND OPERATING VERIFICATION OF INSTRUMENTS AND PROCEDURES FOR THE MANAGEMENT AND THE SUSTAINABLE DEVELOPMENT OF THE MEDITERRANEAN BEACHES

Roberto Montanari

Regione Emilia-Romagna, Direzione Generale Ambiente e Difesa del Suolo e della Costa, Servizio Difesa del Suolo, della Costa e Bonifica - Via dei Mille 21 - 40121 Bologna (IT) - www.regione.emilia-romagna.it - RMontanari@regione.emilia-romagna.it

Abstract

BEACHMED-e RFO "Strategic management of beach protection measures for the sustainable development of the Mediterranean coastal areas", financed by INTERREGIIIC-Sud European Program, faces several themes related to coastal management, overall related to coastal erosion defence. An entire Component of the Operation is dedicated to the feasibility study of a European "Observatory System" for the Defence of Mediterranean Coast, presented as a useful tool foretold by several administrations involved and with competences on coastal management. They expressed a diffused awareness of the need to monitor erosion in all its aspects, as a territorially based phenomenon on a continental scale and having a structural nature.

Keywords : Erosion, Beach, Coastal Management, Monitoring, Shoreline Evolution.

One of the main lines of activities of the Beachmed-e Operation responds to the need to create a European Observatory for the Defence of the Mediterranean Coast in order to survey the morphological changes (erosion, shoreline evolution, etc.). The study for this proposal includes the census of the infrastructures involved in the monitoring and defence of the Mediterranean beaches, the description of methods and control systems for each region and the assessment of these systems. The motivation comes from the interpretation of a diffuse awareness, within scientific and administration bodies, about the need of a systematic survey and monitoring of coastal erosion phenomena at a continental Mediterranean basin scale [1, 2]. The idea is to create a network with already existing structures, to promote the creation of new structures were needed and to provide services to them. In order to maintain its indispensable flexibility and overall applicability, then, the feasibility study must not just concern "an observatory" but "an Observatory System" which must find its basic foundations in current, potential or existing organisational assets.

The Observatory should be an opportunity both for administration bodies, already having or not having dedicated structures, and for scientific community all around the Mediterranean basin, in order to optimise data acquisition/purchase, elaboration processes, techniques and outputs, exchange of best practises. The system should allow registering and observing the phenomenon of coastal erosion, analysing the morphological changes in a quantitative way, predicting crisis in wide areas in medium or long term, informing about work, initiatives and opportunities in the field of coastal defence, offering advices in environmental, technical and juridical matter concerning dredging and nourishment work in the Mediterranean sea. Additionally, a structured IT system would be carried on for the management and collection of data, modelling and simulation of dynamic processes in large Coastal Zone, helped by a geographic information system (GIS) that would be able to distribute statistical and cartographical data of the Coastal Zone.

To build up a first nucleus of organisations which already hold some experience in coastal defence represents a primary importance goal, especially if these structures are already integrated within existing administrative structures or have anyway some authority in terms of defending coastlines.

In fact, the strategy of giving preference to or highlighting those administrative situations which are directly connected to the management of coastal defences, is to be encouraged. In this way the link between the "Observatory System" and planning activities can be favoured if not guaranteed (for obvious structural reasons).

The work method proposed for the development of the sub-project therefore focuses - thanks to the required technical/scientific contributions on existing structures and those that may potentially be developed within Public Administrations, specialised in local planning and managing initiatives for coastal defence. These are the main planned activities:

1. CURRENT STATUS: census and analysis of the structures which carry out coastal monitoring activities, especially in terms of erosion or climatic phenomena, through direct contacts and questionnaires.

2. NEEDS: Exploratory analysis of information needs for structures to

defend coastlines.

3. METHODOLOGY: proposal of an observatory system for an organisational and operative point of view (type of organisation, activities to be carried out, costs, etc.).

4. RESOURCES: Exploratory cost analysis (in monetary and organisational terms) currently incurred to monitor coasts, potential costs incurred for operations - not necessarily public - interested in supporting monitoring activities

The study of feasibility is already started in the 2005 and will be ended within June 2008. The first issues are already published on the web site www.beachmed.it in the OBJECTIVES REPORT (measure 4.1) and the future developments will be dealt in the pages of OBSEMEDI sub-project [3].

INVESTIGATION OF BLACK SEA COASTAL CURRENT CIRCULATION BY REMOTE SENSING AND OCEANOGRAPHIC DATA

Edip Muftuoglu¹*, Cem Gazioglu², Volkan Demir² and Erdogan Okus¹

¹ Istanbul University, Institute of Marine Sciences and Management, Department of Physical Oceanography and Marine Biology, 34116 VEFA Istanbul-Turkey - edip@istanbul.edu.tr

Abstract

Increasing resolution of satellite data and recent coastal oceanographic researches has contributed significances to our present information of the Black Sea coastal current circulation. Coastal eddies observed in the Black Sea are normally elongated, anticyclonic gyres jammed between the cyclonic Rim Current over the coast and the shelfbreak. In this study, near-shore current system of the Turkish Black Sea coasts is investigated in the light of the data collected in six main cruises handled between the years 2003 and 2005 and the satellite images of the region.

Keywords : Black Sea, Remote Sensing, Surface Waters.

Introduction

The Black Sea is a nearly enclosed basin connected to the Marmara Sea and the Azov Sea by the narrow Turkish Strait system (Bosporus, Marmara Sea and Dardanelles) and Kerch Straits, respectively. Its catchment area covers large parts of Europe and Asia, providing a total freshwater supply of 3 x 102 km³ per year. However evaporation exceeds precipitation, the freshwater flux remains large in comparison to basin volume (approximately 5.4 x 105 km³), making the Black Sea having brackish water. Because of the large freshwater flux and the narrow opening in the strait of Bosporus, the exchange between the Black and Marmara Sea is asymmetric: the volume of water transported by the out flowing surface current is two times larger than the inflowing deep counter-current, thus the Black Sea's surface salinity is about half that of the Mediterranean's salinity. Unlike other large estuarine basins (e.g., the Baltic Sea), the Black Sea is a deep basin (maximum depth of 2200m) with a large shelf. A distinct vertical avering is created between the surface waters in the upper 100 m and the deep waters, limiting the vertical exchange and creating a unique chemical and biological environment.

The Black Sea circulation involves a complex, eddy dominated system with different types of structural organization in which eddies and gyres of the interior cyclonic cell interact continuously among themselves and with meanders and filaments of Rim current system [1].

Fig. 1. Coastal surface circulation of the Black Sea observed by satellite images.

Results and Discussion

As bottom topography is known to be the main controlling agent of the Black Sea surface circulations, we can talk about wind curl effects to be the secondary in triggering relative vorticity for the Black Sea basin. In addition to these, along the Turkish shores, the shoreward side of jet is a regional of strong anticyclonic shear typically 40 cm/sn per each 10 km. An other derived result is the strong seasonal stratification cycle that probably has an important effect on coastal anticyclogenesis through nonlinear dynamics.

EVALUATION DES RISQUES D'INONDATION DUS A UNE ÉLÉVATION DU NIVEAU MARIN: ANALYSE PRÉVISIONNELLE DE LA ZONE COTIÈRE DE TÉTOUAN, MAROC

Saïda Niazi * and Maria Snoussi

Université Mohamed V- Agdal, Faculté des Sciences, Département des Sciences de la Terre, Rabat, Maroc - saidaniazi@hotmail.com

Résumé

En raison du réchauffement climatique, le niveau moyen global des océans est en hausse et les risques d'inondation des terres basses et peuplées sont à craindre. Une étude prospective de telles menaces a été réalisée sur le littoral de Tétouan situé au Nord du Maroc, pour les horizons 2050 et 2100. L'analyse montre que quelque soit le scénario d'élévation du niveau marin, les submersions y seraient préjudiciables, particulièrement sur la côte sud plus basse et où la population y serait plus menacée. Les pertes en terre par inondation sont estimées entre 36 et 50% de la superficie totale de la zone d'étude; ce qui aura des impacts considérables sur les écosystèmes et les valeurs socio-économiques. Une stratégie d'adaptation est par conséquent nécessaire pour protéger cette côte de plus en plus convoitée par le tourisme, contre un phénomène incontournable.

Mots clès : Sea Level, Shoreline Evolution, Coastal Systems, Mapping, Western Mediterranean.

Les conséquences potentielles du réchauffement climatique en termes de hausse du niveau de la mer, sont inquiétantes pour les infrastructures et les populations des zones cotières. Mais le plus menaçant serait la probabilité d'une intensification et d'une fréquence plus grande des événements extrêmes qui entraîneraient des inondations exceptionnelles. Le Maroc, qui possède 3500 km de côtes dont certaines très basses, n'est pas épargné par ces risques, d'autant plus que plusieurs secteurs côtiers ont été modifiés et aménagés de façon intensive au cours des dernières décennies; ce qui les a fragilisés et rendus plus vulnérables à une remontée du niveau marin. Cette étude consiste en une évaluation prévisionnelle des risques d'inondation dus à une accélération de l'élévation du niveau de la mer sur le littoral de Tétouan. Il s'agit d'une cote qui s'étend sur 44 km entre Fnidek au Nord et Azla au Sud et qui présente deux zones sableuses basses séparées par un cap rocheux. Ce littoral, l'un des plus urbanisés de la Méditerranée occidentale marocaine, comprend trois centres urbains totalisant une population de 500,000 habitants [1]. Sur le plan naturel, ce littoral recèle en outre des écosystèmes variés potentiellement très vulnérables: plages, plaines alluviales et zones humides cotières. L'économie du secteur est basée principalement sur le tourisme balnéaire. La méthodologie adoptée est basée sur le choix d'un certain nombre de scénarios : (i) L'élévation relative actuelle du niveau moyen de la mer utilisée est celle mesurée par Topex /Poseidon depuis 1993 en Méditerranée occidentale, et qui est en moyenne de 2.5 mm/an. Cette valeur ne tient cependant compte que de l'effet du forçage anthropique du climat. (ii) Les scénarios d'élévation eustatique future du niveau marin utilisés sont ceux du troisième rapport du GIEC [2], qui suggère une augmentation du niveau global de la mer entre 0.09 et 0.88 m d'ici 2100, avec une valeur médiane de 0.48 m. Trois scénarios d'élévation future du niveau marin ont été considérés pour les deux horizons temporels 2050 et 2100 : des prévisions sans accélération de l'élévation du niveau marin, une hypothèse moyenne et une estimation haute de l'élévation du niveau de la mer. (iii) Deux scénarios d'inondations avec un niveau minimum et un niveau maximum ont été déterminés à partir de la formule de Hoozemans et al. [3]. Afin d'évaluer les zones à risque d'inondation, ces niveaux ont été ensuite digitalisés en tenant compte de la topographie et de l'occupation des sols. Les résultats montrent que pour un niveau d'inondation minimum de 5 m, 36% de la totalité du littoral étudié seraient submergés. Ils atteindraient 50% de la superficie totale pour un niveau d'inondation maximum de 10 m. Ce dernier correspondrait à la conjonction exceptionnelle de tempêtes extrêmes et de l'hypothèse haute de l'élévation du niveau de la mer. L'invasion marine se ferait particulièrement par les plaines littorales (Restinga, Smir et Martil) avec une extension plus importante de zones submergées dans la côte sud à topographie basse (Fig.1). Les bouleversements environnementaux affecteraient la population cotière, particulièrement celle de la ville de Martil qui serait la plus menacée, ainsi que tous les écosystèmes côtiers. En outre les impacts seraient catastrophiques pour les infrastructures (ports, routes, unités industrielles, complexes touristiques et centre urbain de Martil) et par conséquent tous les secteurs socio-économiques seraient affectés. L'élévation accélérée du niveau de la mer conjuguée aux événements climatiques extrêmes, pourrait avoir de lourdes conséquences sur l'avenir du littoral de Tétouan. Une stratégie d'adaptation est impérative pour faire face aux impacts d'un tel phénomène et à ceux des changements climatiques en général.

