EVALUATION DE LA QUALITE BACTERIOLOGIQUE DE LA FRANGE COTIERE DE TETOUAN «KABILA - OUED LAOU»

Soumaya Khannous ¹*, Hassan Er-Raioui ¹ and Rachid Boutaib ² ¹ Faculté de Sciences et Techniques de Tanger, 90000, Maroc - khsoumaya@yahoo.fr ² INRH Centre Regional d'Oceanographie, Tanger, 90000, Maroc

Abstract

Parallèlement au développement industriel et urbain, la contamination du milieu littoral par des produits organiques et chimiques générés par les activités humaines est devenue un fléau préoccupant. Ce travail présente une caractérisation bactériologique portant sur l'appréciation de la contamination globale et de la contamination fécale. Les résultats révèlent une bonne qualité microbiologique des eaux du littoral étudiées, avec une variation saisonnière de la charge bactérienne, présente à un niveau important durant les périodes pluvieuses.

Keywords: Bacteria, Coastal Waters

Introduction

Le littoral méditerranéen présente quelques zones de forte densité de population, particulièrement entre Tanger et Tétouan, ce qui entraîne un développement du tissu industriel dans cette région. Ce développement a un impact négatif sur l'environnement naturel et le milieu marin en particulier. Des études antérieures [1] montrent que les eaux de la zone littorale méditerranéenne comprise entre Fnideq et Kaâ-srass, indiquent une bonne qualité microbiologique, excepté pendant la période des pluies où de légers dépassements du seuil de la salubrité sont observés au niveau de Kabila, Martil et Oued Laou. Afin de caractériser la qualité microbiologique de l'eau de mer de la frange côtière de Tétouan, allant de Kabila à Oued Laou, une analyse dénombrant la flore mésophile aérobie totale, les coliformes fécaux et totaux et les entérocoques fécaux perfringens a été mise en place.

Matériel et méthodes

Les analyses bactériologiques permettent de dénombrer la flore mésophile aérobie totale (FMAT), les coliformes totaux (CT) et fécaux (CT) et les streptocoques fécaux (SF) après filtration sur membrane (45µm). La gélose PCA a été utilisée comme milieu de culture pour la FMAT, la gélose VRBA pour CT et CF et le milieu de Slanetz et Barthely pour SF.

Résultats et discussion

Les résultats obtenus montrent que la charge bactrienne moyenne de cet écosystème pélagique est de 2,89 10^2 UCF/100ml. La station de l'embouchure de l'oued Laou semble être la plus contaminée avec 1,04.10³ UCF/100ml. Les précipitations enregistrées dans la région durant la période d'échantillonnage sont importantes pendant toute l'année excepté durant l'été. Des pics maximums sont observés en automne et au printemps . Ce profil de variation est semblable à celui de la charge bactérienne enregistrée durant la même période sur les mêmes sites. Ce travail suggère une relation étroite entre la quantité de charge bactérienne et les précipitations. Il semble que la pluviométrie et les crues jouent un rôle déterminant dans les processus de contamination correspondant également à l'importance de la charge polluante.

Conclusion

Cette étude révèle que le site le plus exposé à la contamination bactérienne est l'embouchure de l'oued Laou et suggère une relation étroite entre la pluviométrie et la charge bactérienne sur tous les sites examinés. Cela se produit parallèlement à une augmentation de la charge polluante.

³ Université de Franche-Comté, Laboratoire de Chrono-Environnement, UMR CNRS 6249

Abstract

The solar saltern of Sfax sustained an abundant phytoplankton community with higher diversity in the outer than the inner zone in terms of Shannon-Weaver diversity index (H'). Some environmental parameters such as salinity seem to play an important role in determining the phytoplankton community succession and then diversity, favoring or limiting the growth of the different phytoplankton groups.

Keywords: Phytoplankton, Salinity, Biodiversity

Introduction

Several investigations on plankton were conducted in the solar saltern of Sfax [1, 2, 3]. In this ecosystem, phytoplankton was found to tolerate different salinity [1]. That's why, they could be found in the five ponds of our study, but most of them concentrated in the pond of low salinity [3]. In this study, phytoplankton density was described in 2000 and 2003 in five ponds of increasing salinities.

Material and methods

2-1- Sampling

Sampling was carried out in the central part of the five ponds A1, A16, C2-1, M2 and TS in 2000 and 2003.

2-2- Phytoplankton

Water samples (200 ml) were fixed by Lugol's iodine solution and counted under an inverted microscope (\times 400) using the Utermöhl method. Phytoplankton identification was made from morphological criteria after consulting various keys.

2-3- Statistical analysis

Mean and standard deviation (SD) were reported when appropriate. The potential relationships between variables were tested by Pearson's correlation coefficient.

Results and discussions

The density of total phytoplankton community marked differences between ponds and years. Phytoplankton density ranged between $0.44\times10^6\pm0.62\times10^6$ cells l^l (pond A1) and $1.23\times10^6\pm1.87\times10^6$ cells l^l (pond M2) during the year 2000 (Table 1).

Tab. 1. Annual Mean \pm SD of total phytoplankton density, diversity index and salinity in ponds A1, A16, C21, M2 and TS during the years 2000 and 2003.

Ponds	Years	Total phytoplankton (×10 ⁶ cells. I ⁻¹)	Diversity index (bits. cells ⁻¹)	Salinity (p.s.u)
A 4	2000	0.44 ± 0.62	1.68	42.6 ± 2.3
AI	2003	0.64 ± 0.82	1.26	45.2 ± 5.3
440	2000	0.55 ± 0.91	1.36	74.8 ± 3.0
A10	2003	0.41 ± 0.28	1.0	78.9 ± 8.2
004	2000	0.96 ± 1.09	1.19	84.7 ± 5.1
621	2003	0.6 ± 0.71	1.14	90.2 ± 11.2
142	2000	1.23 ± 1.87	1.17	171.9 ± 11.0
IVIZ	2003	3.34 ± 4.38	1.09	190.1 ± 12.9
TC	2000	0.73 ± 1.05	0.23	393.3 ± 38.4
15	2003	1.39 ± 1.39	0.36	423.8 ± 33.1

Throughout the year 2003, phytoplankton density increased in all the ponds. The most important phytoplankton density was recorded in pond M2, at about $3.34 \times 10^6 \pm 4.38 \times 10^6$ cells l⁻¹ (Table 1).

The density of total phytoplankton decreased in pond TS. The highest density recorded in pond M2 was due to the high abundance of *Dunaliella salina* (66%) recorded in 2000, and the coexistence of *Dunaliella salina* (51%) and *Chlamydomonas rublifilum* (49%) throughout 2003. The density of the species

controlled by salinity was a density-controlling factor [1,2]. Several studies confirmed this result [1,2,3,4]. In consistency with this finding, Elloumi et al. [2]reported that *D. salina* was the major phytoplankton taxon in the Sfax saltern. The majority of these studies mentioned the decrease of aquatic communities' densities with the salinity gradient. The diversity index decreased with the increasing of salinity. This can be explained by the negative correlation recorded between salinity and diversity index (r = -0.96; n = 3; p < 0.05), (r = -0.94; n = 3; p < 0.05) in 2000 and 2003 respectively.

Abstract

The majority of prokaryotes live in marine habitats and play a key role in global element cycling. Yet, most of them are still unexplored and little is known about their functions as well as their reactions to the rapidly changing environment. Plus, they are expected to be a treasure trove for new genes interesting for biotechnology and medical applications. Transcriptomics and Metatranscriptomics are currently the techniques of choice to assess gene expression and to unravel the reactions of the microbes to environmental changes. In this study we present gene expression studies for the marine model bacterium *Rhodopirellula baltica* SH1^T and metatranscriptome studies employing 'Next Generation Sequencing' to analyze seasonal changes in the North Sea. *Keywords: Bacteria, Genetics, Time Series, Monitoring, Surface Waters*

The complete genome sequencing of the marine planctomycete *Rhodopirellula baltica* SH1^T revealed many fascinating and rare features like a high number of sulphatases and a global mechanism of gene regulation. In order to gain further knowledge about this intriguing organism, it was cultured under various conditions in chemostats and the resulting gene expression was analyzed with whole genome microarrays. The presented data (Fig. 1) illustrates the reaction of the organism to heat, cold and salinity shocks. Separately for each condition, the gene regulation was monitored during time series, with sampling after 10, 20, 40, 60 and 300 min. The response to heat shock was most pronounced after 40 min, while adaptation to salinity up-shift took 300 min. The strongest overall response was observed in the heat shock experiment. During cold shock, the cells seem to reduce their activity. Hence, the number of upregulated genes is significantly smaller than the number of downregulated ones.

number of downregulated ones

Fig. 1. Stress answer of R. baltica with the number of regulated genes

R. baltica shows a general stress response as well as a specific answer to different stress situations. While heat shock mainly influenced the classical heat shock genes, cold shock also had an impact on genes from the lipid metabolism. In addition, genes involved in recombination, in secondary metabolites biosynthesis, transport and catabolism were induced at enhanced temperature. Interesting was also the upregulation of SecA, which belongs to the extracytoplasmic stress response. In the cold shock experiment, genes for amino acid biosynthesis as well as for protein fate and synthesis were down-regulated, emphasizing the switch to a passive state of the cells. Genes involved in sporulation (oppB) and pilus assembly were repressed, leading to reduced motility and budding ability. The salinity shift changed the expression of genes, which encode for enzymes with a function in ion transport and in morphology. Glutamate and trehalose act as cytoplasmic osmoprotectants, which is why the respective genes involved in the synthesis of these components were upregulated due to the osmotic shock.

The experiment also enabled us to predict new functions to a set of genes without an assigned function by analyzing coregulations with known genes. This will not only enrich the functional information in the databases but might also lead to the discovery of new enzymes for biotechnology or medical applications.

Open questions : Can knowledge gained by pure culture experiments be transferred to natural habitats? Do microorganisms behave similar in the environment and in the lab and how do the over 90% of uncultivable species react to environmental changes?

To answer these questions, the MIMAS "Microbial Interactions in MArine Systems" project was set up. It aims at investigating the seasonal changes in the microbial communities at two long term ecological research sites in the North Sea (Helgoland Roads) and the Baltic Sea (Gotland Deep). The Gotland Deep is known for its stable waterbody and an Oxic-Anoxic intersection at a depth of 120 m. In contrast, Helgoland Roads captivates with its fast exchanging waterbody. In order to explore the biodiversity of the Helgoland Roads research site, single cell *in situ* hybridization and ribosomal RNA sequencing are performed. However, the core of the project is based on a "Meta-Omics" approach: Metatranscriptomics and Metaproteomics will shed light into the active fraction of genes, while Metagenomics will address the genetic potential of the bacterial community as a whole. This integrated approach will give new insights in the ecological role of marine bacterial communities and their response to environmental changes such as climate change.

Metatranscriptome analysis (Fig. 2) will be performed via pyrosequencing to get a comprehensive insight into the flexible gene expression adaptation of the bacterial community due to seasonal changes of their environment. For this purpose seawater is sampled by serial filtration, total RNA is isolated and the rRNA removed. Subsequently, ds cDNA is synthesized from mRNA using random hexamers. The following cDNA sequencing is performed with a GS FLX Titanium Pyrosequencer. Finally, Metatranscriptomic data are analyzed in relation to environmental parameters using a novel data analyzing pipeline invented and

developed in house.

Fig. 2. Experimental approach of the Metatranscriptomic part in the MIMAS project

We thank the Max Planck Society and BMBF (contract number 03F0480D) for funding and Jens Harder and Matthias Gottschalk, Microbiology, MPI Bremen, for the chemostat cultivations.

RESEARCH OF SERUM AMYLOID A AND TRANSFERRIN LEVELS FOLLOWED AFTER STREPTOCOCCUS INIAE- INFECTED IN TILAPIA (OREOCHROMIS NILOTICUS)

Azime Küçükgül Güleç¹*

¹ University of Tunceli Fishing Faculty/TURKEY - azimekucukgul@yahoo.com

Abstract

Streptococcus iniae is an important bacterial pathogen of fish, causing up to 50% mortality in stocks, which has recently been associated with human infections. Some disease states are associated with, or are causally related to acute phase proteins (APPs). Acute phase responses (APRs) to *S. iniae* (ATCC 29178) were characterized in plasma of tilapia following intraperitoneal (i.p.) infection. Two experimental groups, including *S.iniae*-infected and *S.iniae*-infected+handling stress, with a group of nonstressed control fish, were examined. Samples for plasma analysis were utilized to analyze serum amyloid A (SAA) and transferrin (Tf). The diseases signs observed in tilapia were erratic, slowdown in fish motions and darkened skin. SAA and Tf has been reported to decrease in acute phase plasma.

Keywords: Bacteria, Diseases, Fish Behaviour

Introduction

Streptococcus spp. have been recently listed among the emerging problems in aquaculture. Fish farms in many parts of the world have suffered serious economic losses due to this bacterial pathogen. For fish populations, many parameters (factors) have been measured as biomarkers. APPs that is one of them are plasma or serum proteins whose levels change in response to tissue damage, infection, or inflammation (Gaby and Kushner, 1999). APPs are an established diagnostic tool as early indicators of inflammation and disease Recently, studies have showed significant diagnostic informations in prognose and fixing of diseases of APPs consantration levels in plasma [2].

Materials ve Methods

Tilapia (mean 60 g) were acclimated in the experimental ponds for 1 month prior to experiments. The fish were fed with carp feed at 2-3% body weight daily. For each treatment, there were triplicates and each pond was stocked with 5 fish (72 fish in total). Tilapias were injected intraperitoneally (i.p.) of S. iniae (ATCC-29178) obtained from Deutsche Samlung Von Microorganismen Zellkulturna Gmbh (DSMZ). In first group, tilapias were susceptible to 3.3x10⁵ (sublethal dose) S. iniae colony forming units (CFU). The second group were exposed to both S. iniae-infection and handling stress for 15 minutes additionally. The last group was the control group. The fish were sampled on the 0, 7th, 14th and 21st day after the end of the challenge trial. Samples for plasma analysis were collected from caudal venepuncture of infected fish. Serum SAA was measured using the N-high sensitivity CRP assay with latex-enhanced immunonephelometricy assay on a BN II analyzer (Dade Behering, Milan, Italy). Transferrin were analyzed by Roche/Hitachi 902 machine used immunoturbiditometric immune assay with Randox (Kat. no: TF 7197). T-test (Independent samples) and Mann-Whitney test and Student's t were used for statistic analyses.

Results and Discussion

Macroscobic diagnosis obtained darkening of the skin, untidiness in fish motions and slowing down, immobility in pool edges were the first signs observed in tilapia. In microscobic datas, haemorrhages were observed on the ventral side of the body, lesions and hyperemiae in skin. Dermal hemorrhages on the body surface and around the mouth, opercles, base of fins and anus [3] have been observed in *S. iniae* infected moribund tilapia. These observations are often assumed to be identical to those that occur from *S. iniae* infections. While SAA levels increased in the first and second week, it decreased at the last of the third week. In constrat to SAA, a contrary situation was followed in transferrin levels of the same weeks. Jensen et al (1997) were examined changes in APPs in salmonids. In this study, fish were injected with live *A. Salmonicida.* Increases in SAA levels has been determined. Transferin levels, for both group of the first week, were occured decreased but following weeks its level reached to control levels. Determination of APPs can help in monitoring health of individual subjects.

GROWTH KINETICS OF TWO DIATOMS SKELETONEMA COSTATUM AND THALASSIOSIRA SP. FROM IZMIR BAY (EASTERN AEGEAN SEA /TURKEY).

S. Kukrer ¹, F. S. Sunlu ^{1*}, B. Buyukisik ¹, H. Aydin ² and U. Sunlu ¹ ¹ Ege University Faculty of Fisheries Dept. of Hydrobiology - f.sanem.sunlu@ege.edu.tr ² Celal Bayar University, Fac. of Arts And Sciences, Muradiye, Manisa, Turkey

Abstract

The purpose of this research is to reveal the detailed information on growth kinetics of *Skeletonema costatum* and *Thalassiosira sp.* sampled from Izmir Bay. From the results of enrichment experiments under batch culture conditions it has been found out the limiting nutrinet for *Skeletonema costatum* is nitrate and for *Thalassiosira sp.* isreactive phosphate (RP). *Keywords: Aegean Sea, Phytoplankton, Nutrients, Growth, Eutrophication*

Introduction

Primary production impetus is depending on the presence of nutrients in water column and their uptake rate by phytoplankton. The most important sources of nutrient enrichment in coastal waters are atmospheric deposition, enrichments from bottom waters and rivers as a point sources. Eutrophication is a process whereby water bodies, such as lakes, estuaries, or slow-moving streams receive excess nutrients that stimulate excessive plant growth (algae, periphyton attached algae, and nuisance plants weeds). This enhanced plant growth, often called an algal bloom, reduces dissolved oxygen in the water when dead plant material decomposes and can cause other organisms to die. The understanding and preventing of europhication are depending on knowing the relationship between nutrients and phytoplankton.With the batch culture experiments carried out using the diatoms Skeletonema costatumand Thalassiosira sp. from Izmir Bay it was aimed to point out the physiological properties of this species. Additionally, to form a base for model studies by parameterise its exponential growth rates, nutrient limiting growth rates and the Michealis-Menten curves that indicate dependence on nutrients. Being spread in a wide area of oligotrophic regions to eutrophic regions shows that these species' environmental adaptation is quite interesting. Nutrient enrichment experiments have been performed for determination of growth limiting nutrient for species in community and nutrient limited growth of them. MONOD kinetics equation was used for this purpose ([1],[2],[3],[4]).

Material and Methods

Izmir Bay is one of the largest and polluted bay of the Turkish Aegean coast. The Izmir Bay is divided into inner, middle and outer Bay due to topographical and hydrographical characteristics. The main pollutants affecting the bay water quality are organic matter, suspended matter, hydrocarbons, metals and pathogenic organisms. The pathways through which these pollutants reach the bay are domestic and industrial wastes, rainfall, bay activities and ship traffic, rivers and streams, erosion, agriculturel and other sources [5]. For this study, experiment bottles were conducted in a constant temperature room at optimal temperature of the species and irradiated at 1300 ftCd (foot-candle) by daylight fluorescent lambs. Cultures were maintained on a 12:12 light:dark cycle. For stock culture and batch culture experiments, f/2 and h/2 mediums were used described by [6]. The experiments were carried out in 1 liter Pyrex bottles initially containing 1 liter of seawater. For the experiment, the concentrations of nutrients in f/2 medium were changed and thus, for every nutrient, a different concentration was obtained. For the experiment groups, nutrients, trace elements and vitamins were added seawater according to f/2 medium [6]. Our experiment was performed under non-limiting nutrient, light and temperature conditions except the nutrient exposured. Ammonium, phosphate, silicate and nitrate were analysed by spectrophotometric methods ([7],[8]). All of the spectrophotometric analyses were carried out by using Bosch-Lomb Spectronic 21 UVD model spektrophotometer and also chlorophyll α analysis were performed using Turner 10-AU Model Fluorometer.

Results and Discussion

According to analytical results, background seawater concentrations are given below: Nitrate: $3.2 \,\mu$ M, Ammonium: $15.79 \,\mu$ M; RP : $2.6 \,\mu$ M and Silicate: 29.20 μ M. When we examined the growth curves of *Skeletonema costatum* at the different concentrations of silicate, ammonium and phosphate, we found no limitation for these nutrients hence these nutrient concentrations are not reached to limiting values in natural marine environment. Estimated growth rate means are μ_{avg} : $2.06 \, day^{-1}$ for silicate, $1.97 \, day^{-1}$ for ammonium and $1.70 \, day^{-1}$ for RP. At the different concentrations of nitrate enrichment experiments we observed that the population of *Skeletonema costatum* is not able to grow in low nitrate concentrations. In the previous study it was

reported S.costatum is growing better in batch culture with high N:Si ratio [9]. In winter period (in February) Skeletonema costatum growth was limited by nitrate. The highest cell number was reached to 38 millions cell/L. at the concentration of 886.2 µM nitrate. Maximum spesific growth rate of S. costatum was calculated as 2.34 day⁻¹ and half saturation constant (Ks) as 6.9 µM using Monod equation. There is no limitation observed at enrichment experimets of Thalassiosira sp. for the different concentrations of silicate, ammonium and nitrate. Estimated average growth rates are μ_{avg} :1.49 day⁻¹ for silicate, μ_{avg} :1.25 day⁻¹ for ammonium and μ_{avg} :0.97 day⁻¹ for nitrate in natural environment. Enrichment experimets of RP at 10 different concentrations, the highest cell concentration was observed at 38.9 µM and the growth was stopped at high concentrations. At low concentrations the growth limitation could be clearly seen. At the natural background concentration we deduce that the growth rate of *Thalassiosira sp.* was reduced 50%. Using Monod equation, estimated maximum growth rate for Thalassiosira sp. was μ_{max} :1.73 day⁻¹and Ks was 2.018 μ M for RP. In conclusion, according to our experimental results, it was determined that species which do not need high silicate concentration were dominant in winter period. Thalassiosira sp. species' high phosphate uptake ability was limited by RP. Skeletonema costatum's growth rate was limited by nitrate. Light density is low in winter at Izmir Bay. In this condition it is known that certain species uptake nitrate at the precence of ammonium and can produce lower energetic fotosenthetic productions [10]. We pointed out that this species has an adaptation ability from oligotrophic conditions to eutrophic conditions.

THE COMPARISON OF K_S VALUES OF *CHAETOCEROS GRACILIS* ISOLATED FROM THE BAY OF IZMIR AND HOMA LAGOON

Banu Kutlu 1*

¹ Tunceli University - banukutlu@tunceli.edu.tr

Abstract

Diatoms contribute to the global carbon cycle and they have an important role in regulating climates by using 40 percent of carbon in oceans [1]. *Chaetoceros gracilis* were exposed to various concentrations of NH4⁺-N based on f/2 medium in order to determine which nutrients have a limited effect on the growth of *C. gracilis*. As a result, while μ_{max} values of the *C. gracilis* isolated from two different medium are approximate, their Ks values are different. This may be related to the water's nutrient value. *Keywords: Algae, Biokinetics, Chlorophyll-a*

Introduction

Unicellular marine algae are used as food for marine organisms which have commercial value. *Chaetoceros* sp, in particular, have good nutritional value because of their small cell structures and unsaturated fatty acids. They are widely used as food for cructaceans, mollusks and fish in larval stage in aquaculture.

Materials and methods

Izmir Bay: The bay of Izmir is located in the Western part of Turkey and surrounded by a densely populated community. The bay is divided into the Inner, the Middle and the Outer Bay from the standpoint of topographical and hydrographical characteristics. The Inner bay occupies a small area and is shallow in depth. Homa Lagoon: This study was conducted in the Homa (Sufa) Lagoon area located at the outer part of Izmir Bay. Microalgal Culture: For this study *C.gracilis* was isolated from Izmir Bay (Aegean Sea) and Homa lagoon. At the time of the study, cultures of *C.gracilis* were unialgal but non-axenic. *C. gracilis* cultures were grown in 21 Erlen mayer flasks containing 1.5 of sterile f/2 medium [2]. Experiments were conducted at a constant room temperature at 28 C and irradiated at 52 µmol/m²s by daylight fluorescent lamps. Specific-growth rates: chlorophyll a specific growth rates were calculated from each growth. The specific growth rate was obtained from each growth curve calculating the following equation. $\mu = 1/(t2-t1)*\log 2(N2/N1)$

Result and discussion

Another parameter, without doubt, is nutrients which have an affect on the growth of algae that have been taken from two different environments after they were isolated. Chaetoceros gracilis were exposed to various concentrations of NH4+-N on f/2 medium in order to determine which nutrients have a limited effect on the growth of C. gracilis. Ks, which is regarded as the affinity of C.gracilis in terms of nutrient in two regions, is used as the index of species' potential survival capacity in low density food concentrations [3]. The value is $> 1 \,\mu gat/L$ and it indicates that the waters of the Bay of Izmir and Homa lagoon aren't very poor in terms of NH4+-N. But this value is greater in Homa lagoon. The difference of the calculated K_s value (3.86) can be explained by the fact that the aforementioned species may be showing environmental adaptation to the lagoon. Besides, the maximum growth rates of the cells grown in ammonium are greater than those grown in nitrate and this may be originating from the cells of species, which go into the other phases of life. μ_{max} values of Homa lagoon and Bay of Izmir are the same [4]. Found the Ks values of C. gracilis species, which have been isolated from waters poor in nutrients, as 0.1 Nm. As a result, while μ_{max} values of the C. gracilis isolated from two different medium are approximate, their Ks values are different. This may be related to the water's nutrient value.

Abstract

The Homa lagoon is the enclosed bay of Izmir which has been subjected to a variety of human influences such as agriculture in the surrounding area. In this study, bio-chemical system was studied using some biological, chemical and physical parameters obtained from the Homa lagoon. Temperature, salinity, $NH_4 + N$, $NO_3 - N$, $PO_4 - P$, Si, *in vivo* Chl-a were measured. To determine the variation of the parameters and to assess the dynamics between the nutrients and the microplankton of the Homa lagoon, nutrient enrichment bioassays were performed from the selected main sampling station. During the spring bloom of 2006, four main growths were observed. The first one appeared as bloom of *Chaetoceros* sp. In he second growth, an increase of *Licmophora abbreviata* algae was observed. In the third one, *Tintinopsis beroidea* appeared. *Keywords: Biokinetics, Chlorophyll-a*

Introduction

Homa lagoon is a natural fish production area in the Izmir. The Homa lagoon is the enclosed bay of Izmir which is subjected to a variety of human influences such as agriculture in the surrounding area. Nutrient inputs from agriculture are the main antropogenic pollution source. In this study the bio-chemical structure was investigated using some biological, chemical and physical parameters obtained from the Homa lagoon. Temperature, salinity, $NH_4 - NO_3$, PO_4 , Si, Chl-a were measured. To assess the dynamics between the nutrients and the microplankton of the Homa lagoon, nutrient enrichment bioassays were performed from the selected main sampling station. The region where the lagoon water and the experimental bottles to find out growth curves and kinetic parameters. The obtained data were plotted as growth curves and chl-a based exponential growth rates were calculated. Growth rates as a function of nutrient concentrations were fitted to the monod equation.

Methods and Materials

Water for nutrient samples was collected in 100 ml polyethylene cans. (Nitrate+Nitrite)-nitrogen (NO₃+NO₂)-N, reactive phosphorus (RP), reactive silicate (RSi) were measured spectrophotometrically according to Strickland and Parsons [1]. During the sampling periods bioassay samples were collected from Homa lagoon. Water samples in pet carboys were filtered from 245 micrometer (µm) plankton net to remove mesozooplankton and distributed to the experimental bottles. *In situ* conditions were simulated in the laboratory by using constant temperature and light room (52 µmol/m light intensity). Experiments were carried out in March, April and May 2006 to find out about nutrient limitation and to assess phytoplankton community. Nutrients such as nitrogen, phosphorus, silica were added to the one litter bottles which contained seawater sample. This known nutrient concentration enrichments help find out growth rate. The obtained data were plotted as growth curves and chl-a based exponential growth rates were calculated. Growth rates as a functions of nutrient concentrations were fitted to monod equations.

Result and discussion

The surface waters of the main station are rich in chl-a for most of the year. In spring bloom, the values were as follows: 2006, (NO₃-N + NO₂-N (4.03 - 7.25), RP (0.62-0.97), RSi (13.15-19.15) µ gat/l. The values ranged in (mM) for the analyses in May 2006 (NO₃-N + NO₂-N (6.41 - 12.27), RP (0), RSi (1.19-9.83). The surface molar ratios of nitrogen to phosphate (N/P) were calculated as 2.98 in spring time. Temperature values ranged between 15 and 22°C in March, April, and May 2006. Salinity values ranged between 36 and 44.716 psu in March-April and May respectively. Spring bloom time fourth main growths were observed. The first one appears as bloom of Chaetoceros sp. In the second growth, there was an increase of Licmophora abbreiata. The third one was Tintinopsis beroidea. After all these observations, the specimens of copepod were seen in the bay. Bio assay experiments can be summarized as follows. Phytoplankton level of most of the experimental bottles reached the exponential phase immediately, while some of the bottles exhibited lag phase (for NO3-N up to 4.11 µM). The greatest variation took place for Max chl-concentrations and phosphate concentrations. Growth rate and carrying capacity were calculated by formula 1 and 2 respectively. Results of the growh rate and chl a max for NH_4 are calculated as $\mu = 2,54$ and Chl a max in situ = 12.12.

ARCHAEAL DIVERSITY AT SHALLOW HYDROTHERMAL SYSTEM OFF PANAREA (EOLIAN ARCHIPELAGO, ITALY) AS REVEALED BY 16 S RDNA PCR-DGGE ANALYSIS

Valeria Lentini^{1*}, Concetta Gugliandolo¹ and Teresa Luciana Maugeri¹

¹ Dip. di Biologia Animale ed Ecologia Marina, Università di Messina, V.le F. Stagno d'Alcontres, 31, 98166 Messina, Italy -

vlentini@unime.it

Abstract

A molecular phylogenetic survey of occurring archaeal diversity at four different shallow hydrothermal vents was carried out by using the 16S rDNA PCR-DGGE fingerprinting method. Most of retrieved archaeal sequences did not match with those of yet-described *Archaea*, suggesting the presence of new archaeal genotypes.

Keywords: Aeolian Arc, Biodiversity, Thermal Vents

The shallow marine hydrothermal vents of the Eolian Islands in the Tyrrhenian Sea are located in tectonically active areas and despite their accessibility, several aspects concerning microbial ecology of these ecosystems have been much less investigated than those of deep-sea vents. Among Eolian Islands, thermal springs and shallow hydrothermal vents of Vulcano are considered the "type locality" of hyperthermophilic Archaea. Very few studies have been concerned the microorganisms living at near hydrothermal system of Panarea Island [1,2,3]. On the basis of culture-dependent techniques, microbial communities of extreme environmentswere thought to be dominated by Archaea [4,5]. The recent application of molecular methods revealed a different picture, in which Bacteria dominated the microbial communities in most of these environments [2,3]. Here we report the archaeal diversity studied by molecular tools in environmental samples collected from four shallow thermal sites characterised by different temperatures and depths located off Panarea Island. Archaeal diversity was investigated by means of 16S rDNA PCR-DGGE fragment analysis, as previously described [2]. DGGE profiles showed that total number of bands, equivalent to the archaeal richness, was higher in water (24) than in sediment samples (18). Comparison among the DGGE profiles, performed on the basis of Bray-Curtis similarity coefficient, showed low similarity levels among vents, suggesting that archaeal community was differently distributed at four sites, according to physico-chemical parameters. The similarity matrices were also used for constructing a non-metric multidimensional scaling (NMDS) diagram (Fig. 1).

Fig. 1. NMDS diagram showing the clustering of the archaeal community

Phylogenetic analysis revealed that most of the archaeal DGGE 16S rRNA gene sequences matched with uncultivated *Archaea* and these results did not allow us to speculate about their physiology. Only two sequences, obtained from sites 1 and 4, were distantly affiliated (<96% similarity) with *Paleococcus helgesonii*, an obligate chemo-heterotrophic, hyperthermophilic, microaerophilic euryarcheon, recently isolated from a geothermal well at Vulcano Island [6]. The

low similarity levels of sequences with yet-described clones of *Archaea* suggest the presence of new indigenous archaeal phylotypes.

VIRIOPLANKTON AND BACTERIOPLANKTON DYNAMIC IN AN ITALIAN COASTAL AREA OF THE SOUTHERN ADRIATIC SEA SUBJECTED TO POLLUTION

Maria Ilaria Leopizzi¹, Loredana Stabili²*, Federica Lugoli¹ and Antonella De Donno¹ ¹ Istituto per l'Ambiente Marino Costiero (IAMC)-CNR, U.O.S. Taranto - loredana.stabili@iamc.cnr.it ² DiSTeBA, Unviersità del Salento

Abstract

The discovery that viruses may be the most abundant organisms in marine ecosystems, surpassing the number of bacteria by an order of magnitude, has inspired a resurgence of interest in viruses in the aquatic environment. In the present study we evaluated the virioplankton, total culturable heterotrophic bacteria, luminous bacteria, *Escherichia coli* and somatic coliphages abundances, over an annual cycle, at two sampling points located in the Southern Adriatic Sea (Italy) differently subjected to a sewage pipe impact. *Keywords: Adriatic Sea, Bacteria, Bio-Indicators, Sewage Pollution*

Introduction

Coastal marine ecosystems are characterised by a complex set of dynamic interactions between organisms including viral lysis [3]. Marine viruses are the most abundant biological particles in the sea [4]. The evidence to date suggests that virioplankton communities are mainly composed of bacteriophages and that by specifically infecting heterotrophic bacteria, virus are likely to play critical roles in the structure and function of aquatic food webs[1]. Although an increasing number of work has been conducted on marine viruses, little is known about their biology and ecology (relationships with hosts and the environment) in the Southern Adriatic Sea Italian coasts. The aim of this study was to describe the virioplankton, total culturable heterotrophic bacteria, luminous bacteria, *Escherichia coli* and somatic coliphages abundances over an annual cycle as well as the relationships between these planktonic components at two sampling points located in a coastal area of the Southern Adriatic Sea (S. Cataldo, Lecce, Italy). The former point was near the mouth of a sewage pipe and the latter at 1000 m from the pipe.

Material and Methods

Water samples were collected from surface (0.2 m depth) in 300 ml capacity sterilized glass containers. To enumerate viruses water samples were filtered through 0.02 μ m pore-size filters, stained with SYBR Green I and observed by an epifluorescence microscopy. For enumeration of heterotrophic and luminous bacteria the number of colony forming units was determined by plating 1 ml of undiluted seawater in triplicates on Complete Seawater. The plates were incubated at 21°C for 20-24 hours. *Escherichia coli* presence was assessed through the filtering membrane technique. Somatic coliphages were detected through the double-layer agar technique, after a tangential flow ultrafiltration (on 10 l of water) to increase the recovery capability for phages.

Results and Discussions

Our results indicated that microbial parameters displayed a much higher abundance in the polluted point where the mean virioplankton abundance was 1.2×10^7 cells/ml and mean culturable heterotrophic bacteria density was 6×10^3 cells/ml. Furthermore viral density followed the pattern of luminous bacteria abundance as confirmed by regression analysis [2]. In the impacted point the highest concentrations of *Escherichia coli* were recorded in the summer-autumn period (100 c.f.u./100ml) whilst in January they showed values near to zero. By contrast, in the point at 1000 m from the discharge pipe, somatic coliphages concentration recorded the highest value (128 p.f.u./100ml) in the coldest month (January). Our results show that somatic coliphages are less sensitive to temperature than the classical indicators of acacl contamination. These findings suggest that somatic coliphages could be used as indicators to evaluate the quality of coastal seawater, in order to provide a more accurate analysis of the hygienic-sanitary quality of the marine ecosystem.

Abstract

Analyses of 478 polymorphic AFLP loci and about 540 base pairs COI provided an account of genetic variation among *Ruditapes decussatus* populations from both the French Atlantic coast and the Mediterranean Sea. AFLP analyses of 357 specimens from 17 locations revealed evidence of significant genetic differentiation among populations (Fst = 0.16; P<0.001). Data on COI sequences from Mediterranean and Atlantic populations showed a lower genetic diversity among populations. Mismatch analysis found signatures of past genetic bottlenecks in *R. decussatus* populations. These findings confirmed the utility of AFLP for population genetic study while indicated that COI sequences, characterized by a lower intraspecific variability, could be more suitable markers for evolutionary studies

Keywords: Western Mediterranean, Genetics, Bivalves, Aquaculture, Lagoons

Introduction

The grooved carpet shell clam *Ruditapes decussatus* is a bivalve well appreciated for human consumption and one of the most expensive and commercially important clam species in fishery and aquaculture for the Mediterranean countries. Since wild stocks in most of the *R. decussatus* native range have been in decline over the last decades, to ensure a successful species management, it is extremely important to monitor the genetic variability both natural and hatchery populations. In the present study we examined both nuclear (AFLP) and mitochondrial DNA (COI) variation among samples of the Mediterranean basin and Atlantic Ocean with the goal of characterize its populations.

Material and methods

The majority of samples were collected in lagoons of the western Mediterranean basin: along the Sardinian coasts (n=10), in the Adriatic (Italy and Albania, n=4), in the Thau Lagoon (France, n=1), in the Ebro Delta (Spain, n=1). One sample came from the Arcachon lagoon (Atlantic coast, France). AFLP marker profiles were generated using the procedures described in [1] with minor modifications. Allele frequencies were estimated with AFLP-SURV v. 1.1. Genetic diversity within and among populations were estimated with ARLEQUIN 3.1 [2], and COA analysis using Adegenet [3]. Partial sequences of the mitochondrial COI gene were obtained using novel internal primers designed from the partial mitochondrial sequence of *Ruditapes decussatus* (GenBank Accession DQ184830). All sequences were aligned with MEGA 4 [4] and analysed with DnaSP 5.1 [5], and ARLEQUIN 3.11.

Results

AFLP analysis was successfully performed on all 357 individual samples and the two selected primer combinations produced a total of 478 polymorphic markers. Among populations, the percentage of polymorphic loci ranged from 41.6 % to 60.9%, the expected heterozygosity values were generally low (from 0.14 to 0.17). AMOVA showed a high genetic differentiation among populations (Fst = 0.16, P<0.001), with most of the total variation (83.7%) due to intra-population differences. Among all hypothetical groupings of populations examined, several were found to have significant percentage of among-groups variation but the higher differentiation were measured when populations were clustered according to their genetic distances and not to their geographic origin (Tab. 1: Structure A - 4 groups= Atlantic/ Adriatic/ Sardinia/ WMediterranean; Structure B - 3 groups= WMediterranean+Albania/ SGilla (3sites)/ all others). In particular, COA analyses confirmed these results (Fig. 1). Nucleotide sequences of about 540 bp in length were obtained from the mitochondrial cytochrome C oxidase subunit I (COI) gene. Analysis of sequence variation revealed the occurrence of 19 variable sites, a low nucleotide diversity (π : 0,00203) and haplotype diversity (Hd: 0.565). The most common haplotype was found in about 60% of the specimens and in all populations; other two less frequent haplotypes were present. Contrary to what is shown by the AFLP data, COI sequences seems to indicate that populations are not significantly differentiated. Mean overall Kimura genetic distance was K2P=0.2%, and pairwise inter-population distances ranged from 0.1% to 0.4%. The mismatch analysis and the star-like maximum parsimony network of COI sequences indicate the occurrence of past bottleneck events followed by recent population expansions of R. decussates populations. Our study confirm the utility of amplified fragment length polymorphism (AFLP) markers for population genetic studies; they permitted to retrieve a higher

genetic diversity, and were developed at a relatively low cost and in a short period of time, which can make them ideal tools for generating large data sets for species that need a continuous monitoring. On the contrary, mitochondrial sequences resulted to be far less variable, and could be more suitable for evolutionary studies.

SALT MARSH ACCRETION BY ENDOGENOUS CYANOBACTERIA TO REDUCE EROSION IN VENICE LAGOON

Davide Marchetto¹, Giovanni Cecconi², Claudia Cerasuolo² and Franco Baldi^{1*} ¹ Department of Environmental Sciences, Cà Foscari University - baldi@unive.it

² Consorzio Venezia Nuova - Thetis, Venezia

Abstract

Different strains of cyanobacteria were isolated from salt-marsh of Venice Lagoon. One of them was used in the laboratory to colonize artificial substrates to induce a better colonization of eroded sediments. Different materials for cyanobacteria colonization were used from silica, zeolite to sediments. Different tests were made to improve cyanobacteria survival and exo-polysaccharide production under diverse conditions to consolidate sediments.

Keywords: Cyanobacteria, Sediments, Erosion, Lagoons

Fig. 1. Eroded sediments in the Northern Lagoon of Venice

Fig. 2. Natural stratified sediments colonized by filamentous cyanobacteria

During the last century the Venice lagoon wetlands underwent to a severe reduction of intertidal shoals and salt marshes. These geomorphologic components of the lagoon are particularly vulnerable and they have been already affected by intense erosion (Fig. 1) passing from 17.0% to 8.8% [1]. By many observations we know that cyanobacteria in the Venice Lagoon form stratified sediment (Fig. 2). These structures are very stable and consolidate sediments by naturally reducing the erosion. The aim of this work was to mitigate this process by promoting the consolidation of sediment surface with endemic cyanobacteria mat, by growing these autotrophic bacteria on suitable solid substrates to seed and colonize sediments in order to understand the colonization process for facilitating the self-preservation of salt-marsh habitats.

Cyanobacteria were isolated from salt marshes sediment in the northern basin of Venice Lagoon using solid media ASN-III [2]. A filamentous cyanobacteria strain was selected among other isolates. The strain CyV3 was used in colonization experiments on sandy quartz, commercial zeolites grain and natural lagoon sediments. The growth and adhesion of bacteria were followed on these

substrates by determining photo pigments, carbohydrates, uronic acids, exopolysaccharides (EPS) and proteins. Adhesion of cyanobacteria on sediments was also studied with epifluorescence microscopy using PNA lectine and other conventional fluorochromes. Experiments were performed also in microcosmos, using lagoon sediments to study cyanobacteria colonization. Four glassware vessels containing each 1 kg of sediments, sampled from the same salt marsh station, were used for the experiment with natural and autoclaved sediments with and without additions of cyanobacteria grown on porous zeolite. These experiment was followed for 15 days and all parameters were determined to understand the colonization process.

The CyV3 strain, belongs to Phormidium sp, grown significantly faster than other isolated strains and so we use this strain to reproduce at the multilayers structure (Fig 2). The strain was grown on coarse silica sand and fine zeolite: the growth was faster in silica but the material consolidation was weak. With finer grains of zeolites, the growth rate was longer but CyV3 produced higher amounts of ESP and total carbohydrates to give a more consolidate structure.

So commercial zeolite grains (0.5 cm diameter) colonized by strain CyV3 were used to seed CyV3 strain in microcosmos with lagoon sediments. The cyanobacteria viability and reproducibility on colonized zeolites was monitored for two months. The same percentage of viability was maintained for two weeks, after a sensitive decrease of viability with an extended lag-phase was observed. Results of experiments in the four microcosms indicated that a strong microbial competition occurred in natural sample so cyanobacteria strain seeded on zeolite did not produce significant augmentation of cyanobacteria population in relation to native autotrophic population. Conversely, the inoculated cyanobacteria zeolite grains in sterilized sediments gave a wide contribution to the formation of consolidated cyanobacterial mat.

MICROSATELLITE MARKERS FOR POPULATION GENETIC STUDIES OF THE GIANT RED SHRIMP ARISTAEOMORPHA FOLIACEA (CRUSTACEA, DECAPODA)

Sandro Marcias¹, Flavio Sacco¹, Alessandro Cau¹ and Rita Cannas¹*

¹ Com.Bio.Ma. Centro di Competenza sulla biodiversità marina, Dipartimento di Biologia animale ed ecologia, Università degli Studi di

Cagliari - rcannas@unica.it

Abstract

Microsatellite markers have been isolated and characterized from the giant red shrimp *Aristaeomorpha foliacea* in order to investigate on the presence of distinct stocks in the Western Mediterranean Sea. Polymorphism of the newly obtained loci was assessed in a restricted sample of 30 specimens, nine loci provided markers with polymorphism (range 2–19 alleles per locus). Six loci, the most polymorphic and easiest to amplify and to score, were tested in a larger sample of 6 populations from the Western Mediterranean Sea. Microsatellite data revealed a substantial genetic homogeneity and no signs of recent bottlenecks, suggesting the existence of a high gene flow that connects all populations.

Keywords: Genetics, Crustacea, Western Mediterranean, Deep Waters, Fisheries

Introduction

The giant red shrimp, *Aristaeomorpha foliacea*, is a cosmopolitan crustacean species, widespread in the eastern and western Atlantic, the western Pacific, the Indian Ocean and the Mediterranean Sea. It is one of the most important exploited crustaceans, having a long traditional and economical significance for the deep fishery of the western and central Mediterranean countries. Despite its commercial importance, little is known about the genetics, population structure, and migration patterns of this species. Since direct tracking movements of individuals is very difficult for marine species, the use of indirect methods, including genetic approaches, for the measurement of connectivity among populations can be very informative. With the aim of studying the population structure and genetic connectivity among giant red shrimp populations from the Western Mediterranean Sea and obtaining new and powerful genetic markers, microsatellites loci were isolated from *Aristaeomorpha foliacea* genome using the FIASCO protocol [1] from a partial genomic library enriched for an AC motif.

Results

Among 96 recombinant clones obtained, a total of 43 sequences had a microsatellite, 14 of which with flanking region of appropriate length and sufficient quality to allow the design of primers that were used to amplify the genomic DNA of a subsample of 30 specimens from two locations. Four out of 14 microsatellites were immidiately discarded because of their low amplification success, while one was found to be monomorphic.

The remaining 9 loci were characterized by a high variability in PIC values (0.36-0.91) and in the number of alleles (range 2 - 19).

In this study only the 6 most polymorphic loci were tested in a larger sample and used to make a preliminary investigation on the genetic structure of Mediterranean giant red shrimps. A total of 115 specimens were analysed from 6 populations: 4 samples were collected off the Sardinian coast (Sant'Antioco, Cagliari, Siniscola, Asinara) and two samples off Sicily (Messina and Sicily Channel). Two loci (Cea17 and Cia82) significantly deviated from HWE and this could be explained by their associated elevated frequencies of null alleles (10% and 19%, respectively) calculated with the algorithm of Dempster [2]. A. *foliacea* populations resulted not genetically differentiated as indicated by the low and not significant pair-wise Fst values calculated with Arlequin 3.1 [3].

Analysis of molecular variance AMOVA clearly showed that genetic variability was largely due to differences among individuals (99.31%) rather than to differences among populations (0.69%).

The absence of population structure was further confirmed by the bayesian clustering method implemented in Structure 2.3 [4] indicating K=1 as the most probable structure.

The PCA performed with Adegenet [5] showed a substantial genetic homogeneity among populations separated by hundreds of kilometres suggesting that western Mediterranean populations could represent a unique panmictic stock (fig 1).

Finally, the bottleneck test [6] and interlocus g-tests [7] did not find signs of recent bottlenecks (reduction of population size) or growth (increase of population size after the recovering from a demographic collapse), leading to hypothesize that, up to now, the Western Mediterranean giant red shrimps have experienced a sustainable fishing pressure.

All these results clearly indicate that the microsatellite markers tested here can represent very useful tools for population genetic studies of *A. foliacea*, for instance for monitoring the detrimental genetic effects of any future increasing fishing pressure.

Fig. 1. Typology of giant red shrimp populations obtained by interclass PCA. Eigenvalues corresponding to the represented components are filled in black. Points represent genotypes; samples are labelled inside their 95% inertia ellipses

DIVERSITY AND ABUNDANCE PATTERNS OF PHYTOPLANKTON IN COSTAL WATERS OF THE NORTHERN ADRIATIC

D. Maric ¹*, J. Godrijan ¹, M. Pfannkuchen ¹, T. Djakovac ¹ and R. Precali ¹ ¹ Center for marine research, Institute Rudjer Boskovic - daniela.maric@cim.irb.hr

Abstract

The distribution and abundance of different phytoplankton groups and species composition are described for costal waters along the Istrian peninsula and Kvarner Bay, in the northern Adriatic. Hydrochemical and biological properties were investigated during one year. The coastal system is rather heterogeneous due to the influence of several rivers and other anthropogenic inputs in the system, but also due to hydrography and complex circulation system in this area. The microphytoplankton community was dominated by diatoms while the dinoflagelates appeared when the nutrients were scarce, generally after the diatom blooms. The general trend followed expected succession patterns.

Keywords: Adriatic Sea, Phytoplankton, Coastal Waters

Introduction

Along the northern Adriatic (NA) coast the ecological factors (anthropogenic, like e.g. nutrient input as well as naturally e.g. bathygraphy and river outflows) are diverse. Hence the phytoplankton community is under equally diverse influences and any disturbance in marine ecosystem is strongly affecting the primary production at the first trophic level.

Fig. 1. The investigated area with the sampling stations. The piecharts show the phytoplankton community structures in March 2008.

Materials and Methods

Water samples were collected during seven cruises at 15 stations, each, one, nautical mile from the Istrian coast and Kvarner Bay (NA) during 2007 and 2008 (Fig.1). Temperature and salinity were measured using a CTD probe (Seabird, USA). A total of 315 water samples were analyzed during the study period. Samples were collected with 5 L Niskin bottles, subsamples for the determination of the nutrients were preformed using standard oceanographic methods (1). Phytoplankton samples were preserved in 2% (final concentration) neutralized formaldehyde and analyzed following the Utermol method (2) on Zeiss Axiovert 200 inverted microscope. For statistical analysis the software packages Systat 12 and Primer 6 were used.

Results and discussion

A total of 237 species were recorded. There were 126 species of Bacillariophyceae, 83 Dinophyceae, 13 Haptophyta and 5 species of Crysophyta while nanoplankton fraction was divided in 10 distinct groups (diatomeae, dinoflagelata, cryptophyta, chlorophyta, cocolitophoridae.). Statistical analysis of the phytoplankton community structure showed that the stations along the western Istrian coast were significantly different from the stations along the eastern Istrian cost and in Kvarner Bay (Fig.2). The nanophytoplankton component was the dominant plankton guild throughout the whole year in the NA while the microphytoplankton (size >20 μ m) was restricted to sporadic (late spring and autum) blooms. During the investigated period the most prominent bloom event was the autumn bloom (October 2007, September 2008) characterized mostly by diatoms. The phytoplankton community during the bloom was dominated by *Chaetoceros* species and

Pseudonitzschia species which were pronounced especially along the Western Istrian stations (4.2×10^{5} cell/l Fig.2.). The peak cell abundance of the spring/summer bloom was recorded in June in the surface layer of Rijeka Bay where *Skeletonema spp.* reached 3.6×10^{5} cell/l, while the deeper water layers were dominated by Coccolitophoridae like *Emiliana huxleii* (1.1×10^{5} cell/l). The Rijeka Bay can be described as mainly influenced by the harbour city of Rijeka and the karstic Rjecina river, where the nutrient rich fresh water input triggered the *Skeletonema* sp. bloom only in this restricted region. Phytoplankton community structure alowed to discriminate different regions along the NA cost.

Fig. 2. Abundances of main phytoplankton groups and *Pseudonitzschia spp.* with the distribution over the stations

HOLOCENE SEA-LEVEL CHANGE IN THE MEDITERRANEAN SEA: QUANTITATIVE RECONSTRUCTIONS **BASED ON FORAMINIFERAL TRANSFER FUNCTIONS**

Yvonne Milker^{1*}, Gerhard Schmiedl¹ and Christian Betzler¹ ¹ University of Hamburg, 20148, Germany - Yvonne.Milker@uni-hamburg.de

Abstract

Results from Late Glacial and Holocene relative sea-level estimates in shelf carbonate environments of the Western Mediterranean Sea based on various regression methods and, on Plankton/ Benthos ratios, are presented. The relative sea-level estimations for the different regions are similar to the global sea-level history underlying the potential of benthic foraminifera for quantitative sea-level reconstructions.

Keywords: Western Mediterranean, Sea Level, Foraminifera

Introduction

Quantitative sea-level reconstructions using planktonic and benthic foraminifera were more applied in the recent past and, give a potential for paleo-sea level reconstructions over various timescales or for climate modeling.

Methods

The sea level estimations were based on various regression methods such as Weighted Averaging (WA), Partial Least Squares (PLS) and, a combination of both. Further, Modern Analoque Technique (MAT) and, a method based on Plankton/ Benthos ratios were used. The transfer functions generated from recent benthic foraminiferal assemblages in surface samples were applied on fossil data-sets from the Alboran Platform, the Oran Bight and the Mallorca shelf (cores 342-1, 367-1 and 401-1).

Results

The best predictive potential is given for the WA-PLS method. The relative sealevels estimates are similar to the global sea-level history on the Alboran Platform and off the Mallorca Shelf (Fig. 1). In the Oran Bight, our estimates show also a sea-level rise for the past 6000 cal. years BP, but exhibit significant deviation from the global trend likely attributed to age model uncertainties. The sea-level estimates based on transfer functions generated from recent P/B ratios show in generally the global sea-level development, but with a higher inaccuracy. Species-environment relations were investigated, showing that on the Mallorca Shelf substrate and food effects interfere with the sea level signal resulting in an partly overestimation of paleo-water depths.

Fig. 1. The relative sea-levels estimates are similar to the global sea-level history on the Alboran Platform and off the Mallorca Shelf

MOLECULAR MODELING IN BLUE BIOTECHNOLOGY: A COST-EFFECTIVE AND SUSTAINABLE APPROACH TO EXPLOIT MEDITERRANEAN CHEMICAL DIVERSITY

Ernesto Mollo ¹* and Pietro Amodeo ¹

¹ CNR - Institute of Biomolecular Chemistry, 80078 Pozzuoli NA Campania, Italy - ernesto.mollo@icb.cnr.it

Abstract

Within this study, metabolites isolated from marine organisms living in the MediterraneanSea have been investigated by both a chemoecological and a computational approach to decode the "information content" of marine natural products in terms of possible biotechnological applications. This led us to predict, from 3D chemical structures, the interaction of selected metabolites with macromolecular targets underlying crucial ecological and pharmacological actions. *Keywords: Biotechnologies, Alien species*

Natural products possess an extraordinary pharmacological effectiveness and specificity compared to artificially designed molecules because evolutionary selection has been the "nature's own high-throughput screening" process for the optimization of biologically active compounds [1, 2]. As a result, a broad range of bioactivities has been found within the increasing number of novel secondary metabolites isolated from the under-explored marine sources [3]. However, similarly to their terrestrial counterparts, marine natural products often interact with more than one specific target, also producing toxicity and other side effects which often prevent their use as drugs. By combining a chemo-ecological approach in the study of the natural function of small molecules isolated from Mediterranean flora and fauna with modern "in silico" target fishing techniques, we propose an efficient method for "a priori" predictions of possible exploitation of marine natural products, or their analogues, in biotechnological fields. Selected cases will be presented, with emphasis on possible uses in biotechnology of undesired biomaterials from invasive alien species, which are altering the Mediterranean community structure [4]. This research has led us to select promising candidates in drug discovery, and to design structural analogues for lead optimization. We believe that our approach to blue biotechnology should prevent the negative impacts of dispersive pharmacological evaluations and randomly-guided sampling activities on the Mediterranean ecosystem, also providing sustainable opportunities for the sea-based economy of coastal communities.

CNIDARIA SHARE HOMOLOGOUS SECRETED PHOSPHOLIPASES A2 WITH BACTERIA AND FUNGI

Timo Nevalainen 1*

¹ Department of Pathology, University of Turku, Finlande - timneva@utu.fi

Abstract

Secreted phospholipases A₂ (sPLA₂) containing conserved domain pfam09056 Phospholip_A2_3: Prokaryotic PLA₂ are present in bacteria and fungi. In the current study, prokaryote-type sPLA₂s were identified also in eumetazoans of the Phylum Cnidaria, such as sea anemone *Nematostella vectensis*, hydroid *Hydra magnipaillata* and hard coral *Acropora millepora*. The functions of cnidarian prokaryote-type sPLA₂S are unknown.

Keywords: Bacteria, Cnidaria, Enzymes, Symbiosis

Introduction

Phospholipases A_2 comprise a large family of intracellular and secreted enzymes. Secreted PLA₂s participate in important physiological and pathological functions, such as digestion of dietary phospholipids, inflammatory reaction and antimicrobial defence against bacteria and other pathogens. Conserved domain pfam09056 Phospholip_A2_3: Prokaryotic PLA₂ [1] is characteristic of a number of sPLA₂s of both Gram positive and Gram negative bacteria. The catalytic site motif of prokaryote-type PLA₂ (XCXXHDXX) contains the conserved histidine and aspartic acid residues typical of sPLA₂s. In addition to bacteria, prokaryote-type sPLA₂ have been identified in fungi. The observations reported here indicate that prokaryotetype sPLA₂ is present also in eumetazoan organisms of the Phylum Cnidaria.

Material and methods

Conserved domain pfam09056 was identified at web site http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi in PLA₂ sequences retrieved at NCBI and Swiss-Prot databases at web sites http://blast.ncbi.nlm.nih.gov/Blast.cgi and http://www.expasy.ch/sprot/, respectively. Multiple sequence alignment was done by the program CLUSTAL W2 at http://www.ebi.ac.uk/Tools/clustalw2/index.html.

Results and discussion

The genome of starlet sea anemone Nematostella vectensis (Cnidaria, Anthozoa) [2] contains a rich selection of PLA₂s [3] including prokaryotetype sPLA₂s. In addition to fungi, cnidaria are the only eukaryotes that contain prokaryote-type sPLA2s. The current observations show that there are in Nematostella vectensis distinct sPLA2s that contain the conserved domain pfam09056 Phospholip_A2_3: prokaryotic PLA₂. In other cnidaria including hydroid Hydra magnipapillata and hard coral Acropora millepora there are sPLA₂s homologous to prokaryote-type sPLA₂. The presence of prokaryote-type PLA₂s in cnidaria seems to be unique; PLA₂s containing the conserved domain pfam09056 Phospholip_A2_3: prokaryotic PLA2 were not found in any other metazoan (or eukaryote) besides fungi in the current study. The function and evolutionary origin of prokaryote-type PLA2 in cnidaria is unknown. Besides vertical inheritance, horizontal gene transfer should be considered as a possibility. A further explanation for finding DNA sequences of prokaryote-type PLA2 in cnidaria would be the presence of bacteria (or fungi) in these marine invertebrates, either as symbionts, commensals, pathogens or inert contaminants. However, the latter alternatives seem unlikely, since measures were taken to exclude contamination of the specimens used for sequencing the genome of Nematostella vectensis (Putnam et al. 2007).

PATTERNS OF BACTERIOPLANKTON DIVERSITY IN RECREATIONAL MARINAS IN THE ISLAND OF MALLORCA (BALEARIC ISLANDS) AND ITS RELATION TO HYDROCARBON POLLUTION

B. Nogales ¹*, M. P. Lanfranconi ¹, J. Piña-Villalonga ¹, L. Y. Suárez-Suárez ¹ and R. Bosch ¹

¹ Dept. Biologia, Universitat de les Illes Balears, Palma de Mallorca, Spain - bnogales@uib.es

Abstract

The analysis of bacterioplankton in surface seawater from different recreational marinas evidenced common patterns in the diversity of some bacterial groups, i.e. *Alphaproteobacteria*. In particular, certain phylotypes of the *Roseobacter* clade predominated in these environments. Although this clade seemed to be stimulated by experimental diesel-oil pollution, their apparent success in polluted environments, such as marinas, is most likely due to a combination of factors and not only to hydrocarbon pollution. *Keywords: Bacteria, Balear Islands, Biodiversity, Pollution, Coastal Waters*

Studies on bacterioplankton diversity in man-made, artificial habitats, such as ports and marinas are scarce (1-3). Besides, we do not know which are the key factors determining changes in bacterioplankton diversity in areas adjacent to ports (2), nor the importance that these changes might have in the overall functionality of the coastal ecosystem. The increasing pressure of nautical tourism justifies the importance of improving our knowledge about the microbiota of these environments. Preliminary studies done by our group in Mallorca (Balearic Islands) indicated that there might be common patterns in the bacterioplankton diversity in recreational marinas. Therefore, our first aim was to demonstrate that such patterns in diversity really existed. We also hypothesised that at least some of the components of the bacterioplankton in marinas were selected by the stress caused by hydrocarbon pollution and we made two laboratory experiments to address this issue.

Surface water samples from seven marinas around the Island of Mallorca were taken from the shore throughout a year period (2008-2009). For molecular characterisation of diversity, DNA was extracted from 0.22 μ m filters through which 2 litres of pre-filtered water (5 μ m) was filtered. Bacterial diversity studies were based on terminal restriction fragment length polymorphism analysis (T-RFLP) of 16S rRNA genes with primers for *Bacteria* and for *Alphaproteobacteria*, and by the generation of clone libraries as described previously (2-3). For the experimental pollution experiments, surface water samples from a pristine coastal location (39°29'05''N, 2°28'16''E) were taken at two time points, late winter and summer 2007. Each time, four laboratory microcosms were prepared (45 1 of water): two controls and two treated with low concentrations (30 mg l⁻¹) of diesel oil. Diversity analysis was based in the amplification of ribosomal RNA by reverse transcription and PCR (RT-PCR). Changes in diversity were followed for a period of 89 h.

Our study in surface water from different recreational marinas confirmed that there were common trends in the composition of bacterial communities. Fig. 1 shows a non-metric multidimensional plot representing the similarity of T-RFLP profiles for *Alphaproteobacteria* obtained for the different marinas. Different marinas harboured similar alphaproteobacterial populations.

Fig. 1. NMDS plot of the similarities of T-RFLP profiles for 16S rDNA of *Alphaproteobacteria* from different recreational marinas in Mallorca Island. Marinas are identified by a three-letter code. Sampling data: September 2008, squares; March 2009, circles. Solid lines encircle profiles with similarities >70% (Bray-Curtis coefficient) and dashed lines those with similarities >80%. Stress value, 0.108

We also observed a temporal dynamics in the diversity of these populations; samples from different times separated well in relation to the vertical axis, and the dynamics were the same in different marinas. There were phylotypes, (defined at 99% sequence similarity cut-off), particularly in the *Roseobacter* clade of the *Alphaproteobacteria*, which predominated in all the marinas. In the pristine waters used for microcosm experiments the *Roseobacter* clade

constituted a minor component of the bacterioplankton. However, this group increased in abundance in response to diesel addition, and contributed, among others, to the rapid changes (within hours) in bacterial composition observed after diesel addition (Fig. 2), particularly in summer. Although we have evidences that some isolates of this group can grow on hydrocarbons we think that their apparent success as main components of the bacterioplankton of recreational marinas is the result of a combination of factors, and not only to hydrocarbon pollution.

Fig. 2. UPGMA dendrogram of the T-RFLP profiles for metabolically-active bacterioplankton (16S rRNA) in control (label C) and diesel-treated microcosms (label D). Winter samples, W; summer samples, S. Sampling times are: T0, 0h; T1, 3h; T2, 17h; T3, 27h; T4, 41h; T5, 65h and T6, 89h. Numbers next to the nodes correspond to Bootstrap values (1000 replicates) >50%. Scale bar represents similarity (Bray-Curtis coefficient)

LEPTOLYNGBYA SPECIES ISOLATED FROM THE SPONGE *PETROSIA FICIFORMIS* AS POTENTIAL SOURCE OF NOVEL COMPOUNDS

Patrizia Pagliara¹ and Carmela Caroppo²*

¹ Institute for Coastal Marine Environment, National Research Council - carmela.caroppo@iamc.cnr.it

² DiSTeBA - University of Salento

Abstract

A cyanobacterial species belonging to *Leptolyngbyagenus* has been isolated from the marine sponge *Petrosia ficiformis* and cultured in laboratory conditions. Aqueous extracts from this *Leptolyngbya* strainshowed a biological activity, influencing *Artemia salina* vitality, being cytotoxic with human erythrocytes and interfering with the sea urchin development. *Keywords: Cyanobacteria, Biotechnologies, Porifera*

Introduction

Cyanobacteria are important primary producers of the marine and freshwater environments. But they have also been identified as one of the most promising groups of organisms producing novel, bioactive, natural compounds [1, 2]. Indeed, many investigations in this field indicated that marine microorganisms are substantially involved in the biosynthesis of marine natural products isolated from macroorganisms such as invertebrates. [3, 4]. The chemical structures of over 13,000 novel compounds from marine organisms has been already determined and their potential use in pharmaceutics widely considered [5]. Antibacterial, antiviral, antifungal, algicide and cytotoxic activities have been reported by many authors [6, 7, 8, 9].

Material and Methods

One strain of *Leptolyngbya* wasisolated from *Petrosia ficiformis* and cultured in laboratory conditions. The extracts were obtained after sonication and centrifugation of cyanobacterial cells. *Artemia* nauplii, human red blood cells and sea urchin gametes and embryos were exposed to the cyanobacterial extracts under controlled conditions, then examined for lethal (mortality) and sub-lethal effects.

Results and discussions

Aqueous extracts from Leptolyngbya sp. isolated from the Mediterranean sponge Petrosia ficiformis were able to exert a biological activity. The extracts influenced the vitality of Artemia salina nauplii, induced the human erythrocytes lysis and interfered with the normal development of sea urchin. In particular, the presence of the extract induced a 90% of nauplii mortality after 24hrs of contact at the concentration of 15 mg/ml (w/v) and 100% of mortality at the concentration of up 0.9 mg/ml (w/v) after 48 hrs of contact. The ability to disrupt the integrity of erythrocytes was weak, inducing only 10% of haemolysis, but a strong activity was detectable against sea urchin embryos. In particular, the segmentation process was inhibited after treatment of eggs and embryos with Leptolyngbya sp. extract. While male and female gametes were able to perform the fertilization process, the resulting embryos were unable to correctly develop to the pluteus larva. In conclusion, this cyanobacterial species may be regarded as good candidate for drug discovery, with applications especially in pharmaceuticals as inhibitor of cell division, also if further investigations will be necessary to better clarify its biological activity.

RAPID ENZYMATIC METHOD FOR THE ENUMERATION OF FAECAL BACTERIA (ENTEROCOCCI) IN BATHING SEAWATER

Marion Peirache ¹*, Stephane Mounier ¹, Nathalie Patel ¹ and Yvan Martin ² ¹ Laboratoire PROTEE, 83957 La Garde, France - marion-peirache@etud.univ-tln.fr

² Institut Oceanographique Paul Ricard, Île des Embiez - Le Brusc

Abstract

The bathing water monitoring has a great interest for both bathers and authorities. The European community has actually lowered the suitable tolerance levels of the two major fecal indicators: *Escherichia coli* and *Enterococci*. The enzymatic assay enables the microbiological quality evaluation in less than an hour. Now available for *Escherichia coli*, this method doesn't work for *Enterococci* yet. Our present work first of all aims at adapting this method for *Enterococci* and in a second time at explaining biotic and abiotic discrepancies met during on site application.

Keywords: Beach, Bacteria, Pollution, Monitoring

Since the new requirements of the European Community (Directive 2006/CE 07), rules have changed and the bathing water quality monitoring has to be improved. The challenge is to combine rapidity and sensitivity with faster techniques than those currently available, <u>allowing real-time results</u>. Such kinds of methods are relevant for a good beaches management, since public health and economic issues are concerned.

The rapid enzymatic detection method is able to produce a fast result, but may be disturbed by interference. The principle of this technique, developed for *Escherichia coli* [1], is to filter a defined volume of sea water through a membrane (0.22 μ m) which retains bacteria. Then, the membrane (*i.e.* bacteria) is submitted to a specific substrate enriched with a fluorescent compound, Methylumbelliferone (MUF). The more bacteria are present in the sample, the faster is the lysis of the substrate. The kinetic of the fluorescence apparition during 30 minutes gives a straight line which slope is proportional to enzymatic activity. This slope is correlated to the enumeration of bacteria by standard methods (membrane filtration and/or microplate) giving the number of bacteria in function of enzymatic activity.

To explain discrepancies (figure 1), this work first establish the original response for *Enterococci* by working on pure strain of bacteria, then test different parameters, biotic or abiotic ones, on the enzymatic response.

Fig. 1. Log-log linear regression between β -D-glucosidase activity (ng MUF/ mL) and *Enterococci* enumerated by standard method (CFU/100mL) N=58

The presence of micro-organisms, of plankton or suspended matter in natural samples can actually induce both biotic and physical interferences. Biotic interferences are confirmed, as previously found in literature for *Escherichia coli* [2] : some phytoplankton organisms are able to degrade the substrate. In the same way, autochthonous bacteria (*Vibrio* spp.) enhance the enzymatic activity. Suspended matter can moreover lead to an underestimation of bacteria numeration : a phenomenon of adsorption may occur, depriving contact of bacteria with substrate. Futhermore organic matter could have influence as its natural fluorescence wavelengths are located around the MUF ones (figure 2).

Fig. 2. A) The 3D spectral representation of the fluorescence of the MUF (λ_{ex} = 362 nm; λ_{em} = 445 nm) and natural fluorescence of bacteria at the end of measure (T=30 minutes).The biggest peak (MUF) is over the characteristic peak C (visible humic-like). b) The degradation of the substrate is showed towards the 2D curves of fluorescence of released MUF every 5 minutes along the kinetic (λ_{em} = 445 nm)

The first results of this work is the optimal conditions (pH, temperature, MUF concentration, ...) for enzymatic response of Enterococci (6 strains) found by simplex optimization design.

The second result is obtain by chemometric experimentation on both Enterococci and *Escherichia coli* (3 strains). Coefficient of factorial analysis for 7 parameters (suspended matter, hydrophobic and hydrophilic organic matter, phytoplankton, autochtonous bacteria, heavy metals). are extracted giving the impact of each parameter on the method efficiency.

SPATIAL VARIABILITY OF PLANKTON COMMUNITIES IN A SEMI-CLOSED DISTURBED MEDITERRANEAN ECOSYSTEM (TOULON BAY, FRANCE)

S. Personnic¹, J. L. Jamet¹, G. Durrieu¹, D. Jamet¹, N. Jean¹, H. Zhao¹, E. Tessier¹, N. Patel¹, B. Poste¹, C. Le Poupon¹ and C. Garnier¹*

¹ Laboratoire PROTEE, Université du Sud Toulon Var, BP20132 83957 La Garde, France - cgarnier@univ-tln.fr

Abstract

Plankton and chemical composition of seawater have been studied along a transect of thirteen sampling stations in Toulon Bay during June 2009. Toulon Bay, located in the northwest Mediterranean coast of France, hosts major commercial and navy harbours. According to location of the sampling stations, this bay is variably affected by anthropogenic inputs, raw sewage from the Toulon area and maritime traffic. To understand spatial variability of the plankton communities in this disturbed ecosystem (little and large bay), measurements of physical and chemical parameters were carried out in the water column of Toulon Bay. According to all parameters analysed, several patterns have been obtained to explain the spatial variability of the plankton communities in this ecosystem. *Keywords: Plankton, Coastal Waters, Metals, Organic Matter, Bacteria*

Experimental

Samplings were carried out the 11 June 2009 at thirteen stations, chosen strategically to be representative of the entire Bay and clearly separated from the open sea (Fig. 1). Samples for chemical analysis were collected in 1-L Teflon (Nalgene) bottles by scuba diving at 3-m depth, microbial and larger photosynthetic cells with a Niskin 10L-sampling bottle at 3-m depth and zooplankton samples were collected with a plankton net (0.5 mouth diameter, 2.5 m long, 90 μ m mesh size) along the 0 to 5-m depth water column. Additionally, at 2 stations (in each part of the Toulon Bay), water sampling were performed at 1, 3 and 5-m of depth to investigate the vertical variability of the measured parameters.

Fig. 1. Location of the sampling points (open diamond: 3-m depth sampling: black diamond: 1, 3 and 5-m depth sampling)

Physico-chemical parameters (temperature, salinity, pH, O₂, Eh, turbidity) were measured in-situ using a multiprobe (Hydrolab MiniSonde 4a). Microbial communities (heterotrophic bacteria, cyanobacteria and autotrophic pico eukaryotes) were counted by flow cytometry [1]. Larger phytoplankton cells were enumerated by inverted microscopy [2]. Zooplankton was characterized by microscopy and proteomics identification (Electrophoresis analysis). After filtration on 0.2μ m on line filters (Sartorius) chemical samples were studied to (1) characterize the dissolved organic matter (DOM) by TOC-meter (TOC-V, Shimadzu) and 3-D fluorescence spectroscopy (Hitachi F-4500) measurements, and (2) analyse the total dissolved Cu, Cd, Pb ,Zn (by DPASV), total dissolved Hg (by CV-AFS) orthophosphates and nitrates (by colorimetric technique) concentrations.

Results and Discussion

According to the location of the sampling stations [3], major changes in plankton abundances and diversities have been recorded [4]. As a result, cell abundances (*e.g.* heterotrophic bacteria, *Prochlorococcus* sp.) have been multiplied by a factor 2 between the Large Bay and the Little Bay. However, diversity of large phytoplankton cells and of zooplankton declined from the Large to the Little Bay. By localisation, several patterns have been established to determine "explicative variables" of these spatial variations. The results provide a new evidence of the critical role played by anthropogenic inputs in the spatial distribution of the "global" plankton cells (*i.e.* microbial and larger cells)

and highlights the importance to consider further the chemical composition of the water column for a better understanding of the plankton ecology.

Abstract

Man-induced pressures are very important on Mediterranean ecosystems. In order to check the accuracy of the use of faecal bacteria as indicator of anthropic contamination, we assessed them in contaminated and uncontaminated areas of the Calvi Bay (Corsica, France).

Keywords: Bacteria, Western Mediterranean, Sewage Pollution

Introduction - More than 70% of the world's human population lives in watersheds that drain to the coast. Further population growth will be centered in these regions, exerting unprecedented pressure on riverine, estuarine and coastal habitats receiving human pollutants [1]. The Mediterranean Sea is not an exception. Considering its high species diversity and endemism rate, it is one of the richest marine regions of Europe [2]. However, this unit is ecologically vulnerable due to man-induced pressures. Therefore, it is important to check the accuracy of existing methods and to develop new ones more effective to study and counteract man-induced loss of aquatic ecosystem biodiversity, water quality and recreational resources. In this context, microbial bioindicators play a major role in detecting and characterizing these changes. Indeed, microorganisms are generally highly sensitive to and heavily affected by environmental perturbations. They have fast growth rates, and respond to low levels of pollutants as well as other physical, chemical, and biotic environmental changes [3]. Among them, faecal bacteria are used worldwide as indicator of water anthropic contamination, they are used to assess the potential health risk of pathogenic organisms presence in recreational and aquacultural waters [4]. Faecal coliform and faecal Enterococci are recommended by the European Union and the US Environmental Protection Agency (EPA) because they are found specifically in warmblooded animal faeces [5] and not present in non polluted sites.

Material and methods - The bacterial community was studied at two sites of the Calvi Bay, in Corsica (France); at the sewer in the port of the Station de Recherches Sous-marines et Océanographiques (STARESO) and 30m outside STARESO's port, on a patch of sand considered clean and unaltered by the sewage. Samples were collected at different depth and four times a year (April, May, July and November 2009*). Different methods were used; epifluorescence with acridine orange staining to enumerate the total bacteria, and 3MTM PetrifilmTM for aerobic mesophilic flora, Enterobacteriaceae, Coliforms and *Escherichia coli*.

Results and discussion - In July, total bacteria number at the sea surface level of the sewer (Fig. 1-A) was twofold higher $(4.10^5 \pm 3,1.10^4 \text{ Bacteria/ml})$ than in April $(2.10^5 \pm 1,4.10^4 \text{ Bacteria/ml})$ and was more constant at the bottom level (Fig. 1-B), with values comprised between $7,2.10^4$ and $1,2.10^5$ bacteria per ml throughout the sampling campaign. Comparatively, results were less variable and bacteria are less abundant (Fig. 1-B) on the patch sand, except in April in the *Posidonia* matte, where there were $4,2.10^5 \pm 1,5.10^5$ Bacteria/ml.

Fig. 1. Variation of bacteria number per ml at the sewer (A) and at the patch sand (B) counted by epifluorescence with acridin orange staining (mean \pm SD).

3M[™] Petrifilm[™] analysis (Fig. 2) showed that there were fewer bacteria identified in April comparatively to May and July. This could be explained by the low presence of scientists and tourists in the station during this period. We can also observe that the abundance of aerobic mesophilic bacteria was still more marked at the sewer (Fig. 2-A and B) than at the patch of sand (Fig. 2-C,D,F and E) for all sampling periods. This difference was also highlighted by the presence of a greater number of Enterobacteriaceae, Coliforms and *Escherichia coli*. Surprisingly, these bacteria were also found in smaller

number in the matte and in the canopy of *Posidonia oceanica* meadow next to the sand patch. These biota may be more conducive to abundance by protecting against predators, increasing nutrient and organic carbon availability and providing colonisable surfaces than in the water column [6].

Fig. 2. Variation of aerobic mesophilic flora, Enterobacteriaceae, Coliforms and *Escherichia coli* CFU per ml at the sewer surface (A) and bottom (B) and at the patch sand surface (C), bottom (D), *Posidonia* canopy (E) and *Posidonia* matte (F) with 3M Petrifilm test (mean \pm SD).

Conclusions - These preliminary results show the applicability of $3M^{TM}$ PetrifilmTM for analysis of marine samples. Nevertheless, further analyses have to be done to check the accuracy of this product. Moreover, it seems that some faecal bacteria are able to survive in *Posidonia* meadow. Therefore, new bioindicators must be developed to detect water anthropic contamination. In this context, *Bangiophyceae* could be a potential candidate.

Acknowledgement This study was supported by the FRIA of Belgium and by RACE (ACR n°05/10-33). The authors tanks 3M[™] Petrifilm[™] and all the staff from STARESO. *Data from November 2009 are under sampling and analysing, the results will be added later for the conference.

ANALYSIS OF LIPID CLASSES AND FATTY ACID COMPOSITION IN MUSCLE OF THE GREY MULLET CHELON LABROSUS LIVING IN TUNISIAN GEOTHERMAL WATER

I. Rabeh ¹*, I. Chetoui ¹, K. Telahigue ¹, A. Besbes Benseddik ², M. Azaza ² and M. El Cafsi ¹ ¹ FACULTE DES SCIENCES DE TUNIS - Rabehimen@yahoo.fr ² Institut National des Sciences et Technologies de la Mar (INSTM Centre de Monastir)

² Institut National des Sciences et Technologies de la Mer (INSTM Centre de Monastir)

Abstract

Lipid classes and fatty acid composition of polar, neutral lipid fractions and the fatty acid composition of grey mullet *Chelon labrosus* from the geothermal water were determined. (PC) and (PE) was the main component in the Polar class as the TAG in the neutral lipid. Docosahexaenoic acid (22:6n-3) and eicosapentanoic acid (20:5n-3) were rich in the PC and PE fractions. Saturated fatty acids (SFA) were the most representative, followed by Monounsaturated fatty acids (MUFA) in the neutral fraction. The major constituents of total fatty acids in *Chelon labrosus* were saturated: palmitic (16:0) andstearic acid (18:0), monoenes: oleic (18:1) and palmitoleic acid (16:1), polyunsaturated: arachidonic (20:4 n-6), eicosapentaenoic (20:5 n-3) and docosahexaenoic acid (22:6n-3), but their amounts differed significantly.

Keywords: Aquaculture, Fishes, Physiology

Introduction

The thick lipped grey mullet (*Chelon labrosus*) belongs of the family Mugilidae order Perciformes. This species are very euryhaline with some estuarine and freshwater families providing a good model for the assessment of physiological plasticity related to changes in environmental salinity. Grey mullet (Osteichthyes, Mugilidae) commonly inhabit tropical and warm-temperate estuaries [1]. In Tunisia It has been demonstrated that *Chelon labrosus* can live in geothermal water in the south of the country. In the past ten years, investigations have shown the significant potential of the geothermal, brackish water for the successful culture of aquatic organisms (fish, crustaceans, algae, etc). The present study was carried out to examine lipid classes, and fatty acid compositions of the grey mullet muscle adapted to the geothermal water, in order to acquire data for lipid biochemistry in grey mullet (*Chelon labrosus*).

Materials and methods

Fish: Immature thick lipped grey mullet (*Chelon labrosus*) (30–40g body mass) were provided by an experimental fish culturing centre in south of the country (Béchima (INSTM -Tunisia).

Lipid analysis: Total lipids were extracted with chloroform: methanol (2:1, v/v)) using the method of Folch [2].

Separation of lipid classes: Lipid class separation was performed by thin layer chromatography TLC Two dimensional on silica-gel plates according to [3]. Each lipid class is subjected afterwards to gas chromatography.

Statistical analysis: data were analysed for significant difference of means, ANOVA, and inspected by Duncan test at level of p < 0.05.

Results and discussion

In the analysed muscle tissue samples, we identified 22 identified fatty acids in *Chelon labrosus* in muscle tissue samples. Palmitic (16:0, 34.25 %), stearic (18:0, 6.8 %) oleic (18:1 n-9, 22.2 %) and linoleic (18:2n-6, 12.52 %) acid were the most abundant fatty acids in muscle of *Chelon labrosus*. Lower quantities of docosahexaenoic acid (DHA 22:6 n-3, 1.7%), eicosapentaenoic acid (EPA 20:5 n-3, 1.4%), arachidonic acid (20:4 n-6, 0.8%). Polar lipid fractions (PI, PS, PC, and PE) from the analysed fish species in this study contained a great variety of different fatty acids. On the other hand, TG were poorer in the diversity of fatty acids and contained a minor of different fatty acid. All of the identified fatty acids were found in Polar lipid fractions.

ABUNDANCE AND BIOMASS OF FILAMENTOUS CYANOBACTERIAE IN A MEDITERRANEAN SALT MARSH

R. Rebai ¹*, N. Annabi Trabelsi ¹, W. Guermazi ¹, J. Elloumi ¹, A. Bouain ¹ and H. Ayadi ¹

¹ Université de Sfax, Faculté des Sciences de Sfax, Département des Sciences de la Vie. Unité de recherche UR/05ES05 Biodiversité et Ecosystème Aquatiques, Route soukra Km 3,5, B.P. 1171, CP 3000 Sfax, Tunisie - raydakobbi@yahoo.fr

Abstract

The aim of the present study is to understand the changes in the abundance and biomass of filamentous cyanobacteria with increase of salinity. Monthly samples over a period of one year (2007-2008) at three ponds (A1, A5 and C21) in the salt works of Sfax were collected and analyzed. Densities and biomasses of filamentous cyanobacteria decreased with the increase of salinity. This group uptake preferentially nitrites and ortophosphates at high salinities (> 62). *Keywords: Nutrients, Salinity, Cyanobacteria*

Introduction

Phototrophic prokaryotes cyanobacteria are important primary producers especially in oligotrophic waters and the open ocean [1]. They have a higher nutrient affinity than eukaryotic algae, enabling them to grow under low nutrient concentrations [2]. They are thought to be favored by low (lower than 15) [3] N:P and Si:N ratios [4]. The objective of this study is to evaluate the influence of salinity increase on cyanobacteria abundance, biomass and nutrients uptake.

Materials and methods

Monthly samples were collected over a period of twelve months (September 2007 - August 2008) at three ponds (A1, A5 and C21) in the salt works of Sfax (central-eastern coast of Tunisia, about 34°, 390N and 10°, 420E). Salinity was estimated by the dry residue method, which consisted in evaporating a 50 ml sample (24 h, 120°C) in a previously sterilized crystallizing dish (by heating at 550°C for 1 h), and calculating the salt content from the difference in weight before and after evaporation. Samples for dissolved inorganic nitrogen (nitrite: NO_2^- , nitrate: NO_3^- , ammonium: NH_4^+), silicates Si(OH)₄ and orthophosphates (PO₄³⁻) were stored at -20 °C before analysis with an automatic BRAN and LUE BBE-type 3 analyzer. Phytoplankton samples (200 ml) were fixed by Lugol-iodine solution (final concentration 1%, v/v) and counted under an inverted microscope (x 400) [5]. In this study, filamentous cyanobacteria were determined together with phytoplankton and not as single cells, e.g. Synechococcus, because we did not use epifluorescence. Biomass was calculated from mean biovolumes taking into consideration that $10^6 \,\mu\text{m}^3 = 1 \,\mu\text{g}$ (wet weight), assuming that organic cell carbon represented 12% of wet weight biomass. Pearson's correlation test was applied.

Results and discussion

The mean values found for all parameters during this study are summarized in Table 1.

Tab. 1. Average values of the biological, physical, and chemical parameters in three ponds (A1, A5 and C21) in Sfax salt works

Ponds	A1	A5	C21
filamentous cyanobacteriae density (ind.l ⁻¹)	1850	1025	400
filamentous cyanobacteriae biomass (µg.l-1)	667	309.8	150.9
Salinity	50.44 ± 7.12	62.79 ± 10.73	101.20 ± 12.58
NO ₂ ⁻ (µmol. I ⁻¹)	0.25 ± 0.20	1.33 ± 2.24	0.54 ± 0.40
NO ₃ ⁻(µmol. I⁻¹)	6.52 ± 3.73	2.4 ± 1.29	4.87 ± 2.59
NH4 ⁺ (µmol. l ⁻¹)	5.21 ± 5.81	6.37 ± 5.73	3.82 ± 4.25
Si(OH) ₄ (µmol. I ⁻¹)	12.65 ± 13.84	6.22 ± 6.66	7.41 ± 8.66
PO ₄ ³⁻ (µmol. l ⁻¹)	19.19 ± 11.95	15.37 ± 5.06	13.86 ± 10.64

Microscopic counting of water samples showed that filamentous cyanobacteria constituted only a small proportion of the entire phytoplankton biomass ranging from 0.59% at C21 to1.91% at A. Although, Over the year, N:P and Si:N ratios were very low in the three ponds not exceeding 11.4 and 8.1 respectively. The phytoplankton biomass was dominated by small unicellular (protozoa) dinoflagellates and diatoms. The average abundance and biomass of

filamentous cyanobacteria decreased with the increase of salinity. The highest mean was recorded at A1 and the lowest one was found at C21 (Table 1). The persistence of filamentous cyanobacteria in the extreme saline conditions exerted upon them some ecological challenges, e.g., the production of some extracellular enzymes [6]. Both filamentous cyanobacteria abundance and biomass showed highly significant positive correlations (P<0.01) with orthophosphates only at C21. They were able to accumulate phosphorus directly and they became enriched in phosphorus to a greater degree than other phytoplankton organisms [7]. Nitrites were preferentially and significantly used by filamentous cyanobacteria at A5 (r= 0.996; P<0.01) and C21 (r= 0.845; P<0.01).

Abstract

By an original patented technology we have obtained a bioactive complex from *Engraulis encrassicolus ponticus*, *Sprattus sprattus sprattus and Odontogadus merlangus euxinus*, constituted by glycosaminoglycans, essential amino acids, essential fatty acids, eicosanoids, glycerolphosphates, and microelements. So, by their chemical composition, the bioactive extracts from small sea fish is useful to prevent unsettle of the macromolecular structure and keep the functionality of the extracellular matrix from conjunctive, cartilaginous and bone tissue.

Keywords: Biotechnologies, Black Sea, Fishes

Sea organisms arouse a major interest for the extraction of biological active substances with multiple and valuable therapeutical applications all over the world [1], [2]. This work provides for the elaboration of an original extraction and purification technology of glicosaminoglicans from sea organisms (small sea fish) and their chemical, biological and pharmacological analysis together with in vitro and in vivo tests, for the purpose of extracts' conditioning towards their use as pharmaceutical products (unguents, pastilles) with antiinflammatory activity, tissue restitution properties, anticlotting and antithrombothic activities, biostimulating, antioxidative, hepatoprotective and antiproliferative qualities. The physico-chemical analysis of different batches obtained in laboratory revealed that obtained extracts from small see fish represent a complex of active biological substances composed from glycosaminoglycans (44-60% sulfated form), amino acids 3.5-12%, from which 2-6.5%, essential amino acids (valine, leucine, isoleucine, threonine, methionine, lysine, phenylalanine, tryptophan), essential fatty acids 1-2% (linoleic acid, arachidonic acid). There were identified glicerophosphates, creatinin, mineral salts (Ca, Na, K, Fe, Mg, Se, Ni, Cu, Si) [3]. The extracts show a dose dependent inhibition of hyaluronidase and induce a significant decrease of elastase (MMP12) and collagenase (MMP1) ezymatic activity; also favor the in vitro collagen fibrils formation, manifest a strong antioxidant activity, that is present a very valuable therapeutically activitywhich will be capitalized in medicine and dermo-cosmetics products. Bioactive complexes rich in glycosaminoglycans obtained from small sea fish manifest a strong antiinflammatory activity comparatively with "diclofenac". Taking into consideration the presented results, the chemical composition of the bioactive complexes obtained from small sea fish and the therapeutic effects highlighted by in vitro and in vivo experiments shows that these extracts can be conditioned and used successfully in the form of medicinal products with valuable therapeutic properties and minimal side effects.

Abstract

To study the potential "hidden" biodiversity of the plankton in the Western Black Sea and species that could represent an ecological concern in the future, resting cysts were analyzed for the first time in superficial sediments along a transect offshore the city of Varna (Bulgaria) and a sediment trap material from the open sea. An interesting finding was the record of eight species (in resting phase), new in the Black Sea. Based on the bioinvasion history and the ecological affinity of the observed species (cysts), the results suggest future implications for the Black Sea ecosystem and biodiversity.

Keywords: Plankton, Biodiversity, Blooms, Sediments, Black Sea

Introduction

Resting stage (cyst) production is a common life-cycle trait in many species of the marine plankton of multiple function: a strategy to overcome unfavourable conditions, a "seed population" for bloom initiation and re-colonization of the pelagic domain, aiding in the genetic recombination of the population and more effective mobilization of nutrients. Both, the abundance of resting stages in the sediments and the number of cyst-producing species suggest this trait as a driving force of plankton dynamics and biodiversity [1]. As in the framework of the EU SESAME Project, one of the general objectives was to assess and predict changes in the Black Sea ecosystem, the study of cyst bank produced by plankton was deemed an efficient approach, since these assemblages play the role of a "memory" and "early warning" of the plankton structural dynamics, storing the information about past and future communities. As the first targeted research of this scale in the Black Sea, the primary goal was to study plankton biodiversity hidden in the sea floor as modern cyst assemblages.

Study area and Methods

Surface sediments were sampled between April 2008 and April 2009 at 12 stations in the Western Black Sea (Galata transect) during 3 cruise campaigns. In addition material collected by a sediment trap deployed at 900 m in the deep sea was analyzed too. Sub-samples were processed by means of a sieving technique [2] to concentrate cysts for their identification under light microscope and for germination experiments.

Results and Discussion

In the surface sediment samples a total of 59 cyst morphotypes were determined, mostly produced by dinoflagellates, out of which 5 were identified as ciliate resting stages based on their peculiar flask-like shape. In the sediment trap sample, 45 different morphotypes were found, mostly dinocysts, together with two ciliates flasks, one rotifer and two *Acartia* resting eggs (copepod). In the sediment trap material 12 different cyst morphotypes not present in the

surface sediments were discovered. Thus the total number of cyst morphotypes observed in this study was 71, out of which 61 produced by dinoflagellates, 7 by ciliates, 1 by rotifers and two by copepods, corresponding to 64 *taxa* (Table 1).

Even if cyst-forming species constitute a small part of the plankton dinoflagellates recorded in the area, eight species, have never been observed in the Black Sea (Table 1). Three of them were detected also for the first time in the plankton samples collected during the SESAME cruises. *Alexandrium tamarense* (cyst) and *Cochlodinium polykrikoides* (motile cells) have been reported in surface sediments and water column respectively from Odessa Bay (Northern Black Sea) [3], but for the Bulgarian area this represents the first record.

The most abundant cyst morphotypes at all stations were those produced by Scrippsiella trochoidea (Stein) Loeblich III, a species responsible for frequent blooms in the area. As evident from the species (cyst) list a high variety of Scrippsiella species (cysts) was recognized among which 4 new for the Black Sea phytoplankton. The proportion of cysts density shed light on the coexistence of Pentapharsodinium dalei - P. tyrrhenicum - S. trochoidea, confirming the dominance of S. trochoidea in the phytoplankton assembly. The results suggest that the originally reported S. trochoidea, in fact, represents a variety of species, e.g. should be treated as Scrippsiella complex. Some interesting findings were related to the paleontological taxa Bicarinellum tricarinelloides, Calcicarpinum perfectum, Calciperidinium asymmetricum and Melodomuncula berlinensis, whose active stages are not known. But, their increasing records from the surface sediments and trap samples, together with some successful germination experiments, testify the modern status of the species, as the case of Calciodinellum operosum, originally described as fossil by Deflandre. These new records confirm the need to carry out an integrated study of water column and sediments which could complete the list of species [4] and add value to potential implications for the pelagic ecosystem. The recent history of bioinvasions in this particular environment, calls for further investigations of biodiversity as an imperative for the sustainable management of the Black Sea ecosystem.