Fig. 1. Superficies inondables avec des niveaux de submersion de 5 m et 10 m du littoral de Tétouan en réponse à l'élévation du niveau de la mer

CU AND PB INPUTS FROM A SMALL RIVER TO THE MEDITERRANEAN SEA

Rudy Nicolau, Véronique Lenoble *, Patricia Merdy and Yves Lucas

PROTEE Laboratory, Université du Sud Toulon Var, BP 20132, 83957 La Garde cedex, FRANCE - lenoble@univ-tln.fr

Abstract

The particulate and dissolved Cu and Pb inputs to the Mediterranean Sea from a small, anthropized Mediterranean coastal river located in the South of France were quantified along a whole hydrological year. More than 90% of the annual metal inputs were due to short, intense floods, occuring after a long dry period. Extrapolation to the whole Mediterranean basin indicates that the Cu and Pb inputs from such small rivers are of the same order of magnitude than the inputs from large rivers, and they should not be neglected in their pollution contribution to the sea.

Keywords : Coastal Waters, Metals.

Most studies concerning continental inputs to the sea focused on large rivers. However, small coastal rivers, can have a high ecological impact because they rapidly bring to the sea the contamination produced in the coastal area, especially when it is located in dense human population area. Among the studies of small coastal rivers, only a few deal with the Mediterranean area, despite its fast anthropization and its climate specificities: long dry periods corresponding to low water levels (base-flow) are interrupted by short, severe floods.

We chose to study the Eygoutier river, whose watershed is representative of modern anthropization, mixing urban, semi-urban, small industrial and agricultural areas. The base-flow of the river is typically around 10 $m^{3}h^{-1}$, while the river flow rapidly (commonly within 15 minutes) increases up to $40,000 \text{ m}^3\text{h}^{-1}$ during floods. After the end of a rainfall, the river returns to its base-flow level within less than 24 h. We characterized the base-flow along one hydrological year and we studied into details 5 representative flood events occurring within one year. We quantified the fluxes of suspended particulate matter (SPM, fraction >0.22 μ m), dissolved organic carbon (DOC), particulate organic carbon (POC), as well as dissolved and particulate Cu and Pb and nutritive ions brought to the sea. The base flow was studied by a bimestrial sampling and the floods by the mean of an automatic sampler providing 25 samples per flood, the sampling interval being smaller at the beginning of the flood because of higher concentrations. The water flow was measured every 30 minutes all along the year 2004. The base-flow fluxes were calculated by multiplying the mean concentration values by the mean base flow. Flood fluxes were calculated considering that any flow higher than $200\,\mathrm{m^3}\,\mathrm{h^{-1}corresponded}$ to a flood event. Consequently, 1432 hours of flood (16% of theyear) were registered during the year 2004 with a mean flow around 5100 m³.h-1. The Table 1 presents the fluxes calculated over the whole year.

Tab. 1. Species annual fluxes at the outcome of the river.

	Base flow	Flood	Total
Flow (m ³ .yr)	0.39 10 ⁶	7.34 10 ⁶	7.73 10 ⁶
MES (t.yr ⁻¹)	5.1	2638.4	2643.5
DOC (t.yr ⁻¹)	4.7	125.7	130.4
$POC(t.yr^{-1})$	1.2	384.7	386.0
Dissolved Pb (kg.yr ⁻¹)	0.1	8.2	8.3
Dissolved Cu (kg.yr ⁻¹)	1.9	26.0	27.9
Particulate Pb (kg.yr ⁻¹)	1.2	452.4	453.6
Particulate Cu (kg.yr ⁻¹)	1.4	466.3	467.7

The total Pb concentration transferred to the sea was estimated around 462 kg.year⁻¹ (98% in the particulate phase) and the total Cu concentration around 496 kg.year⁻¹ (94% in the particulate phase). More than 99% of the total Pb and Cu were transferred during floods, exceeding the values acceptable for a good quality water. This indicates that brief periods of high metal concentrations occurred at the outcome of the river, and could have a negative impact on biological life in the sea. Considering the whole Mediterranean basin, the annual input of riverine water is 620 km³.year⁻¹, with 81% brought by the northern half of the basin [1]. Six large rivers (Nile, Rhône, Pô, Drin, Ebro and Neretva) contribute for 43.4% of the annual input, and the 56.6% remaining are due to small rivers. Extrapolating our small river data to the corresponding water vol-

ume, small rivers input to the Mediterranean Sea would be around 25 and 420 t.year⁻¹for dissolved and particulate Cu, respectively, and around 7 and 408 t.year⁻¹for dissolved and particulate Pb, respectively. This extrapolation is somehow excessive, but gives an order of magnitude of what would be small rivers input by a fully anthropized Mediterranean coastal area. For comparison, realizing a similar extrapolation to larger river inputs to the Mediterranean scale using the Rhône annual transfers values [2], 517 t.year⁻¹ of total Cu and 26 t.year⁻¹ of total Pb were obtained. Such values do not go beyond rough estimate, but, being of the same order of magnitude than the input from small rivers, indicate that the latter cannot be neglected in contaminant balance at the Mediterranean scale.

DUMPING OF HARBOUR-DREDGED MATERIAL: A MULTIDISCIPLINARY MONITORING STUDY OF TWO DISPOSAL SITES IN CENTRAL ADRIATIC SEA (ITALY)

Ornella Nonnis *, Chiara Maggi and Claudia Virno Lamberti ICRAM - Via di Casalotti 300, 00166 Roma - o.nonnis@icram.org

Abstract

About 600.000 mc of sediment from Port of Pescara (Central Adiatic sea, Italy) were dredged and dumped in two sites located 3-4 Nm from the coast, during the period 1994-2004. In order to assess the potential environmental impacts due to the dumping of harbour-dredged material, the Central Institute for Marine Research (ICRAM) performed a multidisciplinary monitoring plan that carried out during three cruises (1999, 2001, 2004).

Keywords : Adriatic Sea, Chemical Analysis, Coastal Systems.

Accessibility of ports, harbours and navigable waterways is very important for the economic growth of coastal regions. Navigable depths must be maintained by repeated dredging and the disposal of dredged materials is one of the most important problems of coastal zone management. Depending on their chemical and sedimentological characteristics, dredged sediments may be disposed of in different ways. Sometimes good quality dredged materials are dumped in appropriate off-shore disposal sites.

In this context ICRAM (Central Institute for Marine Research) in 1999, 2001 and 2004 performed monitoring activities in two dumping sites of material dredged in the harbour of Pescara (Central Adriatic Sea). In these zones (defined as site A and site B), partially overlapping, about 600.000mc of materials were dumped between 1994 and 2003. These sites are located 3-4 Nm offshore, between 21 and 60m of depth.

Fig. 1. Location of sampling stations and dumping sites.

During the monitoring activities acoustic investigation and sampling of sediment for physical (grain size), chemical (heavy metals, PCBs, Pesticides, PAHs, TBT, DBT, TOC and organic substances) and biological (benthic fauna) analyses were carried out.

The acoustic investigation performed by side scan sonar highlights a non homogenous distribution of harbour-dredged materials in the dumping sites. In particular the most amount of materials is concentrated in the landward part of site A, with some deposits out of the authorized area. In the overlapping sector between sites A and B sporadic deposits were also observed.

The grain size analysis shows the preponderance of clayey silt and silty clay, with the fine fraction increasing with depth. In the sampling station S1, located in the landward part of site A, a dysfunctional content of coarser sediments (gravel: 7.12%, sand: 29.45%), with respect to the previous monitoring activities is observed. In the same station, an anomalous concentration of lead (604.5 mg/kg d.w.) is found. This value can be associated with the presence of dumping material. Lower values of TOC

and organic substance are found in the sampling station S1 and S3, both located in the site A and characterized by low percentage of mud.

PCBs levels detected in the dumping sites could be considered low (range 3.98-9.61ng/g). Lindane and Aldrin are absent in both sites investigated. DDT and its metabolites concentrations are lower middle (max value 5,55 ng/g d.w.).

PAHs concentrations result very low in all sampling stations (range 53 - 194 ng/g). Levels of contamination by TBT ranging from low (30 - 50 ng TBT/g) to moderate (65-85 ng TBT/g). Instead DBT concentrations are lower than the detectable limit.

Finally, the macrozoobenthic communities do not show any effects related at dumping of harbours sediments.

In conclusion, we point out that in site B, located at a gretaer distance of the coast, only sporadic deposits of harbour-dredged materials were observed. Moreover, these deposits were located in the landward part of site B, which is overlapping with site A. Evidence of recent and more consistent harbour-sediments deposition was found in site A; in addition some cumulus were found outside the authorized area on the landward side.

We underline the necessity to limit the dumping of harbour sediments derived from dredging activities in off-shore disposal sites and to prefer other, less impacting solutions.

TOURIST INDUSTRY GROWTH PRESSURE ALONG THE BULGARIAN BLACK SEA COAST

Atanas Palazov * and Hristo Stanchev

Institute of Oceanology, 40 Parvi May Str., POBox 152, 9000 Varna, BULGARIA - palazov@io-bas.bg

Abstract

Coastal zone representing the boundary between sea and land is a highly dynamical and sensitive area that comprises a large variety of natural resources. Population growth in the littoral causes rapid urbanization of the coast, development of infrastructures, transport system and so on. Therefore, coastal ecosystems experience pressure and become vulnerable to pollution, habitat degradation and loss, overfishing, and increased coastal hazards. Accelerated tourism development during the recent years is an extra risk factor for the Bulgarian Black Sea coastal zone. Considering that the coastal zone is a limited and very vulnerable land area, the high population increase due to tourism is one of the most hazardous factors for coastal zone sustainability. Although tourism growth and coastal development give rise to a number of economic benefits, they also could lead to loss of habitat, green space, and biodiversity. *Keywords : Black Sea, Coastal Management.*

Introduction

Coastal zone is a highly dynamical and sensitive area that comprises a large variety of natural resources. This predetermines the attractiveness of the littoral for settlement and other human activities, like tourism, recreation etc. Population growth causes rapid urbanization of the littoral, development of infrastructures, transport system etc. Therefore, coastal ecosystems experience pressure and become vulnerable to pollution, habitat degradation and loss, overfishing and increased coastal hazards [1]. Vast sand beaches along the Bulgarian Black Sea coast, in combination with favorable climate and clean seawater, are valued preconditions for tourist industry development. The speeded tourism development during recent years is an extra risk factor for coastal zone. Both local residents and tourists cause pressure to the ecosystem, therefore population in the coastal regions is used as pressure indicator for ICZM [2].

Analysis

The Bulgarian Black Sea coast, situated in the Western part of the Black Sea, has a 378 km long coastal line, 140 km of which occupied by 78 beaches. 14 of 262 state municipalities [3] are located in the coastal zone. The Bulgarian Black Sea coastal zone is 5.21% of the country territory and hosts 8.85% of the national population.

Official census results [4] show that during 1934-2001 the total coastal population growth is almost six times higher than in the entire country. Thus, the Bulgarian Black Sea coastal zone is one of the most rapidly growing and developing areas at national scale.

Tourism and in particular coastal tourism is one of the fastest developing world industry sectors [5], and Bulgaria follows this tendency. Data for tourist international arrivals in Bulgaria during the period 2000 - 2004 show that the number of tourists has been continuously increasing: from 2 354 052 in 2000 to 4 010 326 in 2004, so the gain is more than 70 %. Rapid development of coastal tourism is analyzed on the basis of official data [6] and the results are presented in Fig. 1.

Fig. 1. Tourist industry growth along the Bulgarian Black Sea coast.

It is found out that from 1999 to 2004 the number of hotels in coastal municipalities increased from 322 to 640, almost 100 %, beds number increased in 82.8 %, and the spending in 112 %. The biggest growing is registered in the most famous Bulgarian Black sea resorts - Golden

sands, Sunny beach and Albena, which now represent 76.25 % from the hotels, 84.18 % from beds, and counted 88.33 % from all spending in the Bulgarian Black coast. There is also a big disproportion between these 3 municipalities and the remaining 11, which indicates that some costal areas are critically overcrowded.

The number of tourists preferring to spend their vacation at the seacoast continuously increases as well. For the investigated period the growth is 118 % and the total number reached 1 450 188 that is more than twice the local coastal population. Most of the tourists (85.58 %) stay in the big resorts. Every tourist spends 7 days in average, but the busiest months are July and August. In these months, total coastal population increases with approximately 20%, but in some resorts more than 200%. The trend shows that at least a 10% yearly tourists' growth can be expected for the next few years.