BIOFILM COMMUNITY AS A TOOL FOR MONITORING DISSOLVED AQUACULTURE WASTES

C. Sanz-Lázaro^{1*}, F. Navarrete-Mier¹, M. D. Belando¹, P. S. Morillo-Velarde¹, D. Celdrán¹ and A. Marín¹ Departamento de Ecología e Hidrología. Facultad de Biología. Universidad de Murcia, 30003, Spain - carsanz@um.es

Abstract

The aim of this work was to test biofilm as a tool to detect and quantify fish farm wastes related to OM and metals. Glass slides were deployed along a spatial transect from a fish farm in June and September of 2008 for the same time span (16 days). After the retrieval of the slides element concentrations and stable isotopes concentrations δ^{13} C and δ^{15} N were measured. This work demonstrates that fish farm releases important quantities not only of carbon and nutrients but also of Cu and Zn and demonstrates that biofilm can be used as a useful tool to monitor these wastes.

Keywords: Aquaculture, Eutrophication, Organic Matter, Metals

Relatively few studies have examined the effects of fish farm inputs on the pelagic environment [1] and these studies have shown little or no effect of dissolved wastes on most of the studied variables [2]. Even though, the release of dissolved wastes from aquaculture practices is considerable large and maybe, the experimental designs used in the studies to date, have failed to demonstrate aquaculture impact on the water column [3] due to the dilution of the pollutants. Metals are other pollutants derived from aquaculture practices, (e.g. feed and antifouling products), which have being little studied in the benthic system [4], but nothing in the water column. Microbial communities are highly sensitive to changes in water quality and respond rapidly to changing environmental conditions. Analysing shifts in microbial community structure on artificial biofilm surfaces facilitates a direct comparison of communities between sites without confounding environmental and physical variables [5]. Stable isotopes are used to elucidate the source of carbon (C) and nitrogen, but also have helped to investigate the trophic status of the whole community compared to another. The aim of this work was to test biofilm as a tool to detect and quantify fish farm wastes related to OM and metals.

Glass slides were deployed along a spatial transect from a fish farm in June and September of 2008 for the same time span (16 days). After the retrieval of the slides C, N, P, Fe, Mn, Cu, Zn, Cd, Pb, Ni, As, Cr, Tl, Ba, Se, Sn, Sb concentrations were measured. Same, stable isotopes concentrations δ^{13} C and δ^{15} N were measured. Results showed that C, nutrients (N, P) as well as Cu and Zn were clearly affected by fish farm activity, showing a marked accumulation compared to reference stations in both seasons. This work demonstrates that fish farm releases important quantities not only of C and nutrient but also of Cu and Zn and demonstrates that biofilm can be used as a useful tool to monitor these wastes.

EFFECTS OF DRYING PROCESS ON LIPID QUALITY OF SILVERSIDE (FISH) ATHERINA LAGUNAE

Salah Selmi¹, Nawzet Bouriga²* and Monia Trabelsi²

¹ Institut National des Sciences et Technologies de la Mer

² Faculté des Sciences de Tunis. Unité de Biologie Marine. Manar II, 2092 Campus universitaire. Tunisie. - hanounawsset@live.fr

Abstract

Changes in lipid quality of silverside during solar and hot air drying process were investigated. Total fatty acid content in silverside was 5.42 g/100g fresh sample. N-3 and n-6 polyunsaturated fatty acids levels were 0.59 and 0.62 g/100g fresh silverside respectively. Therefore, all fatty acid groups increased significantly (p<0.05) within processing with higher levels in experimental drying process. After hot air and solar drying treatments, PV and TBARS of the total lipids increased significantly (p<0.05) to reach 2.58 and 3.41 meq active O_2/kg oil and 0.87 and 1.27 mg MA/kg oil, respectively.

Keywords: Fishes, Chemical Analysis

Introduction

Lipids of marine fish are rich in n-3 long chain polyunsaturated fatty acids [1] of excellent nutritional value. However, they are very prone to oxidation which is also favoured by processing. In Tunisia, silversides are traditionally dried by spreading out on sand along the beaches for about 4 and 5 days in summer. In attempt to reduce some of the problems associated with losses, especially in lipid quality and time processing, experimental drying with automated conditions have been investigated and compared with traditional drying process.

Materials and methods

Tunisian silversides *Atherina lagunae* (belonging to the same sampling catch) were separated into three lots : (i) the first one was used for raw material, (ii) the second lot was traditionally sun dried, (iii) the third lot was dried using an electric drying unit. The temperature and relative humidity were maintained at 50°C and 15.02 % respectively. After lipid extraction and derivatisation, the resulting methyl esters were analysed using an Agilent Gaz chromatograph system 6890N. Peroxide value PV was determined according to the ferric thiocyanate method [2]. Thiobarbituric acid reactive substances TBARS were determined according to the AOCS method [3].

Results and discussion

In fresh silverside, saturated fatty acids SFA (2.49 g/100g silverside) constitute the majority of the fatty acids pool, followed by monounsaturated MUFA (1.7 g/100g silverside) and polyunsaturated fatty acids PUFA (1.23 g/100g silverside) (Table 1).

Tab. 1. Fatty acid profile (expressed as g fatty acid /100g edible silverside) of total silverside *Atherina lagunae* lipids

Fatty acid FS		SDS	EDS		
Total SFA	2.49 ±0.06	7.09 ±0.08	7.38 ±0.08		
Total MUFA	1.70 ±0.07	4.43 ±0.08	5.03 ±0.08		
Total PUFA	1.23±0.13	2.96 ±0.12	3.51 ±0.16		

N-3 and n-6 PUFA levels were 0.59 and 0.62 g/100g fresh silverside respectively, in which, 22:6 n-3 and 18:2 n-6 were the prominent PUFA. Drying processes show significant differences (p<0.05) in fatty acid content. Therefore, all fatty acid groups increased within drying treatment with higher levels in experimental drying process. These results suggest that dried silverside is a good source of n-3 and n-6 fatty acids. Results show that drying process had a significant effect (p < 0.05) on the formation of primary oxidation products in the samples, with higher PV levels obtained in solar dried silverside.

Tab. 2. Changes in PV and TBARS of silverside *Atherina lagunae* during solar and experimental drying process. PV: peroxide value. TBARS: Thiobarbituric acid reactive substances. MA: malonaldehyde

	FS	SD S	EDS
PV (meq active O ₂ /kg oil)	0.73 ±0.06	3.41±0.11	2.58 ±0.13
TBARS (mg MA/kg oil)	0.48 ±0.06	1.27 ±0.09	0.87 ±0.07

The increase in PV levels is probably due to the temperature of drying and the high content of unsaturated fatty acids. Such results are in agreement with

other authors [4] who reported that peroxide value of *migaki-nishin* lipid increased rapidly from 5.52 to 11.86 meq/kg within 4 days of drying and then gradually increased up to 10 days of drying (16.07 meq/kg). The initial value of TBARS was 0.48 mg MA/kg oil, suggesting that lipid oxidation did not occurre during post-mortem handling to some extent. From this result, TBARS slightly increased within drying treatment to reach in solar and experimental dried silverside1.27 and 0.87 mg MA/kg oil respectively.

Conclusion

Results show that solar and experimental drying processes have significant effects on lipid quality. Fresh silverside showed considerable polyunsaturated fatty acids content, and these results suggest that dried silversides are good sources of n-3 and n-6 fatty acids.

ANTIBIOTIC RESISTANCE OF ENTERIC BACTERIA ISOLATED FROM SOUTH-WESTERN ISTANBUL COAST (TURKEY)

Nüket Sivri^{1*}, Gozde Ozbayram¹ and Zeynep Karatut¹

¹ Istanbul University, Engineering Faculty, Environmental Engineering Dept. - sivrin@gmail.com

Abstract

The aim of this study was to evaluate the impact of an urban effluent on the antibiotic resistance of enteric bacteria. A total of 72 strains were isolated from five different sampling stations of south-western Istanbul coast during the year of 2008. Among the isolates, 55,6% were *Escherichia coli*, 29,2% *Enterococcus fecalis*, 6,9%, *Proteus* spp., 5,6% *Klebsiella* spp., 2,7% *Pseudomonas* spp. Strains of enteric bacteria were selected for antibiotic susceptibility testing. The antibiotic resistance tests resulted in bacteria being the most resistant against Ampicilin (100%) and the most sensitive against Imipenem (0%) and Amikacine (7,6%). The results reveal that study area faces bacteriological pollution and existing pollution level in this area is above the criterion specified for aquaculture, fishery and recreational activity.

Keywords: Antibiotics, Bacteria, Sewage Pollution

Introduction

The quality of water is of vital importance to the society. If a bacterial pathogen is able to develop or acquire resistance to an antibiotic, then this substance becomes useless in the treatment of infectious disease caused by this pathogen [1,2]. The aim of this study was to evaluate the impact of an urban effluent on the antibiotic resistance of enteric bacteria isolated from surface water of southwestern Istanbul coast, Turkey.

Materials and Methods

The enteric bacteria were isolated using the MPN Method from five different sampling stations of south-western Istanbul coast on a monthly basis during the year of 2008 (Figure 1). A total of 72 strains were isolated and strains of enteric bacteria were selected for antibiotic susceptibility testing. The minimum inhibition concentration was determined by the disk diffusion method in Mueller-Hinton medium in accordance with the Clinical and Laboratory Standards Institute (CLSI) guidelines. Ten antimicrobial agents were selected as representatives of important classes of antimicrobials: ampicillin (AM), 10 μ g; anoxicillin-clavulanic acid (AMC), 10 μ g; tetracycline (TE), 30 μ g; streptomycin (SM), 10 μ g; inipenem (I), 10 μ g; ceftazidime (CAZ), 10 μ g; trimethoprim-sulfamethoxazole (CO²⁵), 25 μ g. The results were separately interpreted, using the breakpoints from the CLSI guidelines for the family *Enterobacteriaceae* and non-fermenters [3,4,5,6].

Fig. 1. Sampling stations of south-western Istanbul coast [7]

Results and Discussion

In this study, 72 isolated strains were 55,6% Escherichia coli, 29,2% Enterococcus fecalis, 6,9 % Proteus spp., 5,6% Klebsiella spp., 2,7 % Pseudomonas spp. The results of the antibiotic sensitivity test were interpreted and are presented as the antibiotic resistance pattern of the bacterial isolates among sampling stations. It can be seen in Table 1. When comparing the antibiotic resistance level between sampling stations, highest resistance to antibiotics was determined in the first and third stations because those stations have drainage water that contains high concentration of fecal coliforms. Also indirect influences of bacterial pollution and negative environmental conditions may be assumed to be related to antibiotic-resistant strains. The antibiotic resistance tests show bacteria being the most resistant against Ampicilin (100%) and the most sensitive to Imipenem (0%) and Amikacine (7,6%). As detecting the antibiotic susceptibility profiles of the isolates, it would be possible to design a general classification of the isolates and beside this, the risk factors of the resistant strains in stations were determined. The results show that existing pollution in this area is above the given criteria's for aquaculture, fisheries and

recreational activity.

PROLIFERATIVE STATUS DETERMINATION OF BENTIC INVERTEBRATES COELOMOCYTES/ HEMOCITES

Mirta Smodlaka¹* and Sanda Ravlic¹

¹ Center for Marine Research, Ruder Boškovic Institute - mirta@cim.irb.hr

Abstract

Flow cytometry was employed to determine the coelomocytes/hemocytes DNA content in five selected marine invertebrates from the Adriatic sea (sea mouse *Aphrodita aculeata*, spiny crab *Maja crispata*, starfish *Echinaster sepositus*, sea urchin *Paracentrotus lividus* and tunicate *Phallusia mammillata*). The cell cycle analyses identified sea mouse coelomocytes as proliferating cells and revealed that spiny crab hemocytes and sea urchin coelomocytes complete their division in the hemolymph and coelom, respectively. The diploid DNA content (2C) in sea mouse was 1.24 pg, spiny crab 7.76 pg, starfish 1.52 pg and sea urchin 1.08 pg *Keywords: Adriatic Sea, Cell, Bio-Indicators, Physiology*

Marine invertebrates play a very important role in the maintenance of the health of marine ecosystems and serve as bio-indicators. Coelomocytes/hemocytes of benthic invertebrates, as primary immune effectors that respond to stress conditions, injures, host invasion and cytotoxic/genotoxic agents, have been used for the monitoring of environmental conditions [1, 2]. As a free circulating they are easily collected and analyzed by flow cytometry.

Fig. 1. (1) Aphrodita aculeata. (2) Maja crispata. (3) Echinaster sepositus. (4)

Paracenthrotus lividus. (5) Phallusia mammillata. - (A) DAPI - stained nuclei and cells (3A1). (B) DAPI-fluorescence (FL6) distribution

The DNA content is a marker of cellular maturity since the frequency of cells is G0, S and G2 phases could determine the proliferative status of the investigated cells. When the measurement of DNA content is performed with internal standard, flow cytometry provides information about genome size [3].

Tab. 1. Descriptive statistics of genome size variation within 5 species of marine invertebrates calculated from distribution of DNA values of 10 specimens

Species	DNA content (2C)/pg	Range	cv
Aphrodita aculeata	1.24±0.06	1.15-1.30	4.8
Maja crispata	7.76±0.10	7.63-7.91	1.3
Echinaster sepositus	1.52±0.03	1.46-1.54	2.0
Paracenthrotus lividus	1.08±0.02	1.05-1.12	4.6
Phallusia mammillata	0.11±0.05	0.07-0.14	45

Conclusions

1. Flow cytometry analyses of DAPI-stained nuclei identified the sea mouse *A. aculeate* coelomocytes as proliferating cells.

2. Fluorescence microscopy of DAPI-stained cells identified the presence of phagocytic activity in unchallenged red starfish *E.sepositus*.

3. Evidence of karyokinesis of both spiny crab hemocytes and sea urchin coelomocytes revealed that their division is completed in the hemolymph and coelom, respectively.

4.The diploid DNA content (2C) in sea mouse *A. aculeata*, spiny crab *M. crispata*, red starfish *E. sepositus* and sea urchin *P. lividus* is 1.24, 7.76, 1.52 and 1.08 pg, respectively.

5. DNA content of sea mouse *A. aculeata* and spiny crab *M.crispata* are the first records of their genome size. Furthermore, the DNA content of the sea mouse *A. aculeata* is the first genome size record among the species in the Aphroditidae family.

Abstract

L'étude du cycle nycthéméral de la répartition verticale du phytoplancton au niveau de la zone 23°30'N en hiver et en été 2002 a révélé que le phytoplancton se développe principalement dans des eaux froides et moins ensoleillées. L'ensoleillement et le réchauffement thermique des couches de surface s'intensifieraient en hiver entre midi et 14h et en juillet au cours de la journée (entre 8h du matin et 20h), aboutissant à une diminution du développement du phytoplancton sur toutes la colonne d'eau en juillet et sur les couches superficielles en hiver, et favorisant ainsi son développement dans les eaux sous-jacentes froides et moins ensoleillées. *Keywords: Phytoplankton, Density, Vertical Profile, Upwelling*

Introduction - Le phytoplancton constitue une composante de grand intérêt puisqu'il représente la base de toute vie dans les écosystèmes aquatiques. Son pouvoir élevé de multiplication, sous des conditions écologiques déterminées, permet un renouvellement rapide de la biomasse, et donc, le maintien des autres maillons trophiques ayant un intérêt économique (poissons, crustacés, céphalopodes, ...) [1]. L'objectif de cette étude vise à décrire les variations journalières verticale et saisonnière des densités et structures des populations phytoplanctoniques.

Matériels et Méthodes - A bord du navire N/R Al Amir Moulay Abdallah, des prélèvements d'eaux destinés au dénombrement du phytoplancton, ont été effectués, au niveau d'une station côtière fixe située à $23^{\circ}30$ 'N. La position longitudinale de cette station diffère légèrement d'une saison à l'autre ; $16^{\circ}7'W$ en janvier - février (31/01 au 01/02/2002) et $12^{\circ}22'W$ en juillet (07/07 au 08/07/2002). L'échantillonnage a été réalisé avec un intervalle de temps régulier, toutes les 4 heures au cours de la saison froide et toutes les 6 heures en juillet 2002 et ce, à différentes profondeurs à l'aide de bouteilles reliées à une multisonde CTD qui s'ouvrent à chaque niveau de profondeur retenu. Le dénombrement du phytoplancton a été réalisé par la méthode d'Utermohl [8] et est exprimé en nombre de cellules par millilitre (cell.ml⁻¹).

Résultats et Discussion - L'étude de la variation du cycle nycthéméral de la répartition verticale du phytoplancton au niveau de la zone du 23°30'N en hiver et en été 2002, a révélé que les diatomées dominent l'ensemble du peuplement phytoplanctonique avec plus de 98%, aussi bien en surface qu'en profondeur et durant les deux saisons. Cette dominance est liée principalement à l'existence d'une remontée côtière hivernale et estivale connue de la région et un filament situé à la limite du talus continental de la zone de Dakhla. Ces deux facteurs contribuent à la haute disponibilité des nutriments au niveau de cette zone [3]. Plusieurs auteurs notamment Tilstone et al. [7] ont souligné que les nutriments élevés dans la zone euphotique pendant l'upwelling coïncident avec une biomasse élevée des diatomées. De même, les densités estivales du phytoplancton sont plus importantes que celles hivernales. La densité maximale hivernale était de l'ordre de 1 400 cell.ml⁻¹, alors que celle, estivale dépasse 2 000 cell.ml⁻¹. Ceci pourrait s'expliquer par la disponibilité des nutriments issus des remontées des eaux profondes qui caractérisent cette région, et qui sont intenses en été par rapport à l'hiver [4, 5, 3]. De plus, cette étude a montré une hétérogénéité inter saisonnière de la répartition journalière et verticale du phytoplancton. En hiver, les fortes densités phytoplanctoniques ont été observées dans les couches profondes entre 8h et 16h et principalement entre 12h et 14h, et dans les couches superficielles le soir à partir de 20 h (figure 1).

Fig. 1. Variation journalière et verticale des densités (cell.ml⁻¹) du phytoplancton total en janvier- février 2002

En été, les fortes densités ont été rencontrées le soir à partir de 20h dans les

couches profondes et en surface la nuit à partir de 2h du matin (figure 2).

Fig. 2. Variation journalière et verticale des densités (cell.ml⁻¹) du phytoplancton total en juillet 2002

Donc, le degré d'ensoleillement et de réchauffement thermique pourrait être l'origine de la variabilité inter- et intra-saisonnière de la répartition verticale journalière du phytoplancton. Cet ensoleillement et réchauffement s'intensifieraient en surface en janvier – février entre midi et 14h et en juillet au cours de la journée (entre 8h du matin et 20h), aboutissant à une diminution du développement du phytoplancton sur les couches superficielles entre 12h et 14h en hiver et sur toutes la colonne d'eau en juillet durant la journée, et favorisant ainsi son développement dans les eaux froides et moins ensoleillées. Cela corrobore les résultats de Goffart *et al.* [2] qui ont noté que l'ensoleillement intense des eaux provoqueraient une auto inhibition du développement du phytoplancton du bassin Ligure (secteur Corse), où de très faibles densités phytoplanctoniques ont été observées dans toute la couche réchauffée. De même, les fortes intensités lumineuses ont une action inhibitrice sur les mécanismes photosynthétiques [6].

ANTIBACTERIAL ACTIVITY OF *GRACILARIOPSIS LONGISSIMA* (RHODOPHYTA, GRACILARIALES) LIPIDIC EXTRACT

L. Stabili ^{1*}, M. I. Acquaviva ¹, F. Biandolino ¹, R. A. Cavallo ¹, E. Cecere ¹, R. Lo Noce ¹, M. Narracci ¹ and A. Petrocelli ¹ ¹ Istituto per l'Ambiente Marino Costiero (IAMC)-CNR, U.O.S. Taranto - loredana.stabili@iamc.cnr.it

Abstract

In this work we report the presence of an antibacterial activity in a seaweed, *Gracilariopsis longissima*, common in the Mar Piccolo of Taranto (Northern Ionian Sea, Italy). In particular, algal lipidic extract shows a bacteriostatic activity against several *Vibrio* species. Palmitic acid is predominant among the fatty acids and is presumably responsible for the antibacterial activity observed. *Keywords: Antibiotics, Algae, Bacteria, Ionian Sea*

Introduction

With the advances in phytochemistry and pharmacology methods, several medicinal plants were screened for active principles and biological activities. Seaweeds are very abundant in coastal zones, where they sometimes reach high biomasses. Inspite of their abundance, they are less used than terrestrial plants as source of bioactive compounds with potential biotechnological interest. Only in recent years they increasingly attracted interest in the search for new drugs and have been shown to be a primary source of bioactive natural products including antibiotics. Therefore, an effort is made in the present investigation to screen a common red alga, namely *Gracilariopsis longissima*, for its antimicrobial activity.

Materials and Methods

In summer, *Gracilariopsis longissima* (S.G. Gmelin) Steentoft, L.M. Irvine et Farnham) was collected in the Mar Piccolo of Taranto. The selected algal material was washed 3-4 times in distilled water then shade dried for 8 d, and the fully dried material was powdered. The powdered material was subjected to Soxhlet extraction using chloroform/methanol (2:1 at 55-60 °C for 24 h). The extract was concentrated to dryness in a flask evaporator under reduced pressure and controlled temperature. Five milligrams of extract were dissolved in 1 ml of ethanol and assayed for antimicrobial activity using the Kirby Bauer method [1]. *In vitro* screening was carried out using several bacterial strains. Fatty acid composition was determined as described by Budge and Parrish [3]. Analysis of fatty acid methyl esters was performed by gas-liquid chromatography using a 6890 Hewlett Packard series gas chromatograph equipped with a Omegawax 250 capillary column (Supelco - USA).

Results and Discussions

Gracilariopsis longissima lipidic extract showed a bacteriostatic activity against all the Vibrio species utilized (Vibrio alginolyticus, Vibrio fluvialis, Vibrio salmonicida, Vibrio vulnificus and Vibrio cholerae non O-1). These results are interesting considering both the resistance against antibiotics developed by bacteria [5] and the need to control fish and shellfish diseases due to bacterial infections, including vibriosis [2]. The fatty acids profile of Gracilariopsis longissima showed that palmitic acid methyl ester (16:0) was the predominant saturated fatty acid (42%), whilst, among monounsaturated fatty acids oleic acid methyl ester (18:1) prevailed (8.5%). Since the palmitic acid represents the main component of fatty acids it is presumably responsible of the antibacterial activity observed in the target algal species. In several studies, indeed, palmitic acid has been reported to be the major antibacterial compound in a mixture of fatty acids from other algal species. The exact mechanism by which fatty acids exert their bactericidal action remains unresolved but it has been suggested that these molecules initiate peroxidative processes and inhibit bacterial fatty acid synthesis [6]. However, fatty acids may interact with cellular membranes causing leakage of molecules from the cells, reduction of nutrient uptake or inhibition of cellular respiration [4].

Table 1. Results of *in vitro* experiments showing the antibacterial activity of *Gracilariopsis longissima* lipidic extract .

Bacterial strain	Diameter of bacterial growth			
	inhibition (cm)			
Vibrio alginolyticus	2.5			
Vibrio fluvialis	0.8			
Vibrio salmonicida	0.8			
Vibrio vulnificus	1.5			
Vibrio cholerae non O-1	1

VARIABILITY OF PHOTOSYNTHETIC PARAMETERS IN A SHALLOW TEMPERATE COASTAL AREA (GULF OF TRIESTE, ADRIATIC SEA)

Iva Talaber ¹* and Patricija Mozetic ¹

¹ National Institue of Biology, Marine Biology Station Piran, Slovenia - Iva. Talaber@mbss.org

Abstract

We studied the relationship between physico-chemical factors and photosynthetic parameters. P^{B}_{max} was mostly affected by temperature and phosphate. Overall, photosynthetic parameters showed less variability over the annual cycle in contrast to environmental factors and phytoplankton biomass.

Keywords: Adriatic Sea, Coastal Waters, Phytoplankton, Primary Production

INTRODUCTION

The highly variable hydrological and physicochemical conditions of the northern Adriatic are reflected in a high variability of phytoplankton. There is little information about the effect of environmental factors on photosynthetic properties of phytoplankton [1]. We studied this relationship in a shallow coastal area (Gulf of Trieste) and tried to establish the degree of variability of these parameters.

MATERIAL AND METHODS

Sampling was carried out biweekly from February 2009 onwards at one sampling site (1.3 NM off the coast, 22 m depth). *P-E* experiments were performed in a light incubator with samples taken from 5 and 15 m depth and inoculated with ¹⁴C. Physicochemical parameters (CTD profiles, nutrients) and Chl *a* concentration were measured at each sampling. The photosynthetic parameters were derived from the experimental data fitted to the continuous exponential model of Platt *et al.* [2] (without the photoinhibition parameter, which was statistically equal to zero in all cases). Coefficient of variation for each variable and coefficients of correlation between variables (r) were calculated and the significance of r was tested with the two-sample paired *t*-test.

RESULTS AND DISCUSSION

Photosynthetic capacity ($P^{\rm B}_{\rm max}$)varied from 0.72 to 6.10 mg C mg (Chl *a*)⁻¹ h⁻¹. The lowest value was found in April during mixed water column conditions, while the highest in July in the subsurface layer of higly stratified water column. Photosynthetic efficiency (*a*) ranged from 0.005 to 0.020 mg C (Chl *a*)⁻¹ h⁻¹ (µmol photons m⁻² s⁻¹)⁻¹. In general, higher *a* were typicall for the 15-m depth layer. Coefficients of variation showed that nutrients and Chl *a* biomass were more variable than the photosynthetic parameters suggesting some physiological response of phytoplankton to environmental perturbations in order to maintain similar rates of photosynthetic capacity.

Tab.	1.	Coefficients	of	correlation	(r)	between	variables	(n=23)	and
corres	spon	ding level of s	signi	ficance (** J	o<0.0)5, * p0.10)		

	T in situ	EPAR(z)	PO4 ³⁻	α	₽ [₿] max	Eĸ	Chl a
T _{in situ}	1						
EPAR(z)	** 0,49	1	5. 5.	3			
PO4 ³⁻	0,27	0,32	1	8			
α	-0,10	0,11	-0,12	1			
₽ [₿] max	** 0,49	* 0,38	** 0,46	0,17	1		
Eĸ	* 0,39	0,17	** 0,59	** -0,53	** 0,67	1	
Chl a	-0,17	** -0,45	0,01	0,17	-0,33	-0,29	1

 α was not significantly correlated with any of the tested variables (table 1), and also varied independantly from $P^{\rm B}_{\rm max}$, which is in agreement with the fact that both parameters are controlled by independent mechanisms of the photosynthesis [3]. $P^{\rm B}_{\rm max}$ was significantly correlated with temperature, which relates to the enzymatic control of photosynthesis. It was also significantly correlated with phosphate, which is the most limiting nutrient of the northern Adriatic [4]. The Chl *a* concentrations were significantly negatively correlated with $E_{\rm PAR}$ (2), which suggests adjustment of Chl *a* cell content to the ambient light through photoacclimation.

SEASONAL DYNAMICS OF THE BACTERIAL COMMUNITY IN CORRELATION WITH DIFFERENT ENVIRONMENTAL FACTORS IN THE GULF OF TRIESTE (NORTHERN ADRIATIC)

Tinkara Tinta ¹* and Valentina Turk ¹

¹ National Institute of Biology, Marine Biology Station - tinta@mbss.org

Abstract

Seasonal dynamic of bacterial community was studied in the Gulf of Trieste (northern Adriatic). The bacterial abundance, productivity and community structure together with dissolved inorganic phosphate uptake by the ³³P orthophosphate incorporation method and nutrients factors were followed along the vertical profile. Preliminary analyses of bacterial community structure were performed. *Keywords: Adriatic Sea, Bacteria, Nutrients, Phosphorus*

Introduction

total community fingerprints using DGGE.

The Gulf of Trieste, located in the Northern Adriatic sea, is a shallow, semienclosed basin, which oceanographic properties are strongly affected by water mass exchange from the Southern Adriatic, river inflows and meteorological conditions ([1]). Enrichment experiments proved that phosphorous is the primary limiting element for the growth of phytoplankton as well as for bacterioplankton in the Gulf of Trieste ([2]). Being an integral members of ecosystems, microbes are fundamental to the functioning and the health of the marine environment. Bacterial community abundance and productivity in the Gulf of Trieste has been studied in the past ([3]). However details of microbial processes in the Gulf of Trieste are still poorly understood. The aim of this study was to investigate in more details the seasonal dynamics of the bacterial community in correlation with different environmental factors in the Gulf of Trieste.

Material and methods

The seawater samples for chemical and biological parameters were collected during the period from 2007 to 2009 at standard sampling station, the oceanographic buoy, located in the middle of the Gulf of Trieste (northern Adriatic). Sampling was performed biweekly at six different depths (1m, 3m, 5m, 10m, 15m and 20m) using a Niskin sampler. At the same time vertical distribution of temperature, salinity, chlorophyll a and dissolved oxygen was also determined using CTD probe. Samples were analyzed for nutrients, bacterial abundance and productivity as well as bacterial community structure. Bacterial abundance was determined according to standard protocol, by staining cells with 4',6-diamino-2-phenylindole (DAPI) and examining them under an epifluorescence microscope ([4]). Bacterial carbon production was measured by the incorporation of ³H-leucine into newly synthesized proteins in the bacterial cells ([5]). Subsamples for nutrient analysis were filtered through glass fibre filters (GF/F) and analyzed according to standard protocols ([6]). Bacterial community structure was analyzed using two approaches: (i) by isolation of colony - forming bacteria on ZoBell media and (ii) by culture independent genetic analysis. Subsamples for bacterial community structure analysis were obtained by filtering defined volume of unfixed seawater onto 0.2 µm polyethersulfonic PALL filters (25 mm diameter, PALL Inc.). DNA was extracted from the filters according to Böstrom ([7]) with slight modifications. Community fingerprints were determined using the denaturing gradient gel electrophoresis (DGGE).

Results and discussion

Bacterial abundance showed seasonal dynamics, with the highest values in the late spring - early summer period (6.5 x 10⁸ cells L⁻¹ in May) and at the beginning of the autumn period (9 x 108 cells L⁻¹ in September). From the late autumn until the early spring we observed lower bacterial numbers and equal abundance distribution along the vertical profile. In the winter period and in the spring - early summer there were somehow higher values at the surface. On the other hand, in the late summer - early autumn period, the bacterial abundance was increasing towards the bottom of the water column. Bacterial carbon production showed seasonal dynamics as well, with the highest values measured in the summer (20 μ g C L⁻¹ day⁻¹) and lowest productivity in winter - early spring (5 µg C L⁻¹ day⁻¹). From the late autumn to the early spring the productivity did not vary much along the vertical profile. From late spring until the middle of summer we observe higher bacterial productivity at the surface and at the bottom of the water column. At the end of the summer, on the other hand, the productivity at the surfaces in low, but increases with the depth, reaching the highest values at the bottom. Seasonally changes in dissolved inorganic phosphate uptake measured by the ³³P orthophosphate incorporation method were determined in total sea water and > 1 micrometer size fraction. Preliminary analyses of bacterial community structure were performed by sequencing dominate bacterial isolates and by determination of

HIGH NITRATE SUPPLY INDUCES CHLOROPHYLL DEGRADATION CHLORELLA SP.

Inci Tüney¹, Dilek Unal¹* and Atakan Sukatar¹

¹ Faculty of Science Biology Dept., Ege University, Izmir, Turkey - dilek.unal@mail.ege.edu.tr

Abstract

The effects of high nitrate concentrations on chlorophyll degradation in *Chlorella* sp. were investigated. The decrease in the ratio of chlorophyll a/b with enrichment of high nitrate concentration (0.5 and 1 mM NaNO₃) was also caused by a decrease in chlorophyll a and an increase in chlorophyll b concentration in *Chlorella* sps. cultures. *Keywords: Algae, Chlorophyll-a, Nutrients, Pigments, Physiology*

Introduction - Nutrient concentrations play an important role in the growth of phytoplankton, and the nitrogen sources considered most important for the growth of phytoplankton are nitrate and ammonium. Much higher nitrate concentrations have been found in aquatic ecosystems which were strongly contaminated by agricultural and urban activities [3], [1]. Enrichment of nitrogen and phosporus in aquatic enviroment can lead blooming of algae. Previously studies have also reported that nitrate could affect photosynthesis, growth and cellular toxicity of phytoplankton and metal toxicity to phytoplankton [3], [4], et [5]. Previosuly studied demostrated that excessive nitrogen fertilization causes osmotic stress, in which reactive oxygen species (ROS), hydrogen peroxide (H2O2) and hydroxyl radical (•OH) are produced [6]. ROS are highly toxic and can highly damage normal metabolism of lipids, proteins and nucleic acids and then inhibit plant and algae growth. Although, they found high nitrate concentration lead to inhibiton of growth of phytoplankton, effects of high nitrate stress on chlorophyll content, chlorophyll degradation and lipid peroxidation is still unexplored. In order to gain some insight into toxicity of nitrate in green algae, this study examined the effects of nitrate stress on chlorophyll degradation.

Material and Method - Cultures and materials : Chlorella sp. was obtained from EGEMAC culture collection, University of Ege, Izmir, Turkey. Eight flasks of 100 ml Chlorella sp. were used for the experiment. Chlorella sp. culture was grown photoautotrophically in Rudic Medium (RD) at 31°C in under continuous illumination (Table 1). Illumination provided by daylight fluorescence tubes at 20 µmol photons m⁻²s⁻¹. Chlorella cells were harvested by centrifugation and transferred to a fresh medium, grown under the same conditions for 1 day; 0.05, 0.5 and 1 mM NaNO3 were then added to the nitrate stress groups, respectively. The cultures were sampled 1, 3, 18, 24 and 44 h by removing 30 ml of the culture each time. All the experiments were repeated three times. Cell density was mesaured by spectrophotometer at 663 nm. About 20 mg cells was extracted in the dark for 1 h at 65 °C in 3 ml dimethyl sulfoxide (DMSO) in presence of polyvinylpolyrrolidone to minimize chlorophyll degradation. To assess chlorophylls, absorbance of the extracts was read at 665.1, and 649.1 nm. Statistical analysis was performed with one-way analysis of variance (ANOVA)(SPSS for Windows version 11.0).

Results and Discussion - Chlorophyll intermediate molecules are also potential chloroplast signals that could regulate photosynthetic gene expression, growth rates, and cell-death processes [7]. Our present results showed growth rate decrease closely correlated with decreasing chlorophyll a/b ratio following to supplemental different NaNO₃ concentration (Figure 1). Chlorophyll b is formed from chlorophyll a by the oxidation of the methyl group on ring II to the aldehyde and the ratio of chlorophyll a/b is more sensitive to modification than chlorophyll a+b. In green plants, antenna size is determined by the amount of light-harvesting chlorophyll a/b protein complex that is associated with the photosystems [7]. Conversion of chlorophyll b to chlorophyll a not only impacts the chlorophyll a/b ratio but also is the first step of chlorophyll degradation. In this study, on nutritional Chlorella sp. media and supplement 0.05 mM nitrate media, pigment levels were not significantly different (Table 1), but they did differ between groups in the presence of different nitrate concentration. The chlorophyll a/b ratio was significantly decreased in both 0.5 and 1 mM nitrate enrichment groups (Table 1). Our present results confirmed that supplemental NaNO3 causes a significantly increase in chlorophyll b and a concomitant decrease in chlorophyll a, consistent with accelerated conversion of one to the other (Tab. 4). In conclusion, the levels of nitrate concentrations used in the present study ranged from 0.05 to 1 mM. According to the present study, these high nitrate concentrations caused chlorophyll degradation. Therefore, further research is required to investigate the effect of high nitrate concentrations on antioxidant mechanism in green algae. Table 1 shows Chlorophyll a /Chlorophyll b (Chla/b) ratio of the alga Chlorella sp. cultivated with a nutritional level of nitrate (control) and nitrate supplement of 0.05, 0.5, and 1 mM.

THE DEGRADATION OF DIFFERENT SCYHPOZOAN JELLYFISH SPECIES BY THE AMBIENT BACTERIAL COMMUNITY

Valentina Turk ¹*

¹ National Institute of Biology, Marine Biology Station - turk@mbss.org

Abstract

The chemical composition and degradation of dead jellyfish tissue of *Aurelia* sp., *Pelagia noctiluca* and *Rhizostoma pulmo* by the ambient bacterial community was studied in laboratory experiments using samples from the Gulf of Trieste (northern Adriatic). Preliminary results showed rapid hydrolyzes of proteins in the presence of the natural microbial community and significant release of disolved and anorganic nutrients, which can significantly alter the carbon and nitrogen cycles and oxygen dynamics in the surrounding environment.

Keywords: Adriatic Sea, Bacteria, Medusae, Nutrients, Organic Matter

Introduction

The increasing frequency and intensity of jellyfish outbreaks in the northern Adriatic may have a significant impact on fisheries, tourism and the functioning of the food web. Although eight scyphomedusae species have been discovered over the last 150 years in the northern Adriatic, only a few, have been observed in large numbers [3]. The total organic content of jellyfish is 1-2 % of wet weight and generally consists of high protein (72±14 %) contents, low carbohydrate (7±5 %) and lipid (22±12 %) contents [4]. Proteins, as a quantitatively important compounds believed to be very labile. During the decomposition of blooms, jellyfish carcasses can serve as an important source of protein to the environment. Few studies have addressed the fate of dead jellyfish [6], [8] nor indicated rapid decomposition and nutrient release, either in the water column or on the sediment surface.

Materials and method

Jellyfish for our experiments were collected by dip net from the surface during bloom events in the Gulf of Trieste (northern Adriatic). Bell diameters and wet weight were measured for each jellyfish. Seawater samples were collected with a Niskin sampler at 3 m depth at station BF (45° 32.804 N; 13° 33.034 E) in the Gulf of Trieste. Immediately after sampling, seawater was filtered through a 200 µm mesh net and subsequently through GF/F filters (Whatman) to yield a filtrate containing microorganisms. The filtered seawater was collected in 8 L acid washed and autoclaved polycarbonate bottles (Nalgen) and was used for the jellyfish decomposition experiments. In each experiment equal amounts of jellyfish were selected and their whole tissues, including interstitial water, homogenized with an Ultra - Turrax TP 18/10 (Janke & Kundel) at 20 000 rpm for several minutes. The whole tissue of each jellyfish was used as substrate, diluted in 8 litres of pre-filtered sea water containing the ambient bacterial community. Bottles with filtered sea water without addition of jellyfish served as controls. The bottles were incubated in situ at 3m depth in front of the Marine Biology Station from 24 March to 15 April 2009. Part of the homogenate was frozen and stored for CHNS elemental analysis. All nutrient analyses were performed on a GF/F pre-filtered water sample, using the standard protocols ([2]) and protein concentrations were determined by the Bradford method [1] using the Bio Rad Protein Assay Kit. Dissolved oxygen (DO) concentration was measured in triplicate by the standard Winkler method. Bacterial abundance was determined according to standard protocol, by staining cells with 4',6-diamino-2-phenylindole (DAPI) and examining them under an epifluorescence microscope [5]. Bacterial carbon production was measured by the incorporation of ³H-leucine into newly synthesized proteins in the bacterial cells [7]. Bacterial community structure was analyzed using two approaches: (i) by isolation of colony - forming bacteria on ZoBell media and (ii) by culture-independent analysis using the denaturing gradient gel electrophoresis (DGGE) fingerprinting method.

Results and discussion

Elemental analysis of Aurelia sp., Pelagia noctiluca and Rhizostoma pulmo reveals low dry weight specific carbon and nitrogen content, and rather low C/N atomic ratios (3.9 - 4.9). Preliminary results showed variation in protein concentrations of added dead substrate between jellyfish species. Concentrations were twice as high in the experimental bottles with Pelagia and Rhizostoma compared with Aurelia. After 72 hours of incubation, the protein concentrations were reduced in all experimental bottles with the jellymixture, and significant bacterial growth with biomass increases was recorded. The initially high concentrations of protein, DOP and orthophosphate in the amended bottles, appear to support microbial mineralizations which consume oxygen and release dissolved inorganic nutrients, mainly ammonium. The rate of degradation and bacterial growth depends on jellyfish chemical composition as indicated by the ratio of biomass, ammonium and phosphate accumulation of 1:3 between *Aurelia* and *Pelagia*.

EMILIANIA HUXLEYI BLOOM IN WINTER PERIOD IN THE DARDANELLES, TURKEY

Muhammet Türkoglu ¹*

¹ Yes - mturkoglu@comu.edu.tr

Abstract

Following a strong summer bloom of *Emiliania huxleyi* (Lohmann) Hay & Mohler, 1967 in June and July 2003, a winter bloom was observed for the first time between late December 2003 and early January 2004 in the Dardanelles and the results were appreciated along with hydrography. *E. huxleyi* was the dominant species and represented about 90.0% of the phytoplankton assemblage. The bloom started flourishing after the diatom and dinoflagellate blooms under nitrogen depleted and moderate light, temperature and salinity conditions.

Keywords: Dardanelles, Blooms, Coccolithophores, Hydrography

The Dardanelles is a part of the Turkish Strait System and located between the Aegean Sea and the Sea of Marmara and has two flow system reverse to one another [1]. The data in this study is a part of the data collected during cruises in the period of January 2002 and January 2004, in the framework of a National project of TUBITAK, Turkey [1]. CTD parameters, nutrient and chlorophyll-a were also measured by using YSI 6600 MPS, Autoanalizor and spectrophotometer, respectively [2]. Except for the polar ones, *E. huxleyi* is one of the most abundant coccolithophores occurring globally in the occans in early summer periods. In summer, high surface irradiance, shallow stratification with a mixed layer depth of about 10-20 m, anomalies in salinity and temperature, low phosphate and silicate concentrations compose favorable conditions for *E. huxleyi* bloom in the marine systems [3]. However, following a strong summer bloom of coccolithophore in June and July 2003 [3], a winter bloom was observed for the first time between late December 2003 and early January 2004 in the Dardanelles (Fig. 1).

Fig. 1. Map of the Dardanelles and sampling station

While E. huxleyi revealed small population density (1.60 x 10⁴ cells L⁻¹) in early December 2003, the bloom started in middle December 2003 (7.86 x 10⁶ cells L^{-1}) and then peaked in early January 2004 (5.03 x 10⁷ cells L^{-1}) in the superficial layer. The peak dramatically decreased in late January 2004 (7.50 x 10⁶ cells L⁻¹) (Fig. 2A). E. huxlevi was the dominant species and represented about 90.0% of the phytoplankton assemblage. The bloom started flourishing after the diatom and dinoflagellate blooms (Figs. 2B, C) under nitrogen depleted and moderate light, temperature and salinity conditions. Water temperature (10.31±1.14 °C) and salinity values (27.05±0.88 ppt) were usually stabile. Surface chlorophyll-a concentrations ranged from 1.23 to 2.32 μ g L⁻¹ (1.94±0.43 μ g L⁻¹) during the bloom (Fig. 2E). Vertical profiles of inorganic nutrients showed that the concentrations in the upper layer were lower (0.26±0.14 μ M for NO⁻₂+NO⁻₃, 0.06±0.01 μ M for PO⁻³₄ and $2.51\pm1.16 \ \mu\text{M}$ for SiO₄ than those in the lower layer (0.42\pm0.24 \ \mu\text{M} for NO⁻ $_2$ +NO⁻₃, 0.07±0.02 µM for PO⁻³₄ and 2.80±0.84 µM for SiO₄) due to E. huxleyi blooms in the surface waters during the winter bloom conditions. Although SiO₄ concentration was calculated as mean value of 2.80+0.84 µM. the surface concentration was lower than 2.00 µM in the first period of the E. huxleyi bloom, due to its excessive utilization by diatoms just before the E. huxleyi bloom (Figs. 2A, C). Ratios of N:P (min-max: 2.00-7.33; mean:4.12±2.12,) Si:N (min-max: 3.08-17.33; mean: 9.79±4.32) and Si:P (minmax: 24.00-58.50; mean: 40.35±16.25) of the bloom period were lower than those of the non bloom periods. The strong bloom potential of E.huxleyi in winter period in addition to the summer period [3] has revealed that the

Dardanelles is under the hyper-eutrophication due to the fact that it is a part of the Turkish Strait System affected by the Black Sea.

Fig. 2. The vertical profiles of E. huxleyi (A), dinoflagellates (B), diatoms (C), total phytoplankton (D), and chlorophyll-a (E) in winter in the Dardanelles

SHORT TIME VARIATIONS OF CHLOROHYLL A AND NUTRIENTS IN THE DARDANELLES, TURKEY

Muhammet Türkoglu ¹*

¹ Yes - mturkoglu@comu.edu.tr

Abstract

The distribution of chlorophyll a and nutrients were investigated in relation to the hydrography in the period of January 2002 and January 2004 in the Dardanelles. Nutrient levels were lower in the upper layer waters than in the lower layer waters due to excessive algal blooms in the surface waters. In vision of nutrient ratios (N:P=3.21, Si:P=33.17 and Si:N=12.71), nitrate was more limiting nutrient than phosphate. In addition to high chlorophyll a levels in surface waters ($3.01\pm2.83 \ \mu g \ L^{-1}$), there were secondary high values of chlorophyll a in subsurface depths especially in spring and summer periods. *Keywords: Dardanelles, Chlorophyll-a, Nutrients, Hydrography, Time Series*

The distribution of phytoplankton chlorophyll a and inorganic nutrients were investigated along with hydrography in just nouthern part of the Nara Cape of the Dardanelles (Fig. 1).

Fig. 1. Map of the Dardanelles (Çanakkale Strait) and sampling station (St.)

The Dardanelles is located between the Aegean Sea and the Sea of Marmara and has two flow system reverse to one another [1]. The data were collected during cruises in the period of January 2002 and January 2004, in the framework of a National project of TUBITAK, Turkey [1]. It was collected 74 surface samples for chlorophyll a and nutrient during the two years sampling period. CTD parameters, nutrient and chlorophyll a were measured by using YSI 6600 MPS, Autoanalizor and spectrophotometer, respectively [2]. Results showed that temporal temperature variations in surface waters (6.25-25.99 °C) originated from the Black Sea were higher than deep waters (13.09-18.44 $^{\circ}\mathrm{C})$ originated from Mediterranean. Due to two different water systems, there were two temperature stratification reverse to one another during the year. Since surface water of the Dardanelles was affected by the Black Sea, there was a vertical salinity profile increasing with depth (from 22.28-26.95 to 38.09-38.93 ppt) during the year. Dissolved oxygen in surface waters were generally close to saturation limit (10 mg L⁻¹) and sometimes were higher than the limit (>10 mg L⁻ ¹). Due to excessive algal blooms in the surface waters [1], surface levels of nutrients were lower (0.21±0.22 μ M for NO⁻₂+NO⁻₃, 0.08±0.05 μ M for PO⁻³₄ and $1.80\pm1.14 \ \mu\text{M}$ for SiO₄) than deep levels $(0.50\pm0.35 \ \mu\text{M}$ for NO⁻₂+NO⁻₃, $0.08 \pm 0.06 \ \mu\text{M}$ for PO⁻³₄ and $2.80 \pm 0.97 \ \mu\text{M}$ for SiO₄) except for PO⁻³₄ (Fig. 2). Elemental ratios of N:P, Si:P and Si:N were calculated to be 3.21±2.70, 33.17±34.47 and 12.71±11.52 in surface waters respectively, whereas they were calculated to be 6.66 \pm 5.92, 38.40 \pm 19.86 and 8.76 \pm 7.14 in deep waters respectively. In vision of the elemental ratios, nitrate was more limiting nutrient than phosphate. Chlorophyll a ranged from 0.13 to $15.21 \ \mu g \ L^{-1} (3.01 \pm 2.83 \ \mu g)$ L⁻¹) in surface waters. In addition to high chlorophyll a levels in surface waters, there were secondary high values of chlorophyll a (min-max: 0.47-16.16; mean: $3.18\pm3.02 \ \mu g \ L^{-1}$) in subsurface layer waters (10 m) in some periods, especially in spring and summer periods (Fig. 2).

Fig. 2. Short time variations of nutrients and chlorophyll a in the Dardanelles (Çanakkale Strait)

At sight of high levels of nutrients and chlorophyll a, Dardanelles is under the heavy eutrophication due to the fact that it is a part of the Turkish Strait System affected by the Black Sea.

Abstract

To understand the relative importance of viral shunt vs predation of both heterotrophic nanoplankton (HNF) and microzooplankton on autotrophic and heterotrophic prokaryotes in the pelagic Mediterranean food web, we performed a series of independent incubation experiments along a wide trophic gradient from the Atlantic Ocean to the eastern Mediterranean Sea during a trans-Mediterranean cruise (May-June 2007). Results indicate that nanoflagellates predation, although often strongly controlled by microzooplankton, caused most prokaryotic losses; microzooplankton was more efficient on the autotrophic picoplankton. *Keywords: Bacteria, Predation, Levantine Basin, Western Mediterranean, Plankton*

Surface water samples were collected at 9 stations including: 1 station in the Atlantic Sea (station VA), 4 stations in the western Mediterranean Sea and 4 stations in eastern Mediterranean Sea (fig.1).

The loss of prokaryotic biomass caused by grazing or virus-mediated lysis has different consequences in organic C fluxes and biogeochemical cycles. If the main control of prokaryotic abundance is via protozoan grazing, most of the carbon will be channelled to higher trophic levels in the food web. Conversely, if viral infection accounts for most prokarvotic losses, the flow of carbon and nutrients can be diverted away from larger organisms thus accelerating the transformation of nutrients from particulate to dissolved states. This last process is named "viral shunt". The impact of viruses in pelagic processes depends largely on the significance of the virus-induced prokaryote mortality (VIPM). In the present study VIPM has been estimated on the basis of the viral production and the burst size of viruses (i.e. number of viruses released per infected cell). Viral production rates were measured using the dilution approach, which has been repeatedly applied to several coastal and deep-sea systems [1, 2]. Results reported here indicate that viral abundance was very low and did not significantly vary along the trophic gradient (on average, 6.94 ×10⁴ viruses mL⁻ ¹). Conversely viral production ranged from $1.16 \pm 0.16 \times 10^3$ viruses mL⁻¹h⁻¹, at the station V1, to $2.57 \pm 0.60 \times 10^4$ viruses mL⁻¹h⁻¹, at the station V3, in the western Mediterranean Sea. However, on average, no significant differences were observed between viral production in western and eastern Mediterranean Sea. Assuming a burst size of 15, the fraction of prokaryotes killed by viruses per day ranged from ca. 0.3 to ca. 8% d⁻¹ (at the stations V1 and V3, in the western Mediterranean Sea) and on average similar values of prokaryotic mortality were observed in both western and eastern sectors of the Mediterranean Sea. Previous studies suggested that higher values of VIPM may be related to the probable absence, or extremely low density, of grazers that compete with viruses for prokaryotic cells [2]. In the present study nanoflagellates (HNF) abundance (range: 3.63 \pm 1.18 $x10^2$ - 1.15 \pm 0.05 $x10^3$ individuals L-1) was on average 2 orders of magnitude lower than viral abundance (fig. 2). A positive relationship (n = 9 R = 0.74) was observed between viruses to HNF abundance ratio and VIPM suggesting a higher

contribution of the viral infection to prokaryotic mortality with decreasing HNF abundance. Heterotrophic bacteria abundance (fig.2) ranged from 2.44 ± 7.8 to $6.57\pm3.45\ x10^5$ cells L^{-1} , and on average was higher in the western basin. Microzooplankton (MZ) abundance (fig.2) ranged from 7.64 ± 1.36 to $20.08\pm4.34\ x10^2$ individuals L^{-1} .

Fig. 2. Abundance of heterotrophic picoplankton and nanoplankton, and microzooplankton in the 9 stations of the trans.Mediterranean cruise.

Grazing impact of HNF and MZ on picoplankton was separately assessed using the classic Landry and Hasset (1982) [3] dilution method. Four models of interaction between HNF and MZ were identified: 1) only HNF fed on picoplankton, no MZ grazing was detected on both picoplankton and HNF, 2) MZ fed directly on picoplankton, no HNF predation was detected, 3) MZ caused an increase in prokaryotic loss compared to the only HNF predation, indicating a direct predation of larger consumers, 4) MZ grazing on HNF reduced prokaryotic biomass loss, indicating a strong top down control of MZ on HNF biomass. The experiments of HNF grazing indicated that most of the prokaryotic mortality in surface waters of the Mediterranean Sea is due to predation by HNF, although in few cases, and particularly on autotrophic fraction, MZ was a more efficient predator than HNF. Results show that in the eastern Mediterranean picoplankton mortality due to both HNF and MZ grazing was always higher than growth rate.

Abstract

The identification and quantification of individual algal species remains difficult, time consuming, requiring a great deal of expertise and experience. Alternative to traditional, morphology-based methods, molecular techniques need less expertise for the detection of cryptic species within the bioindicator community. Although these methods require detailed knowledge of the molecular diversity within taxa in order to design efficient specific primers to avoid cross-reaction with non-target sequences. Based on rDNA (large subunit) LSU, RAPD and real-time PCR results and melting curve analysis, a model system to detect marine, planktonic, bloom -forming dinoflagellate *Prorocentrum minimum* using the DNA extracted from the Golden Horn Estuary bloom samples and mixed samples. *Keywords: Bio-Indicators, Toxic Blooms, Population Dynamics, Phytoplankton, Bosphorus*

Introduction

DNA directly amplified from the environment have revealed a rich biodiversity of marine dinoflagellates that has escaped routine detection using microscopy [1]. The rDNA amplification approach to explore for the presence of unknown dinoflagellate DNA in the marine environment includes dinoflagellate-specific PCR of DNA extracted from field samples and cloning and sequence analysis of randomly selected clones [2]. DNA melting curve analysis is a technique that can be applied post-PCR to provide the melting temperature of the amplification products [3]. Sequence differences of each PCR amplicon can be distinguished by the melting curve that is affected by the GC content of the PCR product and the absolute order of the bases in the sequence [4, 5].

Materials and Methods

Field samples used in this work are morphologically identified dinoflagellate *Prorocentrum minimum* obtained from Golden Horn 26.07.2000 bloom. The number of cells were counted to be 70×10^{6} /lt [6]. DNA isolation was done using MN Nucleospin Plant II kit. The sequences of the primers are given in Table 1. For real-time PCR Takara's SYBR Premix Ex Taq kit has been used. Real-time PCR has been done in Rotorgene Thermal Cycler. Confirmation of the real-time results were done on 2% Agarose gels (Figure 1). The size markers used in gel electophoresis have the band sizes 1000bp, 900 bp, 800 bp, 700 bp, 600 bp, 500 bp, 400 bp, 300 bp, 200 bp and 100 bp in descending order.

Results and Discussion

Instabilities in the aquatic ecosystem should be monitored routinely. There are some bioindicator species that can be biomonitored for red-tide events in the Sea of Marmara. Prorocentrum minimum is a toxic species causing frequent redtides especially in Haliç. In our study we have done the detection of this bioindicator species by using real-time PCR as a supporting tool for conventional methods of detection which will facilitate the routine monitoring of this species in the Sea of Marmara. Our approach, using the polymerase chain reaction (PCR) amplification of large subunit gene sequences (LSU rDNA), P. minimum specific sequences and RAPD and sybrgreen RAPD-real-time PCR is a useful and cost-effective genotyping method that can be used to determine both the population complexity and species identification of organisms in harmful algal blooms [7, 8]. DNA fragments (represented as bands on the gel) that were excised from agarose gel and were sequenced to determine the genetic variation data due to spontaneous mutations or taxonomic differences among the various bloom forming Prorocentrum minimum clones. There seems to be intraspecific variation, although spatial and temporal origins of the Haliç bloom samples was the same and approximately 100% cells as biomass and diversity belong to P. minimum [6]. Melting temperature differences are indicating this well and the xn PCR data confirmation with 2% agarose gel electrophoresis figures are indicating the variation as formed polymorphic bands and heteroduplexes detected and shown with arrows in figures confirmed with the sequencing data. x10 real-time LSU-rDNA amplification confirmation of Haliç 2000 Prorocentrum minimum bloom DNA indicating the dimorphism in the amplicon.

Abstract

The cytometric characteristics (Size Scatter and Green Fluorescence) and abundances of HNA (high nucleic acid) and LNA (low nucleic acid) bacterioplankton cells were examined in the frame of a Transmediterranean cruise held in summer 2008. LNA and HNA group showed remarkable distribution following vertical, chlorophyll and bacterial production gradients. *Keywords: Bacteria, Open Sea, Organic Matter, Competition*

In the last decade there has been an increasing documentation on the relationship between key bacterioplankton groups and their role in the heterotrophic bacterial production. Mediterranean Sea being strongly stratified and P limited during a large part of the year, P limitation of heterotrophic bacterial production is not uncommon. In the frame of French (BOUM : biogeochemistry from oligotrophy to ultra-oligotrophy of the Mediterranean Sea) and EU programs (SESAME: Southern European Seas, Assessing and Modelling Ecosystem changes) we examined bacterial production over different basins, with the attempt to focus on the role played by high and low nucleic acid groups (HNA and LNA groups, respectively) in relation to surrounding biogeochemical conditions. Most studies dealing on HNA and LNA after flow cytometry analysis focused mainly on their abundance distribution. Investigations using ³H-leucine labelling coupled to cell sorting technique, since the pioneer study by Servais et al (1999), suggested the importance of HNA group to sustain bacterial production, these cells being not only larger but also more active per unit cell than LNA cells. However, in oceanic areas, the role of LNA to sustain a large part of bacterial production has been also evidenced [1], [2] et [3]. Flow cytometry allows also determination of other HNA and LNA group characteristics: Size Scatter (SSC) and green fluorescence (FL). Recently, it has been suggested that interactions within these two groups could be highly dynamics [1] and partly explained by the relationships between the cytometric characteristics of these 2 groups. However, although these 2 fractions are ubiquitous in aquatic systems, little is known about their distribution in the oligotrophic to ultraoligotrophic Mediterranean Sea, and nothing about their cytometric characteristics. Both HNA and LNA abundances increased with bacterial production, however the slope of increase of HNA being lower than that of LNA, the percentage of HNA slowly decreased when bacterial production increased (Figure 1). The cytometric characteristics of these 2 groups exhibited different types of relations according vertical distribution of chlorophyll, notably distinct groups emerged for layers above the deep chlorophyll maximum (dcm), below the dcm and for deep layers (-250 m). ³Hleucine labelling coupled to cell sorting enabled us to reveal the distribution of high and low nucleic acid groups within heterotrophic bacterioplankton in terms of leucine assimilation and response to amendments, as well as the potential of some cyanobacteria to assimilate organic compounds. HNA cells responded drastically after nitrogen+phosphorus enrichments by both increasing their abundance, their contribution in term of total abundance but also their per cell activity, with a final contribution of total BP reaching 86%, demonstrating its zymogenous-type behaviour. However for in situ steady state conditions of oligotrophy, HNA cells exhibited large variability of per cell activity according to the cell size, the low size HNA group exhibiting the same per cell activity than LNA cells. LNA cells were abundant within the surface layers (41 to 74 % of abundances) and their bulk activity could be responsible of up to 65 % of the total bacterial production.

Fig. 1. Relationship between the proportion of HNA cells and the bacterial production over vertical and horizontal gradient in the Mediterranean Sea. Distinct groups were identified according vertical distribution of chlorophyll a

Abstract

The potential impact of backwash and brine discharge on the standing stocks and productivity of phytoplankton and bacterioplankton was monitored at the area of the outfall of a reverse-osmosis based desalination plant. Preliminary results indicate that the backwash, that includes iron hydroxide used as a coagulant, may have a potentially inhibitive impact on the microbial biota found near the outfall. *Keywords: Chlorophyll-a, Bacteria, Levantine Basin, Primary Production*

Three surveys (April and August 2008 and April 2009) were conducted in the area of a brine outfall of the desalination plant in Ashkelon, Israel. The water quality aspect is described by Dromi et al (Submitted abstract, CIESM 2010) and the current presentation relates to the possible impacts of the brine outfall on phytoplankton and the bacterial community. Although one may assume that brine by itself is diluted rapidly and does not leave a detectable impact even of sessile organisms [1], the discharge of a coagulants and antiscalants (added for the amelioration of seawater prior use in the plant) poses potentially a stress factor for biota. Water samples were collected before, during and after the pulsed discharged of the backwash, along a gradient from the more affected area to apparently clear (non affected) water area. It should be emphasized that brines from the desalination plant and the cooling water from the power station located at the same site were discharged continuously and only the backwash discharged was pulsed. Phytoplankton standing stock was assessed by the measurement of chlorophyll a (Chl) concentration and primary productivity by ¹⁴C-labeled bicarbonate uptake under standard conditions of 20 °C and light flux of 100 mmol photon m^{-2} s⁻¹. Chl in the unaffected area was 1-2 mg m⁻³, but as low as 0.15 mg m⁻³ following the discharge of the backwash. Most of the algal biomass was composed of cells larger than 10 micron in diameter, and microscopic qualitative examination revealed that diatoms and dinoflagellates dominated phytoplankton. Comparison of acidified and non-acidified Chl extracts showed phaeophytin (and Chl degradation products) constituted only a small fraction of chlorophyllous pigments, and thus we may assume that most phytoplankton cells collected from the sea samples were intact, indicating that physical damage was not part of water treatment impact. Chl-normalized photosynthetic activity ranged from 1.1 to 6.8 mg C mg Chl⁻¹ h⁻¹and showed a trend of inverse relationship with the proportion of the coagulant in seawater (Fig. 1). The latter was assed by reddish hue imparted by the presence of iron hydroxide and determined by spectrophotometric examination of the sea water at 400 nm.

Fig. 1. Plot of assimilation number (A.N.), which is the expression of chlorophyll a-based value of primary productivity, against absorbance at 400 nm determined spectrophotometrically.

Bacterial counts were conducted in DAPI stained sub-samples. Bacterial density was also inversely correlated with the distance from the outfall and time elapsed since the backwash discharge, and varied from 1.8 and $41.1*10^8$ cell L⁻¹. Cell number-normalized bacterial productivity, measured under standard conditions by ¹⁴C- labeled leucine, increased from the outfall site towards clear water,

approximately proportionally to the manner seen in the biomass-based phytoplankton productivity. Rates of algal and bacterial productivity were positively correlated, however the relationship between the rates changed between experiments (Fig. 2).

Fig. 2. Comparison of the rates of primary productivity (PP) and bacterial secondary productivity (BSP) offshore the desalination plant offshore Ashkelon, Israel.

While the spatial trend of increase of standing stocks of phytoplankton and bacteria towards the clear, unaffected water indicate, probably, just the dilution impact of the backwash discharge from the desalination plant, modification of rates is apparently a display of the inhibitive role of the saline concentrate and/or accompanying chemicals on microbial physiology. However, further investigation is required to elucidate: 1) what is the mode of action of the backwash discharge, and 2) does the inhibitive action of the backwash water confers a risk of modification of the planktonic microbial community in the area of discharge on the long run.

CHLOROPHYLL A VARIATION VERSUS HYDROLOGICAL CONDITIONS IN THE SOUTHERN MOROCCAN ATLANTIC COAST(BLANC CAPE AND BOJDOR CAPE)

Soukaina Zizah ¹*, Omar Ettahiri ¹ and Mustapha Hasnaoui ² ¹ Institut National de Recherche Halieutique - soukainazizah@yahoo.fr ² Faculté des Sciences et Techniques, BP 523, 23000Beni Mellal

Abstract

Three models were defined depending on the location of the maximum of chlorophyll'a' either in the axis coast/ offshore and in the water column (shallow or deep water). During 1998, in the 1st model two cells of great contents of chlorophyll 'a' were met, one in the coast and the other in the offshore. The 2nd model has an opposite evolution compared to the 1st model. In the 3rd model the chlorophyll 'a' maximum is recorded in the coast describing a decreasing gradient coast-offshore. In 1999, the maximum is at the offshore stations in the 1st model; 2nd model where the maximum occupies an intermediate or central situation. 3rd model two cells were presented: one at the coast, and the other in the offshore identified only at Dakhla region. *Keywords: Chlorophyll-a, Upwelling, Vertical Profile*

Introduction

The vertical movements of the upwellings are interesting from physical and biological point of view, since they affect the quantities of nutrients brought into the euphotic zone and consequently the organic production of water. Thanks to the fertilizing contribution of deep water, the production and the productivity of phytoplankton rise. Moroccan Atlantic coast has the privilege to be among the 5 areas in the world influenced by this phenomenon which is also called resurgence of cold water.

Material and Methods

Data of this study comes from sea cruises onboard of the russian R/V Atlantniro (1998) and Atlantida (1999). The water samples intended for the proportioning of chlorophyll 'a' are analyzed by the fluorimetry. The frequency of buoyancy called also frequency of Brunt Väisälä represents the intensity of the stratification of the water column, and thus its stability. The depth, where this frequency is the highest, it corresponds to the depth of the thermocline (1). And finally, we used the immersion at which 1% of surface radiation arrives, which delimits more or less the euphotic layer or the layer of photosynthesis. In order to comprehend the study, vertical distributions of chlorophyll 'a' detailed by transects were analyzed.

Results and Discussion

Primary production is important within Cape Blanc, a rich place in nutrients brought in one hand, by an upwelling which occurs year along, and on the other hand by SACW (2). Moreover, this zone corresponds to the richest zone in terms of chlorophyll `a' average (calculated within the euphotic layer). It reaches the order of 6 mg/m³ in the area located at the north of this zone, (figure1), where a certain homogeneity of its water column is noticed, represented by low frequencies (not exceeding 0.02 units), except for Cape Bojdor (26°N) where a degree of stability going up to 0.06 units was met.

Fig. 1. Evolution of chlorophyll'a' average versus coastal stations latitudes (mg/m^3)

It is reminded that the character of homogeneity of the majority of the stations of the northern zone was noticed also on the vertical distributions of chlorophyll 'a', and which coincides with rather low values in terms of average of chlorophyll `a'. In the second time and for more clarity reasons, we used the vertical distributions of the frequencies of Brunt Vaïsala along the main transect. Figure 2 shows that in Bojdor Cape, it is obvious that a thermocline on the surface is presented by the isoline of 0.06 units.

Fig. 2. Vertical Distribution of Brunt Vaisala Frequency during 1998

It would be due to an upwelling which has just started, and which would be identifiable by the character of homogeneity of its isolines, by the cold water patch raised at the coast, and likely by an apparent starting of phytoplankton development, schematized by chlorophyll'a' assimilation rate. This can be explained by two ways: (i) A recent upwelling character of Bojdor Cape. Indeed, following (3), in the stations where the upwelling is recent, nutrients are very abundant, but the phytoplankton development starts and water is hence relatively clear. (ii) This second point rises from the first, and which stipulates that high pulses of wind cause a ascendance of cold and nutrient rich water, and turns to be turbulent. The conditions are thus unfavourable, since thickness of the euphotic layer is reduced. Light, becomes a limiting factor and nutrients are not consumed (3). This explains perfectly the high percentages of phosphates of 0.9µgat/l in Cape Bojdor. On the other hand, in Cape Blanc, the frequency of buoyancy reaches its maximum, like it was announced previously. For the other transect, the vertical distributions of Brunt Vaisala frequencies show identical structures to those of chlorophyll `a' in the euphotic layer. In other terms, the two cells of big concentrations (coast and offshore) met in the area of Dakhla coincide with high values of frequency. In addition, the major maxima of chlorophyll correspond to the thermocline. Indeed, 44% of the stations show that the maximum of chlorophyll 'a' is less deep than the pycnocline. Whereas only 23% of the stations are located at the same depth as of the pycnocline and 32% are at a deeper levels.

² IMS-METU (Turkey)

Abstract

Planktonic microbial communities play an important role in controlling the CO₂ flux between the atmosphere and the ocean. C-uptake (primary and bacterial production) have been analysed more extensively than mineralization processes (community respiration). This has given rise to a gap for a complete knowledge of C-flux in the marine environment. The research activity conducted in the frame of the EU Project SESAME (WP 3.8.2) provided new data on biological processes in the Cilician Basin. This area showed the heterotrophic nature of the off-shore site (P/R<1) with the potential to represent a consisting CO₂ source. *Keywords: Bacteria, Primary Production*

The net flux of CO₂ between the atmosphere and the ocean is mostly controlled by the balance among three key processes mediated by the microbial communities: 1) uptake by phytoplankton photosynthesis (CO₂ uptake) 2) mineralization processes (CO2 emission) 3) export toward the ocean depths. Phytoplankton is responsible for roughly half of the CO2 fixation on the earth and at least 50% of the fixed C is channelled through the microbial food web in the dissolved phase [1]. In pelagic ecosystems heterotrophic bacteria mediate a significant conversion of dissolved organic carbon to biomass, which is then transferred to the food web. Only a small fraction of this organic matter is buried in marine sediments being the bulk of the produced organic matter remineralised trough respiration [2]. As a consequence oceans can act as net source or sink of carbon depending on the production or decomposition of organic matter due to biological activities. Recent comparative studies have suggested that respiration may systematically exceed production in large areas of the oceans [3]. The E Mediterranean Sea is considered one of the most oligotrophic regions in the world, in terms of both primary productivity and autotrophic biomass [4]. The Cilician Basin occupies the NE part of the Levantine Basin (Fig.1) and so far no data on primary production, bacterial production and community respiration rates are available.

Fig. 1. Cilician Basin: location of samplig sites utilized in the EU project SESAME

To fill this gap, two short cruises (March 2008 and February 2009) have been carried out in the Cilician Basin, on board of R/V Bilim-2 of IMS-METU, and samples were taken from two sites representative of mid-shelf and offshore conditions. Depth profiles of the microbial community activities were analyzed in terms of primary production (PP, NaH¹⁴CO₃ uptake), bacterial carbon production (BP, ³H-leucine inc.) and community respiration (CR, changes in dissolved oxygen by Winkler method) along with bacterioplankton and phytoplankton cell abundances. Bacterial community composition was analyzed by CARD-FISH along with phytoplankton composition. The frequencies of cells with DNA de novo synthesis were determined by thymidine analog 5-bromo-2-deoxyuridine (BrdU). Chlorophyll a and nutrients were also analyzed along with organic matter concentration. Chemical parameters revealed the ultraoligotrophic conditions of these sites. Chlorophyll a reached the highest concentration (0.2 mg m⁻³) in the mid-shelf station. In the off-shore site photosynthetic C-uptake accounted for 1.6-2.1 mmol C m-2 h-1 whereas bacterial C-uptake accounted for 0.03-0.08 mmol C

 $m^{-2} \ h^{-1}.$ PP and BP rates measured in this survey were comparable with those reported for the near E Mediterranean areas [5-6] for the ultra-oligotrophic Cyprus Eddy and for the oligotrophic Cretan Sea, respectively. The C-release due to community respiration accounted for 3.5-17.3 mmol C $m^{-2} \ h^{-1}$. The mid shelf site differed for a higher C-uptake (PP 2.7-6.5 and BP 0.10-0.15 mmol C $m^{-2} \ h^{-1}$) and a lower C-release (CR 2.0-2.8 mmol C $m^{-2} \ h^{-1}$). The heterotrophic nature of the off-shore site is described by the PP/CR ratio <1. These preliminary results define this area as a potential CO₂ source.

Abstract

We investigated the composition and spatial distribution of hydrocarbons found in Tunisian's marine environments. Although moderate, these hydrocarbon concentrations should ideally be reduced. Then, we investigated the characterization of bacterial diversity of polluted seawater. Molecular analysis of bacterial composition associated with hydrocarbon composition analysis provided evidence that microbial composition dynamics is related to changes in substrate composition, and there is a close relationship between the proliferation of specialized species and their function in the degradation of the different fractions of oil. *Keywords: Bacteria, Pollution, Coastal Management, Monitoring*

Introduction

Sea Coastal were being the receptor of diverse pollutants. Sea water, [1], [2] marine sediment [3] and interstitial water [2] were the subject of this pollution. In the Mediterranean sea, pollution is related to the increase of industrialized and newly industrialized countries. The mediterranean coast in Northern Tunisia is one of such industrialized and populated region [4], [5]. On the other hand, hydrocarbons are one of the most important pollutants that can persist for years [6]. Microbial degradation is the major natural route for cleaning up oil spills [6]. Characterizing microbial diversity and identifying microorganisms which play a key role in the degradation of pollutants could be useful in defining new strategies for bioremediation. The aim of this work is to better understand the present status of environmental pollution by petroleum derives on tunisian coast and to analyze the bacterial diversity during oil degradation in order to contribute to the understanding of the bioremediation technology in a marine environment.

Materials and Methods

Hydrocarbon analysis: Hydrocarbons were extracted using chloroform. The extract (TH) was fractionated into non aromatic hydrocarbon (NAH) and aromatic hydrocarbons (AH) by adsorption liquid chromatography using a column of silica-gel. The TH, NAH and AH were determinate and were analyzed with a gas chromatograph.

Molecular analysis: Direct extraction of total microbial DNA from polluted seawater samples, amplification of 16S rRNA genes, cloning, sequencing, chimera check and phylogenetic rRNA gene sequence analysis were performed. All sequences were imported in the ARB database and compared to the GenBank database using BLAST. They were aligned using the ARB program and then manually checked. A distance matrix was generated and used by the DOTUR computer program to define Operational Taxonomic Units (OTUs). A 97% sequence similarity cut-off was used to define an OTU).

Bioremedation essays : Biodegradation assays were carried out in seawater inoculated directly with fresh culture of an adapted microflora. The efficiency of biodegradation corresponding to each incubation period was calculated for the various fractions of TPH, NAH or AH at various incubation periods.

Results and discussion

1. Evaluation of hydrocarbon pollution

TH concentrations differed from one site to another. NAH and AH levels showed a variation among the collection sites, with an average of 66.22–211.82 μ g/g for NAH and 13.84–115.60 μ g/g for AH. NAH was predominant. GC traces show unimodal distribution of n-alkanes, equivalent distribution pattern of both odd carbon-numbered alkanes and even-carbon-numbered alkanes. All geochemical markers enable us to make the hypothesis of petroleum source contribution. Our results show that the TPH levels were relatively low compared to those of locations around the world reported to be chronically contaminated by oil.

2. Bacterial diversity of polluted seawater

AM microflora represent the natural bacterial population of seawater from a region adjacent to an oil refinery. A total of 94 clone sequences were obtained for the AM clone library. They show a percentage of sequence identity to the closest related sequences in the public databases ranging between 91% and 100%. The 16S rRNA gene sequences can be grouped into 22 OTUs, of which 16 OTUs are affiliated with cultivated microorganisms while a unique OTU is affiliated with a noncultivated microorganism with \geq 97% sequence identity. A total of 5 OTUs represent novel OTUs sharing less than 97% sequence identity. Detailed analyses of the AM clone library indicated that the abundant phylotypes are distributed within the Alpha-, Beta-, and

Gammaproteobacteria subclasses. The minor phylotypes are distributed within the Actinobacteria, the Firmicutes, and the Bacteroidetes groups. The existence of bacteria in petroleum-contaminated sites suggests that many species have evolved specifically in these environments and may be active in the metabolism of hydrocarbon.

3. Bioremediation efficiency of the adapted microflora

The amount of TPH and AH decreased after 3 days. NAH and AH biodegradation reached the highest value (92.6%; 68.7%) at the end of the incubation period. A slight decrease in NAH degradation was detected at day 21. Detailed chromatogram analysis showed visible degradation of n-alkanes ranging from n-C14 to n-C24 during the first week. Branched alkanes were degraded during W2. At the end of W3, the majority of n-alkanes were totally degraded. Community composition changes began during the first week (W1) and remained significant during the whole incubation period. At S3 and S4, we observed a major decrease in bacterial diversity, confirmed by diversity indexes. Bacterial diversity is gradually reduced during the biodegradation process. We found that in W1, W2 and W3. The 16S rRNA sequences are affiliated with the same microorganisms detected in the AM library, with variation in their proportions and the emergence of new species. We concluded that the AM consortium shows a high performance of degradation of both NAH and AH components.

Conclusion

Our findings indicate hydrocarbon contamination in region of study. The use of bacterial diversity analysis could be useful in defining new strategies for bioremediation. Finally, to further elucidate the role of these bacterial groups in hydrocarbon degradation, catabolic gene expression profiling may be necessary.

Abstract

Sea cucumber plays an important role in marine communities besides it's great economical importance to man. By 2000, production increased from 20 tones in 2000 to 2310 tones in 2002, and then dramatically decreased to 6 tons in 2006 [1]. The present study presents abundance, distribution size composition of Holothurians along Alexandria coast of Egypt. Samples were anaesthetized in MgCl₂ (2.5%) solution to overcome the error resulted from contraction and relaxation of body muscles[4]. *Keywords: Eastern Mediterranean, Biodiversity*

Introduction and Methods

Two species of holothurians *Holothuria arenicola* and *Bohadshia* orgus were recorded. The abundance was 98% and 2% for *H. arenicola* and *B.argus*, respectively. 2015 Samples were collected randomly using quadrate transect (20 m \times 10 m) from the selected sites along the Alexandria coast in eastern Mediterranean Sea during the period from January 2005 to July 2007 as in fig. 1. The distribution and abundance of Holothurian species were calculated by counting the number of each species per 200 m². Samples were assume the digital balance, then gently straightened and their lengths measured to 1 mm with a ruler. The total length (TL), total wet weight (Twt) was measured for each species.

Results and discussion

During the present study only two species of holothurians; *Holothuria arenicola* and *Bohadshia argus* were recorded. *H. arenicola* was the most abundant species along the Alexandria Coast of Egypt. The abundance percentage was 98% and 2% for *H. arenicola* and *B. argus*, respectively.

Fig. 1. Length Frequency distribution of male and female Holothuria arenicola

Length distribution of H. arenicola for males and females as presented in fig. (1). Regardless of male and female, the most frequent length was in range of 9.5 to 13.5 cm. By comparing the present results with that [3] decrease in frequent length in clearly observed as 11.0 - 15.7 in 1999 to 9.5 - 13.5 cm in 2007. This reflects the intensive fishing activity in the last years which supports the necessity of rapid management of H. arenicola fishery in Mediterranean Sea. It is found that smaller individuals observed in winter and autumn which may be attributed to the fact that the fishing activity in summer and spring is higher as well as the fishing selection during these seasons is lead to presence of small sized animals in autumn and winter. Further migration and hence greater habitat separation between juveniles and adults of some species may occur as holothurians mature [2]. The regression equations of length-weight relationship for male and female of H. arenicola were described in (Table 1). In the present study, regardless of sex and season, the slope was ranged between 0.8 - 1.3 that was significantly different from 3. This means that length does not grow at the same rate of the weight. [3] reported negative allometric relationship for H. arenicola. The higher regression coefficient in the present study reflectes the fitted length weight relationship. The present information confirmed that H. arenicola along the Alexandria coast of Mediterranean Sea is exposed to over

fishing during the last eight years as a result of drastic increase in demand for sea cucumber as bech-de-mer. The problem of over fishing can be overcome through firm and conservative management as well as aquaculture of this valuable resources.

Tab. 1. Regression equation of weight relationship of male and female Holothuria arenicola

Sex	Regression Equation	R ²	n
Male	W=7.4107 L ^{0.8473}	0.9484	103
Female	W=47.9351 L ^{0.8372}	0.8572	102

MEAN TROPHIC LEVEL ESTIMATION OF THE CATCH OF VARIOUS FISHING GEARS (N. AEGEAN)

Aggeliki Adamidou 1* and Argyris Kallianiotis 1

¹ Fisheries Research Institute, NAGREF, N. Peramos, 64007 Kavala (Greece) - adamidou@inale.gr

Abstract

The mean trophic level (mTL) for the fish catch of bottom trawlers, purse seiners and trammel nets that operate in the northern Aegean Sea was estimated and compared aiming to examine the possible impact of various gears on the marine ecosystem. The mTL of the catch was 3.89 (± 0.021 S.E) for the bottom trawls, 3.69 (± 0.035 S.E) for the trammel nets, and 3.33 (± 0.029 S.E) for the purse seines.

Keywords: Aegean Sea, Fisheries, Food Webs

Introduction

Trophic level (TL) is an ecological indicator widely accepted and used for quantification of the ecosystem effects of fishing and for the management of fisheries resources [1]. Fishing in the Thracian sea is carried out by bottom trawls, purse seines and small-scale fishing gears. The mean trophic level (mTL) of their catches can be used to quantify whether a fishing gear removes high or low trophic level organisms from the ecosystem and the extent each gear contributes to the fishing down of the marine food webs [1]. The aim of the present study was to estimate the mTL of the catches of the three most commonly used fishing gear (purse-seines, bottom trawls and trammel nets) in the northern Aegean Sea.

Materials and Methods

Data were collected by on board sampling during 2004 in the Thracian Sea (northern Aegean Sea). Thirty-six seasonal trials were performed by each gear with commercial vessels. Regarding trammel nets, 9 different mesh sizes were used (36, 42, 60, 64, 72, 76, 80, 84, 90 mm full mesh of inner panel). The mTL of the fish catches was estimated by gear, and weighted by the weight of each species participated in the catch. The mTL of the three gears was compared with ANOVA and the Fisher's LSD test was used to determine which means were significantly different from which others. The values of TL used were obtained from literature [2], [3].

Results and discussion.

The estimated mTL of the total catch was 3.89 (±0.021 S.E) for bottom trawls, 3.33 (± 0.029 S.E) for purse seines, and 3.69 (± 0.035 S.E) for trammel nets (Fig. 1). The comparison of the mTL per gear indicated that there was a statistically significant difference between the means of the 3 gears (ANOVA, F-Ratio:108.75, p<0.0000). The mTL of trammel nets ranged according to target species from 3.3 (for Mullus sp) to 3.9 (for large speciments of Sparidae). The above gears operate in different way and exploit different stocks or different parts of the same stock. Bottom trawls, fish a great variety of demersal and benthic mainly piscivorous species therefore, the mTL of their catches was the highest among the gears. Purse seines fish in the pelagic domain and catch pelagic, planktivorous species of small and medium size thus, the mTL of their catches was lower. Trammel nets exploit certain sizes and species of demersal and benthic fish. The mTL of their catches increased with the mesh size as a consequence of the positive relation between TL and body length [4]. Conclusively, it could be said that bottom trawls contribute more than the other two gears to "fishing down the marine food web". However, the removal of vast quantities of lower TL species, as it happens with purse seines catches, might lead to bottom up cascading effects that also affect negative the marine ecosystem.

Fig. 1. Box-whisker plots of mean trophic level (mTL) per gear

POPULATION STUDY OF THE FAN MUSSEL PINNA NOBILIS L., IN TWO AREAS OF SARDINIA (W-MEDITERRANEAN)

Piero Addis ^{1*}, Marco Secci ¹, Stefano Corrias ¹ and Andrea Manunza ¹ ¹ University of Cagliari - Dep. Animal Biology and Ecology - addisp@unica.it

Abstract

We investigate the population ecology and conservation status of the endangered Mediterranean bivalve *Pinna nobilis*. Spatial distribution, size structure, shell orientation and valve colonization by epibionts were the main descriptors investigated in two areas of Sardinia: S. Antioco island and the Gulf of Oristano (Sardinia, western Mediterranean). *Keywords: Bivalves, Endemism, Conservation, Tyrrhenian Se*

Introduction

The fan mussel, *Pinna nobilis* L., is an endemic Mediterranean species considered to be endangered, whose preservation is urged mainly through the Barcelona Convention and the Habitats Directive. There has been a knowledge-gap in the ecological status of the populations and also in the response to the enforcement of conservation measures, particularly in the insular areas as well as the north African countries [1]. The fan mussel has historically been harvested for different purposes: human consumption, shell collection and for the production of "sea silk" from byssus. In Sardinia (W Mediterranean) were known four main critical areas characterized by large fan mussel beds: the Gulf of Alghero (NW coast), the Gulf of Olbia (NE coast), S. Antioco island (SW coast) and the Gulf of Oristano (W coast). In order to assess the conservation status of this species an investigation started in 2008. Here we present the main results from two areas studied.

Material and Methods

Underwater visual counts of specimens (live and dead), size measurements (total height in cm), shell orientation $(0-360^{\circ})$ and epibiosis of valves (by digital pictures), were collected within a detailed sampling design. Data collected refers to 50 quadrats (10x10 m) randomly replicated and georeferenced. Density was expressed as the number of specimens/100 m². Valve orientation was analyzed by the Rayleigh test, while epibiontic data were analyzed using one-way Analysis of Similarities (ANOSIM) based on differences in the spatial scales.

Results

A total of 530 and 725 specimens of P. nobilis were counted and measured respectively in Gulf of Oristano and S. Antioco island. Specimen densities showed significant differences between the two areas analysed. Density of live + dead specimen varying from 4.42 (\pm 3.09 SD) to 20.33 (\pm 6.76 SD) specimens/100 m² in Gulf of Oristano; from 1.75 (\pm 1.22 SD) to 48.67 (\pm 21.42 SD) specimens/100 m² in S. Antioco island. Specifically we found that spatial distribution and shell orientation of specimens depends on local ecological features (Fig. 1-2).

Fig. 1. Rose diagram reporting shell orientation in the the Gulf of Oristano

Fig. 2. Rose diagram reporting shell orientation in S. Antioco island

Discussion

The high density values found in both areas to indicate the good health conditions of these populations; moreover values found are much higher than those estimated in other Mediterranean areas [2,3]. *P. nobilis* populations are particularly vulnerable to anthropogenic impacts such as structural changes of seagrass meadows, mechanical impacts due to dredging, anchoring, trawling and entanglement nets and we argue the fact that the protection of populations should match with the protection of the habitat.

TEMPORAL VARIATION OF HYDROCHEMICAL PARAMETERS IN THE TRABZONCOAST (SOUTHEASTERN BLACKSEA) DURING THE SPRING OF 2009

Ertugrul Agirbas ¹*, Ali Muzaffer Feyzioglu ² and Ulgen Kopuz ¹ ¹ Karadeniz Technical University Faculty of Marine Sci. 61530 Çamburnu Trabzon TURKEY ² Rize University, Faculty of Fisheries,53100 Rize/TURKEY - eagirbas@gmail.com

Abstract

The study was conducted between March and May 2009 at one station in the Trabzon Coast (Southeastern Black Sea). Physical parameters were obtained by Idronaut Ocean Seven 316 CTD probe. Nutrients were measured by spectrophotometric methods (Parsons et al.1984). Chl-a analysis were carried out by HPLC technique. During the sampling period, Oxygen minimum layer was observed between at 160-170 meter depth. The seasonal thermocline was observed above 55 m in May 2009. PAR depths were observed min at 22 m and the max at 30 m in May and March respectively. Among the sampling period, the minimum nitrite, ammonium and silicate concentrations were observed in May 2009. Because of no nutrient limitation, among the environmental parameter studied, the light intensity is more important for phytoplankton spring bloom at the coastal area. *Keywords: Black Sea, Nutrients*

Introduction

The Black Sea is a unique marine environment representing the largest landlocked/semi-enclosed and deep anoxic basin in the world. The coastal waters of the Black Sea are principally fed by the river input and by the lateral/ vertical nutrient transport mechanisms (1). In the spring period; the coastal area is characterized by homogeneity of the water column in respect of temperature, salinity and nutrients. Dissolved Oxygen (DO) gradually decreases with depth. The coastal marine eutrophication is significant which is characterized by higher nutrient content with compare to the surface water of the offshore areas. The aim of this study was to evaluate hydrochemical parameters of region, reveal hydrographic status and response of the phytoplankton biomass to environmental factors during the spring 2009, mixing period.

Material and Methods

The sampling was performed between in March-May 2009 at one station in the Trabzon Coast (Southeastern Black Sea). Water samples were taken from the surface to 60 m, 5 meter interval using 5 liter Niskin bottles mounted on a SEB 32 Carousel Rosette sampler. Hydrographic data were collected by using Idronaut Ocean Seven 316 CTD probe. Nutrients (nitrite, nitrate, ammonia and silicate) were measured by Shimadzu UV 1800 spectrophotometer (2). PAR was measured by Li-193 SA Spherical Quantum Sensor and Li-190 SAT Quantum terrestrial sensor. Chl-a analysis were carried out by using Shimadzu LC-20 AT/ Prominence HPLC (3).

Result and Discussion

The vertical distribution of temperature, salinity, dissolved oxygen and pH profiles were given in figure 1.

DO was obtained as 9,96 mgL⁻¹, 10,72 mgL⁻¹ 10,62 mgL⁻¹ in March, April and May respectively at the surface water of sampling station. During the sampling period,Oxygen minimum layer was observed between at 160-170 meter depths. pH showed similar profile for March, April and May during the sampling period. Although the stagnation was present in March and the April 2009, the seasonal thermocline was observed above 55 m in May 2009. PAR depths were observed min at 22 m and the max at 30 m in May and March respectively (figure 2). Throughout spring 2009, the maximum concentrations of nitrate, nitrite, ammonium and silicate were not higher than 0,29 μ M, 38,48 μ M, 3,06 μ M and 0,58 μ M respectively in the whole sampling depth. Among the sampling period, the minimum nitrite, ammonium and silicate concentrations were observed in May 2009. Although the chlorophyll-a, which can be used as indicator of phytoplankton biomass, was to be expected to have high values at surface water in May , the maximum value was found as a 6,41 μ gL⁻¹ at 15 m in March 2009 (figure 2).

Fig. 2. Chl-a concentrations (A) and PAR values (B)

Because of no nutrient limitation, among the environmental parameter studied, the light intensity is more important for phytoplankton spring bloom at the coastal area. When not only the nutrient but also the chlorophyll-a concentrations were considered, it seem that the coastal water of Trabzon was eutrophic in spring 2009.

PARTITIONING OF THE NORTHERN TUNISIAN COASTS INTO HOTSPOTS OF CETACEAN DISTRIBUTIONS

Mehdi Aïssi ¹* and Mohamed néjib Daly yahia ¹ ¹ Faculty of Sciences of Bizerte - mehdi.bfsa@yahoo.fr

Abstract

For two years 2008 and 2009, indications about cetacean sightings' aggregations were supplied by fishing boats. Based on weekly questionnaires to fishermen the most frequently encountered species were the bottlenose dolphins *Tursiops truncatus* representing 77.8% of all sightings and the common dolphin *Delphinus delphis* (22.2 %). Sightings positions were distributed over a grid of 5' longitude and 5' latitude to localize the "hotspots".

Keywords: Cetacea, Distribution Coefficient, Mapping

Introduction

Despite of the occurrence in Tunisian waters of all cetacean species known to be regular in the Mediterranean basin except Cuvier's beaked whales [1], [2], [3], [4], the information about their distribution is very scarce due to a lack of continuous studies [5]. This work was carried out by gathering data collected over two years 2008 and 2009 to reveal preliminary indications of cetacean distribution areas in northern Tunisian coasts.

Material and Methods

We estimated the aggregation of cetacean observations in some selective fisheries area from reports received from fisheries boats (2008 and 2009). This area encompasses the coastal and offshore waters of the northern Tunisian coast extending from the coastline to 38° N and from 009° E to 010° 30' E. Data were collected by means of questionnaires including specific questions about fishing area and cetacean sightings. 20 fishing boats were considered in this study according to two main variables: educational profile of fishermen and experience level in identifying cetacean species. Sighting is defined in this study as a visual detection of a group of cetaceans recorded at least by two different fishing boats. Sightings were distributed on the grid of the studied area with a cell size of 5' x 5', reaching 190 cells. Hotspots are cells where the species occurred more than three times during the same season.

Results and Discussion

For instance, 54 cetacean sightings were admitted and more than 20 were excluded due to incertitude. All observers reported sightings of small cetaceans principally bottlenose dolphins reaching the 77.8% and occasionally the common dolphins (22.2%). From the total of cells where fishing boats set sail, we identified 17 hotspots. Common dolphin sightings occupied only 4 hotspots confined to deep water in the northeastern part of the study zone, however bottlenose dolphin occupied 13 hotspots in coastal and offshore areas (Figure 1). Coastal cells were classified as a school ground for juvenile bottlenose dolphin to learn hunting techniques during autumn season [4].

This study highlights the ecological importance of particular zones off the northern Tunisian coasts that should be monitored.

Fig. 1. Distribution of hotspots for common dolphins (in dark grey) and bottlenose dolphins (in light grey) in the northern Tunisian coasts estimated from fisheries boats during 2008 and 2009, with isobaths each 100 m

MORPHOLOGICAL AND ECOLOGICAL CHARACTERISTICS OF MALVUFUNDUS REGULUS FORSKALL, 1775 FOUND IN ANTALYA BAY, TURKEY

Deniz Aksit 1*, Beria Falakali mutaf 1 and Emine sükran Okudan 1

¹ Akdeniz University Faculty of Aquatic Sciences and Fisheries - denizaksit@akdeniz.edu.tr

Abstract

Malvufundus regulus, an alien species in the Mediterranean Sea has been examined morphologically and ecologically in connection with submarine caves in Antalya Bay.