In the analysis of human population pressure on the coastal ecosystem, it is assumed a total population of local residents plus tourists. In the last twenty years there is no significant local population growth. The continuously improved infrastructure has the capability to meet and reduce anthropogenic impact on the ecosystem caused by local population growth.

Conclusions

Tourist spate towards Bulgarian Black Sea coast dramatically increased during last fifth years and will continue to growth at least for few more years. The existing facilities in some municipalities are not able to meet this additional pressure and to reduce adequately anthropogenic impact to the marine ecosystems. Considering that the coastal zone is a limited and very vulnerable land area, the population increase due to tourism is one of the most hazardous factors for coastal zone sustainability. Although tourism growth and coastal development give rise to a number of economic benefits, they also could lead to loss of habitat, green space, and biodiversity, especially in case of new constructed tourist sites, some of which are in very low populated coastal regions or neighboring protected territories. Public policymakers and coastal managers are now facing the challenging task of finding a balance between benefits of touristm growth and mitigation of its effects on the coastal environment.

DISSOLVED OXYGEN AND NUTRIENT CONCENTRATIONS IN KORINTHIAKOS GULF DURING 2004-2005

Roza Psyllidou-Giouranovits * and Alexandra Pavlidou

Hellenic Centre for Marine Research, Institute of Oceanography, 46.7 km Athens-Sounio Av., 19013, Anavyssos, Greece -

rpsill@ath.hcmr.gr

Abstract

In this paper dissolved oxygen (DO) and nutrient data in the Korinthiakos Gulf are presented. Four sampling cruises were conducted by the Hellenic Centre for Marine Research, during 2004 - 2005, within the framework of the monitoring program "MED/POL". High DO concentrations were measured at all the stations of Korinthiakos Gulf. High values of nitrate and silicate were also measured in the deep basin of the Gulf. According to the DO and nutrient concentrations, it seems that the water column of the deep basin of Korinthiakos Gulf was fully homogenized.

Keywords : Eutrophication, Oxygen, Pollution.

Korinthiakos Gulf with a maximum depth of 900m, is connected to the west with the Ionian Sea through Patraikos Gulf and with the Saronikos Gulf to the east, through Korinthos channel. It is noteworthy, that very few scientific data for Korinthiakos Gulf are available and that makes the study of the area very interesting [1, 2]. The study area is affected by agricultural activities in the coastal zone as well as pollutants from domestic and industrial effluents (e.g. PECHINEY Power Plant Station in the north coast). Water samples for DO and nutrient (nitrate, nitrite, silicate, ammonium and phosphate) determination were collected during four sampling cruises in May and September 2004 and in February and December 2005, over a grid of six oceanographic stations [3]. The samples for the determination of nutrients were collected in 100 ml polyethylene bottles and kept continuously under deep freeze (-20 °C) until their analysis in the laboratory [4-7], whereas the DO analysis was performed on board, immediately after sampling using the modified Winkler method [8]. DO concentrations were high at all the stations of the Gulf showing temporal as well as spatial variation. The minimum DO concentration (4.73 ml/l) was observed in September 2004 at the relatively shallow station (depth 80m) in Itea bay. It is noteworthy, that at the deep basin of Korinthiakos Gulf the water column was well oxygenised. The comparison with existing data (2000) [2] confirmed that the deep waters of Korinthiakos Gulf are quite often renewed. During the period 2004 - 2005, nutrient concentrations in Korinthiakos Gulf ranged as follows: Phosphate: 0.097 - 0.264 μmol/l; Silicate: 0.98 - 7.23 μmol/l; Nitrite: 0.040 - 0.608 μmol/l; Nitrate: 0.07 - 5.87 µmol/l; Ammonium: 0.010 - 1.429 µmol/l. Spatial and temporal variation of nutrient concentrations was observed. Relatively high ammonium concentrations at the surface waters were measured probably related with anthropogenic pollution. High values of nitrate and silicate were observed in the deep basin of Korinthiakos Gulf (bellow 100-150m). It is interesting to notice that nitrate concentrations at the deep stations of Korinthiakos Gulf were lower than those recorded in the deep basin of the Western Saronikos Gulf (depth 420m). According to the nutrient data, the deep waters of Korinthiakos Gulf are enriched in nutrients showing the high rate of productivity in the area. The comparison with the previous data of 2000 showed a decrease in nitrate concentrations in the deeper layer (near the sea floor) as well as an increase in phosphate concentrations [2, 3].

Abstract

Submarine groundwater discharges were estimated on two coastal area of the Mediterranean Sea from 222 Rn analyses in the water column. In the large Vaccares Pond (Rhone deltaic plain), the 222 Rn budget reveals a submarine input of about 1 10⁵ m³/d. In the small cove of Es Canutells (Minorca Island), this input is very low and probably below 2 m³/d. Both examples highlight the use of radionuclides in the estimation of SGD which could be an important information for coastal zone management

Keywords : Coastal Waters, Radionuclides, Geochemistry, Western Mediterranean, Coastal Management.

Submarine groundwater discharges occurs in various coastlines around the world [1, 2]. They are relatively well known and easily identifiable in karstic areas, but they are more difficult to evidence when groundwater and seawater are exchanged across sand sediment. However, this exchange could bring excess nutrients or dissolved pollutants to the coastal sea being the issue of growing concern [3]. Our understanding of submarine groundwater discharges (SGD) has improved during the last decade with the use of natural radionuclides to estimate the input of fresh or brackish water into the coastal zone (e.g. [4, 5]). Radon and radium are suitable nuclides for this purpose due to their short half-lives and their conservative behavior in salty water. They are highly enriched in groundwater compared to coastal water (factor up to 1000) due to in situ production in the aquifer, and thus, even a small input in the coastal zone may be evidenced. Here we present preliminary results of SGD estimations based on the noble radioactive gas 222 Rn ($T_{1/2}$ = 3.8 days) for two different coastal areas of the Mediterranean Sea : the Vaccares lagoon (France) and the Es Canutells cove (Minorca). These examples highlight the use of radionuclides in the estimation of SGD which could be an important information for coastal zone management.

The Vaccares lagoon system in the center of the Rhone deltaic plain is a good example of strong inter-relationships between human activities and ecosystem evolution. This hydrosystem is representative of human influences upon water and salinity regimes: for the last fifty years, the water resource management has led to complex situations with numerous conflicting objectives. The national GIZCAM project is dedicated to propose an integrated coastal zone management plan for this area. One of its objectives is to define the hydrological and salt budgets of the system, with a particular attention to the potential groundwater inputs. A RAD7 system was used to measure 222 Rn activities from water sam-

A RAD7 system was used to measure 222 Rn activities from water samples collected in June 2006 within the lagoon (surface 65 km²; maximum water depth = 2m) and from adjacent aquifers. Activities ranged from 25 to 150 Bq/m³ showing relatively constant values over the entire lagoon. Inputs of 222 Rn to the lagoon are due to diffusion from the sediment, in situ production from 226 Ra, irrigation canals and SGD inputs. The outputs correspond to the exchange with the atmosphere and in situ decay. By assuming a steady state balance, SGD can be estimated based on the measurements of the other terms. Doing so, the flux of 222 Rn from SGD required to sustain the water column inventories range from 8.5 to 11.3 Bq/m²/d. Assuming a 222 Rn activity of 6000 Bq/m³ for the SGD endmember, it corresponds to a groundwater input of 9.2 10⁴ to 1.2 10⁵ m³/d. This value is in good agreement with the one estimated from hydrological budget using long term measurements of water levels, precipitations and canal inputs (around 1 10⁵ m³/d).

The same approach was conducted in February 2006 in a small cove of Minorca Island (surface : 6000 m^2), where SGD inputs occurred through both the surrouding calcareous cliffs and the sand beach (program PICS). The radon budget based on calculations similar to those for the Vaccares Pond indicates a relatively low SGD with values lower than 2 m³/d. Important errors can be associated to some parameters with such a low SGD value (especially for the exchnage with the atmosphere) and they will be presented and discussed. Additional sampling is also required to reduce

these uncertainties. It will be done in winter 2007 and the first results will be presented.

CONNAISSANCE ET PROTECTION DES ESPACES NATURELS MARINS ET CÔTIERS DE LA CÔTE ALGÉRIENNE

Chafika Rebzani-Zahaf

Faculté des Sciences Biologiques/USTHB BP 32 16111 Alger Algérie - chafika4@caramail.com

Résumé

Devant le développement urbain et industriel en Algérie, la connaissance et la protection des sites naturels est le souci actuel. La diversité floristique, faunistique et paysagère est sans égal dans le bassin occidental de la Méditerranée. Plusieurs sites naturels ont été classés prioritaires et un réseau d'aires protégées (parcs nationaux et réserves naturelles) ont été mis en place. Une présentation d'une partie de ces espaces côtiers et marins sera exposée mettant en évidence l'importance et l'intérêt de la conservation de ces sites écologiques. *Mots clès : Biodiversity, Conservation, Coastal Management, Coastal Engineering.*

Le littoral algérien est l'un des pays les plus originaux d'un point de vue géographique, climatique et écologique et par voie de conséquence, parmi les plus intéressants sur le plan biologique et biogéographique. Plusieurs facteurs se sont conjugués pour offrir à l'heure actuelle une diversité floristique, faunistique et paysagère sans égal dans le bassin occidental de la Méditerranée. Le souci de protéger et de conserver ce patrimoine naturel [1, 2, 3, 4] est croissant devant le développement urbain et industriel. Plusieurs sites naturels ont été classés prioritaires et un réseau d'aires protégées (parcs nationaux et réserves naturelles) ont été mis en place. La connaissance, la protection et la conservation des sites naturels et plus particulièrement côtiers et marins sont présentées d'Est en Ouest :

Le Parc National d'El Kala, d'une superficie de 80 000 ha, est situé au Nord Est et fait partie de la Wilaya d'El Kala. Ce parc couvre 40 km de littoral de Cap Rosa au Cap Roux. Ce parc englobe une zone humide unique en son genre et classée réserve de la biosphère en 1990 par le programme M.A.B. de l'UNESCO. Ce parc est classé comme zone d'importance internationale (Convention de RAMSAR). Il est caractérisé par une grande variété d'écosystèmes :

 - L'écosystème marin et littoral: composé essentiellement de formations à corail rouge, d'herbiers à Posidonies. Les dunes littorales sont occupées par les formations naturelles à pins,

- L'écosystème lacustre : au niveau des lacs (Tonga, Oubeira, Bleu, ...), une flore très diversifiée est observée avec la présence de plusieurs espèces endémiques,

- L'écosystème forestier : composé principalement de forêts de chênes.

Le Parc National de Taza (Wilaya de Jijel) est situé dans la région Est de la côte algérienne, il comprend le massif forestier de Guerrouche tout en présentant une façade maritime puisqu'il offre 9 km de plages et de corniches. Il s'étend sur 3 807 ha. Ce parc a pour objectif de protéger la flore et la faune à intérêt écologique, floristique et faunistique, ainsi que les sites géomorphologiques (grottes et falaises).

Le Parc National de Gouraya : il s'étend sur une superficie de 2 080 ha et est situé au Nord Ouest de Béjaia (Wilaya de Béjaia). Il est caractérisé par un massif montagneux qui se brise dans la mer, il comporte 10,6 km de côte de rochers et de falaises. Il a pour objectif de protéger les sites aux paysages exceptionnels, de conserver et de sauvegarder l'écodéveloppement de la nature.

La Réserve Naturelle de la Macta : s'étalant sur une superficie de 19 750 ha, les marais de la Macta sont situés au Nord Ouest de l'Algérie à une vingtaine de km à l'Ouest de Mostaganem. L'intérêt de la création de cette réserve vise à la protection et au maintien de l'équilibre écologique des espèces faunistiques et floristiques menacées d'extinction.

La Réserve Naturelle Marine des Iles Habibas : elle s'étend sur une superficie de 2 684 ha, et se situe à l'Ouest de la côte algérienne (baie d'Oran). Cette réserve vise à protéger les espèces endémiques de faune et de flore. Plusieurs autres sites naturels méritent un intérêt écologique important, notamment le Mont Chenoua qui appartient à la baie de Tipaza-Bou Ismail à 70 km à l'Ouest d'Alger ; il présente une superficie de 8 000 ha sur sa partie terrestre et 2 000 ha en zone marine. Ce site est exceptionnel sur tous les plans: paysager, historique, culturel et naturel. La connaissance et le suivi scientifique sont indispensables à la protection et à la conservation des aires protégées. Il est important d'intégrer les phénomènes nouveaux ou potentiels qui interfèrent avec l'équilibre de ces écosystèmes, et d'appréhender le suivi des activités anthropiques directement ou indirectement liées aux intérêts patrimoniaux des sites, ou tout simplement pouvant interagir avec le fonctionnement écologique des écosystèmes protégés.