Keywords: Western Mediterranean, Mollusca, Bivalves

Introduction

Levantine Sea where the fauna has always been shown to get influenced by the lessepsian migration through the Suez Canal [1,2,3]. The Bay of Antalya is always exposed to that migration pressure. Many bivalve species belonging to the Indo-Pacific fauna were already recorded in Turkish waters. A member of Malleidae, *Malvufundus regulus* Forskall, 1775 is one of those remarkable lessepsian species, has been already extended to the Greek waters [2,5]. This work is to be informative about this alien species for better understanding its adaptation to a new ecosystem.

Material and Methods

Specimens were collected near the cave entrances at the depths of 1-5m by Scuba diving along the rocky cliffs of the Antalya Bay at $36^{0}53'02''N-30^{0}40'$ 47''E and $36^{0}53'$ 05''N- $30^{0}41'54''E$. Samples of *Malvufundus regulus* were taken to the laboratory for further investigation.

Results

Members of *Malvufundus regulus* were found as attached on rocks among other cemented bivalves such as *Spondylus spinosus*, and *Pinctada radiata* while a measurement of faunal abundance of the caves in the littoral zone of Antalya Bay. Solitary *M. regulus* seemed to prefer shaded rocks or their crevices but not on bare substrates and was observed in close association with the vegetal cover of the rocks (Fig.1).

Fig. 1. Malvufundus regulus

The rocky littoral zone of Antalya is found mostly covered by coralligen formations, constituted by several species of rodophyta, heterokontophyta and chlorophyta in numbers of 23, 9 and 8, respectively. Living forms of M. regulus were in upright position and adhere themselves to hard surfaces by a small but strong bundle of byssus threads. Shell has thin, translucent valves generally elongated posteroventrally, and shows a striking contrast in its shell form. Right valve is moderately convex, while the left is nearly flat or a little concave. A posterior tooth extends along the posterior part of the dorsal margin. The shell thickness differed that the dissoconch part was much harder and softened towards the posterior end gradually. Colour is found variable, some were dark purplish throughout, but yellow is also frequent. A pattern was seen to give a butterfly wing appearance at the posterior margin (Fig. 2a). The nacreous layer is very thin and restricted to the dissoconch. Valves held shut by one large adductor muscle. The body is laterally compressed. Soft tissues were mainly the mantle (M), adductor muscle (A), body (B) and the ctenidia (C). The foot (F) appeared a very degenerative. Body organization could not be determined as it was almost flattened in shape. Byssus is produced from the center just above the ctenidia and extended out by the hinge. The gills were the most prominent structure (Fig.2b).

Fig. 2. A-b

Discussion

Submarine caves are semi-closed systems within the marine ecosystem [6] . Many marine invertebrate groups use cryptic habitats for settlement. Malvufundus regulus is such one that was frequent in the study area. The species is also described to inhabit in deeper waters [4].M. regulus is found singly. It is not a burrowing species as burrowers are usually lost their byssal aparatus [7]. The organism seemed to burrow slightly at its post-larval stage and then a permanent attachment is provided by byssus. The soft parts were confined in a much smaller and narrower chamber. But after settlement, the shell stated to grow only posteroventrally to an elongated valve which is to facilitate the posterior end in free communication with the water above [7]. The shell strength of the specimens differed along the shell as thickness is gradually reduced, is reckoned that shellstrength is directly correlated withshell thickness. The opportunity to examine the ecological and morphological status of such alien species helps for better comprehension of their connection between ecosystem and biodiversity changes in the Levantine Sea. The species become a strong competitor for space and food to persist under the fixed condition in the settling site. Surrounding vegetation seems an important biological factor as well as the physicals of light and wave exposure. It is assumed that a hydrodynamism is generated as a consequence of seaweed plasticity which helps to determine the sustainability of this alien species. Due to water currents the food particles become available for this filter feeding organism. Oxygen profile of the water is backed up by the existing seaweeds because oxygen consumption is closely related to production. Further studies will be needed focusing particularly the population dynamics of this organism relative to seasonal biological and physical conditions within the area.

HOTSPOTS OF INTRODUCTION OF MARINE ALIEN SPECIES IN ITALIAN SEAS

S.I.B.M. Allochthonous Species Group ¹ and Anna Occhipinti-Ambrogi (Coordinator) ²* ¹ DET - Dipartimento di Ecologia del Territorio, Sezione di Ecologia, University of Pavia - occhipin@unipv.it ² Italian Society of Marine Biology (SIBM), Piazzale Mascagni 1, 57127 Livorno (Italy)

Abstract

A group of Italian marine biologists, covering most taxa, has been volunteering for collecting data on the distribution of alien species for several years. Starting from mid twentieth century, the lagoon of Venice and the Mar Piccolo di Taranto have resulted as the main hotspots of introduction, with 40 and 24 alien species, respectively. High numbers of introduced species are related to the presence of ports, marinas, aquaculture facilities, and of disturbed environmental conditions. The intensity of observations during scientific research programs may have added a bias in the evaluation of hotspots.

Keywords: Alien species, Species Introduction

Methods

Distribution of alien species has been assessed for the whole Italian coast, gathering literature records for the following taxa: Macrophyta, Porifera, Ctenophora, Cnidaria, Annelida, Mollusca, Crustacea, Picnogonida, Bryozoa, Tunicata and Vertebrata. Only species of "recent" introduction (after 1945) have been taken into account. The data have been checked by experienced taxonomists of the group, and compared to recent findings in the Mediterranean at large [1]. The number of total records has been calculated for the most representative locations, in order to identify sites where the introduction of alien species is more likely to occur along the Italian coast.

Fig. 1. Hotspots of introduction of alien species

Results & Discussion

Fig. 1 shows the main hotspots of introduction along the Italian coasts. Circle diameter is proportional to the number of introduced aliens. Three main hotspots can be clearly identified: the Lagoon of Venice, Taranto and Sicily. Fig. 2 shows the distribution of main ports, aquaculture sites and research institutions where SIBM members operate. It is obvious that in many cases there is a correlation between such factors, explaining the high numbers of recorded aliens. For example, 10-15 species have been recorded in each of the three sites with important commercial, military and recreational ports (Genoa, Naples, Otranto), having also been studied by experienced teams of marine biologists.

Lagoon of Venice (N-Adriatic Sea) - Venice is the main hotspot of introduction in Italy, and probably one of the most important in the whole Mediterranean: 40 alien species have been recorded here since 1945. In the Venice lagoon there is a unique combination of factors that have favoured such a massive introduction of non-native organisms. Venice hosts commercial and tourist ports, recreational marinas, aquaculture facilities. It has experienced rapid environmental changes over the past decades, with detrimental effects on the native biota, which has easily been replaced by invaders brought by shipping and aquaculture [2]. Furthermore, in Venice there is an uncommon concentration of research institutions displaying taxonomic expertise in most taxa and constantly monitoring its fragile ecosystem and its biota.

Taranto (N-Ionian Sea) - The Gulf of Taranto, containing the coastal lagoon "Mar Piccolo" and the second most important commercial port in Italy, is another hotspot, where 24 species of alien species have been introduced. As for the Lagoon of Venice, the factors that favour introductions are: shipping, aquaculture activity, degraded environment; an active research group based in Taranto [3] has performed routine surveys in the area.

Sicily (S-E Tyrrhenian and Straits of Sicily) - In the main island of the Mediterranean Sea, Sicily, also including smaller islands, the number of alien species has been increasing throughout the investigation period. While aquaculture industry is less developed there than in other parts of Italy, the geographic location might be viewed as the main determinant for the spotting of a large number of alien species: 11 in Catania, 13 in the S-Thyrrenian (Aeolian islands and Ustica), and 18 in the Straits of Sicily (Pantelleria and Pelagian islands). Located at the crossroads between the Eastern and Western sectors of the Mediterranean, Sicily is interested by an intense maritime traffic including fisheries and recreational fleets made of relatively small vessels. It also presents climatic conditions favouring the establishment of species until recently restricted in the Levantine waters. The presence of many marine biology centres based in Sicily is an obvious counterpart.

Fig. 2. Distribution of main ports, aquaculture sites and research institutions where SIBM members operate

Conclusions

A total of 163 alien species introduced has been recorded in Italian waters (Occhipinti-Ambrogi et al., in preparation), following a trend common for the whole Mediterranean Sea [1]. Some localities have yielded a very high number of species, and can be considered hotspots for present and future bioinvasions. Intense ship traffic in large ports and non voluntary transport of species connected with aquaculture activities are common in the three main hotspots examined, but the high number of species identified is also a consequence of the concentrated marine biological monitoring effort by expert teams.

ANCHOVY AND SARDINE JUVENILE GROWTH DETERMINED USING THE SARDONE PROTOCOL: THE CASE OF THE GULF OF LIONS

Itziar Alvarez^{1*}, Juan pablo Beltran², Beatriz morales- Nin¹ and Isabel Palomera²

¹ IMEDEA (CSIC) - itziar.alvarez@uib.es ² ICM (CSIC)

Abstract

This contribution is a first attempt for sardina (Sardina pilchardus) and anchovy (Engraulis encrasicolus) juveniles growth analysis in the Gulf of Lions. A first conclusion is that growth rates and increment widths are different depending on their hatching dates. Both clupeoid species growth is faster and higher when their hatch dates are closer to the warmer conditions, which is at the end of the spawning season for sardine and at the peak spawning for anchovy. In this period, environmental factors, such as SST, are more favorable for the early life stages growth.

Keywords: Growth, Life Cycles, Recruitment, Larvae

Introduction

In larval and early juvenile stages of fish, information on age structure can be used to clarify the effects of changes in the environment on growth and survival, and can result in an improved understanding of factors affecting recruitment success [1]. Rearing experiments under different environmental conditions provide valuable data on larvae growth but there is a limitation in rearing older individuals [1, 2, 3]. Long term series of data or different areas shall be used to determine the possible differences in growth determined by different environmental conditions in the wild. Sardone Project is aimed at developing a series of tools to better understand stock assessment and fishery management of small pelagic fish resources (anchovy and sardine) of the Mediterranean. The three major stocks and fisheries: the NW Mediterranean, the Adriatic and the Aegean have been chosen and a unique reading protocol and several calibration exercises were performed in order to minimize differences in interpretation between readers. All the differences in growth between the three areas will then be understood as induced by different environmental conditions. In this study we present the Gulf of Lions results, ready to compare with the other areas.

Material and Methods

Sardine and Anchovy juveniles from the different Sardone surveys were used to determine growth parameters. Sardine juveniles were caught at early August 2007, while anchovy juveniles were caught at early December 2007. Otolith preparation and interpretation were based on the protocols prepared by IMEDEA and AZTI for the SARDONE project [4]. The individual hatch date was calculated by subtracting its age (number of increments) from sampling date. According to [1] and [2], increment formation on anchovy and sardine otoliths starts from the hatching ring and the deposition is daily thereafter. The period in which all fish from each sampling period had hatched was divided into sub-periods and the evolution of increment widths was examined separately for each subperiod (subgroup).

Results and Discussion

a) Somatic growth

A total of 49 Sardine juvenile were analyzed, with TL ranging 65-97mm, the age interpreted range was between 101 and 120 days and the average growth rate was 1.01 mm day⁻¹. Based on the hatch dates, 3 groups were made and the evolution of increment widths was examined separately for each subgroup (Fig. 1). The three groups followed the same growth pattern but with differences in the slopes (JuvSp3 increments widths grew faster than JuvSp2 and JuvSp1), and differences in the maximum width reached.

Fig. 1. Increment width (5-point running mean) by age (number of increments) for the different hatch-date grouped Sardine and Anchovy iuveniles

ranged 48-95 mm, the age interpreted ranged between 42 and 101 days and the average growth rate 0.851 mm day⁻¹. Juveniles were grouped depending on their hatch date. The three groups had different growth rates, different maximum increment widths, and different period in life were the growth slows down (day 30, 45 and 60, figure 1)

b) Environmental implications in growth

For the sardine groups, as later they hatched in the season (Fig. 2), higher were their growth rates and higher the maximum increment width reached. The opposite occurs to the anchovy groups, where the higher growth rates and maximum increment widths reached belonged to the individuals hatched in September (JuvEe1). Around late November, the three groups growth patterns were synchronized.

Fig. 2. Increment width (5-point running mean) for the hatch-date grouped S. pilchardus and E. encrasicholus juveniles

Environmental factors, such as sea surface temperature, which is higher in the central part of the year, might be responsible for those intra-area differences in growth. Growth plasticity in early life stages for both species depending on hatch date might also be present depending on the geographical area considered. Further comparisons between individuals hatched in different areas (different environments) will allow to identify key environmental factors affecting early life stages growth and will also allow to establish new growth patterns related to changes in those key factors.

Abstract

The purpose of this work was to study the dynamics of two *Paracartia* species in two ponds in the Sfax saltern: A1 (salinity: 50.44 ± 7.12) and A16 (71.51 ± 13.46).*Paracartia latisetosa* and *P. grani* showed different population dynamics at the two different sites, but the influence of salinity could be ignored. *Keywords: Salinity, Brackish Water*

Introduction

Paracartia latisetosa and *P. grani* are present in Sfax saltern. P. latisetosa is a seasonally dominant copepod species in northern Tunisian coastal waters [1]. P. grani is typical of highly turbid semi-enclosed systems in which food is often unavailable [2]. The aim of this work was to compare dynamics of this two species in two ponds of different salinity.

Material and methods

The Sfax solar saltern is located in the central-eastern coast of Sfax (Tunisia, 34° 390 0.100 N and 10° 420 3500 E). It is a confined ecosystem (sensu [3]) with evaporation exceeding water import. Sampling was carried out monthly from September 2007 to August 2008 in ponds A1 and A16. The zooplankton was collected by filtering 50l of water through 50 µm-mesh net, then transferred to a sterile 125 ml flask, and fixed with formaldehyde (5% final concentration) for further quantitative and qualitative analyses.

Results and discussions

The two ponds differed in the salt concentration. Salinity varied from 41.80 to 62.20 ‰ at A1 (average, 50.44 ± 7.12 ‰) and from 50.20 to 98.00‰ at A16 (average 71.51 ± 13.46‰). Temperatures were not greatly different in both ponds. They ranged from 11.50 to 29.00° C at A1 (average, 20.71±5.57° C) and from 12.50 to 30.00° C at A16 (average, 20.91±5.86° C).

The population density of *P. latisetosa* was higher in A16, whilst the population density of *P. grani* was higher in A1 (table. 1).

Tab. 1. Average annual abundances of *P. latisetosa* and *P. grani* (adult specimens) in two ponds (A1 and A16) of Sfax salt works

	A1	A16
P. latisetosa (× 103ind. m-3)	1.232	2.161
P. grani (× 10 ³ ind. m ⁻³)	5.135	2.915

At pond A1 total copepods abundance positively correlated with Salinity (r = 0,840), and negatively correlated with temperature (r = -0,610). At pond A16, total copepod and single species abundances did not correlate significantly with Salinity. Monthly abundance fluctuations of both species were different in both ponds (Fig. 1). *P. grani* was absent for 7 months in A16, and only 1 month in A1. *P. latisetosa* was absent for 6 and 4 months in A1 and A16 respectively.

Acartiidae are typical resting egg producers in confined areas [4]. P. latisetosa is well-known for the production of diapause eggs which allow it to overwinter [5], but the species was absent from the water column of both basins also from April to June 2008. Also P. grani is known to produce resting eggs [6]. Hence the intermittent population of these species is affected by the hatch of eggs, rather than by the development rate of juveniles under different salinity conditions. Paracartia grani drastically diminishes its abundance from A1 to A16. Notwithstanding, both ponds saw a demographic prevalence of that species. In A16, in fact, P. grani is only slightly more numerous than P. latisetosa which here shows an opposite trend, being more abundant than in A1. P. latisetosa, whose demographic growth seems to be directly correlated with Salinity in the two salt works studied, is also a typically brackish water species. Apart from features which interact in affecting the species reciprocal affirmation in such extreme environments, it emerges clearly that salinity could not be considered as the driving condition in assessing the Paracartia populations in confined environments.

Fig. 1. Monthly variations of *Paracartia latisetosa* and *Paracartia grani* in Sfax salt works

BIODIVERSITE DES DIGENES PARASITES DE QUELQUES SPARIDES PROVENANT DE LA LAGUNE DE BIZERTE

Rym Antar¹, Tahani Chargui², Najoua Trigui El Menif² and Lamia Gargouri Ben Abdallah^{1*}

¹ Unité de Biologie, d'écologie et de parasitologie des organismes aquatiques, Faculté des Sciences de Tunis, Manar II, 2082, Tunisie lamiagargouri@yahoo.com

² Laboratoire de Biosurveillance et de l'Environnement, Faculté des sciences de Bizerte, 7021 Zarzouna, Tunisie

Abstract

L'examen de 69 individus appartenant à 4 espèces de poissons sparidés provenant de la lagune de Bizerte, a permis de recenser 8 espèces de parasites (*A. stossichi, B. israelensis, H. pycnoporus, L. album, L. pegorchis, M. monorchis, R. fractum* et *S. pagelli*). La richesse spécifique de ces sparidés est faible. La comparaison de la faune digénétique des sparidés lagunaires avec celle des poissons marins montre une diversité et une fréquence plus faible dans le premier biotope. *Keywords: Biodiversity, Fishes, Lagoons, Parasitism*

Introduction

En Méditerranée, les travaux de recherche sur les digènes ont surtout concerné les poissons téléostéens marins [1-6] le milieu lagunaire a été peu étudié. Le manque de données sur la faune digénétique lagunaire nous a incité à entreprendre l'étude des trématodes de quelques sparidés provenant de la lagune de Bizerte et d'effecteur une analyse comparative avec les données disponibles concernant le golfe de Tunis.

Matériel et méthodes

Les poissons examinés (*Boops boops, Pagellus erythrinus, Pagrus pagrus, Spondilyosoma cantharus*), provenant de la lagune de Bizerte, située au nordest de la Tunisie, représentent un effectif total de 69 spécimens. Le poids et la taille de chaque individu ainsi que la date sont notés sur une fiche topographique parasitaire. L'animal est, ensuite, incisé médio-ventralement à partir de l'anus. Le tube digestif prélevé est déroulé et divisé en différentes parties (œsophage, estomac, caecums pyloriques, intestin antérieur, intestin moyen, intestin postérieur et rectum). Chaque partie est placée dans une boîte de Pétri contenant une solution physiologique, puis disséquée et examinée.

Les mésoparasites prélevés sont déterminés, dénombrés et leurs localisations notées. Ils sont, par la suite, soit directement étudiés *in vivo* au microscope, soit préparés pour une étude ultérieure *in toto*. La nomenclature appliquée pour la détermination des valeurs épidémiologiques est celle utilisée habituellement [7-8].

Résultats et discussion

L'examen du tube digestif des poissons récoltés nous a permis de recenser 8 espèces de trématodes appartenant à 6 familles distinctes : Faustulidae (*Bacciger israelensis*), Fellodistomidae (*Steringotrema pagelli*), Gyliauchenidae (*Robphildollfusium fractum*), Hemiuridae (*Aphanurus stossichi*), Monorchiidae (*Monorchis monorchis*) et Lepocreadiidae (*Holorchis pycnoporus, Lepocreadium album, Lepocreadium pegorchis*). L'étude de la distribution de ces parasites au sein du tube digestif des différents hôtes montre que *B. israelensis* et *R. fractum* se limitent

respectivement à l'intestin moyen et l'intestin antérieur, d'autres espèces (A. *Stossichi, H. pycnoporus, L. album, M. monorchis* et *S. pagelli*) ne semblent pas montrer de préférence biotique et sont donc présents dans différentes parties de l'intestin. L'examen de la répartition des espèces parasites qui fréquentent divers sparidés montre que *L. pegorchis* n'occupe pas le même microbiotope chez les deux espèces d'hôtes ; en effet, ce parasite colonise les caecums pyloriques chez *B. boops* et l'intestin moyen chez *P. erythrinus. L. album*, qui se limite à l'intestin antérieur chez *P. pagrus*, semble étendre son aire de répartition aux caecums pyloriques chez *S. cantharus* Ceci est sans doute en relation avec le polymorphisme du tube digestif des hôtes et leur résistance différentielle aux parasites [9].

Concernant la richesse spécifique de ces sparidés, la plus importante est enregistrée chez *B* .boops (4 espèces). *A. Stossichi* semble être le parasite dominant chez ce poisson. *S. cantharus* héberge 3 espèces de digènes. La parasitofaune de ce sparidé est dominée par *S. pagelli* et à moindre degré par *L. album.* La diversité de la faune digénétique de *P. pagrus* et *P. erythrinus* est faible ; elle ne dépasse pas, respectivement, 1 et 2 espèces.

L'examen de l'ensemble des parasites présents dans un individu hôte a révélé que la majorité des espèces hôtes loge une seule espèce de parasite et rarement deux ou trois espèces ; les infracommunautés sont donc pauvres.

La comparaison de la faune digénétique des poissons lagunaires avec celle des poissons marins [10] montre une diversité et une fréquence généralement plus faible dans la lagune de Bizerte. Ceci peut être en relation avec une faible fréquence des hôtes intermédiaires dans le biotope, à une action néfaste de la

pollution sur les hôtes intermédiaires et les stades libres de parasites ainsi qu'à un faible effectif de l'échantillonnage. Par ailleurs, nous signalons trois nouveaux hôtes dans la lagune de Bizerte, deux (*B. boops, P. erythrinus*) pour *L. pegorchis* et un (*P. pagrus*) pour *L. album*.

ANALYSIS OF SIGHTINGS OF MONK SEAL (MONACHUS MONACHUS, HERMANN1779) IN THE **CROATIAN PART OF THE ADRIATIC 2006-2009**

J. Antolovic^{1*}, N. Antolovic¹, M. Antolovic¹, E. Coppola¹, G. Pecchiar¹, M. Piccoli¹ and M. Hervat¹

¹ The Mediterranean Monk Seal Group, The Association for Reasearch and Protection of Nature, Krešimirov trg 15, 10000 Zagreb,

Croatia - jasna.antolovic@zg.t-com.hr

Abstract

The monk seal (Monachus monachus, Hermann 1779) belongs to the order Pinnipeds (Pinnipedia), family seal (Phocidae), sae monk genus (Monachus). The total population amounts to about 350 individuals in smaller, isolated and endangered groups. The aim, during a four-year systematic research (2006-2009) the data on the sightings of monk seal in the Croatian part of the Adriatic Sea have been collected. The results, the sightings were reported in the area (79 sights). According to the systematic research of the habitat (21 caves) of the open-sea islands and the Adriatic coast and their recordings, it has been determined that a monk seal stays in them.Conclusion,For the survival of the species it is essential to protect areas of open-sea islands in the Adriatic and to place infrared cameras inside the caves thus giving us the insight of their use. Keywords: Adriatic Sea, Islands

Introduction

The monk seal (Monachus monachus, Hermann 1779) belongs to pinnipeds (Pinnipedia), of family seal (Phocidae), sea monk genus (Monachus). It lives in small groups at the Mediterranean and Adriatic [1]. It uses caves which have a sunny beach or stone plaques as habitats [3]. In the Atlantic it leaves along the West Sahara coast, Mauritania and Morocco. They stay in the litter area. Due to its sensitivity, rarity and critical status it belongs to ten most endangered mammals of the world. [2]. Once, the number of the individuals in the Adriatic was 64 and today this number has drastically decreased[5]. It feeds on molluscs, cephalopods and fish. The population of the species is decreasing. The exact cause is not known. It is presumed that it is caused by killing of sexually mature individuals and decreased reproduction activity and mortality due to viral disease. The biology of the species is still quite unknown [4].

Material and Methods

The aim of a four year (2006 - 2009) systematic research is gathering data on sights of the monk seal in the Croatian part of the Adriatic and to research new caves/habitats of the species. The interest group - fishermen are given a questionnaire/postcard during a terrain visit of the researched area at the Adriatic. The gathered data on the sights of the individual and their analyses will enable new ideas on the behaviour of the individual during meeting and time of keeping back/observation.

Results

The four year systematic research of the habitat (21 caves) of open-sea islands and the Adriatic coast and their recording, it has been determined that a monk seal stays in them. The monk seal is present in the Adriatic Sea. The sights were reported in the area of the whole Croatian part of the Adriatic (79 sights, picture 1). The photoidentification method of video records and photographs of the monks seals was used. Based on these results it is presumed that several various individuals have been living in this area of the Adriatic (a male, a female and a young of the animal) and individuals for which a gender could not have been determined by photoidentification.

Fig. 1. Sightings of the Monk Seal (Monachus monacshus) in the Croatian part of the Adriatic 2006 - 2009

Discussion

The public became interested in reporting their sights of the species by educational methods/lectures, distributions of questionnaires on the sights of monk seals. Simultaneous sights in various areas indicated that a smaller population of the monk seal lives in the Adriatic in two colonies of 5-7 individuals. Material evidence is video records and photographs of individuals taken in caves or near them, in various areas of the Croatian part of the Adriatic. Survival of the species can be obtained by establishing specially protected areas of open sea islands of the Adriatic and placing infrared cameras inside caves which would give us the insight into their use.

BIODIVERSITY OF ZOOBENTHOS ASSOCIATED WITH A *CLADOCORA CAESPITOSA* BANK IN THE NORTH AEGEAN SEA

Chryssanthi Antoniadou¹* and Chariton Chintiroglou¹

¹ Aristotle University, School of Biology, department of zoology, Thessaloniki, 54124, Greece - antonch@bio.auth.gr

Abstract

Biodiversity of zoobenthos associated with a *Cladocora caespitosa* bank was assessed in the north Aegean Sea, during summer 1998. Overall, 31 megabenthic and 54 macrobenthic species were recorded, 58 of which are reported for the first time to live in association with *C. caespitosa*; thus, the biodiversity of *C. caespitosa* assemblages is increasing to 286 species. 12 species dominated in frequency and abundance and the estimated diversity indices gained high values. These results indicate that the associated assemblages are probably differently structured among individual colonies and banks. *Keywords: Aegean Sea, Biodiversity, Rocky Shores, Zoobenthos*

Introduction

Cladocora caespitosa (Linnaeus, 1767) is a colonial zooxanthellate Scleractinian, occurring throughout the Mediterranean [1]. The species usually forms subspherical colonies of small size [2]. Occasionally and mostly to the SE Mediterranean, these formations can be of very large size, described under the term banks [3]. Such biogenic structures, recently considered as ecosystem engineers, have been intensively studied [2, 3] but very few data exists about the structure of the associated benthic assemblages [4]. Accordingly, the aim of the present work is to contribute to the study of the fauna associated with a *C. caespitosa* bank, by providing information about species richness and distribution.

Materials and Methods

The study was conducted at the north Aegean Sea (Figure 1), where a large bank (3m high and 5 m long) has been described at 20m depth. Sampling was carried out in summer 2008 by SCUBA diving and involved: (1) the assessment of megabenthic diversity using visual census along transects, (2) the assessment of abundance of the most conspicuous, epibenthic, sessile animal species, applying the method of randomly placed frames, and (3) the collection of quantitative macrobenthic samples, by totally scraping of the substrata using a quadrate sampler (5 replicates 400 cm², each). The collected material was sorted, identified at species level and counted. Common biocoenotic methods were employed to analyze data.

Fig. 1. Map of the study area where C. caespitosa bank is located

Results and Discussion

Thirty-one megabenthic animal species were recorded, 3 of which have been previously reported from *C. caespitosa* colonies [4]. The most conspicuous and abundant of these species were *Agelas oroides* (22 individuals m⁻²), *Axinella cannabina* (5 individuals m⁻²), *A. verrucosa* (2 individuals m⁻²), *Chondrosia reniformis* (5 individuals m⁻²), *Diplastrella bistellata* (19 individuals m⁻²), *Petrosia ficiformis* (11 individuals m⁻²), *Ircinia variabilis* (9 individuals m⁻²) and *Halocynthia papillosa* (1 individuals m⁻²). All these species are very common at sublitoral cliffs in the Aegean Sea [5]. Fifty-four macrobenthic animal species were recorded, 24 of which have been previously reported to live in association

with *C. caespitosa* colonies [4]. Polychaeta was the most speciose and abundant group, followed by Gastropoda and Peracarida (Figure 2).

Fig. 2. Taxa contribution to species richness and abundance at the studied *C*. *caespitosa* bank

The species Hiatella arctica, Syllis hyalina, Nereis rava, Trypanosyllis zebra, Vermilliopsis infundibulum, Microdeutopus anomalus, Lycidice ninetta, N. zonata, S. prolifera, Modiolus adriaticus, Phascolosoma granulatum, Caecum trachea and Paranthura nigropunctata dominated in terms of frequency of appearance and abundance. Diversity indices gained high values, 4.83 and 0.86 for Shannon-Wiener and Pielou's Evenness, respectively. According to literature data 16 megabenthic and 212 macrobenthic species inhabit Cladocora caespitosa colonies at the north Aegean Sea [4]; including the results of the present study, the total number of species associated with C. caespitosa is increasing to 286 (242 macrobenthic and 44 megabenthic species). It seems also that the associated assemblages are probably different structured among individual colonies and banks. Considering that C. caspitosa is affected by necrosis under increasing temperature [6] further research is required since such mortality events could have cascade effects to the associated assemblages.

THERMAL POLLUTION IMPACT ON BENTHIC FORAMENIFERAL ASSEMBLAGES AS ANALOG TO GLOBAL WARMING, SE MEDITERRANEAN SHORE (ISRAEL)

Ruthie Nina Arieli¹, Sigal Abramovich¹, Ahuva Almogi-Labin²* and Barak Herut³ ¹ Geological Survey of Israel - almogi@gsi.gov.il ² Departent of Geological and Environmental Sciences, Ben Gurion University ³ Israel Oceanographic & Limnological Research, Israel

Abstract

This study examines the effects of heated water originating from the "Orot Rabin" power plant on benthic foraminifera known to be sensitive bioindicators of environmental change. We performed 10 sampling campaigns during a period of one year, at 4 stations located along a temperature gradient of approximately 10 °C. The SST along the transect vary between 25/18 °C in winter, and 36/31 °C in summer. A significant negative correlation was found between SST and benthic foraminiferal abundance, species diversity and species richness. If this research is taken as a model, it may be concluded that global warming has a primary negative effect on foraminifera assemblage characteristics and thereby most likely on other marine organisms as well. *Keywords: Foraminifera, Thermal Pollution, Eastern Mediterranean, Biodiversity*

Over the past several decades public and scientific awareness to global warming has increased significantly. As a result, many studies have examined the potential deleterious effect of global warming on the natural environments, though few have explored its effect on marine living organisms in the southeast Mediterranean Sea. As of today, an accepted forecast for the next two decades is that ocean temperatures will rise at a rate of 0.2 °C per decade [1]. The current rate of warming in the Mediterranean Sea is in accordance with the rate of global warming and stands at 0.028 °C/year [2].

This study was set to examine the effects of increased SST on benthic foraminifera known to be sensitive bioindicators of environmental change. The thermal patch originating from a power plant on the coast of Israel was chosen as a sampling area for this research, since it presents a unique small-scale analog for the expected future rise in sea surface temperatures. Ten monthly sampling campaigns, were performed in 4 stations located along a temperature gradient of approximately 10 °C, from the discharge site of the heated seawater to a few kilometers south. Benthic foraminifera were collected from a shoreface complex of macroalgae and sediment trapped within. The SST varied between winter, 25/18 °C and summer, 36/31 °C along the transect (Fig. 1). During the summer temperatures becomes a threat.

The natural seasonal pattern in this near-shore environment, depicted best by station 4 located beyond the thermal patch, shows that foraminifera reach maximal abundance in winter and spring, ~2 months prior to a deeper (~40 m) inner shelf habitat, probably due to faster warming of the shallow waters. A significant negative correlation was found between SST and benthic foraminiferal assemblage characteristics. The abundance and species diversity show negative correlation with the SST anomaly throughout most of the sampling period, though the species diversity was not as significant as the abundance. The total foraminiferal abundance was significantly lower at the thermally polluted stations, especially during the summer, but also throughout the entire year, indicating that the thermal pollution has a detrimental effect on benthic foraminifera, irrelevant to the natural cyclic changes in SST. The foraminiferal abundances decrease as the SST rises (Fig. 1), reaching minimal abundances when the SST rises above 30 °C, indicating that this temperature maybe a critical threshold above which foraminifera growth and reproduction are severely retarded.

Species richness reached extremely low values at the thermally polluted stations during the summer, with a minimum of 3 species compared to a maximum of 24 in the natural, unaffected station. This indicates that some species have adapted to the elevated temperatures better than others. The foraminiferal assemblage at the sampling area is composed mostly of epiphytic species. A total of 42 species belonging to 24 genera were identified with six species dominating the assemblage throughout most of the sampling period. These species appeared to have different seasonal patterns, out of the six dominant species *Rosalina globularis, Tretomphalus bulloides* and *Textularia agglutinans* show a clear preference to the winter months, while species belonging to the genus *Lachlanella* reach maximum abundances in spring and *Pararotalia spinigera* in summer. The temperature tolerance varied considerably among the different species with some being more tolerant to the raised SST than others. The miliolids, *Lachlanella* sp. 1 and sp. 2 seem to have high tolerance to the termally

polluted stations.

In this research we show that even a rise, as small as 2 °C, in SST can have serious ramifications on the benthic communities living in the near shore environment. If foraminifera are affected to such an extent it is not unlikely that other more developed marine creatures will be negatively affected as well, either directly by the rise in SST or via the decrease in organisms lower down the marine food chain, such as foraminifera. If this research is taken as a model, it may be concluded that global warming has a primary negative effect on foraminifera assemblage characteristics and thereby most likely on other marine organisms as well.

Abstract

In 2000 the use of beach seining and trawling was prohibited in the Bay of Izmir, on the Aegean coast of Turkey. Ever since artisanal fishermen have been using stationary gear such as gillnets and longlines. Trammel nets have been used between May and October to fish the native Mediterranean prawn Melicertus kerathurus. In 2008 large numbers of an alien prawn, *Metapenaeus affinis*, were collected for the first time in the inner part of the bay. Because of their higher value and longer fishing season than the native prawn, fishermen began to exploit them.

Keywords: Alien species, Aegean Sea, Crustacea, Fisheries

Introduction

Metapenaeus affinis (H. Milne-Edwards) is an Indo-West Pacific species which ranges from the Arabian Gulf to the Malay Archipelago [1]. It is commercially valuable in some Asian countries and in the Persian Gulf. Trawlers, trammel nets, beach and boat seines are used to catch this species. Soon after the population of the jinga shrimp was discovered in Izmir bay, local fishermen began catching them using shrimp trammel nets.

Extensive studies conducted in 2003-2005 of the commercial prawn trammel net fishery targeting the native Mediterranean prawn *Melicertus kerathurus* (Forskål, 1775) in Izmir Bay have revealed no alien prawn either in the landed catch or in the discard [2,3]. The aim of this study was try to determine the fishing method and technial details of the trammel net which used to capture Jinga shrimp.

Fig. 1. *Metapenaeus affinis* a) Lateral view of male, b) 5th Pereiopod of male, c) Rostrum of male d) petasma and 1st pereiopods (Photo: I.AYDIN)

Material and Methods

This study was realized in Izmir Bay with a commercial F/V *EFSANE 6* between April 2008-October 2009. Depth of the fishery areas varied 8-12 meter. The shrimp trammel nets which are popular for the bay were used to collect specimens[4].

Results and Discussion

Jinga shrimp specimens were occurred in April 2008 in Izmir Bay where is the eastern shore of the Aegean Sea [5].Trammel nets for jinga shrimp set in the inner part of the bay catch other species as well: Whiting (Merlangius merlangus), meagre (Argyrosomus regius), red mullet (Mullus barbatus), chub mackerel (Scomber japonicus), squid (Loligo vulgaris), sole (Solea solea) are the most commercially valuable abundant species in all seasons. Twaite shad (Alosa fallax) and annular sea bream (Diplodus annularis) are commercial between May – September during the closure of trawling and purse seining. 72 species were identified from prawn trammel nets in the bay of Izmir, and 46 of them are considered discards [2]. We identified 8 species collected in the jinga shrimp fishery in the bay and only two of them are discards during the trawl fishing season. The difference in number of species may be due to the location of the fishery, which is in the innermost part of the bay, closer to the harbour of izmir, whereas M. kerathurus is fished in the middle and outer part of the bay.

The fishermen use 8-9 pieces of netting per fishing operation. The average catch was ere 18, 26, 12 kg respectively in spring, summer and autumn of 2008, and 10, 15, 3 kg respectively in 2009. In winter the prawn fishery does

not operate, however other types of nets are set for sparid fish and occasionally few individuals are caught as well. The jinga shrimp fishery lasts from April to October.

A SIMPLIFIED VISUAL CENSUS METHODOLOGY TO DETECT VARIABILITY TRENDS OF COASTAL MEDITERRANEAN FISHES UNDER CLIMATE CHANGE SCENARIOS

Ernesto Azzurro^{1*}, Francesc Maynou² and Paula Moschella³ ¹ ISPRA - High Institute for Environmental Protection and Research - eazzurr@tin.it ² ICM-CSIC, Passeig Maritim de la Barceloneta 37-49, 08003 Barcelona, Spain

³ CIESM - The Mediterranean Science Commission - Monaco

Abstract

Here we tested a simplified visual census methodology in which the sampling unit consisted of snorkeling trials of 5 minutes. Censuses were conducted over 4 different Mediterranean locations, according to a hierarchical sampling design. Results discriminated the assemblages at different spatial levels and confirmed the importance of Latitude gradient for the distribution of T. pavo and S. cretense. Aim of this contribution is to discuss the potential of this method to detect variability trends of Mediterranean fish species. Keywords: Fishes, Sampling Methods, Global Change

Introduction

The contemporary change in the species geographical ranges is one of the most apparent signals of climate warming worldwide [1] and now in the Mediterranean Sea, a number of thermophilic coastal fish species seems to be extending their distribution and increasing in abundance [2]. Our capacity to monitor and understand this phenomenon is limited by the pragmatic constraints that arise in encompassing large spatial and temporal scales, being the most of information generally given by the sum of sporadic observation. As recently emerged by a CIESM workshop [2], to select a reliable network of variables, to use simple methods and a minimal investment in extracting local information can help much in overcome these difficulties. Therefore, on the basis of these guidelines, we propose a simplified visual census methodology to monitor a set of coastal fish species. The method was specifically intended to be used by a wide group of observers over large geographical scales and, hopefully within long time series.

Materials and Methods

Our sampling unit (count) consisted of a snorkelling transect of 5 minutes, parallel to the shore. During this time, the observer takes abundance data for a set of species (i.e. Epinephelus marginatus, Caranx cysos, Thalassoma pavo, Coris julis, Sparisoma cretense, Serranus scriba, Serranus cabrilla, Sarpa salpa), that were chosen for their wide distribution and different affinity to temperature. The study, performed during September-October, 2009, was limited to rocky bottoms, in order to minimize the sources of variability. The sampling design consisted of 2 different latitude ranges (low and high) with 2 locations nested in each of it, 3 sites nested in each location and 4 replicate trials, for a total of 48 fish counts (Fig. 1). Data were overall square root transformed, univariate and multivariate analyses were performed by using the PRIMER 6+PERMANOVA software package.

Fig. 1. Study locations (black diamonds) (low latitude: Linosa and Capo Milazzo; high latitude: Punta Arasu and Cap de Creus) and sites (black circles).

Results and Discussion

We counted 2257 individuals overall. According to PERMANOVA analysis (Tab. 1), significant differences in the fish assemblages were detected at the spatial scales of 'locations' and 'sites' but no significant differences were found for the factor 'latitude'.

Source	df	SS	MS	Pseudo-F	P(perm)
Latitude=La	1	23920	23920	1.9264	0.3388
Location (La)	2	24834	12417	19.583	0.0001
Sites(Location(La))	8	5072.5	634.06	1.7738	0.0455
Res	36	12868	357.45		
Total	47	66695			

Fig. 2. Permutational multivariate analysis of variance based on the Brav Curtis dissimilarity measure for square root transformed abundance data.

The lack of statistical significance for the factor 'latitude' can be explained by a inadequate number of replicates at the location level. Therefore we proceeded with the SIMPER analysis that indicated T. pavo (Contribution to the dissimilarity 28.79%), S. salpa (24.17%) and S. cretense (13.72%) as mostly important to discriminate between low and high latitudes. T. pavo and S. cretense are species that are typical of the south Mediterranean and these results confirmed the importance of latitude in shaping their distribution. According to 3-way PERANOVA, T. pavo resulted to vary significantly according to the factor latitude (Pseudo F= 120.71; p = 0.461), but also with the factors 'location' and 'site'. In sum, despite the poor quality of information that was extracted by each single trial, these preliminary data were effective in to discriminate spatial differences at the level of location and sites. The study represented an useful test to plan future sampling and hopefully an incentive to discuss the potential of this simple method to detect variability trends of Mediterranean fish species. We believe that powerful information could be obtained by means of a structured sampling design where many other similar observations are assembled to build a wider-scale picture. The census method was simplified to the maximum in order to be used also by not-specialist alike. Future investigation could be conceived to test for the influence of overriding factors that act at global scales. Hopefully, in a next future we could: 1) test the importance of latitudinal gradients and temperature in shaping species distribution; 2) start building long time series, which is one of the research priorities under climate change scenarios.

Abstract

Time series decomposition of remote sensing observations (Aqua-MODIS) of sea surface chlorophyll (SSC) since July 2002 to June 2009 is performed at various coastal and open sea areas in the Mediterranean and Black Seas. The evolution of SSC is assessed against satellite sea surface temperature (SST) and wind vector data provided by ECMWF, in order to disclose possible connections of the environmental variables on the regional chlorophyll trends. The interaction between SSC and the environmental variables is assessed using time-lagged cross-correlations of the variables. Then, the time lags showing the highest significant correlations were chosen for further hypothesis validation using generalized additive models. Results are discussed within the framework of seasonal changes in the Mediterranean area and at global scale.

Keywords: Time Series, Chlorophyll-a, Temperature, Wind/Font

Introduction

Atypical warmer summers and cooler winters have been reported in recent years in the Mediterranean Sea areas. For instance, winter periods in the Gulf of Lions, like those in 1999 and 2005 were atypically cooler and windy, producing submarine cascades with vertical velocity of 80 cm s⁻¹ from nominal 10 cm s⁻¹, thus altering benthic organisms and transporting down from surface an atypical large amount of organic matter [1], [2]. We postulate the hypothesis that local unusual seasonal events could leave a signal in upper water layers properties (i.e. not only in the bottom), as they have a direct connection with the atmosphere. Phytoplankton species, with relatively fast growing rates are good indicators of environmental changes. Temperature and wind strength are responsible for changes in surface water density and are potential factors for inducing surface fertilization (increasing phytoplankton primary production) and transporting phytoplankton from surface to deeper water layers altering phytoplankton primary production. The present study deals with sea surface phytoplankton chlorophylls variability in the last seven years (2002-2009) and its relationship with sea surface temperature and wind velocity.

Methods

Twelve locations were selected in the Mediterranean seas and Black Seas for the present study (Fig. 1). Inter-annual trends of 8-day AQUA-MODIS composite SSC and SST, along with 8-day ECMWF composite wind velocity estimated from vectors u and v at 10 above the sea surface, from the week 24 in 2002 up to the week 23 in 2009, were assessed using loess smoothing (non-linear). Then, cross-correlation analyses of chlorophyll time series against SST and wind velocity was performed to investigate for potential real-time and time-lagged connections. Finally, hypothesis validation of potential connections between chlorophylls and the environmental variables was performed using Generalised Additive Models.

AQUA-MODIS Sea-surface chlorophyll, September 2009

Fig. 1. Monthly composition of Aqua-MODIS sea-surface chlorophylls in the Mediterranean and Black seas(Source:http://oceancolor.gsfc.nasa.gov)

Results

Trends of surface chlorophylls along with temperature and wind velocity are not linear. Chlorophylls in Aegean Sea and Levantine basins show an upward trend of 0.25 mg m⁻³ in last seven years. Seasonal patterns of surface temperature and wind velocity are local, not extending to the whole Mediterranean area, as reported from mesoscale models [3]. Events of highest and lowest values of the variables are generally equivalent to those values observed in the past. Present data do not provide evidence of clear (linear) trends of the variables within last seven years. Just a few local trends seem to be linear, but their linearity is not guaranteed with time. Wind velocity is an environmental factor explaining a minor part of the chlorophyll variability in surface waters in the Mediterranean stations. Most of the chlorophyll variability is generally explained by SST. Relatively strong winds in the Gulf of Lion and Aegean Sea do not affect significantly the surface chlorophyll variability. In the Gulf of Lion, factors other than SST and wind (such as river discharges) are responsible for the variability of surface chlorophylls, whereas in the Aegean Sea, SST is an important factor explaining most (70%) of total phytoplankton variability. In the Levantine basin, SST by itself (i.e. with no covariates in a model) explains the highest variability of surface chlorophyll (81%) compared with the lower variability explained by the models in the remaining 11 stations. The prediction of surface chlorophylls in the Black Sea slightly improves with the addition of wind velocity to SST as explanatory variable. The stations in the Black Sea are the least influenced by SST and winds. The upper water layers of the pelagic ecosystem could not be strongly altered by extreme changes in wind regimes. The pelagic ecosystem was generally sensitive to changes in SST, except in the areas of strong influence of river discharges such as the Gulf of Lions. This leads us to suggest that atypical cool and windy winter seasons in the Gulf of Lions, although altering the deep ocean, do not seem to affect the upper layers of the pelagic ecosystem. Further analysis with data taken in the areas around the deep canyons (where cascading events takes place) in the Gulf of Lions is required to validate the present conclusion.