FAST COASTAL PROCESSES ON VOLCANIC SHORELINES: EXAMPLES FROM STROMBOLI, ITALY

Claudia Romagnoli

Dip. Scienze della Terra e Geol-Ambientali, University of Bologna, Italy - claudia.romagnoli@unibo.it

Abstract

Very fast coastal processes occur on volcanic coastlines, particularly in response to alternating constructive (eruptive activity) and destructive (erosion or collapse) stages. Rapid morphologic readjustment has been documented at Stromboli after the 30/12/2002 landslide and tsunami. Studies of historical coastal evolution of the island, reconstructed from maps and aerial photographs dating back to the past century, clearly indicated that coastal processes develop at high rates. Alternating coastal accretion and erosion stages have been recognized, in fact, for the main beaches of the island, where accretion is related to main stages of eruptive activity and to littoral drift processes redistributing sediment along the coasts.

Keywords : Aeolian Arc, Coastal Processes, Tyrrhenian Sea.

Stromboli is located at the NE end of the Aeolian Archipelago in the Southern Tyrrhenian Sea. It is known worldwide for its persistent, mainly mildly explosive, central volcanic activity spanning at least the last 2000 years. In historical times, volcanic activity has been mostly concentrated on one flank of the island (western), which supplies sediments for most of the northern beaches. Sciara del Fuoco, a horseshoe-shaped feature located in the western flank of the island, is in fact where most of the volcanic products/lavas of recent activity have been accumulated. It is a partially filled scar, formed in the last of a series of major flank collapses; its steep lateral walls extend well below sea level and act as a channelway to the sea for most of the eruptive products. Loose volcaniclastic materials (breccia, gravel and sand) are reworked gravitationally down the steep Sciara scree slope (>38°) to the sea shore. Small lava deltas, built when lava flows reached the sea during the last main historical eruptions (such as in 1930, 1954-55, 1967, 1975, 1985-86, 2002-2003), have invariably been almost completely eroded away by wave action within a few days or months after formation. As directly observed during the 2002-2003 eruption, the entrance of lava flows into the sea at the foot of Sciara del Fuoco, and the interaction with seawater there, directly produces large quantities of volcaniclastic deposits by quenching and fragmentation due to phreatic explosions. This caused, for instance, the initial filling of the slide scar created by the 30/12/2002 landslide event, at present almost completely obliterated.

The foot of the Sciara del Fuoco slope is exposed to westerly winds; from data on the marine climate, it is expected that nearshore waves and windgenerated currents induce a prevalent clockwise drift along the N half of the island. From Sciara del Fuoco, in fact, sands and gravel drift alongshore, due to this prevalent and most energetic wave climate approach, and reach beaches on the north and northeastern side of the island, where the sediment residence in the nearshore is promoted by the physiographic setting.

Evolution of the N and NE coastlines of Stromboli in the last 50 years has been traced in detail using historical maps and series of vertical aerial photographs, taken on average at decadal intervals [1]. There are evidences that the historical evolution of beaches at Stromboli can be related to the occurrence of volcanic activity. While cliffed tracts were relatively stable, in fact, beaches on the N and NE side of the island experienced alternating accretion and erosional stages linked, respectively, with the contemporary eruptions and with sediment redistribution and/or the washing out and loss of sediment to deeper waters.

In particular, in the northern and northeastern sector of the island, from a condition of prevailing coastal erosion at the end of the 1800s, beaches accreted until 1938 and during the period of 1967-1987 and were slowly but consistently eroded during the intervals 1938-1955 and 1987-2001. Periods of coastal accretion follow episodes of relatively intense volcanic activity, as recently observed after the 2002-2003 eruptive crisis. On the other hand, during stages of lowered eruptive activity (as, for instance, in the interval 1938-55 or 1987-2001), a diffused reduction in beach volume has been documented, possibly induced by washing out and loss of sediment to deeper waters under storm conditions, particularly where active canyons and gullies dissect the coastal sectors.

Complementary information from field studies and beach sediment analyses (granulometric data and rounding observation) also support the clockwise longshore drift model along the western, northern and north-eastern coasts of the island.

RIVERBORNE HEAVY METALS AS INDICATORS OF PARTICLE DYNAMICS AND ANTHROPOGENIC PRESSURE IN THE GULF OF LIONS (NW MEDITERRANEAN)

V. Roussiez¹*, W. Ludwig¹, O. Radakovitch², A. Monaco¹, J.-L. Probst³, P. Ollivier²

Abstract

Particle dynamics has been traced in the Gulf of Lions (NW Mediterranean) through the use of particulate heavy metals introduced by rivers. It allowed first to reconstruct the main trends of the hydro-sedimentary functioning of this non tidal environment and second to draw a global portrait of the distribution of the metallic contamination. Results evidenced the determinant role of the prodeltas - i.e. shallow sedimentary units off the river mouths - in the control of land-derived sediment and associated contaminant fluxes. *Keywords : Metals, Sediment Transport, Pollution, River Input, Gulf Of Lions.*

The Gulf of Lions is one of the largest continental shelves of the Mediterranean Sea, receiving various sources of particulate materials delivered by far from rivers. Around 80 - 90 % of this terrestrial input originates from the Rhône River [1], the most important river of the western Mediterranean basin. In contrast, the other rivers (e.g. Têt, Aude, Orb and Hérault) are characterized by smaller watersheds and show a highly variable discharge regime governed by episodic flood events. The Gulf of Lions is, in this respect, a heterogeneous system, and hence represents an interesting worksite for the exploration of land-to-sea transfer of sediments. Another factor of interest is that this zone is bordered by numerous cultivated/industrialized watersheds, which release a large panel of contaminants such as trace metals that preferentially incorporate the particulate phase. These elements can therefore be used as tracers of the particle dynamics in an attempt to determine the ultimate fate of contaminated sediments, and hence their subsequent impact in the marine system. On this basis, the main trends of the hydro-sedimentary functioning of the Gulf of Lions have been pointed out: (i) the nearshore sedimentary units off the river mouths (i.e. the so-called prodeltas) are the first repository areas for riverborne particles owing to early sedimentation at the saline front. They act as sink but also as source of fine particles [2], depending on meteorological conditions, (ii) finest-grained sediments are advectively exported from direct continental sources and/or prodeltas towards the middle-shelf mudbank, and (iii) a homogeneous material is exported outside the continental shelf under the influence of the western general circulation, which is intensified during storms. Tightly bound to these sedimentary mechanisms, the distribution of the metallic contamination reveals that the most impacted areas concern the prodeltas. When going seaward, the persistence of the contamination likely depends on elemental behaviours, which makes that only conservative metals (i.e. fixed on particles) still depict anthropogenic enrichments [3] [4].

MARINE TOURISM DEVELOPMENT AND SUSTAINABILITY. CASE STUDY OF THE SARONICOS GULF MARINAS, GREECE

Fani Sakellariadou

University of Piraeus, Dept of Maritime Studies, 40 - fsakellar@yahoo.gr

Abstract

The coastal region development should be accomplished under the umbrella of sustainability, bearing in mind the specific ferrying capacity of the area. The concept of a holistic approach should be applied, in an effort to establish and conserve a healthy business in a well being environment. In the present study, the Saronicos gulf marinas (in Greece) are studied and compared, according to their effectiveness to correspond to high quality standards, respond to consumer needs and preserve the environment. *Keywords : Pollution, Aegean Sea, Coastal Management.*

The coastal region is a fragile and complex ecosystem with a variety of land uses. Sustainability emphasises the interdependence of social and economic development as well as environmental protection. Marine tourism is one of the extremely growing today's industries and it is incorporated in the recent EU Marine Policy [1]. Improper marina operations and maintenance activities have the potential for environmental degradation. The marina ecosystem receives a variety of pollutants [2, 3] from activities such as re-fuelling operations, boat maintenance and boat cleaning, while domestic wastes and other discharges produced on board, as well as water runoffs from the parking, maintenance and repair areas have a strong potential to enter the water basin with its limited water circulation. On the other hand, marine tourists, as typical consumers, ask for high quality standards, such as a healthy coastal and marine environment. Trying to sustain long-term profit, improved competitiveness, continuous growth and enhanced employment rates, the marina industry has begun to embrace the need to promote clean boating, clean facilities and clean operations. For a sustainable marina's development, adverse impacts on water quality and disturbances to wetland should be minimized, animal and plant habitat conservation should be promoted and land use policies aiming to a healthy environment should be established.

Studying the Saronicos gulf marinas, based on information provided by the facility owner/manager and a representative number of users, it is obvious that most of them do not offer high quality standards services. A boat supplies shop, that could promote environmental friendly goods, a boat maintenance and repair facility, a technical support of electronic devices facility and a repairs supply shop are absent, apart from one case. Public education for pollution prevention, and relevant publicity are rare. There is a need to establish a list of economically achievable measures to control the addition of pollutants to coastal waters. In all of them, apart probably from one case, the best management practices should be applied in order to eliminate, control and reduce environmental pollution, bearing in mind that for a marina's appropriate management scheme, the business availability is strongly related to the environmental health. Research is continued trying to identify a marina that, through best management practices adoption, has already resulted in positive economic benefits. That will be of great help in an effort to persuade marina's decision makers to make the required environmental changes. In other words, findings will act like economic tools, helping marinas to meet their environmental responsibilities.

INTERACTIONS BETWEEN KAMCHIA RIVER AND COASTAL WATERS (BULGARIAN BLACK SEA)

Galina Shtereva *, Anton Krastev, Boryana Dzhurova and Ognyana Hristova Institute of Oceanology - BAS, Bulgaria, Varna 9000, P.O.Box 152 - chem@io-bas.bg

Abstract

Understanding the connection between Water Quality (WQ) in the coastal zone (CZ) and river catchment is important in order to better assess the CZ processes. One of the main sources of pollution in CZ is certainly that one produced by human activities in the associated river basin. The goal of the paper is to estimate the river impacted zone during the high flow period of the largest Bulgarian Black Sea river. The analysis of data reveals the presence of fresh water low transparency layer with thickness of 3 - 5 m. Vertical distribution of the chemical parameters confirms the location of the impacted area at <1mile. There is a good correlation between nutrient content and salinity.

Keywords : Black Sea, River Input, Coastal Waters.

The coastal zone is a dynamic area of natural changes and increasing human use. One of the main sources of pollution in CZ is certainly the human activity in the associated river basin. Understanding the connection between WQ in CZ and river catchment is important in order to better assess CZ processes and to evaluate various management options leading to improvement of the staus of the coastal ecosystem. The largest national Black Sea rivers, Kamchia River, is the main source of fresh water for the Bulgarian part of the Black Sea (19.25 m3/s). Kamchia River length is 245 km with a catchment area of 5358 km², which covers 40 % of the Black Sea watershed. The catchment of Kamchia River includes some industrial and urban areas as well as regions with agricultural activity [1, 2]. In this regard WQ of the river is affected by human activities (industry, urbanization and agriculture). The river water transports pollutants to the sea and the magnitude of pollutants discharge is often related to watershed changes, utilization and river basin management. There is a lack of knowledge about Kamchia River influence on the coastal waters. Few publications provide information on this subject [3, 4].

The goal of the paper is to estimate the extent of the coastal zone impacted by the river during the high flow period (spring). The study of the interaction between Kamchia River and the related CZ focuses on nutrient emissions and eutrophication.

The study is based on monthly monitoring of Kamchia River, during the period 2005-2006 on the following parameters: BOD₅,nutrients as dissolved phosphorus (P), nitrogen (N) and silica (Si). The investigation of water column in the coastal zone in front of the river mouth was carried out during the high flow period by *in situ* measurements of temperature, salinity, transparency, pH and oxygen. The collected samples were analyzed for nutrients and suspended matter by standard methods [5].

The results for the river show a nutrient content, exceeding the allowed concentration maximums established by Bulgarian WQ standards (more frequently for nitrites). The analysis of data for coastal waters during high flow period reveals a significant influence of the river discharge on the 1 n.m. coastal zone. Several parameters (nutrients and salinity) are used to define the impacted area which spreads in the South and East due to the current circulation along the coast. As a consequence of river discharge the WQ of close coastal zone does not correspond to the Bulgarian standards.

The size of this area, related to the advection of the river plume, depends on the amount of Kamchia River waters discharged into the sea, as well as on the winds and current system in this part of the Western Black Sea. The vertical distribution of the observed parameters confirms the location of the impacted area (Fig. 1 and 2). The main features of the river which influenced the waters in the coastal area are the lower salinity, higher nutrients and suspended matter content. The analysis of the data recorded reveals a presence of fresh water low transparency layer with thickness of 3-5 m. High Si content leads to significant increase of Si:P and Si:N ratios. There is a good correlation between the nutrients and salinity distribution in the coastal area ($r^2=0.57$ for N and $r^2=0.81$ for P and $r^2=0.70$ for Si). The river directly influences the brackish waters in the immediate proximity of the river mouth. Due to the current circulation along the coast the transformed river waters at near mouth stations are characterized by low transparency (0.5-1.5 m), pH values 8.09-8.25, salinity <8.3 psu. The farthest two stations on transect in front of river mouth with distance >1 n.m., have similar vertical distribution of the biogeochemical parameters, showing that the river has no impact in this area.

Fig. 1. Vertical distribution of salinity (psu) a front of Kamchia River.

Fig. 2. Vertical distribution of nitrates (Îijg/l) a front of Kamchia River.

Abstract

In situ knowledge of phytoplankton community dynamics and environmental factors remains a powerful tool for determining processes underpinning changes in species assemblages in relation to time, space, resources, and competition. This study aims at investigating changes in phytoplankton assemblages before, after and during the development of blooming in the Kalloni Gulf (Aegean Sea) under the influence of environmental parameters and particularly terrestrial runoff. Links between environmental parameters and species abundance data have been analysed using multivariate methods and biodiversity patterns. Our results indicate that assemblages thriving under nutrient loading from runoff have a different structure in comparison to natural blooms occurring in summer and in autumn. *Keywords : Biodiversity, Blooms, Coastal Waters.*

The Gulf of Kalloni is a semi-enclosed shallow water body, occupying a surface area of 110 km^2 . The climate of the area is typically Mediterranean. During the rainfall period (November to March) a notable amount of nutrients is carried into the gulf through leaching from the surrounding agricultural land. A six station network was sampled monthly from August 2004 to July 2005. Stations 1 and 2 were positioned in the open sea and the inlet of the gulf respectively. Stations 3, 4, and 7 were in the vicinity of three important rivers which discharge at the northern part of the gulf. Station 5 was placed in the middle of the gulf to characterize the overall condition of the gulf water mass.

Data related to physical parameters, nutrients and Chl α were collected from 1 and 5 m depths. Phytoplankton samples were quantitatively analyzed using the Utermöhl method [1] as well as using bright field (BF) in order to identify nanoplankton species at 1000x. Phytoplankton biovolume and biosurface values were also calculated according to Hillebrand et al. [2]. Multivariate analysis of species abundance data were applied using the Primer 6.0 package, and statistical comparisons with the permutational multivariate analysis of variance known as PERMANOVA [3].

We tested the effect of time (month) and space (location of stations) in a two-way multivariate analysis of variance. The effect of month (PER-MANOVA F=37.07, P<0.05) was much stronger than the effect of location of stations (F=2.14, P<0.05) in the grouping of samples, since the latter was found significant only within February and July. Similar results were obtained when the test was applied on presence-absence phytoplankton data. These results suggest that the phytoplankton community of the Kalloni Gulf is well diversified over time through the formation of distinct assemblages, which are however spatially homogeneous within the gulf. Moreover, each assemblage is distinct because of differences in the relative abundance of species as well as in its species composition.

Samples from late autumn and winter months formed a wide "winter" group characterized by rather low species abundances and without any specific proliferation (Fig. 1). The phytoplankton community sampled in February was particular since it was marked by a *Pseudo-nitzschia calliantha* bloom. Spring and summer assemblages were marked by high densities of the diatom *Chaetoceros diversus* followed by *Proboscia alata f. gracillima* and *Rhizosolenia setigera*. Finally August and October phytoplankton assemblages were characterized by high abundances of small diatoms such as *Cyclotella spp.* and *Thalassionema nitzschioides f. parva*.

Total cell number during the February bloom was higher by three orders of magnitude. However, due to the small biovolume of the blooming species *P. calliantha*, the total biovolume did not differ from that of summer and September assemblages which were dominated by more voluminous cells, such as those of *Rhizosolenia* species. Although the February assemblage maintained relatively high species richness, mainly due to the contribution of dinoflagellate species, it was characterized by significantly lower evenness (J') and diversity (H') values compared to any other assemblage.

Fig. 1. Multidimensional scaling of the stations inside the gulf using the Bray-Curtis similarity index with 40% similarity contours.

The above results indicate that the winter bloom, initiated by high nutrient loading through surface runoff, presented a different phytoplankton assemblage structure than the natural blooms occurring in early summer and early autumn. The development of the early summer bloom as well as its decline was progressive evolving over a time period of more than one month. No apparent relation seemed to exist between available resources and the bloom initiation, apart from the increased light availability during summer. Conversely during the *P. calliantha* winter bloom which lasted for less than 20 days, there was a clear-cut connection between peak abundances and peak nutrient densities, and the bloom declined soon after the nutrients were exhausted. Finally, low values of biodiversity indices during the winter bloom suggest that a sudden heavy nutrient loading into the system may greatly destabilize phytoplankton community structure, however stability is rapidly regained as soon as nutrients are exhausted.

Résumé

L'étude écologique des foraminifères benthiques et des ostracodes de la lagune de Nador (littoral méditerranéen, Maroc) a été réalisée pour la première fois à l'aide de la méthode des courbes des fréquences relatives. Elle a permis de reconstituer les milieux écologiques, de suivre leur évolution spatiale pour l'actuel (hiver 2003, été 2004) et pour une période ancienne (1000 à 1200 ans BP) et de préciser les facteurs naturels (climat, géomorphologie, morphodynamique et hydrologie) et les facteurs anthropiques qui contrôlent leur répartition et leur évolution. Par ailleurs, cette étude a mis en évidence l'existence d'une relation étroite entre l'évolution des ostracodes et celle de la famille des Spiroloculinidae qui pourraient constituer des bio indicateurs de la pollution. *Mots clès : Lagoons, Coastal Systems, Western Mediterranean, Foraminifera.*

Introduction

La lagune de Nador est située dans le littoral méditerranéen marocain oriental, (Fig. 1), elle a fait l'objet d'une étude écologique des foraminifères benthiques [1]. Mais, ces travaux ne tiennent compte ni des périodes de prélèvement ni de la différence d'âge entre les associations des bases et des sommets des carottes pour la reconstitution des milieux écologiques. Il était donc nécessaire d'entreprendre dans le cadre du projet COLASU, une étude de ces microfossiles qui sont d'un grand intérêt écologique. Pour ce faire, une démarche nouvelle a été adoptée, elle est basée sur : 1) l'application pour la première fois de la méthode des courbes des fréquences relatives aux foraminifères et aux ostracodes ayant été déterminés par I Bouimetarhan et A. Slimane, pour l'identification des milieux écologiques et 2) l'étude de l'évolution spatiale des milieux écologiques pour la période actuelle (hiver 2003 et été 2004) et pour une période estimée à 1000 - 1200 ans BP d'après les datations [2].

Fig. 1. Les zones hydrologiques et hydrochimiques de la lagune de Nador.

Les milieux écologiques : caractérisation, évolution et contrôle

Trois milieux écologiques ont été identifiés pour la période actuelle (Hiver 2003), ils corroborent la zonation écologique proposée par l'étude des ostracodes [3].

- Le milieu écologique I correspond à la bordure continentale nord de la lagune (station 14). Il se caractérise par : 1) une association d'ostracodes qui montre des proportions voisines de *Cyprideis* (40.1%) et de *Loxoconcha* (37.7%), une faible densité et une biodiversité assez élevée et 2) une association de foraminifères où prédominent les formes péritidales, en particulier *Ammonia tepida* (68%) comme cela a été signalé [4].

- Le milieu écologique II correspond à l'extrémité NW (stations 4 et 47) et la bordure continentale sud (station 11). Il se caractérise par : 1) une association d'ostracodes où *Loxoconcha* (>50%) prédomine sur *Cyprideis* (20 à 30%), contrairement à ce qui était proposé [3], une faible densité et une biodiversité en général moyenne, et 2) une association de foraminifères dominée par le groupe peritidal où la famille des Nonionidae (*Ammonia tepida* suivie de *Nonion depressulum*), atteint un pourcentage de 60 % et comportant des espèces marines épifauniques (Miliolidae et Bolivinidae).

- Le milieu écologique III correspond à la bordure interne de l'île barrière (stations 23 et 24), la partie centrale (stations 27 et 37) et la zone de la passe (station 31). Il se caractérise par: 1) une association d'ostracodes où Cyprideis (>60%) prédomine sur Loxoconcha (10 à 20%) et généralement une forte biodiversité et une densité movenne et 2) une association de foraminifères avec des espèces péritidales (36 à 48 %) représentées par Ammonia tepida, des Bolivinidae et des Rotaliina qui dominent sur les Miliolidae partout sauf dans la station 37 où les Miliolidae sont dominants. Le contrôle saisonnier ne s'exprime de manière significative que dans la station 23 où le milieu écologique III évolue en milieu écologique II durant l'été. Les conditions estivales entraînent en général une augmentation de Loxoconcha au dépens de Cyprideis et les décharges fluviatiles de l'hiver, affectent la biodiversité et la densité des stations de la bordure continentale. Par ailleurs, l'impact du stress anthropique s'exprime dans les stations proches des cages d'aquaculture et de la bordure continentale, en particulier durant les périodes d'été. Les teneurs élevées en éléments nutritifs engendrées par l'aquaculture, induisent une diminution des pourcentages de Loxoconcha (10.5%) et de Cyprideis (62%) dans la station 31. L'impact des eaux usées de Oued Bouaroug (station 11) et de la station de lagunage (station 14) se traduit par une diminution du pourcentage de Loxoconcha au profit de celui de Cyprideis, la disparition des foraminifères épifauniques marins et l'augmentation des Spiroloculinidae. Enfin, dans la station 4, l'impact de la pollution qui est accentué durant l'été, se traduit par une diminution du pourcentage de Loxoconcha au profit de celui de Cyprideis. La reconstitution des milieux écologiques pour la période ancienne (1000 à 1200 ans BP) a montré que la station 14 se caractérisait par le milieu écologique III et que l'influence marine était plus importante dans les stations 37, 47 et 4 et plus faible dans les stations 31, 27 et 23. Ces résultats s'expliquent par le fait qu'il y a 1000 à 1200 ans, la limite interne de la lagune devait coïncider au moins avec la limite actuelle du marais salant de Taouima et la passe était située au niveau du double tombolo.

ARTIFICIAL BEACH NOURISHMENT PROJECTS IN ITALY

Renzo Valloni¹ and Mattia Barsanti² *

¹ Department of Earth Sciences, University or Parma, 43100 Parma, Italy

² ENEA Marine Environment Research Centre, 19100 La Spezia, Italy - mattia.barsanti@santateresa.enea.it

Abstract

The first results of the University of Parma-Enea La Spezia survey on artificial beach nourishment projects in the 8000 km long Italian coasts are shown. The state of the art in 2002 is represented by 72 projects, a database sufficiently large to allow the discussion of the principal types and the main sedimentologic characteristics of the projects. *Keywords : Beach, Coastal Engineering, Erosion, Sediments.*

Introduction

The social-economic consequences of coastal erosion in the Mediterranean coasts are extremely important. Nowadays artificial beach nourishment is a common remedial measure to beach erosion, particularly effective in Spain and Italy [1].

The database discussed below rely on survey data aimed to classify the relevant information on artificial beach nourishment [2]. The preparation of the data-form benefits of the contributions of several investigators from the Enea Centre of La Spezia, the Consortium *Venezia Nuova* and the Regione Emilia-Romagna.