SPATIAL DENSITY AND MORPHOLOGY VARIATION OF *CAULERPA SCALPELLIFORMIS* (BROWN EX TURNER) C. AGARDH (CAULERPACEAE, CHLOROPHYCEAE) IN ANTALYA GULF (TURKEY)

Beylem Banbul acar ¹*, Halil Çolak ¹ and Mehmet Gökoglu ¹ ¹ Akdeniz University, Faculty of Fisheries - beylemb@akdeniz.edu.tr

Abstract

Morphology and density variations of *C. scalpelliformis* at four locations in the Gulf of Antalya (Levantine Basin) are studied in the period July-September 2009. There were differences in 6 (frond length, number of frond, rhizome length; P<0.05 and apical frond width, pinnule length, diameter of stolons; P<0.01) of 10 morphological characters among the stations. The lowest total stolon length (197 cm/m²) and density (94,76±0,99 frond/m²) are observed at the station IV with highest sediment porosity (%44,35). *Keywords: Levantine Basin, Phytobenthos, Density*

Introduction

The first record of alien species *Caulerpa scalpelliformis* (Brown ex Turner) C. Agardh from Turkey is reported from Antalya harbour in the period August-September 1995, from depth of 0,5 to 2 meter in seawater with a temperature range of 26.5-27°C. But that species was not found at the same location in the period 1995-1997 because of the low water temperature[1]. Hereafter *C. scalpelliformis* was observed again around the same station at 25.02.99 (low water temperature) from dept of 1-3 meter[2]. This green alga has been cover property as other invasion species and has the rapid spread[2][3]. It may negatively effect biological diversity when didn't take measure[2].

Materials and Methods

Specimens of *C. scalpelliformis* were hand-collected by SCUBA diving in the period July-September 2009 in the Gulf of Antalya from 4 locations (St.I: 36°53'02.78"N,30°42'02.70"E; St.II: 36°52'35.56"N,30°39'56.79"E; St.III: 36°52'11.87"N,30°39'17.98"E; St.IV: 36°51'36.49"N,30°38'21.58"E). The morphological characteristics were measured by using 150 mm 1/100 digital caliper in the laboratory of Faculty of Fisheries. Analysis of variance (ANOVA) and Duncan Multiple Range Test were employed to test the effect of morphological characters and density of *C. scalpelliformis* between the locations. Pearson Correlation Coefficients were measured to indicate the relationship between morphological characters. SPSS version 14.0 was used for all analyses.

Results

The colonies of *C. scalpelliformis* were found at the each station from depth of 15-25 meter in seawater with a temperature range of $28-29^{\circ}$ C and salinity of 38.2 psu. The feather-like thallus is delicate with narrow stolons, erect fronds and wide pinnules. The stolons are slender, 0.12-0.17 cm in diameter, with long rhizoids, 4.17-5.91 cm long. The fronds are olive to dark green, 7.26-8.74 cm high and 1.17-1.37 cm broad. Total stolon length (cm), frond number and dry weight (g) of *C. scalpelliformis* in m² have higest value (977, 645.79±2.44, 48.3 respectively) on the sandy-slimy sediment with lowest porosity at the Station I (Table I).

Discussion

C. scalpelliformis is an Indo-Pacific species with a wide distribution in the Indian Ocean and the Pacific as well as on warm-temperate Atlantic coasts[4]. It was found on concrete walls sheltered from waves from depth of 0,5 to 2 meter with stolons 20-21 cm long, 1.2 mm wide, with well-developed rhizoids 1.4 to 4.1 cm long; fronds, up to 5-5.5 cm high and 10-13 mm wide[1]. Our results are greater than these for some morphological characters but correspond to morphological data of C. taxifolia[5]. C. scalpelliformis was not observed shallower than 15 meter and deeper than 40 m in our study. Despite monthly observations carried out in Antalya harbour as well as in other stations of the Antalya Gulf from October 1995 to June 1997, the species was never detected again. It is indicated that could be due to the low water temperatures occurring in winter at that station which cannot support C. scalpelliformis[1]. Recovery of this species at 1999 in winter time at the same station[2] and at 2009 at 4 stations through the Antalya Gulf indicate expantion of the distribution area of C. scalpelliformis in the Mediterranean Sea. Our results show that species prefer sandy-muddy bottom to spread.

Abstract

The field identification guide surveys marine organisms of commercial and potential commercial importance. The region covered extends from the Mediterranean coast of Turkey proceeding in a general southwestern direction to that of Morocco. Species were selected carefully according to economic interest, commonness and sometimes according to their endangered or invasive status. A total of 372 marine species were considered, including the most common exotic ones. Also presented are their relevant diagnostic features, biological information, and geographical distribution while highlighting their importance on local fisheries. The entire field guide was translated into Arabic for a better accessibility among non scientists in Arabic speaking countries. *Keywords: Fisheries, Alien species, Biogeography, Eastern Mediterranean, Western Mediterranean*

Limited knowledge and skills for marine species identification are among the main weaknesses affecting the coastal waters fisheries in the eastern and southeastern Mediterranean countries, namely Turkey, Cyprus, Syria, Lebanon, Egypt, Libya, Tunisia, Algeria, and Morocco. Imprecise species identification hinders accurate estimation of commercial landings and all attempts to develop and manage sustainable fishery measures. The field guide is the first attempt to provide a comprehensive survey of marine species likely to be encountered in fishery landings, on the market and at sea in the covered area. There is a pressing need for such a modern reference work as no similar publication has been presented in over 20 years [1]. Furthermore, the field guide is an original effort to highlight the commercial importance of recent marine introduced species, most of which have well established populations. The field guide is largely based on an extensive list of relevant bibliographic references but also incorporates and organizes a compilation of raw data gathered by nine fishery experts from each of the respective countries. After a brief introduction of the Mediterranean ecosystem's general features and biodiversity, a section is dedicated to landing statistics reported by all concerned countries since the year 1950. A special emphasis is made on introduced species of commercial importance and on those that are a potential threat to humans, fisheries, and the ecosystem. The marine organisms considered were organized under major taxonomic groups and subgroups. These were crustaceans (stomatopods, shrimps and prawns, lobsters, crabs), molluscs (gastropods, bivalves, cephalopods), echinoderms (sea urchins), and fishes (lampreys, cartilaginous fishes, bony fishes, chimaeras), as well as sea turtles and marine mammals. The most relevant morphological terms and measurements, essential for identification, are described by means of labeled illustrations and a glossary. Each chapter is dedicated to one of the aforementioned taxonomic groups and starts by an introduction summarizing general information such as morphology, biology, as well as the commercial importance concerning this specific group in the Mediterranean. The information given by species contains the valid scientific name as well as the official FAO common names in English, French, and Spanish. In addition, a provisional Arabic common name was recommended. Brief information regarding relevant diagnostic features, biological information and habitat, importance to fisheries and geographical distribution of the species is also included. Conveniently, accurate line drawings for all species complement the information. Particular care was taken to make the field guide user-friendly and accessible to the general public without the need for prior knowledge in marine biology or fisheries. Concurrently, it can be used as a practical working tool for scientists, fisheries professionals, and inspectors reporting landings at the national level, as well as by fishermen, students, sports anglers, and naturalists. It is also expected to serve as a baseline document for environmental assessments and fisheries management. Furthermore, the entire field guide was translated into the Arabic language for a better dissemination among Arabic-speaking users, particularly fishermen. Most commonly used vernacular names in Arabic, Turkish, and Cypriot Greek were also summarized in tables that can be found at the end of the document. An undertaking of this magnitude was done in the hopes of establishing a better

form of communication among interested individuals. This "Field Identification Guide to the Living Marine Resources of the Eastern and Southern Mediterranean" was prepared under the coordination of the Fisheries and Aquaculture Management Division, Fisheries and Aquaculture Department, Food and Agriculture Organization of the United Nations (FAO).

COMPARISON OF DISCARDS OBTAINED USING DIFFERENT MESH SIZES AND SHAPES IN THE CODEND OF THE TRAWL

Jorge Baro ¹*, Teresa Garcia ¹ and Jose miguel Serna ¹

¹ Instituto Espñaol de Oceanografía. Centro Oceanoghráfico de Málaga - jorgebaro@ma.ieo.es

Abstract

In this work a comparison of the discards rates among trawl gears using different type of codend is presented. Sampling took place during 6 months in 2008 on-board four commercial trawlers in northern Alboran Sea using three different types of meshes in the codend (40-mm diamond- and square-mesh and 50 mm diamond-mesh). Our results showed that discards rates varied between type of meshes but no differences were found between vessels.

Keywords: Alboran Sea, Deep Waters, Fisheries

At a world level between 17.9 and 39.5 million tons of marine organism are discarded [1]. Mediterranean trawl fisheries are highly diverse in terms of species and many of them are discarded for economic (low commercial value) or legal reasons (minimum landing sizes) [2, 3]. Discards are important for stock management because contribute to fishing mortality and they also represent and economic and ecological impact. The use of bigger mesh size than traditional or more selective shapes in the codend can contribute to reduce the discards and hence the impact of fishing in the ecosystem.

Sampling took place between May and October 2008 on-board four selected commercial trawlers representative of the studied area in terms of size, engine power, fishing capacity and construction characteristics. The overall objective of the surveys was to compare profitability of trawl fishing in northeast Alboran Sea between 600 and 800 m depth, using three different types of meshes in the codend (40-mm diamond- and square-mesh and 50 mm diamond-mesh) under commercial condition. The weights of landed and discarded organism were estimated by on-board observers for 451 trawl daylight hauls following commercial fishing procedures. The average duration of the trawls was 3.5 hours. All species captured were weighted and counted. Two-way analysis of the variance, (ANOVA) was used to test differences in the pattern of the yields (kg/hauls) between fishing vessels and type of meshes.

Discarded rates ranged from 4.4% and 16% of the total catch depending on the vessels and the type of codend. Fishes were the most important group in terms of weight discarded for all the vessels (41.7%-65.9% of the total), followed by crustaceans (11.8%-23.11) and molluses (8.5%-11.16%) (Table 1). Main discarded fishes were Condricthyans and Macroruidae: *Nezumia aequalis, Chimaera monstrosa, Torpedo nobiliana, Etmopterus spinax, Dalatias licha, Trachyrhynchus trachyrhynchus, Galeus melastomus* and *G. atlanticus*. The crustaceans *Dardanus arrosor*, other Paguridae and *Polycheles typhlops* and the molluses *Octopus defilippi Neorossia caroli, Eledone cirrhosa* and *Pteroctopus tetracirrhus* were the main species discarded in these two groups.

Tab. 1. Discards (g/haul) by group of species and type of meshes in the codend (40SQ: 40 mm square-mesh; 50D: 50 mm diamond m-mesh; 40D 40 mm diamond mesh)

	Fishes	Crustaceans	Molluscs	Echinoderms
40C	16883	87	135	103
50R	19420	124	164	106
40R	10940	124	231	98

Discards rates were significant different between type of meshes of the codend (p<0.05), although there were not observed differences between the discards between vessels. In general highest rates of discards were recorded for the 50 mm diamond-mesh codend (Table 2)

Tab. 2. Discarded rates (in percentages) by vessels and type of meshes in the codend (40SQ: 40 mm square-mesh; 50D: 50 mm diamond m-mesh; 40D 40 mm diamond mesh)

	40C	50R	40R
Vessel 1	10,78	15,30	8,70
Vessel 2	10,57	16,24	4,44
Vessel 3	10,20	8,62	5,60
Vessel 4	12,78	11,36	4,37

Abstract

Temporal variation of fish larvae during the winter-summer transition in Cabrera National Park (SE Mallorca) reveal two spawning strategies of coastal species; (1) a few species spawn early in the year coupled with the zooplankton biomass peak (e.g. *Diplodus sargus, Boops boops*), and (2) a larger proportion of species spawn in early summer when hydrographic conditions are milder but food availability is lower (e.g. *Coris julis, Serranus hepatus*). Specific abundances in spring were fairly higher than in summer (~7 fold). We interpret these strategies on the basis of food availability and change in coastal circulation. *Keywords: Ichthyoplankton, Circulation, Fishes*

Introduction

Discerning the environmental factors that are relevant in each coastal area for the survival of early life stages and, particularly, the identification of critical zones and periods for the resource development is essential for the management of marine protected areas (MPAs). Among the physical and biological signals affecting ichthyoplankton assemblages, seasonality is one of the most notable forcings. Yet, there is no unique adaptative response of fish larvae to seasonal changes. Conversely, in order to optimize the reproductive success, larval timing may strongly differ among species. A combination of favorable hydrodynamic conditions, food availability and quality, and predation avoidance, among other factors, may determine the spawning period, particularly in temperate seas such as the Mediterranean Sea with a marked seasonal cycle in temperature.

Archipielago de Cabrera National Park is a marine protected area situated to the south of Mallorca (Balearic Islands). As in other oligotrophic areas, food availability is low and increases in zooplankton biomass generally restrict to a late winter bloom. A major aspect of the circulation around the Mallorcan shelf is the presence of island trapped waves (ITWs) generated by local wind forcing [1]. Transport is thus conditioned by prevailing meteorological conditions. Retention mechanisms near the adult habitat together with food availability are postulated as major constrains to fish larvae survival. This study seeks to identify the consequences of spawning timing of coastal fish species in the waters of Cabrera National Park in the context of these two factors.

Materials and methods

Sampling consisted on fortnightly measurements at three stations located between Mallorca and Cabrera that were visited between February and August 2007. These measurements where complemented with current records from a bottom mounted ADCP. Zooplankton samples were collected with vertical tows of a WP2 net and fish larvae were sampled by oblique hauls of a bongo net (0.6 m mouth opening). Wind maps were constructed by optimal interpolation from wind data recorded by two coastal stations and Quikscat satellite data for the period (2000-2009). Synoptic wind patterns were identified using the Self-Organizing Map (SOM) algorithm. To compute a range of likely larval transport outcomes, an individual based model (IBM) for larval dispersal was developed using velocity fields of a high-resolution (~200 m) ocean circulation model (POM). Simulations were run for 30 days forced by the computed wind patterns to simulate the generation and propagation of ITWs.

Results and discussion

Fish larvae belonging to a total of 57 taxa were identified. Larval mean abundances fluctuated between 25 and 162 ind m^2 which is in the range of average values in Mallorca [2]. Attending adult habitat, fish larvae were grouped into two groups: i) larvae of shorefish and shelf dwelling species and ii) larvae of mesopelagic species, dwelling in the open sea. The species included in the latest group, the majority of them belonging to Myctophidae family, were more abundant in summer, but their presencewas episodic and presumably associated to oceanic water intrusion in the continental shelf. Concerning the species included in the first group, a clear temporal variability in the ichthyoplankton composition was observed between spring and summer, with an increase in the number of taxa in summer. Some species, such as Diplodus sargus and Boops boops were particularly abundant in spring and showed the highest abundances in April, following the seasonal peak of zooplankton. Other species, such as Serranus hepatus or Coris julis, peaked in summer though, in general, their abundances were lower than that of the spring species. The onset of the spawning period for these species occurred in early June when water temperatures raised above 20°C.

Wind patterns from SOM classification reveal a seasonal wind regime

characterized by two typical wind modes. Eastern winds are prevalent on summer (Jun.-Aug.) whereas alternation between easterly and westerly episodes occurs in spring (Mar.-May). These changes in wind forcing have consequences in mean coastal transport that reveal a shift in current direction at the beginning of early summer. Numerical simulations of wind forced ITWs capture well the main features of measured current variability suggesting that coastal circulation responds energetically to this local forcing and that shelf currents are relatively uncoupled from oceanic flows. This is also evidenced by the scarce and episodic presence of oceanic fish larvae. Larval trajectories computed with the IBM model reveal the differences in the dispersion patterns attending to wind forcing. ITWs generated by the westerly winds tend to disperse larval particles toward the outer shelf, whereas the eastward winds (prevailing in summer) retain larval particles in the north-western coast of Cabrera. This suggests that while increased food availability may be advantageous for the development of spring species, larvae would be more susceptible to be advected far from the adult habitat. However, loss by dispersion could be partially compensated by a higher abundance of larvae in the plankton during that period. On the other hand, summer spawning would guarantee larval fish retention in the coastal environment. This last strategy would be advantageous for the maintenance of fish populations in the area, what is especially relevant in the context of the MPAs.

AGEING WITH ALCIAN BLUE DUYING TECHNIQUES FOR SOME ELASMOBRANCHS IN ISKENDERUN BAY, EASTERN MEDITERRANEAN

Nuri Basusta¹, Sefa ayhan Demirhan², Asiye Basusta^{1*} and Erdogan Cicek³ ¹ Firat University, Fisheries Faculty, Elazig,Turkey - agirgin@firat.edu.tr ² Mustafa Kemal University, Fisheries Faculty, Iskenderun Hatay, Turkey ³ Nevsehir University, Department of Biology, Nevsehir, Turkey

Abstract

In this study, the vertebrae of the common eagle ray (*Myliobatis aquila*) and backchin guitarfish (*Rhinobatos cemiculus*) were used for ageing. A total of 10 *M.aquila* (females and males) and 10 *R. cemiculus* (females and males) were sampled. Age determinations were carried out using vertebral sections. Alcian blue dying techniques were used to enhance the visibility of the band on vertebrae.

Keywords: Biodiversity, Eastern Mediterranean, Elasmobranchii

Introduction

Chondrichthyan fish are of low productivity compared to teleost fishes. Because of low productivity, target or non-target chondrichthyan species are most affected by commercial fisheries. For this reason, most of elasmobranches are listed in IUCN Red Data Book. Impact of commercial fisheries on chondrichthyan fish population around the world is currently the focus of considerable international concern of both academicals or non-governmental organizations for conservations and management of stocks. One of the most important points in fish and fisheries biology is age determination. Particularly if it is necessary to determine fish population structure, age determination has crucial importance. Bone of chondrichthyan species has not calcium, therefore their age determination is not easy relative to teleost fishes. For this reason, chondrichthyan stocks management strategies become harder. Age determination in chondrichthyan species can be done using some staining techniques which can make growth bands visible. Different staining techniques have been using to make growth bands visible. However success of the age determination varies for each technique. Numerous techniques have been used in the attempts to enhance the visibility of growth bands in vertebrae of elasmobranchs. All of these techniques show that the success of each technique is often species specific and that slight modifications in the technique may enhance the results. Alcian blue staining technique have used to enhance the visibility of the cartilage skeleton of mouse embryos and cartilage and related tissues in the trunk and fins of teleosts. However, the techniques have used to first time on elasmobranchs vertebrae successfully [1].

Material and Methods

This study was conducted on the north-eastern Mediterranean coast of Turkey). Samples were collected by using commercial gill-net (44 mm mesh size), trawling (44 mm stretch length) and longline fishery. In this study A total of 10 M. aquila (females and males) and 10 R. cemiculus (females and males) were sampled. Age determinations were carried out using vertebral sections. Eight to ten vertebrae were removed from the widest portion of the body, just behind the gill slits for each specimen. Remaining muscle tissue was removed from each centrum using a knife and to remove excess connective tissue, the centra were soaked in 5% sodium hydrochloride for one day and then rinsed in distilled water. The vertebrae were preserved in 70% ethanol until the examination. The diameter of examined vertebrae was measured to the nearest 0.01 mm for each sample, using a manual caliper. The sections were mounted on microcope slides using transparent acrylic glue and were polished with sandpaper until approximately 0.5 mm in thickness. In this study alcian blue dying techniques were used to enhance the visibility of the band on vertebrae. The section was soaked in alcian blue solution (16 ml 100% ethanol, 2 mg alcian blue and 4 ml glacial acetic acid in 0.8 ml distilled water) for 12 h. In order to determine the age (A), the sections were viewed in a stereo microscope (X10 magnification) with both transmitted and reflected light for identification of growth rings. Images of the vertebrae were captured with a digital camera (Kodak, 6.0 MP) and the images were examined using PhotoshopTM 7.0.

Results and Discussion

Alcian blue dying techniques were used to enhance the visibility of the band on vertebrae and were stained and age bands on the vertebrae (Fig.1) were observed to be quite visible.

Fig. 1. Age marks on the vertebrae for Rhinobatos cemiculus

Rhinobatos rhinobatos percentage of readable vertebrae was 84% [1], for this study they were 90%. Thus it can be claimed the alcian blue staining technique can be used successfully for the age determination of elasmobranchs vertebrae [2].

FISH FAUNA OF THE MARKIZ ISLAND (ÇANDARLI BAY, AEGEAN SEA)

Bahar Bayhan ¹*, Murat Kaya ¹ and Tuncay Murat Sever ¹

¹ Ege University, Faculty of Fisheries, Department of Hydrobiology - bahar.bayhan@ege.edu.tr

Abstract

In order to establish benthic and pelagic marine fish in the vicinity of Markiz Island, compherensive submarine observations were conducted by diving with and without scubas. Beside that a 30 minute trawl hauling was made to collect benthic species in north east of the island, with 70 fish species of 25 family being determined. *Keywords: Aegean Sea, Fishes, Teleostei*

Introduction

Northern part of Aegean Sea is under the influence of cool and less saline currents from Black Sea while the southern part is influenced by warm and salty currents. The study area is geographical transition between both seas. The differences observed in ecological features of Aegean Sea were suited to this geographical properties. It is possible to describe its middle section as a transitive zone, therefore there is a rich biological diversity in Aegean Sea where more than 300 fish species and some 5000 invertabrate were reported [1]. Recent lists have included new records a total of 389 marine fish, which indicates that Aegean Sea ranks on the top of the list of species among Marmara, Mediterranean and Black Seas coasts of Turkey [2]. Papaconstantinous [3] however reports that 447 marine species inhabit Greece Seas. This study aims to establish fish species in the vicinity of Markiz Island.

Material and Methods

In order to establish benthic and pelagic marine fish in the vicinity of Markiz Island, located in the enterence of Çandarli Bay in Aegean coast of Turkey, submarine observations were conducted by diving with and without scubas in 2007. Beside that a 30 minute trawl hauling was carried on to collect benthic species in north east of the island, with fish collected being assessed in two categories, namely benthic and pelagic. Taxanomic categories used for fish considered [4], [5] and [6].

Results and Discussion

70 fish species of 25 family were determined and collected fish being assessed in two categories, namely benthic and pelagic. Table 1 includes pelagic species and Table 2 shows demersal species. Sparidae family was the highest in number, followed by Labridae with 10 and Mugilidae with 5 species. These fish species were well known fish fauna in the Mediterranean Sea [2].

PRESENT STRUCTURE AND DISTRIBUTION OF MACROBENTHIC POPULATIONS IN THE NORTH -WESTERN BLACK SEA – ROMANIAN SHELF

Tatiana Begun¹, Adrian Teaca¹, Marian Traian Gomoiu¹ and Mihaela Muresan¹*

¹ National Institute of Marine Geology and Geoecology – GeoEcoMar, Constanta Branch - mmuresan@geoecomar.ro

Abstract

The distribution of soft bottom macrobenthic populations was studied by analyzing 325 quantitative samples in the Romanian Black Sea continental shelf. A total of 240 taxa belonging to 25 systematic groups were found in the assemblages, within Polychaeta had the highest number of species and individuals. The maximum biodiversity occurred in the mud mussels and *Modiolus* biocoenosis, whereas the highest abundances in the shallow waters.

Keywords: Zoobenthos, Continental Shelf, Black Sea

Introduction

In the last decades the Black Sea has suffered major changes induced by human activities. Many species disappeared or decreased in biomass, e.g. the mussel *Lentidium mediterraneum, Donacilla cornea, Mytilus galloprovincialis* [1]. Other species increased explosively in biomass, e.g. the bivalve *Mya arenaria, the* polychaet *Melinna palmata.* It is assumed that these modifications of the ecosystem were essentially caused by changes in nutrient discharges through major rivers, particularly the Danube [1]. This study, based on the results of researches performed in the past 7 years, comes to complete some gaps in the specialty literature concerning spatial distribution of macrobenthic populations of the Romanian Black Sea Shelf.

Materials and methods

In the period 2003 - 2008, a number of 325 quantitative benthos samples were collected at depths ranging between 0 - 213 m by means of the van Veen-type grab, box corer and multicorer. The offshore samples were collected during several cruises (R/V "Akademik" 2003 and 2006, R/V "Parshin" 2005, R/V "Mare Nigrum" 2006, 2007 and 2008), while the inshore samples during several national projects covering only the sedimentary substrata. The sampling was done with 0.1 m^{-2} van Veen grab, 0.25m^{-2} box corer, 0.015 m^{-2} multicorer.

Results and Discussion

The analyses of the samples helped identify 240 taxa (235 species) of which Spongia - 9, Coelenterata – 16, Turbellaria – 3, Nemertini – 6, Polychaeta – 77, Oligochaeta -1, Hirudinea – 1, Mollusca – 48, Bryozoa -1, Sipunculida – 1, Phoronida – 1, Pantopoda -2, Crustacea – 58, Echinodermata – 3, Tunicata - 6 and indeterminated taxa - 7, approximately 70% of the total number of species recorded in period 1960-1970 [2]. The mean abundance of the macrobenthic populations was 11,914.9 ind.m⁻² for density and 573.4 g.m⁻² for biomass.

Most macrobenthic taxa occurred in the samples had a small frequency; out of the 240 taxa recorded, 137 taxa had a frequency of 1-2 %, 34 taxa 2-5 %, 23 taxa 5-10 %, 27 taxa 10-20 %, 17 taxa 20-50 % and only two species had a frequency over 50 % (polychaet *Capitella capitata* and amphipod *Ampelisca sarsi*).

Numerical abundances were dominated by worms $(6,974.4 \text{ ind.m}^{-2})$ and molluscs $(3,689.8 \text{ ind.m}^{-2})$ populations representing 89 % of the total mean density of benthos. As weight, only the molluscs (*Mya arenaria, Mytilus galloprovincialis*) represented more than 66% of the total mean biomass.

The distribution species is conditioned by the input of fresh water from the Danube. The influence of Danube plume extend on the coast between front of Delta and Midia Cape where the number of macrobenthic species is very small, dominated by the opportunistic euryhaline species resistant in conditions of accentuated sedimentation, as: *M. arenaria*, *A. sarsi*, *Alitta succinea*.

The maximum number of species occurred at a mud mussels biocoenosis (21 - 50 m: 159 taxa) and *Modiolus* biocoenosis (51 - 110 m: 153 taxa), whereas the lowest number was found between 111 - 150 m depth (16 taxa) (Fig. 1).

The numerical and biomass abundance of macrobenthos populations diminishes from the shallow waters to the periazoic level (Fig. 2). The curves describing the distribution tendency of the density and biomass according to the bathymetric gradient is a logarithmic type function with a high correlation coefficient ($R^2 =$ 0.93 for density, $R^2 = 0.85$ for biomass). The distribution of macrobenthos fauna on the Romanian shelf is limited by the drastic decrease of oxygen and the increase of H₂S at approximately 150 -170 m depth.

DYNAMIQUE SPATIOTEMPORELLE DES POPULATIONS D'INVERTEBRES VAGILES ASSOCIEES A L'HERBIER POSIDONIE SUR LA COTE NORD-EST DE LA TUNISIE

Walid Belgacem ¹*, Habib Langar ² and Oum Kalthoum Ben Hassine ¹ ¹ Faculté des Sciences de Tunis, Manar I, 1092, Tunisie - walidbelgacem@yahoo.fr ² Institut National des Sciences et Technologies de le Mer, 2025 Salammbô, Tunisie

Abstract

Dans ce travail, 109 espèces vagiles ont été échantillonnées et identifiées. Elles appartiennent à 6 groupes dont les Crustacés, les Mollusques ; les Polychètes sont les plus dominants. Les assemblages faunistiques ont varié en fonction du temps et surtout de la profondeur et des paramètres phénologiques de l'herbier. Le recours à différentes méthodes d'analyse, nous a permis de confirmer l'impact prépondérant de la profondeur et de certains paramètres phénologiques de l'herbier sur la diversité et les assemblages des macroinvertébrés de l'herbier de posidonie.

Keywords: Phanerogams, Biodiversity

Sur les côtes tunisiennes, les travaux qui se sont intéressés à l'étude des macroinvertébrés associés à l'herbier de posidonie sont relativement rares. Cela nous a incité à entreprendre ce travail dont les principaux objectifs sont la connaissance des populations de macroinvertébrés vagile associés à *Posidonia oceanica* et les variations spatiotemporelles de leur diversité et de leurs assemblages. Pour cela, nous avons choisi comme site d'étude la région de Cap Zebib, situé au Nord-est de la Tunisie. Dans cette zone, les prospections ont été réalisées durant la période allant de mai à décembre 2007. L'échantillonnage a été effectué à l'aide d'un cylindre de 25 cm de diamètre [1] au niveau de deux stations localisées respectivement à 3 et à 12 m de profondeur. L'ensemble des échantillons collectés nous ont permis d'identifier 109 espèces d'invertébrés appartenant à 6 groupes : les Crustacés (42), les Mollusques (39), les Polychètes (19), les Echinodermes (6), les Sipunculidés (2) et les Némertiens (1).

La richesse spécifique a toujours été plus élevée à la profondeur de 3m qu'à celle de 12m. L'indice de Shannon Wienner (log e) a varié de 2,2 à 3,53 bits avec une valeur plus importante à 3m.

La classification hiérarchique nous a permis de distinguer deux groupes (A et B). Ces groupes représentent les échantillons récoltés respectivement à 3 et à 12 m de profondeur (Fig. 1a). L'analyse de chaque groupe, pris séparément, a révélé une large similarité entre le cluster des Crustacés et celui de l'ensemble de la macrofaune, ce qui traduit la dominance de ce groupe (Fig. 1b). Cette variation spatiale des populations a été confirmée par l'ANOSIM qui a permis d'obtenir une valeur globale de R significative pour le facteur profondeur (r = 0.338; p < 5 %).

Pour établir les relations entre la faune associée, la profondeur et les paramètres phénologiques de l'herbier, le test de Spearman a été appliqué pour les trois groupes dominants. Ainsi, pour les Mollusques, une corrélation négative a été observée entre la profondeur, d'une part et la richesse spécifique, le nombre d'individus et l'indice de Shannon Wienner, d'autre part. Pour le groupe des Polychètes, le nombre d'espèces et H' sont corrélés positivement avec la densité et la profondeur. Enfin pour les Crustacés, une corrélation négative a été observée entre le nombre d'individus et la surface foliaire. La structure des peuplements d'invertébrés associés à *Posidonia oceanica* est donc plus influencée par les variations spatiales que temporelles. L'ensemble des observations sont en concordance avec les résultats obtenus dans d'autres secteurs de la Méditerranée [2], [3].

Fig. 1. Dendrogramme de similarité de Bray-Curtis représentant toute la faune (a) et le groupe des Crustacés (b).

IMPACT D UNE POLLUTION THERMIQUE SUR UN ECOSYSTEME COTIER A L EST DE LA TUNISIE

Meher Bellakhal ^{1*}, Mouna Bellakhal Fartouna ¹, Ons Kéfi Dali-Yahia ² and Mohamed Néjib Dali Yahia ² ¹ Unité de recherche Exploitation des Milieux Aquatiques, Bizerte, Tunisie - meher2976@yahoo.fr

² Unité de Recherche Ecosystèmes et Ressources Aquatiques, GRPH-INAT, 1082 Tunis

Abstract

L'écosystème côtier de la baie de Sousse a révélé l'existence de variations spatiales importantes influencées par la pollution thermique provenant de la centrale électrique de la région. La valeur moyenne estivale de la température est normalement de l'ordre de 27°C. Cependant, elle a atteint 36°C au niveau du rejet durant la période d'étude. Les densités cellulaires du phytoplancton ont atteint 1 306 050 cellules/l au niveau du rejet contre 13 710 cellules/l au niveau des stations les plus éloignées. *Keywords: Phytoplankton, Thermal Pollution, Eutrophication*

Introduction

Les effluents urbains et industriels sont, la plupart du temps, les acteurs majeurs du déséquilibre écologique au niveau des écosystèmes côtiers [1]. Les rejets d'eau chaude à partir des centrales électriques sont aussi d'une importance non négligeable [2], [3], [4] et [5]. C'est dans ce contexte que la baie de Sousse, située sur la côte Est de la Tunisie (35°50' N ; 10°50' W) a été exposée, au cours de ces dernières décennies, à plusieurs problèmes d'ordre environnementaux. En effet, une prolifération massive inhabituelle de méduses est devenue incontestablement le rendez-vous des baigneurs chaque été. La pollution thermique, provoquée par la centrale électrique, qui déverse de l'eau chaude dans ce milieu par l'Oued Hamdoun, pourrait être à l'origine de cette prolifération via le réseau trophique. Cette étude démontre l'influence de cette pollution thermique au niveau de cet écosystème côtier.

Matériel et méthodes

Les stations d'échantillonnage sont réparties sur 5 radiales séparées l'une de l'autre de 2 Km et dont chacune comprend 3 stations selon les isobathes : 2 m, 5 m et 10 m. De plus, 2 stations ont été choisies à proximité des canaux d'amené d'eau de mer pour la centrale électrique, 2 autres au niveau du rejet et une station de référence en amont du site selon le sens du courant, ont également été choisies. L'identification et le dénombrement du phytoplancton ont été effectués selon la méthode d'Utermöhl. Seules les espèces appartenant aux Dinoflagellés et aux Diatomées ont été prises en considération dans cette étude.

Résultats et discussion

La température de l'eau a oscillé, durant la période d'étude, entre une valeur minimale de 26°C au niveau de la station la plus éloignée du rejet et une valeur maximale de 36°C au niveau de la station la plus proche. Des valeurs de température assez élevées, de 32°C, ont été également enregistrées au niveau des stations de la 1^{re} et 2^e radiale, qui sont très proches de l'effluent. Au niveau des stations de la 3^e, 4^e et 5^e radiales, la température n'a pas dépassé 27 °C. Le regroupement des stations d'échantillonnage en fonction de la température de l'eau (Fig.1), met en évidence trois groupes de stations selon leurs affinités thermales. Le premier groupe comprend les stations OH1 et OH2 qui sont les plus proches du rejet. Le deuxième groupe comprend les stations 12 et 22 qui sont sous l'influence directe du rejet. Enfin, le troisième groupe comprend le reste des stations qui sont relativement à l'abri de la pollution thermique. Les densités cellulaires du phytoplancton les plus élevées (1 250 000 cellules/l) ont été enregistrées au niveau des stations les plus proches de l'effluent. Les stations situées au niveau de la première et la deuxième radiale, présentent, elles aussi, des concentrations phytoplanctoniques relativement très importantes. Le regroupement des stations en fonction des densités phytoplanctoniques sur la base de la distance euclidienne, montre également trois groupes de stations à densités phytoplanctoniques comparables. Les trois stations les plus proches du rejet appartiennent au même groupe présentant les densités phytoplanctoniques les plus élevées. Ce qui révèle encore une fois l'influence directe de ce rejet sur l'accroissement de la production primaire au niveau de cette zone. Néanmoins, cette influence n'est pas de très grande ampleur et elle s'exerce sur une superficie de l'ordre de quelques Km². Ainsi, l'effet de cette pollution thermique semble s'estomper à partir de la troisième radiale située à environ 6 Km du rejet. En revanche, la prolifération du phytoplancton semble être influencée par l'action conjuguée de la température et de la richesse en éléments nutritifs comme cela a été constaté au niveau de quelques écosystèmes comparables [6].

Fig. 1. Regroupement des stations selon la température de l'eau sur la base de la distance euclidienne

Conclusion

Le rejet d'eau chaude en provenance de la centrale électrique de la région, favorise la prolifération du phytoplancton, premier maillon de la chaîne alimentaire en mer. Cette prolifération pourrait être à son tour, à l'origine des blooms de méduses inhabituellement enregistrées ces dernières années dans la région.

CARACTERISATION MORPHOMETRIQUE DE *SCORPAENA PORCUS* POISSON SCORPAENIDAE (LINNE, 1758) SUR LES COTES TUNISIENNES

Myriam Ben Hassena^{1*}, Rafika Fehri-Bedoui¹, Ibtissem Hammami¹ and Oum Kalthoum Ben Hassine¹ ¹ Faculté des sciences de Tunis, 2092, Tunisia - myriam.ben.hassena@gmail.com

Abstract

Une analyse factorielle discriminante des données morphométriques a été réalisée sur trois échantillons, composés au total de 90 spécimens de *Scorpaena porcus* (Linné, 1758) (Scorpaenidae), collectés à partir des apports de pêche côtière de trois sites, localisés respectivement au nord, à l'est et au sud du pays. Cette analyse a révélé l'absence d'homogénéité totale entre les trois échantillons. *Keywords: Analytical Methods, Biometrics, Mediterranean Ridge, Fishes*

Bien que les Scorpaenidés peuplent l'ensemble du littoral tunisien, les études biologiques se rapportant à cette famille ont concerné uniquement trois espèces (S. porcus, S. scrofa et S. notata) de la région Sud [1]. Notre objectif étant de caractériser les populations des côtes tunisiennes, nous avons donc mené une analyse comparative des données relatives aux caractères morphométriques de S. porcus [2], provenant de trois régions littorales tunisiennes, Nord, Est et Sud. Le nombre de spécimens de S. porcus, collectés le long des côtes Nord. Est et Sud est respectivement de 31, 33 et 26. Tous les spécimens ont été photographiés pour être traités à l'aide du logiciel visilog. Des points décrits sur le corps des poissons ont été utilisés pour construire un réseau de distances selon la méthode de Truss [3]. 18 points repères, déterminant 36 distances, ont été ainsi établis et mesurés. Une transformation logarithmique des données morphométriques a été réalisée pour augmenter la linéarité et la normalité [4]. Ces données ont été transformées selon la formule suivante [5]: $V_{trans} = \log V - \beta$ (log LS - log LS_{mov}), où V_{trans} est la mesure transformée ; V est la mesure originale ; ß est la pente de régression de la relation (Log V/log LS); LS est la longueur standard du poisson; LS moy est la moyenne des LS. Les distances transformées ont servi à réaliser une analyse factorielle discriminante (AFD) [6], au moyen du logiciel R. Les deux premiers axes de l'analyse factorielle discriminante absorbent 68,45 % de la variabilité totale. Les résultats obtenus indiquent l'existence de deux groupes morphologiquement différents de S. porcus : le premier est représenté par l'échantillon de la région Sud, le deuxième par les deux échantillons des régions Est et Nord.

Fig. 2. Dispersion des individus définis par les variables métriques dans le plan de l'AFD selon les régions Nord, Est et Sud

Les résultats de notre analyse discriminante mettent en évidence une différenciation significative entre deux groupes de *S. porcus* Nord-est et Sud. L'absence d'homogénéité totale de l'espèce pourrait être interprété comme étant le résultat du caractère sédentaire de *S. porcus*.

LES BRYOZOAIRES ÉPIPHYTES DES HERBIERS À POSIDONIA OCEANICA DES CÔTES TUNISIENNES

Dorsaf Ben Ismail ¹*, Oum Kalthoum Ben Hassine ¹ and Jean-loup D'hondt ²

¹ Unité de recherche Biologie, Ecologie et Parasitologie des Organisme Aquatique, Faculté des Sciences de Tunis, 2092, Tunisie dorsaf.ghriss@gmail.com

² Département milieux et peuplements aquatiques, Muséum national d'histoire naturelle 55 rue de Buffon 75005 Paris, France

Abstract

Dans ce travail, nous nous sommes intéressés à l'étude des Bryozoaires des herbiers de Posidonie au niveau de cinq sites, répartis sur les côtes Nord-est et Sud-est de la Tunisie. Un échantillonnage saisonnier a été effectué durant une période de trois ans. Au cours de ce suivi, nous avons recensé 90 espèces de Bryozoaires appartenant aux trois classes Cheilostomona, Cyclostomona et Ctenostomona.

Keywords: Bryozoa, Posidonia

Les herbiers de posidonie sont traditionnellement considérés comme la superposition de trois biotopes : la matte, les rhizomes et les feuilles. Seules les deux dernières strates sont concernées par la faune des Bryozoaires [1]. L'objectif de cette étude est de contribuer à la connaissance de la richesse spécifique de la communauté des bryozoaires épiphytes des herbiers de Posidonie de la côte tunisienne et à la caractérisation de la faune Bryozoologique de chaque compartiment de l'herbier. Pour cela, un échantillonnage saisonnier a été effectué durant une période de trois ans (octobre 2005 - décembre 2008) au niveau de cinq sites, répartis sur les côtes Nord-est (Bizerte, Gammarth, Sidi Raies, El Hawaria) et Sud-est (Kerkennah) de la Tunisie. Les prélèvements ont été effectués, au cours de plongées sousmarines, au moyen d'un quadrat de 20 cm de côté [2]. Afin de caractériser l'état de l'habitat et du peuplement, nous avons calculé la richesse spécifique (nombre d'espèces), l'indice de Simpson (Is), l'indice de Shannon - Weaver (H') et l'indice d'équitabilité. Au total, nous avons recensé 90 espèces appartenant à trois classes : Cheilostomata (73 espèces), Cyclostomata (13 espèces) et Ctenostomata (4 espèces). Parmi les Cheilostomata, les trois espèces. Electra posidonia, Microporella ciliata et Turbicellepora avicularis. dominent au niveau des cinq sites. Les espèces observées sur les Rhizomes sont plus importantes en nombre (54) que celles trouvées sur les feuilles (36). Six espèces (Copodozum planum, Pherusella tubulosa, Microporella ciliata, Crisia fistulosa, Schizomavella hastata et Reptadeonella violacea) ont été récoltées aussi bien sur les rhizomes que sur les feuilles. Le dendrogramme de la classification hiérarchique (Fig.1) a permis de séparer deux assemblages : le premier est formé par le site de Kerkennah et le second est composé par les quatre autres sites.

Fig. 1. Dendrogramme de la classification hiérarchique des cinq stations étudiées (K : Kerkennah ; BM: Bizerte ; G : Gammarth ; SR : Sidi Rais)

Le test de Simper a montré que *E. posidonia, A. ledigera* et *M. ciliata* sont les espèces qui ont le plus contribué à cette distribution. L'ensemble des résultats obtenus sont conformes aux observations d'autres auteurs en Méditerranée [1], [3] et [4]. La riche faune rencontrée des bryozoaires épiphytes reflète l'intérêt écologique de l'herbier à *Posidonia oceanica*.

Abstract

La caractérisation biochimique d'*Holothuria polii* et *d'Holothuria tubulosa*, récoltées au niveau de la côte Est de la Tunisie a permis de noter quelques différences entre les deux espèces et de montrer leur importance nutritionnelle (teneur en protéines de l'ordre de 8 g/100g, teneur en lipides de l'ordre de 10 g/100g et une teneur moyenne en sucres de 15 mg/g). Leur teneur moyenne en polyphénols est de 50 µg/g. Ces substances présentent une activité antioxydante non négligeable qui permettrait une éventuelle valorisation industrielle de ces espèces.

Keywords: Chemical Analysis, Echinodermata, Infralittoral

Introduction - Les holothuries des côtes tunisiennes constituent une faune méconnue aussi bien sur le plan biologique qu'écologique. Parmi les 11 espèces inventoriées en Tunisie [1], *Holothuria polii* et *Holothuria tubulosa* sont à la fois fréquentes et abondantes le long du littoral Est. Ce travail a pour objectif la valorisation nutritionnelle de ces organismes marins.

Matériel et méthodes - Les holothuries étudiées proviennent de la région de Monastir (Méditerranée centrale). Les spécimens ont été récoltés vivants par plongée en scaphandre autonome à 7 m de profondeur entre le mois d'août 2008 et janvier 2009. Ils ont été directement congelés à -20°C jusqu'à leur analyse. Après tri et identification [2] (figure 1), les individus ont été disséqués. Seule la cuticule a été récupérée et découpée en morceaux. La teneur en protéines a été dosée par la technique « Kjeldahl » [3]. L'extraction et la quantification des lipides totaux (matières grasses) des holothuries ont été réalisées par Soxhlet [4]. Les sucres totaux sont dosés par la méthode au DNS (acide dinitrosalicylique) [5]. Le dosage des polyphénols totaux a été réalisé en utilisant le Folin Ciocalteu [6]. Le dosage de l'activité antioxydante a été réalisé selon Brand-Willizms [7] par réduction du DPPH° (2,2-diphényl-1-picryl-hydrazyl) et en utilisant comme antioxydant standard le TROLOX.

Résultats et discussion - Les analyses effectuées montrent que les teneurs en protéines pour les deux espèces d'holothuries sont proches : 7,78 g/100g pour Holothuria polii et 8,56 g/100g pour Holothuria tubulosa (figure 2). Par conséquent, ces 2 espèces ne constituent pas une source importante en protéines comparativement aux autres organismes marins [8], [9]. Toutefois, la teneur en matières grasses est plus élevée chez Holothuria polii (11,7 g/100g) comparativement à Holothuria tubulosa (9,5 g/100g). Les holothuries constituent une source appréciable en lipides comparées aux bivalves comestibles [8], [9]. Les sucres totaux représentent des teneurs faibles (13,75 mg/g pour Holothuria tubulosa et 16,2 mg/g pour la seconde espèce). Quant à la teneur en polyphénols, elle est de 64 µg/g pour Holothuria tubulosa et de 40 µg/g pour Holothuria polii. Les composés phénoliques peuvent avoir de nombreuses propriétés physiologiques et peuvent jouer un rôle anti-allergène, anti-inflammatoire, antimicrobien et antioxydant. En effet, l'étude des propriétés antioxydantes des substances phénoliques chez Holothuria tubulosa montre un pouvoir anti-radicalaire près de 2 fois plus important que celui d'Holothuria polii (respectivement de 24 et 14 mM équivalent Trolox).

Fig. 1. Caractéristiques physico-chimiques et biochimiques des espèces d'holothuries isolées de Tunisie

Fig. 2. (a) Holothuria polii récoltée à Monastir (janvier 2009); (b) spicules Holothuria polii

Conclusion - La liste des espèces aquatiques utilisables pour des extractions de molécules actives ne cesse de s'enrichir. Elle comporte essentiellement des groupes d'espèces méconnues et n'ayant pas d'intérêt halieutique majeur. Dans ce contexte, une étude préliminaire sur 2 espèces d'holothuries des côtes tunisiennes a été entreprise pour leur valorisation. Les résultats de cette étude mettent en évidence des propriétés nutritionnelles intéressantes. Nos recherches futures seront axées sur l'extraction d'autres molécules actives comme les saponines.