Rationale

This work considers all significant nourishment projects and only part of the fills of relatively small volume. These latter are commonly executed by private beach concessionaires and not always officially recorded. The rationale of the survey is as follows.

1) Simplicity of formulation in order to guarantee reliability and homogeneity of the information collected;

2) The placement of material in the same coastal stretch in separate years with specific financing of the interventions is attributed to distinct projects and recorded on distinct data-forms;

3) Survey of all relevant projects with no temporal limit to the survey given although in Italy significant artificial nourishment works only initiated in the eighties.

Survey data

Data-forms are filled in co-operation with local Administrators. The collected information is presented in the following.

3.1 Project identification

- Municipality, Province (*Prefecture*) and local Administration (*Regione*);

- Aim of the artificial beach nourishment;

- Denomination of the project and year of construction;
- Additional aims pursued by joint projects (e.g. restoration of the dune system).
- 3.2 Technical information
- Length (m) of the restored reach of shore;
- Width (m) of the restored beach;
- Volume (m^3) of fill;
- Total cost of the fill;

- Fill material: sand, gravel and mutual percentage in case of combined use;

- Source of borrow material: land, sea, estuary/port dredging;
- Protective structures: groin, submerged barrier.
- 3.3. Renourishment

Modality of execution and cost of periodic nourishment and monitoring of the restored beach performance.

Discussion

The 72 projects catalogued so far allow some statistically meaningful treatments; a first set of relevant parameters is defined referring to the example of the Poetto project construction in Cagliari (Sardinia).

- Length of restored shore = (L) = 2.500 m
- Average width of restored beach = (W) = 55 m
- Volume of fill = (V) = 370.000 m^3
- Total cost of the fill = (C) = 3.098.741 Euro.
- The parameters above provide the following characteristic indices.
- Length-width ratio L/W = 45,4
- Volume of fill per unit lenght V/L = $148,0 \text{ m}^3/\text{m}$
- Cost per cubic meter of fill C/V = 8,4 Euro/m³.

Characteristic values of Vand L separate two basic categories of

artificially-placed beach materials here named *Fills* (V <100.000 m³ and L <1800 m) and *Nourishments* (V \ge 100.000 m³ and L \ge 1800 m).

Actually among Fills a group of minor interventions characterised by a length-width ratio (L / W) <20 and a volume (V) <40.000 m³ can be distinguished. These projects cannot be considered as real beach replenishments but simply as local sediment pourings.

From the cases considered here the existence of two fundamental categories of artificial Nourishments is shown as a function of the volume of placed materials for unit distance of the restored shore (V/L). Characteristic values are from 10 to 50 m³/m and from 80 to 400 m³/m, here named *Surface* and *Volume* Nourishments, respectively.

Conclusion

Up to year 2002 a total number of 72 Italian beaches has been artificially restored. By project number the ranking of Administrative Regions is Emilia-Romagna (30), Latium (11) and Tuscany and Marche (10). By volume the most important projects are Venice-Pellestrina ($4.000.000 \text{ m}^3$) and Venice-Cavallino ($2.000.000 \text{ m}^3$), Paola ($1.000.000 \text{ m}^3$) in Calabria and Ostia-Levante (950.000 m^3) in Latium.

The purpose of the beach reconstruction projects can be classified in the following four categories: (1) Beach widening for recreation, (2) beach restoration for protecting buildings and roads, (3) beach restoration for protecting parks and natural herritage, (4) removal of groins for realising one of the previous soft restoration projects.

Only projects where the volume of fill is >100.000 m³ and the length of restored shore is >1800 m belong to the generally recognized artificial Nourishments. On the base of the fill Volume-Length ratio these latter can be distinguished in two types named *Surface* and *Volume* Nourishments.

An example of Surface Nourishment is the Cecina project in the Province of Livorno (V/L=26 m^3/m). The highest value of the V/L ratio is provided by the Venice-Pellestrina Volume Nourishment (V/L= 400 m^3/m).

The costs detected here per cubic meter of fill are very informative. They turn out to be particularly low (within 6 Euro/m^3) when the source of borrow material is from dredging an adjacent estuary or port. For the remaining, in most cases the unit costs vary between 10 and 20 Euro/m³.

PRELIMINARY RESULTS OF FORAMINIFERAL ANALYSES: SOLINE BAY (KRK ISLAND, ADRIATIC SEA, CROATIA)

Jelena Vidovic ¹ *, Vlasta Cosovic ¹, Cedomir Benac ² and Mladen Juracic ¹

¹ Department of Geology, Faculty of Science, Horvatovac 102 a, HR-10 000 Zagreb, Croatia - jelena.vidovic@geol.pmf.hr

Abstract

The foraminiferal assemblages were studied at four stations in Soline Bay (Krk Island, Adriatic Sea, Croatia). Soline Bay is a protected lagoon with sediment rich in organic matter, without anthropogenic, industrial, agricultural impact and with negligible water input. The results demonstrated: dominance of hyaline taxa specimens along the Bay with an increase in number toward the shallower part, a decrease in the relative abundance of porcelaneous taxa specimens in the same direction, a low diversity and a high dominance of a very few species at all stations, plankton specimens in the shallow part of the Bay brought by tide currents. *Keywords : Lagoons, Adriatic Sea, Foraminifera, Sediments.*

Study Area

The foraminiferal assemblages from Soline Bay (Krk Island) were studied in May 2006 as a part of seasonal variability of the foraminiferal assemblages monitoring project in the selected localities at the east coast of the Adriatic Sea (Croatian part of the Adriatic Sea). Soline Bay was selected as an example of the protected lagoon with fine-grained sediment rich in organic matter. Origin of the fine-grained sediment is the catchment area of the Bay composed of the Eocene Flysch. There is no anthropogenic, industrial, agricultural impact and there is a negligible water input.

Materials and Methods

Hand collecting by a scuba diver took place in the transect along with the stations from #1 to #4, starting at water depth of 1.2m down to 10.5m. The temperature varied from 17° C in the deeper parts, to 20° C in the shallower parts of the Bay. Two samples were collected from each station. One sample was presently stained with the Rose Bengal, while other sample was left for sedimentological analyses. The stained samples were treated using a standard procedure. Dried fractions were split in aliquots containing at least 300 specimens, which were picked, identified and counted. Living (stained) and dead (empty) foraminiferal specimens were identified. The samples left for sedimentological analyses were processed using a standard procedure.

Results and Discussion

The hypothesis was based on the fact that agglutinated and porcelaneous taxa would decline in abundance toward the shallower part of the Bay with the increase of fine-grained fraction proportion and that hyaline taxa would tolerate the change well [1].

The results have demonstrated a change in the sediment type from sandy mud at the station #1, gravely muddy sand at the stations #2 and #3, to gravely mud at the station #4 [2]. Inverse sediment zonation (fine-grained sediment in the shallower part of the Bay) is explained by the Eocene Flysch sediment supply.

Living (stained) specimens were rare at all four stations, ranging in proportion from 3% at the station #4, to 10% at the station #1. Therefore the interpretation was based on the total assemblage.

The general trends observed at Soline Bay were the following: 1) low diversity and high dominance of a few species at all stations, 2) hyaline taxa specimens domination along the Bay with the maximum at the shallowest station (from 70% at the station #4, to 96% at the station #1), 3) decrease in the relative abundance of porcelaneous specimens in the same direction (from 25% at the station #4, to 3% at the station #1), 4) very low relative abundance of agglutinated species at all stations (1% at the station #2 to 3% at the station #4), 5) high number of genus *Ammonia* specimens along the Bay, 6) decrease in number of genus *Elphidium* specimens toward the shallower part of the Bay, 7) relative abundance of plankton specimens increase toward the inner part of the Bay, most likely brought by tide currents, 8) mechanical damages (fragmentation) of numerous specimens of genera *Elphidium, Ammonia* and *Quinqueloculina*.

Abstract

Beachrocks are coastal sedimentary structures formed by the lithification of beach material, due to precipitation of mainly carbonate cements from the coastal sea and/or fresh waters. In this contribution a discussion of their morphological, ecological and socio-economic impacts is taking place, based upon information from the literature, results of morphodynamic modelling and detailed field studies, as well as from a questionnaire survey on foreign tourists at a Greek island. The results of the study show that coastal wave dynamics and beach morphodynamics are significantly influenced by beachrock formation. Regarding the ecology, the transformation of sandy beaches to rocky foreshores, leads to the development of new habitats and fauna and flora assemblages. Finally the questionnaire survey showed that beachrocks may also decrease the amenity value of beaches, and potentially harm tourism. *Keywords : Biodiversity, Erosion, Coastal Management, Coastal Models, Monitoring.*

Beachrocks are coastal formations resulting from the cementation of beach sediments by mainly calcitic or aragonitic cements. The cementation occurs either on the surface or, more commonly, beneath the littoral/intertidal sediments, and the resulting formations can be kilometres long, attain widths of hundreds of meters and thicknesses of up to several meters. Beachrocks have been thoroughly studied in the 60s and 70s from geologists, mainly regarding their formation mechanism, without reaching to solid conclusions (see [1-4]). On the other hand there are significant indications that they affect beach morphodynamics [5], and they often result to transformation of sandy beaches to rocky ones, followed by significant implications to ecology and socio-economy. However it is very interesting that studies on such impacts are very few and given that Mediterranean Sea is a hot spot for the phenomenon of beachrock formation, of high importance. The objective of the present contribution is to present the impacts of beachrock formation on coastal morphology, ecology and socio-economy.

Fig. 1. Typical beachrock formations on Kalithea, Chalkidiki, Greece (a), mapof reported beachrock occurences (from scientific journals) in theMediterranean (b), beach profile envelopes from Vatera beach, LesvosIsland, Greece, demonstrating the 'reduced' dynamics of the profile, aswell as the morphologic control by the beachrock presence.

The 7.5 km long, microtidal beach of Vatera, Lesvos Island, Greece, was chosen as study area, characterized by the presence of extensive beachrock formations. Seasonal ecological sampling, beach levelling and sediment sampling has been carried out all along the beach, while the buried upper beachrock surface was also levelled (after excavation of the beach). A beach profile evolution model based on the Bussinesq equations [6], was specially modified for the case of beachrock infected beaches [8] and was applied in various wave conditions, to compare the morphodynamic response of the beach profile for a 'normal' and a beachrock presence case. Finally in order to investigate the possible impacts of beachrocks on tourism, a questionnaire survey was carried out in the two infected costal areas of Lesvos Island (Plomari and Vatera).

Regarding beach morphodynamics, the overall analysis of the field data

and the modelling results suggest that: (i) beachrock spatial distribution along the beach is controlled (amongst others) by beach sediment size and wave energy levels; (ii) beachrocks drive the formation of big scour steps (range of 0-1 m) that impede shoreward cross-shore sediment transport, and provoke beach erosion; (iii) beachrocks appear to 'lock' the beach profile and control its final shape which is highly correlated to the one of the formations' upper surface; (iv) affect the waterflows through the porous sediment body in a way that facilitates sediment suspension and transport.

On the analysis of the ecological samples [8], seven algae taxonomic groups were identified as well as 31 invertebrate taxa, most of which are typical of hardbottom communities. Statistical analysis showed decrease in the population density and biomass towards the coastline, as well as an increase of mobile species' population densities with the depth (especially during the spring period).

The questionnaire survey [8] showed that, beachrock presence influences the interviewees beach quality rating in a negative manner; 64 % of the sample considers that the local authorities and the EU should takemeasures to protect the swimmers from the beachrocks and 51 % the coast as well. Eventhough risk perception appears neutral, 55.4 % of the sample is willing to contribute on financial grounds to research, focused on the phenomenon, with widely ranging contributions.

All the above imply that beachrock formation is a natural phenomenon that may have significant impacts, which have not been studied accordingly yet. Particularly in the Mediterranean area, beachrocks are abundant and the latter combined with the intense development of the coastal zone, intensifies the current and anticipated problems due to their presence.

PANEL REPORT BY THE MODERATOR

Ferdinando Boero

Università del Salento, Italy - boero@unile.it

Keywords : Biodiversity, Gis, Eastern Mediterranean, Western Mediterranean.

Information systems are the new powerful tool to collect, integrate and analyse data from different sources and to make them readily accessible to the scientific community worldwide. This panel focused on issues concerning the management of biodiversity databases on the internet (data integration, accessibility, quality control) and their scientific and educational applications.

The session started on time, all speakers where sharp in their presentations, leaving an hour for discussion with the audience. The first two contributions focused on patterns and trends in the introduction and distribution of alien species based on the analysis of datasets from the CIESM Atlases of Exotic Species. Daniel Golani showed the abrupt increase in exotic fish in the Mediterranean Sea in recent years, with 18 newly introduced species since 2002, mainly through the Suez Canal. Many established species extended considerably their range of distribution and for some species real population explosions occurred in just few years time. As the rate of invasion is likely to increase in the future, D. Golani discussed the need for more research on the impact of exotic fish on native assemblages. In particular, he stressed the importance of long-term monitoring of fish invasions and the need for comparative studies between exotic fish and ecologically similar native species for more reliable assessment of impacts on local diversity.

The rate of invasions in the Mediterranean Sea is steadily increasing also for other taxa, as was clearly shown in the communication by Bella Galil. To date, 66 exotic crustacean decapod and stomatopod species have been recorded in the Mediterranean Sea and the number of introductions increased in the last decade. The Eastern basin is the most affected by species introductions, which have been five times higher than in the Western basin. Marked differences between the two basins in the origin and way of introduction were also outlined. B. Galil finally examined potential determinants of the establishment success of tropical species in the Mediterranean Sea, with special reference to climatic changes.

Marc Verlaque introduced the forthcoming CIESM Atlas on Exotic Macrophytes, which is the first inventory of macroalgal species introduced in the Mediterranean Sea. The Atlas provides comprehensive, referenced information on the morphological features, ecology and biogeography of 110 exotic macroalgal species. The Atlas, soon accessible online, will be regularly updated, dynamically integrating records on new introduced species. Since the Mediterranean Sea harbours the greatest number of exotic macrophytes in the world, and since new species introductions are increasing exponentially mainly due to shellfish farming, this Atlas represents a unique benchmark to assess past and future changes on macroalgal diversity.

Giuseppe Notarbartolo di Sciara presented the joint project between CIESM and ACCOBAMS to develop, in cooperation with the Pelagos Sanctuary, a database on cetacean sightings covering the Mediterranean and Black Seas. The database will integrate historic datasets collected and archived by the CIESM Marine Mammals Task Force with current and future records on the presence, distribution, abundance and habitat of cetaceans. The importance of building a scientifically rigorous cetacean sightings database was underlined by the author, who stressed the need for basin scale observations to further scientific understanding of marine mammals and improve conservation measures.

Key issues concerning data integration, accessibility and ownership in web-based information systems were presented by Christos Arvanitidis on behalf of the panellist Edward Van Berghe (excused). As he pointed out, one of the main problems related to integration of several datasets is the lack of a common taxonomic nomenclature. He then described the European Register of Marine Species, an initiative of the EU Network of Excellence MARBEF to provide a standard taxonomic list of European marine species. This list is available online and should serve as a reference guide when integrating datasets using different terminology. A brief presentation of the MedOBIS database on Mediterranean and Black Sea species was given by her colleague Sarah Faulwetter.

Data integration, however, does not only imply the use of a common terminology. The need to adopt an ecosystem-based approach to study biodiversity has prompted the development of information systems which host datasets of numerous biological and environmental variables.

The new CIESM GIS-based application developed at CIESM Headquarters was presented in a joint paper authored by Paula Moschella and Kaveh Rassoulzadegan. It will integrate CIESM datasets on biodiversity, environmental variables and bibliographic resources into one single information system. The multilayer architecture of the application and the partitioning of the Mediterranean into subregional zones allows an at glance visualization of several datasets in a particular area of interest. P. Moschella also explained that the system was specially conceived to make it accessible and easy to use on both shores of the Mediterranean, and to provide scientific information that would equally serve scientists and non-specialist end users.

The last presentation was given by Stéphane Pesant, who highlighted the importance of integrating datasets that provide information on the different levels of biological diversity (e.g. taxonomy, genetics, ecology) to better understand the functioning of marine ecosystems and the biogeochemical fluxes. The problems of data aggregation, quality control, and metadata standardization were also addressed using examples from EurOcean, SESAME and MARBEF initiatives.

The following is a summary of the main questions, answers and comments raised during the general Panel debate.

Comment: Databases are too difficult to use, and not exactly user-friendly, with the exception of that of CIESM.

Answer: Databases are available through the internet, and so are accessible to all those who can take advantage of a connection with the world wide web. Most databases, however, are just for the scientific community and are often not even available without permission.

Question: Are there biological parameters that can be used to show long term changes, as it happens with oceanography?

Answer: It is possible with the fossil record over the long term. Then there are middle term information, like with alien species, where we can reconstruct the recent history of the Mediterranean in terms of arrival of new species from both Gibraltar and Suez. EurOceans and SESAME are working with this aim in mind, collecting past information and assembling it into a single temporal framework. Long term series have been set up at several places (Naples, Villefranche-Sur-Mer, Plymouth, Helgoland) but are being abandoned because they are costly and not scientifically rewarding over the short term (the term that determines scientific careers and funding availability). They should be fostered because they reconstruct the history of biota and are conducive to the understanding of present-day situations.

Question: There is not enough knowledge of the biodiversity of the south shore. No more taxonomists. What about the species living in the southern shore and that have never been recorded due to lack of observation? If they will widen their distribution range, they will be considered as aliens, and they are not. We have to convince the decision makers that taxonomy is important.

Answer: this is correct. We have information from the northern shore, and sometimes we produce floras and faunas, but they do not cover the situation of the southern shore. The exploration of the Mediterranean is far from having been accomplished. The problem does not reside with

THE BLACK SEA COASTAL ZONE: PRESENT-DAY STATE AND THREATS ARISING FROM GLOBAL CHANGE AND FROM REGIONAL VARIABILITY

Nicolae Panin

National Institute of Marine Geology and Geo-ecology - GeoEcoMar Bucharest RO-024053, Romania - panin@geoecomar.ro

Abstract

The total length of the Black Sea coastline is over 4 400 km and it belongs to 6 states: Bulgaria, Turkey, Georgia, Russian Federation, Ukraine and Romania. The proposed zoning of the Black Sea coastal zone evidences 17 main zones characterised by different geology and morphology, as well as specific littoral water circulation, sediment drift systems and sedimentary budget. These zones belong to three main morphodynamic categories: (1) low, accumulative coasts mostly related to the rivers mouth zones (mainly sandy complex barrier beaches with strong longshore sediment drift systems); (2) Erosive coasts within lowstanding plateaux and plains, with active cliffs with very narrow beaches in front of the cliffs; (3) Mountainous coasts, with cliffs, marine terraces, land slides, sometimes with sandy or gravely beaches. An overview of the coastal erosion in the Black Sea and of factors controlling these erosional processes is given. The threats to the coastal zone generated by global changes and anthropogenic pressure are analysed. The most vulnerable sections of the Black Sea coastal zone exposed to environmental risks are presented and analysed. *Keywords : Coastal Processes, Erosion, Black Sea, Global Change.*

The Black Sea coastline

The total length of the Black Sea coastline is over 4 400 km and it belongs to 6 states: Bulgaria, Turkey, Georgia, Russian Federation, Ukraine and Romania. The Black Sea coastal zone can be divided in 17 main zones characterised by different geology and morphology, as well as specific littoral water circulation, sediment drift systems and sedimentary budget [1].

In a more general approach, the Black Sea coast zone could be subdivided into three main morphodynamic categories, with very specific characteristics and behaviour:

1. Low, accumulative coasts mostly related to the main rivers mouth zones. This type of littoral zone consists of sandy complex barrier beaches with strong longshore sediment drift systems; these zones are generally characterised by isostatic adjustments of overloading by rapid accumulation of sediments (subsidence). To this type belongs the Danube Delta front with a very exposed to erosion littoral of about 240 Km; two sections of the River Dnieper liman - Karkinit Bay unit: the Kinburn spit - Dolgyi Island section (\sim 20 Km) and the Tendra spit - Dzharylgatch Island section (\sim 137 Km); the Taman - Anapa unit (about 200 Km long); the Kolkhida (Rioni) Lowland where the rivers Chobi, Rioni, Inguri and Supsa have built up their deltas; on the Turkish coast there are the deltas of Kizilirmak, Yesilirmak and Sakaraya rivers, and finally, in Bulgaria, sandy accumulative beaches related mainly to the rivers Diavolska, Kamchya, Provadyiska and Batova, summing about 100 Km.

2. Erosive coasts in front of lowstanding plateaux and plains, with active cliffs in lœss and lœss-like deposits, sometimes underlyed by older deposits as Pontian limestones, Meotian clays and Sarmatian lumachelles, with very narrow beaches in front of the cliffs. To this type of coasts could be distributed the north-western unit of the Ukrainian coastal zone (from the northern limit of the Danube Delta to the town of Ochakov or the western limit of the Dnieper liman, summing 232 Km), the southern unit of the Romanian coastal zone (Cape Midia - Vama Veche at the Bulgarian border - about 75 Km long), and the northern part of the Bulgarian coast, from the Romanian border to Caliacra Cape (about 50 Km long) [2].

3. Mountainous coasts, with cliffs, marine terraces, land slides, sometimes with sandy or gravely beaches. This type of coasts is generally subject of isostatic and orogenic uplift. To this type are belonging the coasts of Crimea, Caucasus, Pontides, Strandza and Staro Planina Mountains, as well as of Frangensko and Avrensko plateaux [1,2].

Coastal erosion in the Black Sea: factors controlling the erosional process The coastal erosion in the Black Sea represents one of the main environmental concerns of the riparian countries. The erosion is controlled by: a) Global and natural factors. The Black Sea coastlines erosion is strengthened as everywhere in the World Ocean by the global changes and the general sea level rise. The coast erosion will depend on synergetic effect of factors controlling the littoral processes (meteorological regime, wave energy regime, water circulation, sediment supply and drift etc.), global changes and the consequent modification of the energetic level of the coastal sea, general sea level rise and regional characteristics as shoreline morphology, elevation and geologic constitution, subsidence or/and neotectonic regime.

Fig. 1. Erosion of the Danube delta.

b) Anthropogenic factors. The coast zone erosion and the state of the coastal sea ecosystems are strongly affected by anthropic activities, the effect of which is added to the impact of natural factors. The anthropogenic changes of large rivers hydrologic characteristics (water and, especially sediment supply, regularisation of floods etc.), men-made littoral structures as breakwaters, dykes, groins, harbours etc., which are modifying the littoral circulation cells, the uncontrolled use of beach sand, dredging of sand too close to the beaches or within the river mouth bars and many other activities are causing an enhancement of coastal erosion and endangering of the coastal ecosystems.

The low, accumulative coasts (first category of coasts described above) are the most influenced by global change, specifically by the sea level changes and by the changes in the river sediment inputs [1, 3-5]. The decreasing sediment supply and changes in littoral sediment drift due to anthropic activities (river damming, hydrotechnical regularisation, littoral structures

PANEL REPORT BY THE MODERATOR

Scott W. Fowler

Marine Sciences Research Center, SUNY-Stony Brook, New York 11794-5000, USA - s.fowler@free.fr

Keywords : Radionuclides, Monitoring, Metals, Petroleum, Aeolian Arc.

During the introductory session, the Panel Moderator noted that at a similar CIESM Congress some 35 years earlier, the famed explorer Jacques Cousteau had drawn international attention to the health of the Mediterranean by stating his observations had led him to believe that the Mediterranean Sea was "dying" and in fact could be "dead" in a few decades if nothing was done to stop the problems of increasing pollution and overfishing. Fortunately 35 years on, the Mediterranean Sea is far from dead but his comments did more to raise public awareness about the problems of protecting the marine environment and spur international actions to stem pollution in the Mediterranean than much of the sound scientific data being produced by scientists studying the problem at that time. Although over the ensuing years much effort has been put into assessing the degree and extent of chemical contamination in the Mediterranean Sea, an overall lack of baseline information still exists for a broad area of its eastern and southern coasts, as well as for new classes of chemical contaminants that are just now coming to light. It was therefore the task of this Panel to probe and analyze those two aspects in detail and finally debate and suggest approaches and mechanisms for better assessing the overall health of the Mediterranean Sea. To accomplish this the panelists, composed of scientists from both leading national and international institutions, gave seven presentations which dealt with measurement and monitoring of conventional and emerging chemical contaminants in the Mediterranean Sea as well as the ways and means to better integrate ongoing studies, and to build analytical capabilities and monitoring expertise in areas where they are lacking.