LES ESPECES NON INDIGENES DU MACROBENTHOS DES LAGUNES DU SUD-EST TUNISIEN : POINT SUR LA SITUATION

Jamila Ben Souissi ¹*, Chirine Kahri ¹, Mohamed Ben Salem ² and Jeanne Zaouali ¹ ¹ Institut National Agronomique de Tunisie, Tunis, 1082, Tunisie - bensouissi.jamila@inat.agrinet.tn ² Faculté des Sciences de Tunis, 2092, Tunisie

Abstract

Des observations récentes faites au cours de campagnes de prélèvements médio et infralittoraux d'organismes benthiques dans des lagunes côtières tunisiennes nous ont permis de mettre en évidence l'installation de 4 crustacés d'origine lessepsienne signalés pour la première fois en Tunisie et sur la rive Sud de la Méditerranée (amphipode *Caprella scaura*) et en Méditerranée centrale (amphipodes *Maera hamigera, Gammaropsis togoensis* et l'isopode parasite *Anilocra pilchardi*). *Keywords: Crustacea, Biodiversity, Gulf Of Gabes, Infralittoral, Lagoons*

Les prospections menées régulièrement au niveau de la frange littorale marine tunisienne et dans les milieux lagunaires (Boughrara et les Bibans) ont permis d'inventorier parmi les communautés benthiques médio et infralittorales des substrats meubles et rocheux trois nouvelles espèces d'amphipodes et un isopode. La liste de l'amphipodofaune de Tunisie ne cesse de s'enrichir. Des investigations récentes font état de 2 Amphipodes lessepsiens nouveaux *Elasmopus pectenicrus* et *Stenothoe gallensis* [1]. Ces 2 espèces sont récoltées en nombre important dans nos échantillons en provenance de la lagune de Boughrara surtout parmi les algues brunes. De manière concomitante, nos prélèvements regroupent des espèces non encore inventoriées :

Gammaropsis togoensis (Schellenberg, 1925). Cet amphipode originaire des océans Indien et Pacifique et des côtes Est et Ouest atlantiques a été signalé uniquement en Méditerranée orientale en Israël et en Turquie [2], [3]. Nous avons récolté massivement cette espèce (139 individus) en octobre 2009, à Boughrara, sous les pierres à des profondeurs n'excédant pas 1,5m. La taille des spécimens se situe entre 3,8 à 4,2 mm pour les mâles et 2,5 à 2,8 mm pour les individus femelles.

Caprella Scaura (Templeton, 1836) a été trouvée au cours de la saison estivale dans les lagunes de Boughrara et des Bibans (juin à septembre 2009). Cet amphipode euryhalin originaire de l'océan Indien [4], prospère dans les stations peu profondes, principalement parmi les rhodophycées appartenant aux genres *Gracillaria* et *Polysiphonia*. Un total de 287 spécimens ont été échantillonnés avec une densité moyenne oscillant entre 7 et 24 individus/m². C'est une espèce des communautés "fouling" occupant de nombreux habitats comme la végétation marine et les bryozoaires du genre *Bugula* [5]. Cet amphipode a été uniquement signalé dans plusieurs régions des côtes européennes dont la lagune de Venise [6], [7]. Nous le mentionnons pour la première fois sur la rive Sud de la Méditerranée (Fig. 1).

Maera hamigera (Haswell, 1880). Cette espèce a été récemment trouvée au niveau des côtes libyennes [8]. Nous avons récolté dans la lagune des Bibans quelques rares spécimens (11 individus) associés aux amphipodes lessepsiens *Elasmopus pectenicrus* et *Stenothoe gallensis*.

Anilocra pilchardi est un isopode, cymothoïdae parasite. Il a été récolté lors de nos prospections sur de nombreuses espèces ichtyologiques autochtones et exotiques pêchées dans les lagunes de Boughrara et des Bibans. Les poissons hôtes pour cet ichtyoparasite sont nombreux. Nous l'avons trouvé fixé par ordre décroissant de préférence sur les mugilidae (*Chelon labrosus* et *liza saliens*), sur les Sparidae (*Diplodus sargus* et *Boops boops*), sur les Clupéidae (*Sardina pilchardus* et *Sardinella aurita*) et sur l'Hemiramphidae *Hemiramphus far*. Ce parasite hématophage non spécifique a été signalé seulement en Méditerranée orientale (côtes libanaises) [9]. Cet isopode semble bien acclimaté et se reproduit dans son nouveau biotope (tous les stades ont été observés, adultes, sub-adultes et femelles ovigères).

La faune marine tunisienne montre des modifications importantes qui se traduisent par l'introduction et l'acclimatation massive d'espèces non indigènes, surtout d'origine lessepsienne. Ce phénomène de bioinvasion s'est accéléré lors des dernières décades probablement en relation avec le réchauffement des eaux marines et l'intensification du trafic maritime.

PEUPLEMENTS ASSOCIES A CYSTOSEIRA AMANTACEA STRICTA DANS LA REGION OUEST ALGEROISE (TIPAZA)

Myriam Benali¹ and Chafika Rebzani Zahaf¹*

¹ Faculté des Sciences Biologiques (FSB) Université Sciences et Technologies Houari Boumedienne (USTHB), Alger, 16111, Algérie - chafikarebzanizahaf@gmail.com

Abstract

Une étude de la biodiversité faunistique associée à la Chromobionte, endémique de la Méditerranée, *Cystoseira stricta*, de la région de Tipaza a été effectuée au niveau de l'étage infralittoral supérieur de quatre sites. Elle a permis d'identifier 117 espèces quantitativement dominées par les Crustacés.

Keywords: Endemism, Algae, Bio-Indicators, Zoobenthos, Biodiversity

Introduction

L'espèce *Cystoseira stricta* constitue l'élément fondateur d'un écosystème remarquable de l'infralittoral supérieur ; cette espèce est directement soumise à l'impact anthropique croissant dans la région d'étude. L'analyse de la biodiversité qui le compose est un outil appréciable pour la caractérisation du milieu marin et de sa biosurveillance. L'intérêt porté sur l'étude de la faune associée aux Cystoseires est nouveau en Algérie. Cette étude concerne 4 sites de référence de la région de Tipaza : Ain Tagourait, Anse de Kouali, Anse des Carrières et El Hemdania ; ces zones sont considérées comme étant d'intérêt biologique marine. Les objectifs sont la localisation et une meilleure connaissance de l'identité et de la structure de cette biocénose formée par une espèce méditerranéenne endémique et vulnérable [3].

Matériels et méthodes

Les denses recouvrements de *Cystoseira stricta* observés au niveau de la zone infralittorale supérieure des quatre stations d'études ont été investis. Une surface homogène de $2m^2$ par saison (été/hiver) et par station a été délimitée pour les 5 réplicats (20X20cm). Un grattage jusqu'à la roche a été effectué. Le tri du macrobenthos s'est fait sur tamis à mailles d'Imm de diagonale. La biomasse sèche des Cystoseires, par mètre carré, a été estimée pour chaque site.

Résultats et discussions

Les biomasses sèches moyennes des Cystoseires ont été estimées entre 2344 et 3460g MS/m², avec des densités supérieures en été. Bellan-Santini, (1969) [1] estimait cette biomasse moyenne à environ 2 200g MS/m² à Marseille. Un total de 117 espèces a été recensé en association à Cystoseira stricta au niveau des quatre sites étudiés. Un nombre total de 8 485 individus est noté, ils sont répartis en 39 espèces de Crustacés, 37 de Mollusques, 23 de Polychètes, 5 d'Echinodermes, 6 de Cnidaires, 3 de Sipunculidés, 2 de Spongiaures, une de Némerte et une espèce indéterminée de Bryozoaire. Le nombre d'espèces le plus important a été enregistré à l'Anse de Kouali (78 espèces), suivi d'Ain Tagourait (71 espèces), d'El Hemdania (63 espèces) et enfin de l'Anse des Carrières (61 espèces). Cette analyse de la biodiversité met en évidence une richesse spécifique relativement importante au sein des peuplements à Cystoseires, particulièrement ceux à Cystoseira stricta. Selon Bellan-Santini [1], les conditions d'hydrodynamisme intense favorisent le développement d'une faune importante qui trouve « refuge » au sein du peuplement à C. stricta. Il considère que ce peuplement de mode battu ne permet le développement que d'espèces fortement adaptées à ce type de biotope, d'où sa relative pauvreté du point de vue qualitatif.

Le groupe zoologique dominant est celui des Crustacés au niveau de toutes les stations. Néanmoins, les sites d'Ain Tagourait et d'El Hemdania présentent les dominances les plus élevées (supérieure à 60%) pour ce groupe. Les stations Anse de Kouali 3 et Anse des Carrières ont respectivement des dominances de 59,43% et 58,44%. Bellan-Santini [4] indique qu'une richesse spécifique et des dominances quantitatives élevées en Crustacés reflètent un milieu salubre et des eaux pures. L'auteur fixe une barrière moyenne de 15 espèces à cette fin. D'un point de vue spécifique, les résultats obtenus dans cette présente étude indiquent des milieux relativement salubres, avec plus de 18 espèces par site.

Le groupe écologique regroupant les espèces d'Algues Photophiles (AP) domine largement la macrofaune. L'analyse a révélé la présence de 9 espèces communes aux quatre sites dont 4 sont particulièrement importantes. Les Crustacés caractéristiques des eaux pures et agitées *Hyale pontica*, et à moindre degré *Caprella liparotensis*, dominent pratiquement au niveau de tous les sites. La Polychète opportuniste *Platynereis dumerilli*, espèce sentinelle selon Bellan [2], est fortement représentée aux sites Anse de Kouali 3 et Anse des carrières témoignant d'une relative altération de la qualité des eaux ; le premier site étant situé à proximité d'un complexe touristique, le second près de oued Nador (effluents importants du bassin versant). L'analyse des groupes trophiques a révélé la nette prépondérance des brouteurs.

Les valeurs des indices de diversité (Shannon, H' et Equitabilité, E) et les DRF révèlent un peuplement diversifié qui tend à l'équilibre.

Pour les principales espèces, la présence de certaines espèces a permis d'évaluer la situation écologique des sites étudiés. Ainsi, le Crustacé *Elasmopus pocillimanus* est dominant à El Hemdania où il supplante le Crustacé de mode agité *Hyale pontica*, témoignant probablement d'une affinité pour des eaux moins agitées. Les données concernant les peuplements infralittoraux superficiels, entre autre le peuplement à *Cystoseira stricta* (mode battu) ont mis en évidence que *Jassa falcata* affectionnait probablement les zones à fort hydrodynamisme et non les zones polluées au sens strict. Dans cette étude, *Jassa falcata* est une espèce fréquente au sein des peuplements *Cystoseira stricta*, la dominance de *Jassa falcata* varie entre 1,08% (El Hemdania) et 2,59% (Anse de Kouali 3).

Conclusion

L'espèce Cystoseira stricta est une espèce à forte valeur patrimoniale, c'est un atout de classification des zones où elle a été identifiée dans le rang d'espaces d'intérêt prioritaire de protection ; ses biomasses importantes, comparables à celles enregistrées dans d'autres régions méditerranéennes, justifient encore plus la vulnérabilité et la grande valeur écologique de ces sites. L'intérêt des peuplements qui lui sont associés et leur étude est démontré par la richesse spécifique importante qu'ils recèlent, mais aussi par la particularité de cette faune qui permet de caractériser le milieu du point de vue hydrodynamique (mode battu) et du degré de salubrité. Si les espèces indicatrices d'eaux pures sont dominantes au sein de ces sites, il n'en demeure pas moins que des espèces sentinelles indicatrices de perturbations contribuent fortement au peuplement faunistique à l'Anse des Carrières et à l'Anse de Kouali, constituant un premier signal d'une altération de l'écosystème. Pour la conservation des types d'habitats marins naturels et remarquables et sur la base des critères méditerranéens, des fiches techniques d'évaluation écologique ont été établies pour chaque site. Ces fiches synthétisent les données scientifiques recueillies avec pour finalité de fournir des documents de prises de mesures de protection et de conservation à l'usage des gestionnaires.

AGE, CROISSANCE ET REPRODUCTION DU SAR COMMUN DIPLODUS SARGUS (SPARIDAE) DES COTES DE L'EST ALGERIEN

Wafa Benchalel¹* and Mohamed Hichem Kara¹

¹ Laboratoire bioressources marines, Université Badji-Mokhtar, Annaba, El Hadjar, 23000 Algérie - wafachalel@yahoo.fr

Abstract

L'age, la croissance et la reproduction sont étudiés chez le sar commun *Diplodus sargus sargus (L., 1758)* des côtes Est de l'Algérie. La lecture des otolithes de 241 individus a permis de déterminer les paramètres de croissance par le modèle de Von Bertalanffy. La relation liant le poids à la taille est globalement isométrique. L'activité sexuelle a lieu de janvier à mai et la ponte au printemps (mars à mai). La première maturité sexuelle est acquise à partir d'une longueur totale (Lt₅₀) de 20 cm, quel que soit le sexe, et correspond à un âge d'environ 4 ans.

Keywords: Fishes, Algerian Basin, Growth, Reproduction

Introduction

Diplodus sargus sargus (L., 1758) est un poisson démersal assez commun et largement répandu dans l'ensemble du bassin méditerranéen [1]. De bonne valeur commerciale, il est très recherché par la pêche locale et joue un rôle écologique important au sein des écosystèmes côtiers qu'il occupe. Cette étude fournit les premières données sur l'âge, la croissance et la reproduction de *D. sargus sargus* sur les côtes Est de l'Algérie.

Matériel et méthodes

Un total de 241 individus (143 mâles et 98 femelles), de longueur totale comprise entre 11,2 et 34,6 cm et de poids total allant de 20,2 à 746 g, provenant de la pêche aux filets maillants, sont examinés. La détermination de l'âge est réalisée par otolithométrie. La longueur totale correspondant à chaque âge est rétro-calculée par la méthode de Lee [2]. Les croissances linéaire et pondérale sont ajustées au modèle de Von Bertalanffy [3]. Les paramètres L_{∞} , K et to sont déterminés par le programme Fisat II (version 1.2.2). La croissance relative est établie entre la longueur totale (Lt en mm) et le poids éviscéré (Pe en g) [4]. La relation taille-poids porte sur 440 individus (178 femelles et 262 mâles). La période de reproduction est déterminée pour les mâles (N = 262) et les femelles (N = 178) à partir de l'évolution du rapport gonado-somatique (RGS). La taille à la première maturité sexuelle est estimée.

Résultats et discussion

L'analyse des variations mensuelles de l'allongement marginal des otolithes chez les différents groupes d'âge, montre l'individualisation d'un seul anneau d'arrêt de croissance par an et se forme en juin. Les tailles des sars aux différents âges sont rétro-calculées, en tenant compte de l'existence d'une corrélation significative entre la longueur totale du poisson et le rayon de son otolithe (r = 0,897, p \leq 0,01). L'âge maximum des poissons péchés est de 10 ans (tab. 1). La croissance linéaire absolue est exprimée comme suit:

Femelles:	$Lt = 354,1$ ()1-e - $^{0,160}(t + 0,605)$
Mâles:	$Lt = 351,4 (1-e - {}^{0,161} (t + 0,427))$
Sexes confondus:	$Lt = 363.9 (1 - e^{-0.154} (t + 0.488))$

La relation liant le poids éviscéré du poisson à sa taille est isométrique chez les deux sexes confondus, chez les mâles et chez les femelles:

Femelles:	$Pe = 2,720.10-5 Lt^{-2,945}$
Mâles:	Pe =1,900.10-5 Lt 3,009
Sexes confondus:	Pe =2,240.10-5 Lt ^{2,987}

Le suivi mensuel des valeurs moyennes du rapport gonado-somatique (fig. 1) montre que la reproduction de *D. sargus sargus* se déroule entre janvier et mai. Les valeurs maximales du RGS marquant la maturation des gonades sont enregistrées en mars (3,864) pour les femelles et en avril (4,443) pour les mâles. Cette période est identique à celle déterminée dans le golfe de Tunis [5]. Le sar commun se reproduit à partir d'une longueur totale (Lt₅₀) de 20 cm chez les femelles et 20,2 chez les mâles, ce qui correspond à un âge d'environ 4 ans. Cette taille est de 21 cm dans le golfe de Tunis.

IMPACT DES CHANGEMENTS CLIMATIQUES ET DES ESPECES EXOTIQUES SUR LA BIODIVERSITE ET LES HABITATS MARINS AU LIBAN

Ghazi Bitar 1*

¹ Faculté des Sciences, Université libanaise - ghbitar@ul.edu.lb

Abstract

Le changement climatique du bassin levantin et en particulier au Liban est un fait incontestable. Le Canal de Suez et le réchauffement global sont essentiellement à l'origine de l'arrivée et de l'établissement des espèces exotiques et par suite au changement biotique dans la région. Ces espèces à affinité tropicale ont contribué à la restructuration des peuplements et ont réussi à former des faciès particuliers. Plusieurs espèces y sont bien établies et présentent un comportement d'espèces envahissantes. *Keywords: Global Change, Species Introduction, Eastern Mediterranean*

Introduction Depuis 78 ans, Gruvel [1] a souligné la présence en Méditerranée orientale d'espèces « lessepsiennes » en provenance de Mer Rouge, mais ne mentionne pas l'influence de ces espèces d'affinité chaude. Probablement, le rôle de ces espèces dans la structuration des biocénoses indigènes (surtout benthiques) n'était pas encore significatif. En vue des connaissances progressives des habitats marins, la côte Levantine et en particulier celle du Liban représente un domaine intéressant d'étudier les changements biotiques liés à la «tropicalisation» de la Méditerranée et aux espèces introduites qui ont augmenté au dépens des espèces indigènes [2].

Matériel et méthodes Depuis 1991, nous avons prospecté systématiquement la côte libanaise en plongée, en effectuant des relevés visuels et en prélevant des échantillons. Plusieurs campagnes de plongées intensives inspirées par la même motivation (faire progresser l'inventaire de la biodiversité, relever les incidences des activités humaines et en particulier l'impact des espèces exotiques) ont eu lieu dans le cadre de la coopération libano-française et libano-espagnole. La reconnaissance visuelle immédiate des communautés a été complétée par des photographies sous-marines et par prélèvements d'organismes, entre les hauts niveaux et 67 m de profondeur.

Etat des lieux Le changement climatique en Méditerranée est un fait incontestable. Des séries d'enregistrements de température à long terme ont démontré pour la Méditerranée Nord Occidentale une tendance au réchauffement de l'ordre de 1°C. De même des événements extrêmes comme ceux des étés 1999 et 2003 ont aboutit à des mortalités massives d'invertébrés de substrats durs [3]. Au Liban, les études de l'impact du changement climatique sur la vulnérabilité des écosystèmes marins sont peu nombreuses et fragmentaires. Des séries temporelles de 4 ans (1999 à 2002) ont montré des différences interannuelles ainsi qu'un changement de niveau de la thermocline [4]. L'impact du changement global en Méditerranée orientale est plus ancien qu'en Méditerranée occidentale vu que le régime thermique y est beaucoup plus élevé. On a souligné, Il y a 45 ans, une fréquence élevée des espèces à affinité chaude dans le bassin levantin sans mentionner l'influence des espèces exotiques de la Mer Rouge [5]. Probablement, le rôle de ces espèces dans la structuration des biocénoses de la Méditerranée n'était pas encore significatif. Dans les parties les plus chaudes de Méditerranée comme la côte libanaise, les altérations des écosystèmes, les mortalités et la disparition des espèces sensibles au réchauffement se sont produites il y a longtemps. Les gorgones qui ont été signalées au Liban il y a plus de 75 ans [1], ne sont plus citées dans la littérature au moins dans les 60 premières mètres. La moule Mytilus galloprovincialis est remplacée par l'espèce exotique Brachidontes pharaonis. L'herbier Posidonia oceanica n'est plus vu au Liban depuis 1977 (observations personnelles). Cet herbier est remplacé par les herbiers de Cymodocea nodosa et Halophila stipulacea. Pour les poissons herbivores, les deux espèces lessepsiennes Siganus rivulatus et S. luridus sont en cours de remplacer le poisson local Sarpa salpa. Le crabe Charybdis helleri devient de plus en plus abondant aux dépens des Eriphia verrucosa, Pilumnus hirtellus et Pachygrapsus marmoratus. L'arrivée des espèces exotiques est due en grande partie à la tropicalisation et à leur capacité de résistance plus importante que celle des espèces indigènes sans oublier la place disponible. Actuellement, parmi plus de 25 principaux habitats (de la surface jusqu'à 45 m), il y en a 18 qui sont formés d'espèces exotiques dont 4 (soulignées) sont envahissantes: Brachidontes pharaonis, Pomatoleios kraussii, Caulerpa scalpelliformis, Ganonema farinosum, Macrorhynchia philippina, Oculina patagonica, Cerithium scabridum, Phallusia nigra, Spondylus spinosus, Chama pacifica, Herdmania momus, Galaxaura rugosa, Stypopodium schimperi, Caulerpa racemosa var. lamourouxii, Codium taylorii, Halophila stipulacea, Strombus decorus et Codium sp. groupe repens [2, 6 et observations personnelles]. La capacité de résistance des espèces exotiques est expliquée par leur pouvoir de s'installer en mer, à des profondeurs différentes (y compris les ports, les grottes et les salissures), aussi bien dans les zones propres et polluées (e.g. C.

pacifica, S. spinosus, Pinctada radiata, S. decorus, P. Kraussii, Synaptula reciprocans, P. nigra, H. momus, Symplegma brakenhielmi et C. helleri). Le réchauffement d'origine anthropique peut avoir des affections et des conséquences visibles sur les écosystèmes et sur les espèces aussi bien indigènes et exotiques. C'est le cas du blanchissement et parfois la disparition dans plusieurs localités libanaises des coraux Oculina patagonica. Plusieurs espèces et certains écosystèmes sont souvent déjà fragilisés par les pollutions et/ou la surexploitation et la fragmentation des habitats. Ils peuvent ainsi présenter une très grande sensibilité à un changement du climat. C'est le cas des espèces menacées qui deviennent de plus en plus rares : Hippospongia communis, Spongia spp., Charonia lampas, Charonia tritonis variegata, Tonna galea, Stramonita haemastoma, Pinna nobilis, Sabella spallanzanii, et Cystoseira amentacea. Il convient de rappeler que certaines conséquences des changements climatiques et de l'expansion des espèces envahissantes seront irréversibles, et que, dans certains de ces cas, il n'existe donc pas de réduction de la vulnérabilité. C'est là un risque important tout particulièrement pour la biodiversité marine. On est donc en train d'assister à un bouleversement de la géographie du climat et des biocénoses en Méditerranée et en particulier dans sa partie levantine, conditionnant des déplacements dans l'espace des espèces leur permettant de se maintenir dans des conditions environnementales propices à leur croissance et leur reproduction. A titre d'exemple les poissons Thalassoma pavo et Diplodus cervinus cervinus qui sont devenus communs en Méditerranée nord occidentale [3].

Conclusion et perspectives Le fait que le réchauffement global et l'arrivée des espèces exotiques affectent le bassin levantin en général et la côte libanaise en particulier et contribuent à des changements biotique et bionomique, il est nécessaire d'élaborer des plans d'action nationaux et régionaux afin de bien contrôler et suivre la répartition de ces espèces en relation avec le réchauffement global. Une évaluation complète de la vulnérabilité de la côte et des écosystèmes marins ainsi que des études sur les mesures d'adaptation sont nécessaires pour faire face à l'impact du changement de climat. Les séries temporelles de la température, doivent être poursuivies dans le temps et sur une longue période pour qu'ils s'intègrent dans le cadre du changement climatique et par suite des scénarios de projection. En ce sens, la côte libanaise représente un biotope intéressant pour étudier les changements liés à la "tropicalisation" de la Méditerranée et aux espèces exotiques (introduites ou migratrices à travers le Canal de Suez) surtout que les connaissances des communautés benthiques et ichtyologiques ont progressivement augmenté.

³ Estación Aquicultura Andratx

Abstract

By analysing the isotopic composition of the cultured fish *Dentex dentex* and *Argyrosomus regius*, filter feeders and their food sources, it was demonstrated that unassimilated food sources could be reduced by using associated filter feeders in an integrative aquaculturemultitrophic method. This assessment has demonstrated a reduction of waste fluxes to the benthic compartment linked with the *Mytilos galloprovincialis* culture mixed with fish cages.

Keywords: Aquaculture, Balear Sea, Bivalves

Introduction

The rapidly increase of marine aquaculture to global sea food supplies implies changes in energy and nutrient fluxes of marine fish farming, impacting on benthic ecosystems by uneaten pellet food and faecal pellets (as the main components of particulate organic matter, POM) affecting habitats and communities such as the seagrass *Posidonia oceanica* (L.) communities [1]. A multitrophic system to reduce the impact of fish farm cages on the water and communities around cages is a possible solution, including primary sources of organic matter, filter feeders and consumers.

Materials and Methods

Fifteen cultivated specimens of *Dentex dentex* (Linnaeus, 1758), nine of *Argyrosomus regius* (Asso, 1801) and the bivalves *Mytilus galloprovincialis* (Lamarck 1869) and *Chlamys varia* (Linné 1758) were analysed to measure carbon and nitrogen isotope ratio and compared to the food sources supplied. Plankton and the particulated and sedimented organic matter were acidified by adding HCl 2N.

Results and Discussion

The comparision of the fish species and the filter feeders studied and their food sources was showed in figure 1. The percentage contribution of each source to each stable isotope composition (Mixing Models, Isosource, Fig. 2) indicates that filter feeders feds on fish farm wastes and presents some variability in the constancy at the bivalves, which could be related to the physiological and biochemical mechanisms occurring through the trophic increase in d¹⁵N values, and to food selectivity [2]. The additional potential input of organic matter into the system by the excretion of faeces and pseudofaeces associated to filter feeders would not have affected the water-column material neither sediment deposition, as it has been demonstrated [3] according to current velocities in the vicinities of the aquaculture station. Furthermore, it has been documented [4] that the association of *Mytilus galloprovincialis* with fish farm cages has a greatly profit from the aquaculture by the increasing mussel size and a reduction of the duration of the production cycle, which has been also demonstrated with the CI values of the bivalves of the present work.

Fig. 1. Distribution of carbon and nitrogen stable isotope ratios (mean \pm S.E.M.) among the different samples for organic matter fluxes. Food sources (grey squares), filter feeders and occasional species (white triangle), pellet food (grey circle) and cultured fish (white rhombus) are shown.

ISOTOPIC OFFSET BETWEEN MUSCLE AND SCALES OF THREE MEDITERRANEAN FISHES: DENTEX DENTEX, ARGYROSOMUS REGIUS AND XYRICHTYS NOVACULA, AT MARINE PROTECTED AREAS

Andreu Blanco 1*, Salud Deudero 2 and Antonio Box 3

¹ Laboratory of Biology and Physiology of Fish Larvae, Instituto de Investigaciones Marinas (CSIC) - andreublanco@iim.csic.es ² Centro Oceanográfico de Baleares, Instituto Español de Oceanografía

Abstract

The present work test fish-scale sampling as a non-lethal technique for trophic level assessment instead of muscle isotopic determinations in fishes *Dentex dentex*, Argyrosomus regius and Xyrichtys novacula. The isotopic offset (Δ^{13} Cand Δ^{15} N) between muscle and scales indicate that the application of scales instead of muscle allow to apply non-lethal methods on isotopic studies regarding fish species for conservation purposes. This technique has been proven to be appropriate for trophic studies of fishes at marine protected areas

Keywords: Carbon, Food Webs, Trophic Relations

Introduction

Stomach content analysis provides information on recently ingested food sources while stable isotope analyses, particularly carbon and nitrogen, provides information on the long-term diets of organisms. Environmental conditions preserve chemical recording in animal tissues [1]. The analysis of different tissues gives the advantage of revealing the timescale needed to assimilate a new nutrient source [2]. Studies on fish tissue-diet isotope offset of endangered or protected fish species allows us to focus on conservation management. Material and Methods

Fishes Dentex dentex, Argvrosomus regius and Xvrichtvs novacula were selected owing to their wide distribution in Mediterranean waters, their economic importance and their value in the recreational fisheries of the Balearics. Isotopic composition (δ^{13} C and δ^{15} N) of white muscle and scales of *Dentex dentex*, Argyrosomus regius and Xyrichtys novacula are represented in Figure 1.

Fig. 1. Distribution of carbon and nitrogen stable isotope ratios ($\delta^{13}C$ and $\delta^{15}N)$ of farmed Dentex dentex (n = 20), farmed Argyrosomus regius (n = 9) and wild Xyrichtys novacula (n = 41), significant differences (p < 0.001) observed between tissues. Squares represent free-bone white muscle and rhombuses represent fish scales.

Results and Discussion

The present work shown significant correlation between stable isotope muscle tissue and scales signatures in A. regius (p < 0.01) and in Xyrichtys novacula (p < 0.001). No correlation was found in the muscle and scale stable isotope signatures of Dentex dentex. Nonetheless, all the species sampled showed significant differences between muscle and scale stable isotope (δ^{13} C and δ^{15} N) signatures (Paired t-test, p < 0.01). Tissue offset of ¹³C and ¹⁵N values derived from isotopic analyses of D. dentex did not varied significantly (Figure 2) and

presented a constancy in the offset values (enriched $3.02 \pm 0.06\%$ for ¹³C and depleted 0.91 \pm 0.14‰ for ¹⁵N). A. regius and X. novacula presented a linear regression (^{13}C enrichment of 2.27 \pm 0.07‰ and 2.52 \pm 0.04‰ and ^{15}N depletion of $1.69 \pm 0.06\%$ and $0.96 \pm 0.03\%$, respectively). The present work has yielded a correction factor for isotopic analyses that may be applied to marine fish species Argyrosoums regius and Xyrichtys novacula. The constancy in isotopic offset values of the farmed fish Dentex dentex (with a linear regression close to $R^2 = 0$; Figure 2) was related with the straight length values of the sampled individuals. Those results implie that lethal sampling is unnecessary, since other non-lethal tissues can provide a measure of the $\delta^{13}C$ and \delta15N signatures without affecting abundances by removing resources from the ecosystem or reducing their gene pools [3].

Fig. 2. Isotopic offset for $\delta^{13}C$ (A) and $\delta^{15}N$ (B) between free-bone white muscle and scales from Dentex dentex, Argyrosomus regius and Xyrichtys novacula

CHANGES IN THE CILIATE COMMUNITY OF EUTROPHICATED VRANJIC BASIN (MIDDLE ADRIATIC SEA) DURING 2004-2005

Natalia Bojanic ¹* and Olja Vidjak ¹

¹ Institute of Oceanography and Fisheries - Split - bojanic@izor.hr

Abstract

Temporal variability in ciliate abundances was investigated in eutrophicated Vranjic Basin (middle Adriatic), before and after activation of new sewage system. The differences were evident in the absence of nonloricate summer peak and reduction of average nonloricate and tintinnid abundances in 2005, 2.3 and 1.9 times, respectively. The distinction in tintinnid taxonomical composition between years was not noticed.

Keywords: Adriatic Sea, Density, Eutrophication, Zooplankton

The effects of eutrophication in the Kaštela Bay, primarily in the phytoplankton community, were first observed at the end of seventies. Since the end of 1980, summer "red tide" blooms have occurred regularly [1], causing occasional mortalities to shellfish and demersal fish. These biological changes were accompanied by oxygen supersaturation in the surface and hypoxia in the bottom layers. After the activation of modern sewage system in November 2004, disappearance of nutrient and oxygen extremes, decrease in bacterial and phytoplankton abundance and production, and re-establishment of the phytoplankton regular seasonal cycle were recorded [2].

In the Vranjic Basin the ciliates are an important zooplankton fraction, characterised by high biomass and intensive population dynamics [3]. As a result of their short generation time, they respond almost instantaneously to various environmental fluctuations and can act as stabilizers of the water-column community [4]. Therefore the aim of this study was to investigate possible changes in nonloricate (NLC) and tintinnid (TIN) assemblages after the activation of new sewage system.

Monthly samples were collected at one station located in the Vranjic Basin (43° 31.9'N; 16°27.2'E) in the middle Adriatic Sea, from January 2004 until November 2005, at 5 m depth intervals between the surface and bottom (15 m), using 5 l Niskin bottles. The plankton material was preserved and prepared for microscopic analysis as described in the reference [3].

Average column ciliate density values in the Vranjic Basin in 2004 ranged from 404 ± 131 (December) to 2510 ± 1638 ind.L⁻¹ (May), while the oscillations in 2005 decreased by the factor 2.2, ranging from 75 ± 54 (January) to 829 ± 249 (September). Temporal variability was primarily due to changes in NLC community (r=0.95; p<0.0001; N=67), representing 34.0-96.4% of the total ciliate abundance.

The most prominent feature of NLC seasonal dynamics was the occurrence of three peaks in 2004, and two in 2005 (figure 1). Unlike the spring and autumn increases recorded in both years, the summer maximum was not found in 2005. During the whole investigated period, the highest average abundance values of 1545 ± 1350 and 575 ± 283 ind.L⁻¹ were recorded in May, while autumn maxima were somewhat less pronounced. Apart from the high TIN abundances recorded in spring 2004, with the average column values of 966 ± 593 ind.L⁻¹ in May, TIN concentrations did not vary significantly during the rest of sampling period (figure 1).

Fig. 1. Seasonal distribution of ciliates in the Vranjic Basin during the 2004-2005 (NLC, nonloricate ciliates; TIN, tintinnids)

In both sampling years the NLC vertical distribution was characterised by quite homogenous distribution during the isothermal conditions. However, temperature stratification caused the redistribution of NLC, with the maximum in surface layers, particularly in May 2004 (3389 ind-L⁻¹ at 0 m). The exception was noted only in October 2004, when majority of NLC migrated to 10 m depth (2176 ind-L⁻¹). Apart from the hydrographical properties of the Basin, vertical distribution of TIN was related to their taxonomical structure. Among 44 determinated TIN species, statistical analysis extracted *Favella ehrenbergii, Codonellopsis schabi, Tintinnopsis beroidea* and *Helicostomella subulata* as discriminator species that contributed to dissimilarities between the sampling years with 23.4%.

Although the differences in ciliate abundances between 2004 and 2005 were not significant (p=0.0592), the distinction was clearly evident in the absence of NLC summer peak and reduction of average NLC and TIN abundances in 2005, 2.3 and 1.9 times, respectively [3, 5]. The differences in TIN taxonomical composition between years were not evident.

Future long-term investigations of the trophic relationships within microbial food web and interactions with abiotic environmental factors are needed for better explanation and understanding of ciliate role in this eutrophic marine ecosystem.

Abstract

The aim of the present study is to assess the presence of *Clavella stellata* in *Merluccius merluccius* from the southern Tyrrhenian Sea. 859 specimens of European hake, coming from two experimental trawl surveys, were examined for the occurence of copepods. *Clavella stellata* was found in the buccal cavity (76) and gills (2) of 78/859 (9.08%) of hakes. *Keywords: Fishes, Parasitism, Copepoda*

Clavella stellata belonging to the Family Lernaeopodidae (Copepoda, Siphonostomatoida) is a poorly studied copepod. This family is characterized by a sharp sexual dimorphism. Adult females are attached by a permanent anchorage organ, the bulla. This is produced in the frontal region of the cephalotorax (1). Male lernaeopodids are dwarf, and they are usually attached to the females. Males die after copulation (2). The aim of the present study is to assess the presence of C. stellata in Merluccius merluccius from the southern Tyrrhenian Sea. Study area is situated in the southernmost part of the Tyrrhenian Sea. Two experimental trawl surveys were conducted in July and November 2003. A total of 859 fishes belonging to the species M. merluccius were caugth. Macroscopical exam was aimed at evaluating the presence of ectoparasites on the skin, buccal and gills cavities. 10 parasite specimens were fixed in 70% alcohol solution and clarified by lactophenol for optical microscopy study. Parasite identification followed Scott & Scott (3) and Kabata (4). A total of 78 out of 859 (9.08 %) specimens were parasitized, 76 in the buccal cavity and 2 in the gills (Table 1). Each of the infected fish showed only one parasite. The examined parasites, all female sex, showed morphologic features that, according by Scott & Scott (3) and Kabata (4), allowed to classify the copepods as Clavella stellata (Kroyer, 1838) sin. Anchorella stellata - Fam. Lernaeopodidae (Figure 1). As far as we know, C. stellata has been described in the same host in North Sea and Atlantic Ocean (4), but has never been reported in the Tyrrhenian Sea. Our study does represent the first report of this parasite in the European hake in this area. From the literature the elective site of C. stellata is along the rims of the host opercula, although some specimens can be found between the bases of pectoral fins and occasionally even on the top of the head (5). The bulla is not embedded in the host tissues, but rather glued to the surface of scales or to the skin (4). In our observations, parasites were never localized on the skin; In 76 individuals they were in the mouth and only in 2 subjects in the gills, with the bulla glued to the mucosa.

³ Parc marin de la Côte Bleue

Abstract

The lower limit (31-34 m deep) of the *Posidonia oceanica* meadow was monitored (2002 through 2008) at Port-Cros Island (Provence, France, Mediterranean Sea), a national park where the biota and communities are considered to be in pristine condition. Both shoot density and cover conspicuously declined at the seagrass limit. *Keywords: Posidonia, Monitoring, Phanerogams, Temperature*

Introduction

Posidonia oceanica seagrass meadows are utilized as a biological indicator which allows an overall assessment of the quality of the marine environment and an evaluation of the efficiency of management policies. Within the Port-Cros Island national park (Provence, France, Mediterranean), biota and communities are considered to be in pristine condition. As a result, the *P. oceanica* lower limit is expected to be stable, in contrast with many other Mediterranean localities [1].

Material and Methods

Two sets of 10 cement markers were laid down at the lower limit of the *P. oceanica* meadow, i.e. at the boundary between the meadow and the dead matte or the coastal detritic community (sand) which extends downwards and offshore. The first monitoring site is localized near La Palud Cove (34 m deep), on the northern coast of Port-Cros Island. The second one is localized on the southeastern coast, between Pointe du Vaisseau and Pointe du Tuf (31-34 m deep). They were established in fall 2002 and 2006 respectively, and then monitored in fall 2005 and 2008. The *P. oceanica* shoot density was measured in the vicinity of each marker by means of a 20 cm x 20 cm frame randomly placed (three replicates). Shoots were counted within the frame. The cover is the mean percentage of substrate covered by the *P. oceanica* meadow (whatever the shoot density within the meadow or within patches of *P. oceanica*); cover was measured according to the method described by Boudouresque *et al.* [2].

Results and Discussion

The mean shoot density of the *Posidonia oceanica* meadow declined from 123 to 48 shoots/m² between 2002 and 2008 at La Palud (Wilcoxon signed-rank test, p=0.005; Table 1), at a mean annual rate of reduction of 14%. The bottom cover declined at an annual rate of 7% at La Palud (2002-2008; p=0.03; Table 2) and 20% at Vaisseau-Tuf (2006-2008; p=0.01; Table 2). According to Pergent *et al.* (1995) these values fall within the range of "normal densities" for a pristine meadow at the depths considered (61-285 shoots/m² at 31 m depth, 38-262 at 34 m).

2006	22	83	39	48	31	57	54	80	63	57	53%
2008	19	39	26	33	43	44	41	37	30	28	34%

The decline of shoot density constitutes a harbinger for the withdrawal of the seagrass meadow limit [3]. The steady retreat of most deep *P. oceanica* limits in the northwestern Mediterranean [3], including those of meadows in supposedly pristine localities, is a worrying feature, the cause of which is

unclear.

AGE AND GROWTH OF CHELIDONICHTHYS LASTOVIZA ((BONNATERRE, 1788) IN TUNISIA

L. Boudaya ¹*, L. Neifar ¹, P. Rizzo ², C. Badalucco ², A. Bouain ¹ and F. Fiorentino ²

¹ National Council of Research Institute for Marine Coastal Environment , Mazara del Vallo, Italy

² FLaboratoire de Biodiversité et Ecosystèmes aquatiques, Faculté des Sciences de Sfax, Tunisia - 1_boudaya@yahoo.fr

Abstract

A total of 768 specimens of *Chelidonichthys lastoviza* was collected from landings of bottom trawlers between January 2003 and November 2004. The total length ranged from 12 to 22 cm in females and from 13 to 19 cm in males. Marginal increment analysis of otoliths showed that the translucent zone was laid from November to April and the opaque zone laid from May to October. Females were from age group I to V and males from I to IV. Growth parameters of the von Bertalanffy growth function were $TL_{\infty} = 33$; K = 0.13 and $t_0 = -2.94$ in females and $TL_{\infty} = 29.84$; K = 0.13 and $t_0 = -3.73$ in males.

Keywords: Growth, Gulf Of Gabes

Introduction

Chelidonichthys lastoviza (Bonnaterre, 1788), together with *Chelidonichthys lucerna* (Linnaeus, 1758) and *Chelidonichthys obscurus* (Linnaeus, 1764), are the main gurnards landed by Tunisian fiheries. The present study aims to provide information on age and growth, of this species in the Gulf of Gabès (Southern Tunisia).

Materiel and methods

A total of 768 specimens of *C. lastoviza* were monthly sampled from January 2003 to November 2004 randomly from the landings of bottom trawlers operating in the Gulf of Gabès. Total length (TL) and total weight (TW) were measured to the nearest mm and 0.01g respectively. 674 Sagittal otoliths were read as whole. Opaque and transparent rings were counted and one opaque zone with one transparent zone considered as anual growth. Yerly increments are counted considering the tranlucent zones, which are considered to be laid down in winter. Growth was expressed through the "classic" model of Von Bertalanffy. Growth parameters were estimated by non – linear approach as implemented in the FISAT package [1]. For the sake of comparison, the index of overall growth performance φ [2] was used.

Results and discussion

Marginal increment analysis showed that one opaque and one translucent zone were deposited annually. The translucent zone, corresponding to the period of slow growth, occurred from November to April while the opaque zone, corresponding to the period of fast growth, occurred from May to October. A similar pattern was common among other gurnard species [3,4]. The seasonal changes observed in the otolith margin maybe related to seasonal fluctuations in water temperature in the Gulf of Gabès [5]. Nevertheless, the pattern observed may reflect other environmental changes such as photoperiod and prey availability, in addition to internal physiological factors as suggested by Pannella (1980) [6]. Females ranged between 12 to 22cm TL and males between 13 and 19 cm TL. The age group in the exploited stock varied between I to IV (males) and V (females). Von Bertalanffy parameter estimates (table 1) showed that C. lastoviza is a relatively fast-growing and moderately long-living species, like other gurnads species (3). A comparison of male (2.06) and female (2.15) φ' values shows that the population of the Gulf of Gabès had a slow growth performance compared with other populations [7].

Abstract

L'âge, la croissance et la reproduction sont étudiés chez le grand Barracuda *Sphyraena viridensis* (Cuvier, 1829) des côtes Est de l'Algérie. Une clé âge taille et une clé âge poids sont présentées à partir d'un échantillonnage mené sur 683 individus pêchés dans le golfe d'Annaba. L'analyse des coupes des sagittae a révélé que les âges varient entre 0^+ et 9 années. Un dimorphisme sexuel se manifeste à partir de la quatrième année. La première maturité sexuelle est acquise à partir d'une longueur totale (Lt₅₀) de 62,5 cm chez les femelles et 59,5 cm chez les mâles.

Keywords: Algerian Basin, Fishes, Growth, Reproduction

Introduction

Sur les côtes algériennes, tous les inventaires réalisés depuis Dieuzeide *et al.* [1] indiquent que la famille des Sphyraenidés est représentée exclusivement par l'espèce *Sphyraena sphyraena.* Cependant, deux espèces du genre *Sphyraena* ont été identifiées dans le golfe d'Annaba, *Sphyraena sphyraena* et *Sphyraena viridensis* [2]. Nous présentons dans ce travail les premières données sur l'âge, la croissance et la reproduction du Barracuda *Sphyraena viridensis* des côtes de l'Est Algérien.

Matériel et méthodes

Au total, 683 individus de longueur comprise entre 18,4 cm à 113 cm, correspondant à des poids variant de 25,06 g à 6710 g ont été examinés. Ils ont été récoltés dans les poissonneries de la ville d'Annaba. La détermination de l'âge est réalisée par otolithométrie. La longueur totale correspondant à chaque âge est rétro calculée par la méthode de Lee [3]. Les croissances, linéaire et pondérale, sont ajustées au modèle de Von Bertalanffy [4]. La relation taille poids $W = aL^b$ [5] est établie par sexe et pour l'ensemble de la population. La sexualité et la reproduction sont analysées à l'aide du sex-ratio SR (% des mâles), du rapport gonosomatique (RGS) et du rapport hépatosomatique (RHS). La taille de maturité sexuelle, celle pour laquelle 50 % des individus sont adultes, est estimée.

Résultats et discussion

La figure 1 montre que la croissance linéaire est très rapide durant la première année. Son taux annuel diminue ensuite progressivement, surtout à partir de la troisième année, en raison probablement de l'acquisition de la première maturité sexuelle. Sur la base des observations et des mesures prises sur les coupes des otolithes *sagitta*, une forte corrélation a été déterminée entre le rayon total de l'otolithe et la longueur totale du poisson (r = 0,87, p \leq 0,01). L'équation décrivant la relation longueur totale du poisson (Lt en mm) en fonction de la longueur de l'otolithe (Rt en mm) est : Lt = 272,33 Rt - 5,51. La méthode de retrocalcul a permis de définir neuf groupes 1, 2 et 3.

Fig. 1. Croissance linéaire absolue de *Sphyraena viridensis* (o : femelles, x : mâles) des côtes de l'Est de l'Algérie

Le coefficient d'allométrie de la relation entre la longueur totale et le poids total est exprimé par la relation : $Pt = 2,099.10^{-3} Lt^{3,131}$. La valeur du coefficient d'allométrie (b = 3,131) indique une allométrie de croissance majorante. Le cycle du rapport gonado-somatique (RGS) fournit des indications sur la periode de ponte (Fig. 2). Le RGS atteint son maximum en avril chez les mâles (5,606) comme chez les femelles (4,941). Cette espèce est gonochorique, l'évolution temporelle de son sex-ratio montre une dominance des femelles.

Fig. 2. Evolution mensuelle du RGS chez les femelles et les mâles de Barracuda Sphyraena viridensis des côtes de l'Est de l'Algérie

Les tailles de maturité sexuelle sont estimées à partir des observations réalisées en pleine saison de maturation des gonades (avril - juillet). Les individus, répartis par classe de 10 mm, sont supposés tous adultes à partir de 625 mm pour les femelles, de la classe 595 pour les mâles.