With respect to contaminants, a presentation by Francesco Regoli discussed the distribution and bioaccumulation of heavy metals in certain sentinel (bio-indicator) species that have been used to assess metal pollution in both industrialized and relatively clean areas of the Mediterranean. He highlighted the fact that mercury appears to be higher in certain Mediterranean species of top predator fish than in similar species from the Atlantic, and that while the reasons for this observation are far from clear, the increased concentrations might be due in part to the natural mercury anomaly that is present off the northwest coast of Italy. Moreover, his presentation stressed the utility of integrating chemical analyses with determining molecular, biochemical and cellular biomarkers in the species analyzed in order to assess biological effects in the different areas. In one example, using caged mussels placed beneath an offshore drilling platform in the Adriatic Sea, it was demonstrated that early warning signals of environmental stress could be readily detected through specific biomarker analysis. The source and origin of petroleum hydrocarbons along the west coast of Algeria was highlighted in the presentation by Sellali et al. These authors reported the presence of heavy oil contamination in sediments in this sector, most likely derived from the petrochemical complex in the Gulf of Arzew. The very high levels of PAHs noted near Oran were believed to originate from industrial and domestic wastes released from the city, whereas near the outflow of various oueds entering the sea, the hydrocarbons contained a land-based, pyrolytic signal. Their dataset represents one of the first reported for an area of the southern shore where data have consistently been lacking, and it clearly indicates a land-based rather than maritime shipping origin of the contamination.

As concerns emerging contaminants in the Mediterranean, the report of Hélene Budzinski highlighted the need for basic information on the various classes of pharmaceutical substances that have been recently identified in seawater. Her studies have focused on developing analytical techniques for their quantitative measurement in seawater, in particular the use of semi-permeable membrane devices for carrying out integrative sampling. Using these techniques her group has found concentrations of a wide variety of pharmaceuticals in seawater collected off Marseille ranging from a few nannograms to several micrograms per liter, with most of the contamination residing in the dissolved phase.

In terms of strategies for undertaking integrated monitoring studies on contaminants, Hervé Thebault and Alessia Rodriguez y Beana presented results of the first phase of the CIESM Mussel Watch monitoring study of radionuclides using the Mediterranean mussel Mytilus galloprovincialis. Some 20 laboratories from 15 countries were involved in the study, and from that network a regional map for ¹³⁷Cs has been produced showing generally very low concentrations in mussels, viz. on the order of 1 Bq kg⁻¹ or less. Somewhat higher levels were found in mussels from the Black Sea and northern Aegean Sea indicating residual concentrations from Chernobyl fallout. During Phase II the programme will be extended to cover the natural radionuclide ²¹⁰Po as well as include some emerging trace contaminants. In connection with the Mussel Watch monitoring approach, Mai Khanh Pham et al. reported that the quality of the data have been verified by ensuring that all laboratories involved participated in a Quality Assurance intercomparison exercise for radionuclides in mussels. The IAEA Marine Environment Laboratories produced a mussel reference material that was analyzed by all the participating laboratories. During the exercise various analytical problems in some laboratories came to light, and capacity building needs were thereby identified. Based on these results and those from nine additional laboratories located outside the region, information values for ¹³⁷Cs and several other radionuclides were determined. Further work is presently underway to certify this intercomparison material as an IAEA Reference Material.

Concerning regional programme activities, Michel Warnau presented a concrete proposal for linking and integrating on a basin-wide scale many of the similar monitoring programmes that are underway in the Mediterranean region. Difficulties in project implementation often arise owing to the participating countries having major industrial, agricultural, cultural and regulatory differences. Furthermore current programmes are supported by several different entities including national, regional, European, and international funding bodies, a fact which often leads to overlap in both scope and efforts. These programmes often run in parallel with little or no information exchange amongst them. The proposal aims to better integrate all these projects having similar objectives by coupling, reinforcing and equipping them in a similar fashion which would ultimately result in a synergistic effect thereby enhancing the overall output. Within this integrated effort, key international organizations with expertise in organizing training and capacity building would furnish similar support to all the programmes involved thus making the entire monitoring effort far more cost effective. Furthermore such an approach would lead to enhanced quality assurance of monitoring data since all parties' analytical techniques and methodologies would be unified through inter-comparison exercises of the various analyses. In support of such of obtaining such an integrated monitoring network, Oscar Acuña from the IAEA Technical Cooperation Department explained how IAEA could support such a proposal through its current and future technical cooperation programmes in the Mediterranean and West Asian regions. The overall goal would be to eventually enhance the level of expertise in trace contaminant measurements in participating groups from the southern and eastern rim, in order to bring it up to par with that available in the more developed Mediterranean regions.

Following these formal presentations, the panel was open to comments and discussion and the panelists were queried on a number of points raised by the participants. Regarding conventional contaminants such as metals and hydrocarbons, some participants felt that many contaminant data had already been gathered from a large portion of the Mediterranean and that perhaps it was time to synthesize what is now known before proceeding with more monitoring surveys. There was general agreement that much information had already been obtained through some 30 years of monitoring within MedPol and other programmes, but it was also acknowledged that the geographical distribution of those data was "patchy" at best, and that reliable data still lacked for large areas of the eastern and southern shores of the Mediterranean. It was in these areas that the group felt

PANEL REPORT BY THE MODERATOR

Roberto Danovaro

Department of Marine Science, Polytechnic University of Marche, Ancona, Italy - danovaro@univpm.it

Keywords : Deep Sea Ecology, Deep Sea Basins, Deep Sea Processes, Deep Sea Sediments, Biodiversity.

Panel 5 was conceived with the objective of giving a brief but highly interdisciplinary picture of present knowledge and recent advances in Mediterranean deep-sea research, starting from the geosphere and hydrosphere settings, to microbiology and faunal diversity and ecosystem functioning, to conclude with the presentation of Programmes on Mediterranean biodiversity and ecosystem functioning.

The Panel started with a general overview on deep seas presented by the moderator Roberto Danovaro. Deep-sea sediments, covering 65% of the world surface, are the largest ecosystem on Earth. Here microbial processes, driving nutrient regeneration and global biogeochemical cycles, are essential to sustain primary and secondary production of the oceans. Deep-sea ecosystems are also the largest reservoirs of biomass and key elements/compounds. There are no direct estimates of the value of deep seas. However, since the deep-sea floor covers an area ~ 100 larger than that of shelf, even assuming a deep-sea dollar/ha/yr value 10 times lower than that of shelf, the value of deep sea functions is 10 times higher than that of shelves, and potentially higher than actual estimates of world total ecosystem value. In addition, the census of life in the deep sea is just at the beginning and the largest portion of its biodiversity is still unknown (from 0.3 to 8.3x10⁶ species to be discovered). The moderator illustrated also the reasons why the deep Mediterranean Sea can be considered the best existing model to investigate the impact of changes at global scale. The main reasons can be summarized as follows:

1. The Mediterranean is a miniature Ocean (therefore a model of circulation and processes occur at much smaller time scales);

2. There is a long-term history of investigations and impacts in the Mediterranean basin (but not in the deep sea);

3. High deep-sea temperatures, which imply faster responses.

4. Susceptible and sensitive to climate changes (already evident in the deep, relevance of episodic events; EMT, Gulf of Lion);

5. High biological diversity in coastal systems vs. very low biodiversity in the deep.

6. Strong environmental and biodiversity gradients (e.g., West-East gradient in trophic conditions);

7. Complex paleo-ecological history, with periodic mortality events (sapropel formation): scenarios of recolonization;

8. The Mediterranean is the ideal basin for testing factors forcing the evolution of deep-sea life: large proportion of continental margins - source sink hypothesis;

9. The deep-Med contains the most extreme environments for life (e.g., DHABs);

10. The deep-Med is full of hot spot ecosystems at very short distance (cold seeps, deep corals, canyons, slopes, slides, seamounts, anoxic etc).

Deep-sea ecosystems, and the Mediterranean in particular, are highly vulnerable, and increasingly subject to direct and indirect anthropogenic impacts (deep-sea trawling, dumping, oil, gas and mineral extraction, other pollution sources). Moreover, recent findings have revealed that climate change can exert also a significant and rapid impact on deep-sea Mediterranean biodiversity.

The presentation of the first panelist (Miquel Canals) focused on the description of the drivers of Mediterranean deep water sedimentation. Recent observations suggest that the functioning of deep Mediterranean benthic systems, as expressed by particulate fluxes and benthic variables, are characterised by a large interannual variability, which is highlighted by the evidence of episodic or stochastic events, or long-term climate change. Two such large events - the Eastern Mediterranean Transient and the Gulf of Lions cascading - affected significant parts of the eastern and western basins respectively. M. Canals described in detail a highly significant massive sediment transport and seafloor shaping process, not previously documented, and illustrated how Dense Shelf Waters (DSW),

flowing down submarine canyons and slopes, carried large amounts of coarse sediment that eroded and shaped canyon floors (e.g. giant furrows). The main conclusions coming out from this presentation were:

1. This is a mechanism of massive transfer of fresh organic matter, and hence C sequestration, to the deep ocean;

2. DSW flowing down canyons may carry large amounts of highly nutritive fresh organic matter that in intense events (twice from 1993 to 2005 in the Gulf of Lion) reaches the very deep basin thus massively injecting C into the deep ocean;

3. Submarine canyons in the Gulf of Lion drive the deep Western Mediterranean Sea;

DSWC in the Gulf of Lion imprints intermediate and deep waters, and the functioning of the deep ecosystem in the Western Mediterranean Sea;

4. According to predictive models, climate change holds the potential to significantly modify dense shelf water cascading;

5. Global warming will likely lead to a lowering in the frequency of dense shelf water formation, thus reducing the frequency of cascading processes which in turn will cause a severe reduction of the episodes of massive injection of organic matter into the deep ecosystem. The example reported here on the cascade event in the Gulf of Lion is providing new perspectives of investigation and management of the Mediterranean.

Jean Mascle illustrated the geosphere component of the deep-Mediterranean Sea and discussed the present knowledge on the topographic description of the deep Mediterranean seafloor, which is a prerequisite for any subsequent investigation on deep-sea life and ecosystem functioning. He showed the recently published (2005) CIESM/Ifremer high resolution multibeam maps which cover large portions of the seabed morpho-bathymetry in both the Western and Eastern Basin. Additional maps detailing specific areas of the Mediterranean Sea such as the Nile Deep Sea Fan were produced under the same scientific collaboration. J. Mascle also underlined the high scientific value of these maps which provide detailed information on large scale geological processes of the Mediterranean Basin and reveal specific features of the seabed (e.g. mud volcanoes, gas and fluid seepages) which are extremely important to understand biogeochemical processes occurring in the deep.

Anastasios Tselepides illustrated some peculiar aspects of the biology and ecology of deep-sea benthic biota in the Mediterranean, with a specific focus on benthic community structure and function of the deep Eastern Mediterranean Sea. High temperature, high salinity and the strong oligotrophy make this ecosystem very different from all other ocean deep-seas. This difference is also reflected in the species diversity and functional role of the macro- and microbiota of the deep Mediterranean, as illustrated by the author. He also focused on main drivers and recent changes related to climatic events such as the Eastern Mediterranean Transient, which indirectly affected the deep benthic communities. The high vulnerability of the Mediterranean deep sea ecosystem to environmental changes and its close interactions with the upper water column and the coastal ecosystems were underlined.

This talk was followed by a summary on the present knowledge and recent advances in deep Mediterranean microbiology by Christian Tamburini and Gerhard Herndl. They reported the key role of deep-sea prokaryotes (DSP), which are a virtually untapped resource for industrial purposes. Recently, a number of novel metabolic pathways have been discovered, shedding new light on the dark ocean prokaryotes. Non-thermophilic Archaea have been recently found to represent the major source of autochthonously produced organic carbon in the deep sea and play a major role in deep-water nitrification outnumbering bacterial nitrifiers in the oxygen minimum zones of the mesopelagic ocean. Anaerobic anmonium and methane oxidizers have been found in the dark ocean sediments and even more recently, in the deep oceanic water column. The Mediter-