Abstract

The effects of seasonal variations on the fatty acid composition of the silverside *Atherina sp* from Kerkennah islands were determined for a one-year period. The levels of lipid displayed pronounced seasonal fluctuations with the highest values in March. The increase of the polyunsaturated fatty acids (PUFA) percentage was accompanied with a decrease of saturated fatty acids. Docosahexaenoic acid and eicosapentaenoic acid were the most abundant PUFA. The percentages of total n-3 fatty acids were higher than those of total n-6 fatty acids in spring season.

Keywords: Fishes, Islands, Chemical Analysis

Introduction

Atherina is a genus of small inshore fishes with many populations living in brackish, marine water and fresh water [1]. Like marine food products, Silverside are valuable sources of nutrients such as lipids. Lipids of marine fish are rich in n-3 long chain polyunsaturated fatty acids [2], [3], [4] of excellent nutritional value and beneficial effect on human health, especially eicosapentaenoic acid (C20:5n-3) and docosahexaenoic acid (C22:6n-3). Atherina sp is one of the commercially important and highly consumed fish species in Tunisia especially in the centre and south coast of Tunisia. In view of these facts, the aim of this study was to determine seasonal variations of the fatty acid composition and n-3/n-6 ratios of the Silverside which has not been studied in the area. Materials and methods This study was carried out in 2008 and samples were obtained in January, March, May, July, September and November from kerkennah islands (Tunisia). This study was focused on adult fishes and samples were conserved at -40°C until their analysis. Total lipids were extracted according to [5] procedures by chloroform/methanol (2/1) and quantified gravimetrically. A fraction of lipids extract was transesterificated according to the experimental procedure of [6]. The comparison of different biochemical parameters were tested using Duncan's test (95% confidence interval) with one-way ANOVA.

Results and discussion

The fat content of the analysed specie shows an important dependency on season (Table 1) in Silverside, it was minimal in September and November (2.4-2.2%), and maximal in March and May (4.7%-5.9%). The fatty acid profile in silverside was typical of marine animals (Table2), with the dominance of palmitic acid (C16:0) for saturated fatty acids SFA. Also, Oleic acid (C18:1) was identified as the major monounsaturated fatty acids MUFA, Docosahexaenoic acid (DHA) (C22:6n-3), linoleic acid (LA) (C18:3) and eicosapentaenoic acid (EPA) (C20:5n-3) were the most abundant polyunsaturated fatty acids PUFA. The same data were found by [7], [8]. In the present study, the significant increase (p <0.05) of the polyunsaturated fatty acids percentage was accompanied with a decrease of saturated fatty acids. The observed increase in PUFA is likely due to the preparation of spawning period. This finding is supported by the fact that the level of PUFA was lowest both before and just after reproduction [9]. The n-3/n-6 ratio is a good index for comparing relative nutritional value of fish oils [10]. The present data show that in all months except September and November, the percentages of total n-3 fatty acids were higher than those of total w6 fatty acids. n-3/ n-6 fatty acids ratio in Silverside can be significantly influenced by spawning and season.

Conclusion

This study has shown that the maximum levels of lipids were reached during the period of March and May; in contrast, the lowest levels were recorded in September and November. The Silverside is a suitable item in the human diet during the spring period in Kerkennah islands when the levels of EPA, DHA and n-3/n-6 ratio are considered.

CHARACTERISATION AND SEASONAL VARIATION OF LIPID AND FATTY ACID COMPOSITION OF COQUINA CLAM, *DONAX TRUNCULUS* (MOLLUSCA, BIVALVIA) FROM THE GULF OF TUNIS

D. Boussoufa^{1*}, N. Ghazali¹, K. Telahigue¹, I. Chetoui¹, I. Rabeh¹, E. Viciano², J. C. Navarro² and M. El cafsi¹ ¹ Unité de Physiologie et d'Ecophysiologie des Organismes Aquatiques, Faculté des Sciences de Tunis - d.boussoufa@yahoo.fr ² Instituto de Acuicultura de Torre de la Sal (CSIC), 12595 Ribera de Cabanes, Castellón, España

Abstract

The lipid content and fatty acid composition of the coquina clam *Donax trunculus* (Mollusca, bivalvia) sampled from the sandy beach of Borj Cedria (BC) situated in the Gulf of Tunis (the North Eastern coast of Tunisia) were analysed. Total lipid content in dry weight was ranged from 4.8 to 7.3 % and the major fatty acids in *D. trunculus* tissues were palmitic (C16:0), stearic (C18:0), eicosapentaenoic (EPA) (C20:5n-3) and docosahexaenoic (DHA) (C22:6n-3) acids. In comparison with saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA) constituted the highest proportion during the four seasons.

Keywords: Bivalves, Physiology

Introduction

Donax trunculus (Linnaeus 1758) (Mollusca: Bivalvia) is an Atlantic-Mediterranean warm-temperate species. Among bivalves, it is one of the most harvested clams in the world [1]. Generally, gametogenesis takes place during winter and spring and gamete emission starts in late spring and continues until summer. In Tunisia, D. trunculus shows a large distribution with high density along the sandy beaches especially in the Gulf of Tunis coasts. To the best of our knowledge, informations concerning the quality requisites of D. trunculus in lipid and fatty acid composition do not exist. Therefore, the purpose of this work is to study the natural seasonal variations in lipids and fatty acid composition of D. trunculus.

Materials and methods

Specimens of *D. trunculus* were collected at approximately monthly intervals between July 2004 and may 2005 along the sandy beach of Borj Cedria at a depth of 50 cm. Total lipid from each sample (six replicates of the whole animal per season) was extracted with chloroform: methanol (2:1, v/v) [3]. Fatty acids from total lipids were acid catalysed transmethylated [4] and subsequently analysed by high resolution gas chromatography. Tukey Honest Significant Differences (HSD) multiple comparisons test was conducted to determine differences at a significance level of 5 % (p<0.05).

Results and Discussion

Total lipid content in dry weight of Donax tissues was accumulated especially during winter (7.37 %) and summer (5.9 %). The variation of lipid content could be explained by the abundance and quality of the available food in the Donax environment and by the accumulation or utilization of lipid reserves prior to gametogenesis.

Results on seasonal variations of the fatty acid composition ,expressed in percent of total fatty acids, (Table 1) indicate that the major fatty acids in D. trunculus tissues were C16:0, C18:0, C20:5n-3 and C22:6n-3 acids. Compared with SFA and MUFA, PUFA constituted the highest proportion. PUFA were generally low during summer ($38.7 \pm 2.2\%$), and high during winter ($46 \pm 2.2\%$, p= 0.00019). SFA varied between $28.8 \pm 1.9\%$ and $34.7 \pm 2.4\%$ respectively during winter and summer. No significant seasonal changes were observed in MUFA which represent the lowest proportion of total fatty acids. The seasonal variations of PUFA could hardly be correlated with the different phases of the annual reproductive cycle of the animals; this may explain the main function of these fatty acids in gamete formation. During the period under study, *D. trunculus* was characterised by high levels of n-3 PUFA (24.5-34.9\%), important in the human diet especially for their prevention of cardiovascular diseases, low levels of n-6 PUFA (6.4-9.7\%) and relatively high n-3/n-6 PUFA ratio values (3.5-5.6).

Due to their low lipid and the high percentage of healthy n-3 PUFA especially in winter and spring, periods of reserve accumulation, we can conclude that *D. trunculus* can be considered as a food item with interesting dietetic properties.

TUNISIAN FISH FAUNA AND THE GLOBAL WARMING

Mohamed nejmeddine Bradai 1*

¹ Institut National des Sciences et Technologies de la Mer (INSTM) - mednejmeddine.bradai@instm.rnrt.tn

Abstract

In Tunisia, 356 species of fish were reported between 1884 and 2009, some for the first time in this work. After a critical review, we eliminated six species mentioned in the ichthyologic literature. Two others seem dubious but also require a review. They are not considered in this work. Analysis confirms the subtropical character of Tunisia fish fauna and especially of the Gulf of Gabes and that this character is accentuating.

Keywords: Biogeography, Fishes, Gulf Of Gabes, Global Change

Introduction

This work updates the Tunisian fish species inventory [1]. It is based on the new records of species for the Tunisian waters available in the bibliography (after 2002) and on news observations made during surveying campaigns and visits to the main landing points.

Material and methods

A grouping of the recorded fish species is given according to their geographic distribution [2] into: (1) Cosmopolitan (2) Atlanto-Mediterranean (3) Endemic (4) Indo-Pacific. The following categorisation of the recorded species is also given: species mainly distributed in cold and temperate waters and species having affinity for tropical and subtropical waters [2].

Results and discussion

According to the data available in 2009, Tunisian fish biodiversity can be summarized as follows: Petromyzontiformes 1 species, Holocephali 1, Elasmobranchii 63, Chondrostei 1, Osteichthyes 282 for a total of 348 valid species belonging to 115 families, 229 genus and 30 Orders. Most species (294 of 348) have an Atlantic origin, 16 species are considered as sub-cosmopolitan and 25 are endemic to the Mediterranean. The Tunisian coasts are concerned by marine invaders originating from the tropical Atlantic (8 species) and Indopacific areas (13 species) (fig.1). Species coming from the northern Atlantic are mainly found in the northern zone, while the Subtropical and Saharian species are mainly found in the Gabes Gulf area. These results confirm the tropical character of this region. The species distribution along the Tunisian coasts is unbalanced; some species appear to be restricted to a particular sector; 54 were recorded only in the northern sector, mainly distributed in cold and temperate waters and 49 only in the southern sector, having mainly affinity for tropical and subtropical waters. Carcharinus melanopterus, Taeniura grabata, Pagrus coeruleostictus, Rhonchus Caranx, Dicentrarchus punctatus, Solea aegyptiaca and species of genus Epinephelus and Serranus, having frankly tropical or subtropical affinity, are more abundant in the Gulf of Gabes than in the Northern. This work confirms the subtropical fish fauna of Tunisia and especially the Gulf of Gabes. Currently, this character is accentuated by the arrival, in addition to fish Lessepsian, Atlantic species with affinities for warmer waters such as Seriola fasciata, Sphoeroides cutaneous and also because of the development of populations Balistes carolinensis, Caranx crysos, C. rhonchus, Synodus saurus, Sparisoma cretense... The new records are mostly thermophilic species such as the oilfish Ruvettus pretiosus (F. Gempylidae) observed recently in the gulf of Gabes. The specimen was 132 cm (TL) and it weighed 11 kg. Some species restricted to this region have been observed more and more in the north. These changes could be a sign of a climate change and global warming in generally. Climate change is operating in the Mediterranean, it is undeniable! The succession of thermal anomalies and so on stability of water masses occurred in the mid 80s would have greatly facilitated the blooms of jellyfish. In Tunisia the appearance of jellyfish was usually in September when vacationers begin to desert beaches. Over the past five years, the phenomenon became early which attracted public attention. The blooms of several species of jellyfish which mainly pulmo Rhizostoma were spectacular in May and June 2008 and 2009. This is especially due to climatic reasons that are causing their proliferation and possibly depletion of the leatherback turtle, large predatory of jellyfish. These phenomena could have negative consequences on fish stocks.

PRELIMINARY POPULATION GENETIC STRUCTURE OF THE ENDANGERED DUSKY GROUPER, EPINEPHELUS MARGINATUS, IN MALTA AS REVEALED BY SIX MICROSATELLITE MARKERS.

Molly Buchholz-sørensen ^{1*} and Adriana Vella ¹

¹ Conservation Biology Research Group, University of Malta, Msida, MSD 2080, Malta - molly.sorensen@alumni.ubc.ca

Abstract

The objective of this study is to describe the population structure of the endangered marine fish, *Epinephelus marginatus* (Teleostei: Serranidae), in the Maltese archipelago for the purpose of localized conservation management planning. Preliminary genetic population structure of the Maltese dusky groupers was determined by six microsatellite markers. Initial results based on FST values comparing three spatial groups (Group A, North Malta; Group B, South Malta; and Group C, Hurd Bank) indicate group A and B are one continuous population inhabiting the Maltese archipelago ($P_{(a-b)} > 0.05$) whereas group C, an area 23 km east of the main island, is identified as a sub-population to these groups ($P_{(a-c)} = 0$; $P_{(b-c)} = 0$). Results suggest that management should be designed to reflect the archipelago as a single population.

Keywords: Biogeography, Conservation, Genetics, Islands, Teleostei

Introduction

The dusky grouper, *Epinephelus marginatus* (Teleostei: Serranidae), is an endangered marine fish considered to be facing a very high risk of extinction in the wild. Due to concerns of population decline throughout their geographic range, the IUCN has currently listed them as endangered (EN) A2d [1]. Their native range includes the Mediterranean Sea, the eastern Atlantic Ocean along the west and south coasts of Africa around the cape to Mozambique as well as Brazil. Characterized by high site fidelity and protracted development to sexual maturity, this reef-associated protogynous hermaphorodite can usually be found in depths up to 50 meters off rocky coastal shores [2]. Localized population structure parameters include pelagic larval dispersal influenced by surface current direction during spawning season along with limited juvenile stage movement. The purpose of this research is to describe and define the status of the Maltese population of dusky groupers in order to best develop a comprehensive conservation management and monitoring strategy.

Fig. 1. Map of collection locations for Maltese *E. marginatus* with 100 m bathymetry lines (NTS). Group A, North Malta (n = 13); Group B, South Malta (n = 11); and Group C, Hurd Bank (n = 6). Arrows indicate predominant surface current direction mean [3] for pelagic larval dispersal during the spawning months between June and August

Materials and Methods

A total of 30 dusky grouper specimens with known catch locations were sampled from the Maltese archipelago between 2007-2009. Six fluorescently tagged microsatellite markers were used in this study to explicate the population structure: three primers developed for the red hind grouper [4], *Epinephelus guttatus* (RH_CA_001, RH_CA_002 and RH_CA_008) and three developed for the gag grouper [5], *Mycteroperca microlepis* (GAG010, GAG038 and GAG045). Individuals were genotyped using an Applied BiosystemsTM 3130x1 capillary electrophoresis system. Tests of population differentiation were calculated using the software Arlequin [6].

Results

Three sample groups were identified based on log-likelihood assignment tests of

individual genotypes to populations (Fig. 1). Within group analysis reveals observed allelic heterozygosity was greatest in group C ($H_{O(a)} = 0.79$, $H_{O(b)} = 0.67$ and $H_{O(c)} = 0.81$) while group A revealed the most unique haplotypes ($n_{(a)} = 31$, $n_{(b)} = 12$ and $n_{(c)} = 3$). Rare breeding size males ($T_L \ge 85$ cm) were present in all groups with a significantly higher incidence of large size individuals ($T_L \ge 70$ cm) observed in the west Gozo area of group B. Tests of population differentiation reveal little genetic variation between groups A and group B (F_{ST} (a-b) = 0.01, P > 0.05) while group C shows moderate differentiation from all other groups tested ($F_{ST(a-c)} = 0.10$, P = 0; $F_{ST(b-c)} = 0.11$, P = 0).

Discussion

Results indicate moderate genetic partitioning in a limited spatial range based on biogeographical isolation due to depth range and larval retention patterns. Based on preliminary FST values, group A and group B are considered to be a single congruent population inhabiting the Maltese archipelago whereas group C is identified as a sub-population to these groups. Due to long life history traits, population decline does not appear to have deleteriously effected within population allelic variation to date. West Gozo has been identified as a possible spawning site and area of conservation interest due to the relatively high concentration of large size individuals. Group A as a whole is also important since it contains a significant number of unique haplotypes. Average south eastern surface currents originating from the northern tip of Gozo during spawning season as a mechanism for pelagic larval dispersal is a probable mode for genetic homogenization within the Malta population. We theorize Gozitan individuals may be an important source population to the rest of the archipelago. Therefore, we recommend management and pilot monitoring efforts initially focus on the northern (group A) and west (group B) Gozitan meta-populations.

TROPHIC HABITS OF RED SCORPIONFISH SCORPAENA SCROFA (OSTEICHTHYES, SCORPAENIFORMES) IN THE CENTRAL WESTERN MEDITERRANEAN

Serenella Cabiddu ¹*, Claudia Pedoni ¹, Paola Pesci ¹ and Cristina Porcu ¹

¹ Department of Animal Biology and Ecology, University of Cagliari, Italy - cabiddus@unica.it

Abstract

Feeding habits of *Scorpaena scrofa* in the Sardinian waters were analysed. The trophic spectrum of this commercial species was mainly composed of teleosts and crustaceans, in particular Decapoda Natantia, followed by Amphipoda and Decapoda Brachiura. The diet changed according to the sex and the size of the specimens. *Keywords: Diet, Western Mediterranean, Fish Behaviour*

Introduction

The red scorpionfish, *Scorpaena scrofa* (L., 1758), is distributed in the Eastern Atlantic and throughout the Mediterranean at depth of 0-370 m [1]. The knowledge about feeding habits of this commercial species is scarce, then the aim of this work is to provide information on the diet by examining specimens captured in the Sardinian waters.

Materials and Methods

A total of 64 specimens, caught at depths from 14 to 119 m, were analysed. The stomachs were removed and preserved in 6% formaldehyde. Each prey item was identified to the lowest possible taxonomic level. The contribution of each food item to the diet was determined by diet indices: %Cv, %F, %N, %W, IRI [2]. The diet breadth was calculated using Levin's standardized index [3], and the intensity of feeding was determined by gastro-somatic index (IG, gut is expressed as percentage of body weight). Difference in diet composition by size (1: 0-11 cm; 2: 11-21 cm; 3: 21-32 cm) and sex were tested by chi-square test.

Results and Discussion

A total of 13 different prey items, belonging to 9 major taxonomic groups, were identified (Table 1). Teleostea was the most important prey category in the diet followed by Crustacea, Mollusca and Tunicata. Among crustaceans the main items were Decapoda Natantia, followed by Amphipoda and Decapoda Brachiura. Stomatopoda, Euphausiacea and Isopoda were occasional prey. Tab. 1. Trophic spectrum of *Scorpaena scrofa* in the Sardinian waters

Prey item	%F	%N	%W	IRI

TUNICATA	3,45	2,13	0,07	7,56
Taliacea	3,45	2,13	0,07	7,56

Red scorpionfish selected preys according to the size of specimens (Fig. 1 A): Crustacea (IRI1=8041; IRI2=4326) and Teleostea (IRI1=4878; IRI2=10857) dominated the diet in the first and second size classes. The diet of the third size class was more heterogeneous and included Taliacea (IRI1=694) and Cephalopoda (IRI1=210); the importance of Teleostea in the diet increased (IRI1=7495), while the importance of Crustacea decreased (IRI1=1111). Crustaceans taxa changed according to size: Natantia (IRI1=2307) and Amphipoda (IRI1=659) were mainly eaten by youngest specimens whereas Stomatopoda (IRI1=347) and Isopoda (IRI1=209) by adults. Significant difference was found between males and females (p<0.05) (Fig. 1 B).

Fig. 1. Changes in diet (IRI) as a function of *Scorpena scrofa* size classes (A) and sex (B)

Teleostea (IRIf=6851; IRIm=6961) was the most important prey in both sexes followed by Crustacea (IRI=5056) in males specimens. The proportion of empty stomachs (Cv=54.69) varied among sexes (males Cv=42.11; females Cv=73.91) and size classes (Cv1=51.85; Cv2=61.07; Cv3=37.50). The IG index value was lightly higher in males than in females (IGm=3,079; IGf=2,964) and increased from the smallest individuals to the largest (IG1=2.652; IG2=3.163; IG3=3.218). Dietary breadth as indicated by Levin's standardized index was 0.316.

The composition of diet suggested that *S. scrofa* was a benthophagous specialized species that preyed mainly on teleosts followed by crustaceans. Results showed that diet was similar to that described for the northern [4] and the southern Mediterranean Sea [5].

SURVEY OF ALGAL CYSTS IN RECENT SEDIMENTS OF THE TRIESTE (ADRIATIC SEA) AND MILAZZO (TYRRHENIAN SEA) PORTS

Marina Cabrini ¹*, Federica Cerino ¹, Damiamo Virgilio ² and Erika Magaletti ³ ¹ Istituto Nazionale di Oceanografia e Geofisica Sperimentale, Trieste, Italy - mcabrini@inogs.it ² ARPA FVG, Udine, Italy

³ Istituto Superiore per la Protezione e la Ricerca Ambientale, Roma, Italy

Abstract

Harbours are generally considered as areas of build-up of algal cysts which can function as potential seeds for pelagic algal populations. In the autumn 2006, a sampling programme of phytoplankton and sediments was carried out in the ports of Trieste (Adriatic Sea) and Milazzo (Tyrrhenian Sea). In both ports, the analyses of water samples revealed a high specific diversity of the phytoplankton community. At the same way, in sediments many cyst morphotypes were identified. Water and sediment analyses confirmed the importance of these areas as potential reservoir of plankton diversity as well as of harmful species. *Keywords: Coastal Systems, Toxic Blooms, Plankton, Adriatic Sea, Tyrrhenian Se*

The risk of the introduction of non indigenous plankton species including those of species potentially harmful for the environment and humans has been widely documented in many areas of the world [1]. Considering the potential role of the ballast water as vector for marine introductions [2], ports can represent areas potentially at risk for the high number of ships they receive each year. To analyze the composition of phytoplankton community and algal cyst assemblage in the ports of Milazzo (Tyrrhenian Sea) and Trieste (Adriatic Sea), a sampling programme was carried out from 6 to 7 and from 12 to 14 September 2006, respectively. In seven and eight stations, respectively, phytoplankton nets and sediment cores were collected. The analysis of phytoplankton nets revealed a relatively high specific diversity along the water column in both ports, with more of 120 taxa identified belonging mainly to Bacillariophyceae and Dinophyceae. Various toxic species, such as DSP and PSP species, were identified. Finally, in the Milazzo port, the presence of Ostreopsis sp., an epiphytic dinoflagellate responsible for respiratory problems since some years along the Italian coasts, was recorded in many stations. In the port of Trieste, cyst abundance ranged from 459 ind g^{-1} DW recorded at the st. 6 to 3651 ind g⁻¹ DW at the st. 3 (Fig. 1).

Fig. 1. Cyst abundance (number of cyst g^{-1} of dry weight) at different sampling stations in the ports of Trieste and Milazzo.

A total of 32 different cyst morphotypes belonging to dinoflagellate group were identified at least at genus level. *Alexandrium, Protoperidinium* and *Scrippsiella* were the genera more represented. *Calciodinellum operosum* (up to 54 cysts g^{-1} DW), *Lingulodinium polyedrum* (up to 957 cysts g^{-1} DW), *Scrippsiella lachrymosa* (up to 212 cysts g^{-1} DW), *S. trochoidea* (up to 165 cysts g^{-1} DW) and cf. *Woloszynskia* sp. (up to 696 cysts g^{-1} DW) were the most abundant species (Fig. 2). In the port of Milazzo, cyst abundance was lower than those in the port of Trieste, ranging from 19 cysts g^{-1} DW at the st. pont.1 to 250 cysts g^{-1} DW at st. 1 and p.mil. 1. Differently from Trieste, although the most abundant types were the same (*Alexandrium* spp., *Lingulodinium polyedrum*, *Scrippsiella* spp.).

Fig. 2. Some examples of cyst morphotypes identified in this study. A: Diplopsalis group; B: Lingulodinium polyedrum; C: Scrippsiella lachrymosa; D: Protoperidinium compressum; E: cf. Zigabikodinium lenticularis; F: Protoperidinium subinerme; G: Scrippsiella trochoidea; H: cf. Woloszynskia sp. Scale bar = 10 μ m.

The analyses of phytoplankton communities and cyst assemblages of the two sampled ports revealed a rather high species diversity. The occurrence of *Warnowia* and *Woloszynskia* cysts (previously observed as cysts in another site in the Gulf of Trieste [3], but never in the water column) suggests that these species may be common members of the phytoplankton community in this area. However, these taxa are very difficult to identify live in plankton samples, and almost impossible in fixed samples. So, this survey of resting forms allow us to deepen our knowledge on phytoplankton biodiversity. Moreover, the identification of species potentially harmful in both water column and sediments highlights the importance of these studies and the necessity to couple the two different kind of sampling, especially in areas at risk such as ports.

Abstract

Trammel nets are one of the most commonly exploited gears of small scale fisheries used all along the Greek coasts and in Mediterranean. However, knowledge on the discards of this gear is scarce. Discards in trammel net fishery include species with no commercial value, or commercial species, which cannot be distributed in the market because of their small size, or because they come on board already destroyed. The mesh size of the nets and depth of fishing operations are two factors affecting the proportion of the discards.

Keywords: Fisheries, Ionian Sea

Introduction

In general, the coastal fisheries gears are highly species and size selective. The unwanted catches are limited and consequently, the proportion of the fish discarded is low in each fishing operation. Discards in trammel net fishery include species with no commercial value, or commercial species, which cannot be distributed in the market because of their small size, or because they come on board destroyed by polychaetes or other marine organisms while the nets remain into the sea [1]. However, the extended use of the trammel nets by numerous vessels could account for a significant quantity of discards. The aim of this work was to study the discarding practice of trammel nets and the effects of the mesh size, depth and soaking time on the amount of the discards produced.

Material and Methods

Experimental fishing trials with trammel nets of different inner/outer mesh size combinations took place in the Ionian Sea (Greece), during June and July 2004. The mesh sizes used for the inner net were: 44, 56, 72 and 80 mm. The outer panels of the trammel nets had a stretched mesh size of 220, 280, 360 and 400 mm, respectively. All nets were made up of sheets of the four mesh sizes joined end to end to make up a fleet and arranged in random order. Total net length for each mesh size was 500 m. A total of 76 sets of nets were deployed at depths ranging from 10 to 130 m. Normal fishing practices were followed. The nets were set during sunrise and retrieved the following morning, with a soaking time of around 20 h. After hauling, the catch was removed and analyzed separately for each net.

The analysis of the discards was carried out using the logistic regression model. A binomial GLM was used to assess the effect of the soaking time, depth and mesh size on the discard probability, first for all the specimens of all the species caught (n=2144) and then for three of the most abundant species. The goodness of fit was tested using le Cessie-van Houwelingen-Copas-Hosmer test [2] [3] and the ROC (Receiver Operating Characteristic) curve was used to describe the accuracy of diagnostic test.

Results and Discussion

Out of the three covariates used in the logistic regression model for all the specimens of all the species caught, only the depth appeared significant (Tab.1). The le Cessie-van Houwelingen-Copas-Hosmer test (p=0.77, under the null hypothesis assumption that the estimated values by the model are similar to those observed) confirmed that the model fitted the data well.

Tab. 1. Estimates, standard error, and p-value of covariate for the logistic model (*significant at 0.05 critical p-value)

		Logistic model-binomial distribution					
response variable	covariate	estimate	SE	p-value			
specimens discarded	Mesh size (mm)	-0.008	0.004	0.06			
	Depth (m)	-0.02	0.003	0.05*			
	Soaking time (h)	-0.02	0.02	0.44			

The regression model showed that the probability of the discard of specimens decreased by about 10% from 10 to 120 m depth (Fig.1A). Although the depth was significant for the logistic model, the area under the ROC curve was 0.52, so the discrimination capacity of the model was very low (Fig. 1B). The same logistic regression model was used to assess the probability of discarding for *Sciaena umbra*, *Merluccius merluccius* and *Pagellus erythrinus*. For *S. umbra* the model showed that only the mesh size was significant: the discard probability using the 44 mm mesh size was greater than for the 72 and 80 mm. For *M. merluccius* and for *P. erythrinus* no covariates were significant.

Fig. 1. A) The discards probability estimated as a function of depth by the logistic regression model. B) Receiving operating characteristic (ROC) curve of the predicted discards probability for the specimens caught

The logistic regression analysis showed that, for all the specimens of all the species caught, depth was a significant factor in determining the discard probability: increasing depth decreased the probability of specimens discarded. However depth did not completely explain the discard levels, which were probably related to other factors, such as the presence of scavengers feeding on them (i.e. Polychaetes), the weather conditions and the way of fish capture in the nets. The mesh size was significant in determining the discard levels of *Sciaena umbra*: the smallest mesh size implied more discard probability. In this case the use of larger inner panel mesh sizes could reduce the discard level of the species and could also reduces the handling time spent on board in removing the specimens from the nets. The soaking time did not affect the commerciality of the specimens caught, maybe due to the small difference of this factor between the hauls.

In conclusion this study shows that the depth and the inner panel mesh size affect the discard levels in trammel nets fishery but are not enough to explain them completely; in addition the importance of these factors on discard levels varies by species.

AN EVALUATION ABOUT THE COLOUR VARIATION OF *CARCINUS AESTUARII* NARDO, 1847 WITH PARTICULAR REFERENCES TO THE FEATURES OF *CARCINUS MAENAS* (LINNAEUS, 1758)

Elif Can 1*

¹ Dokuz Eylul University, Institute of Marine Sciences and Technology - elif.can@deu.edu.tr

Abstract

The carapace colour variation is distinguished in *Carcinus aestuarii* with a number of 870 male crabs were categorized as green and red. Carapace width of each individual was also measured. The population of *C.aestuarii* followed the terms that the red –coloured crabs were bigger than the green-coloured ones.

Keywords: Estuaries, Crustacea

Introduction

The carapace colour of European green crab, *Carcinus maenas* (Linnaeus, 1758) was referred in several studies, in which a variation is exhibited ranging from light green to deep red [5]. Similar colour variation is also distinguished in the green crab *Carcinus aestuarii*,inhabits the Mediterranean estuarine and lagoons [1]. The differences in terms of behavioral, physiological and ecological features are observed between red and green coloured individuals [2, 3, 4, and 5]. The aim of this study is to identify the features of *C.aestuarii* in order to determine the similarities to *C.maenas* regarding the introduced differences.

Material and Methods

The crabs were collected at monthly intervals for one year from April 2001 to April 2002, by means of a beam trawl. All crabs were counted and sexed. Colour forms were categorized as green and red. Carapace width of each individual was also measured. The male crabs were preferred to be given in this study according to high numbers compared to females. The Mann-Whitney U test is performed to determine the significant differences between green and red forms in terms of carapace width.

Results and Discussion

A number of 870 crabs were categorized as green and red. In this categorization, the red- coloured males had a ratio of 13.6%. The mean carapace width of red males was 29 ± 0.4 mm while the mean carapace width of green forms was 24 ± 0.3 mm. Red males were significantly larger than green males (Z=-6.6; p < 0.05). The population of *C.aestuarii* followed the terms that the red –coloured crabs are bigger than the green-coloured ones, which indicates for both forms of *C.maenas*. Seasonal variation in abundance of red coloured males was observed with small numbers from June to October and during October, the number of individuals increased to the highest (Figure 1). The prediction about the red coloration of the crabs is related to intermolt duration [2, 4] and sexual maturity [5]. According to this approach, red coloured individuals are the mature crabs [5].

Fig. 1. Monthly variation of red males

GIS MAPPING OF SEABIRD DISTRIBUTION - A PAN-MEDITERRANEAN PERSPECTIVE

Carles Carboneras ¹* and Susana Requena ²

¹ University of Barcelona, Faculty of Biology, Dept. Animal Biology - carles@gavines.org

² Institut de Ciències del Mar, CSIC

Abstract

Seabird distribution in the Mediterranean sea was mapped in GIS format in a 10x10-km grid. The resulting cells were weighed according to the conservation value of the species present. This allowed for numerical calculations and direct comparisons. A network of offshore protected areas is recommended to protect seabird biodiversity in Mediterranean offshore waters, as promoted by UNEP RAC/SPA.

Keywords: Gis, Birds, Marine Parks, Biogeography

The Mediterranean region is home to several species of seabird of high conservation value in global terms (1), with several endemic taxa and some additionally in decline. The protection of the key sites for their survival is an essential tool to ensure their long-term conservation. The UNEP Regional Activity Centre for Specially Protected Areas (RAC/SPA) in compliance with the Mediterranean SPA/BD Protocol undertook an initiative to promote the establishment of a Specially Protected Areas of Mediterranean Importance (SPAMIs) network, including seabirds in Areas Beyond National Jurisdiction (ABNJs). Species' known distribution (both breeding and wintering ranges) were obtained from various sources: published references, consultation to experts, data from censuses at sea and satellite telemetry (2, 3; see 4 for full reference list), plus own data. The information was compiled and mapped in GIS format in a 10x10-km grid following the recommendations of the EEA (5). The resulting cells were assigned a numerical value based on the number of species present and their conservation value (endemic and/or in decline). Treatment of the data allowed for graphic representation and for some geographical calculations, as well as for further analysis along with environmental variables.

Fig. 1. Sample map of Region 1-Alboran Sea

The following trends were observed:

- the Mediterranean Sea revealed quite heterogeneous in terms of seabird distribution

nearly two-thirds (59.32%) of the sum of cells had insignificant presence of priority species (cat. 0-1) and large areas of the ocean had relatively low value –with the available information. 'Poor' areas concentrated mostly in the eastern Mediterranean basin, particularly the southern latitudes. Also, in general terms, deep-water areas were poorer in their presence of pelagic birds.
inversely, priority bird species were present in only about one-third (40.68%) of the total cells

- priority bird species were somewhat dispersed over the areas where they were present; no single cells had a value >7, when the highest possible value was 11

- nearly one-fourth (29.04%) of the sum of cells corresponded to cat. 2-4; these were assigned 'priority B'. The distribution of priority B areas marked the influence of large-scale ocean graphical features (increased productivity, mixing of waters, bathymetric zone) and revealed as a general indicator of areas of conservation interest for seabirds. Given the paucity of data for some species and regions, priority B areas were taken as 'good areas' for the development of a network of marine protected areas for the conservation of seabirds

- less than 10% (11.64%) of the total sum of cells had the highest importance

(cat. 5-7) in terms of priority bird species present; these were assigned 'priority A'. Priority A areas are found within the limits of priority B zones in all cases. Characteristically, they are found on the continental shelf, around breeding islands or where key oceanographic features (fronts, upwellings) occur. Also, outstandinly, in the Strait of Gibraltar Information on seabird distribution can be further completed and updated from other sources (telemetry GIS, GLS, PTT) as it becomes available, and used to provide quantitative evidence of use of the [pre]selected areas. Using GIS, seabird distribution can be analyzed against environmental and oceanographic variables, with several examples being provided. This exercise represents an initial step towards the selection of protected areas for seabirds at pan-Mediterranean scale and has been developed in the framework of the activities of UNEP RAC/SPA.

francois.carlotti@univmed.fr

Abstract

A Lagrangian module has been developed and coupled with the 3D circulation model Symphonie to study the influence of hydrodynamic processes on zooplankton transport and distributions in the North Western Mediterranean (NWM) sea. Forward and backward procedures are used to simulate trajectories of planktonic organisms. The individuals are released from March to October from different places of the NWM to study their transport and tracked for 40 days either as passive particles or with a simple diel vertical migrations (DVM) pattern. Teleconnectivity between different regions of the NWM sea are proposed. The model used backward procedure to study the origin of organisms drifted to the coastal line all around the NWM sea. The patterns of distribution of the jellyfish Pelagia noctiluca are discussed.

Keywords: Models, Zooplankton, Western Mediterranean, Circulation Models, Life Cycles

Zooplankton transport in a variety of physical conditions can be considered as the combination of two closely linked aspects. The first involves zooplankton transport by non-stationary flow field and the second involves the behavioral response of the zooplankton organism, mainly swimming, to changes of environmental conditions. Lagrangian particle-tracking models coupled with hydrodynamic models are particularly efficient tool to examine the role played by various physical processes, to study transport processes over an entire basin and to simulate complex and interactive processes acting at different scales.. The North Western Mediterranean (hereinafter NWM) is a favorable area to study the influence of water circulations and estuarine inputs on biological activity and distributions. In the NWM, large scale circulation is dominated by the Northern Current The NWM sub-basin is one of the most productive areas in Mediterranean owing to important river discharges from the Rhône and Ebre rivers and strong wind mixing on the shelf, and in the open sea the central divergence zones of the Liguro-Provençal and Catalano-Balearic Seas, gyres, upwellings and vertical mixing. In this study, we investigate the influence of the hydrodynamic processes on zooplankton transport and distributions in the NWMS. The model is fully described by Qiu et al. (submitted). We simulate the trajectories of passive particles and vertically migrating organisms in the region by using a lagrangian-particle algorithm driven by velocity fields from a three-dimentional (3D) hydrodynamic model. The model will be used in forward and backward procedures for different objectives. The model domain extends between longitude $1.75^\circ W$ and $10.90^\circ E$ and latitude $38.28^\circ N$ and $5.61^\circ N$ In order to classify different zones of the NWM as aggregative or dispersive, we divide the model domain into 9 sectors. Sectors 1 and 2 correspond to shelf areas delimited by the isobath of 200m in the GoL and in the Catalan Sea, respectively; sector 3 marks the shelf area around the Balearic islands; sectors 4, 5 and 6 represent the Ligurian Sea (Here sectors 5 and 6 represent di erent ecosystems in the Ligurian Sea); sector 7 bounds the center of the NWM gyre; sector 8 is the shelf slope where The modeled domain extends between longitude 1.75° W and 10.90° E and latitude 38.28° and 5.61° N (Fig. 1). In order to classify the different zones of the NWM as aggregative or dispersive, we divided the modelled domain into 9 sectors Sectors 1 and 2 correspond to shelf areas delimited by the isobath of 200m in the GoL and in the Catalan Sea, respectively; sector 3 marks the shelf area around the Balearic islands; sectors 4, 5 and 6 represent the Ligurian Sea (sectors 5 and 6 represent different ecosystems in the Ligurian Sea); sector 7 bounds the center of the NWM gyre; sector 8 is the shelf slope where the main branch of the NC passes; sector 9 represents the offshore zone in the Catalan Sea. In a first part, the model is used in forward procedure to study transport from source region to target regions in the way to study connectivity of zooplankton populations between regions in the NWM. Particles are released at D point and R point (Fig. 2) every 3 days from March 1st to August 31, 2001. During the simulations, the particles are simulated as passive zooplankton individuals. The final distributions of the particles are shown in Fig. 3 and 5. The particles released in one month are plotted in one figure. Here Fig. 3 shows the final locations of the particles released at D point and Fig. 5 at R point. The release locations are also included. The percentages of the particles distributions in different sectors are shown in Table 1 and 2. The particles released in one month have been considered as a whole. After 40 days being released at D point, the particles could almost spread anywhere in the NWM (Table 1 and Fig. 1). After being released at D point, the particles are divided

into two parts resulting from the currents. One part follows the anticlockwise circulation, first drifts southern and then eastern along the WCC. After reaching the area northeast to the Corsica Island, the particles flow northern along the continental slopes, then return in the NC and go back at D point again. At the end of simulations, this part remains in the sector 4 and 5, i.e. the Ligurian Sea. Another part of the particles follow the NC westward. From the sector 6, the main particles trap in the NC (the sector 8) along the continental slope and then flow into the Catalan Sea (the sector 2 and 9), a part moves more offshore into the sector 7 and a few particles enter in the sector 1 with the intrusion of the NC at the eastern side of the GoL. In the Catalan Sea, the particles reach as far as the Channel of Ibiza where it splits in two parts. The main part re-turn into the Northwestern Basin and some particles enter in the sector 3 (Fig. 1). Strong seasonal patterns in the transport and distributions of the particles are observed (Table 1, Fig. 1). Only 17% of the particles, which released in May and June, maintain in the Ligurian Sea (the sectors 4-6) while the maximum, over 60% in March. On the contrary, only 9% enter in the Catalan Sea (the sectors 2-3 and 9) in March while 46% in May (Table 1). The distributions of the particles in the path areas of the NC are more offshore in July and August than in other months (Fig. 1). At the end of the simulations, the particles scatter in the northeastern part of the Catalan Sea, which released in March and April. The main particles released in July and August concentrate in the path of the NC. And the particles released in May and June distribute mainly similar with the cases in July. However, comparing to only a few particles locate in the northeastward re-turn branch in July, more particles are in the path of the re-turn branch in May and June, even some flow to the areas east to the Balearic Island in May. Moreover, different patterns appear in the final distributions of the particles with different released depths. At the end of the simulations, the main parts of the particles locate in the path of the NC, which release at -100m. The particles released at -5m distribute more complex than those released at -100m, which scatter in the whole areas of the NWM, and the patterns are different in different months. Moreover, along the path of the NC, the particles released at -5m locate further than the particles released at -100m, and only a few of the latter particles reach the open boundary. Others simulations with launched particles from different origins will be presented and zooplankton connectivity between regions will be discussed The model will be used backward procedure to study the origin of organisms drifted to the coastal line all around the NWM sea. This backward procedure is particularly interesting to investigate the patterns of distribution of the jellyfish Pelagia noctiluca from the area where coastal jellyfish invasion have been observed, i.e. on the French Riviera, the Gulf of Lions and the Catalan and Balearics seas. The simulations offer a tool to suggest potential pathways of jellyfish transports in the NWM sea.

THE LESSER-SPOTTED DOGFISH (SCYLIORHINUS CANICULA): PARASITES AND SCAVENGER HABITS

Margarida Casadevall ^{1*}, Natàlia Martínez ¹ and Pauline King ² ¹ Girona University, Sciences Faculty - margarida.casadevall@udg.edu ² Galway-Mayo Institute of Technology, Galway, Irerland

Abstract

The occurrence of parasites in the digestive tract of the lesser-spotted dogfish (Scyliorhinus canicula) caught in the north western Mediterranean was analysed and the results compared with infestation levels in samples of the same species caught in the Atlantic (off the south west coast of Ireland). The relationships between parasite levels and the scavenger habits of the lesser-spotted dogfish are reviewed. The importance of adapting sanitary controls when working with lesser-spotted dogfish on board commercial fishing vessels is emphasised. It is suggested that protocols be adopted so as to prevent increased parasite loading in the lesser-spotted dogfish.

Keywords: Parasitism, Fisheries, Diseases

The lesser-spotted dogfish Scyliorhinus canicula (Linnaeus, 1758), a small demersal shark (Carcharhiniformes: Scyliorhinidae), is a broad generalist in its diet and habitat requirements. It is an opportunistic feeder and cannibalism is frequently recorded [1] [2]. While not being a targeted commercial species, it is caught as by-catch, and has a moderate commercial value in the NW Mediterranean traditional fish markets. The lesser-spotted dogfish are primarily a by-catch species of the Irish demersal fishery and are normally discarded in Irish waters [3]. A study of metazoan parasites of the lesser-spotted dogfish [4] from Isle of Man waters, in the Irish Sea, showed some 10 different species of parasites. Three of them were nematodes: Anisakis simplex, Proleptus obtusus and Pseudoterranova decipiens. Henderson and Dunne [5] observed a prevalence of 94% of Proleptus obtusus in Scyliorhinus canicula from the Galway area on the west coast of Ireland. A previous study in the NW Spain [6] also reported a 91,2% prevalence of Proleptus obtusus in S.canicula. Also recorded was Anisakis simplex (3,5%). To date, no work on nematode parasitism of S.canicula in the Mediterranean Sea or off the SW coast of Ireland has been published. In 2008, a total of 130 lesser-spotted dogfish were caught from the NW Mediterranean coast (Blanes, Costa Brava) and 28 individuals from the SW coast of Ireland. Samples were sexed, weighed (gr) and length taken (cm). The stomach contents were weighed and the nematodes were counted, weighed, and preserved in 70% alcohol. Prevalence was calculated as the percentage number of hosts infected with one or more individuals of a particular parasite species, divided by the number of hosts examined; mean abundance as the number of individuals of a particular parasite species in a sample of a particular host species divided by the total number of hosts examined; and mean intensity as the total number of parasites / number of hosts infected by the same parasite. Nearly all (97%) the Mediterranean individuals and all (100%) the Atlantic specimens analysed contained the parasite Proleptus obtusus (Physalopteridae, Proleptinae). Individuals of P. obtusus found in the stomach were always adults, and some of them were ovigerous females. S.canicula would therefore appear be an important host and also a possible infection agent for this parasite. One individual from the Mediterranean area was infested by the larval stage of a parasite clearly belonging to the Fm. Anisakidae, which suggests that S.canicula may be an intermediate host for this parasite. In the Mediterranean sample, one stomach also contained an Isopod parasite, Ceratothoa oestroides, of the Fm. Anilocridae. Anisakiasis is a zoonotic disease with a dramatic increase in its reported prevalence throughout the world in the last two decades [7]. In the NW Mediterranean coast, fishermen either discard the captured lesser-spotted dogfish (due to the low commercial value) or eviscerate on board, in order to sell the cleaned fillets in the market. McClelland et al. [8] and Abollo et al. [9] have reported that the lesser-spotted dogfish eat discarded viscera of their own species, leading to increased prevalence of Anisakis in fish products. The practice in the Mediterranean of disposing of infected viscera at sea may therefore lead to increased parasite loading on the lesser-spotted dogfish. A change in viscera disposal practices could alleviate this. It is suggested that sanitary controls/protocols be increased for those areas in the Mediterranean implementing such practices. Such protocols should also be extended to include Atlantic waters in the future.

Abstract

We offer the first data on vertical distribution of anchovy larvae (*Engraulis encrasicolus*) in the Alboran Sea. Preliminary results show that the vast majority of anchovy larvae distributed in the top 25 m during daytime, suggesting either a lack of vertical migration or a type II migration. Data are discussed in the frame of the potential implications of vertical migration data for spatially-explicit individual-based model escercises being implemented in the area *Keywords: Alboran Sea, Models, Fisheries, Ichthyoplankton*

Introduction

Vertical migration of fish larvae is likely to affect their probability of survival. In European anchovy (EA) Engraulis encrasicolus, type I vertical migration, implying nocturnal ascent and diurnal descent, has been described in the NW Mediterranean [1]. However, evidence suggests that this is not a speciesspecific strict behaviour but it may be influenced by the environment: for EA in Benguela, Olivar [2] and Stenevik et al. [3] found either no evidence for vertical migration, with all larvae being at the top 25 m, or a type II (oposite to Type I) vertical migration. This was related to either the presence of a strong thermocline or the avoidance of an offshore Eckman transport layer. Anchovy populations living in the vicinity of the Strait of Gibraltar dwell in coastal areas heavily influenced by the Atlantic Jet, which provokes high mesoscale variability and mixing of Atlantic and Mediterranean waters. Historically, there has been a drastic reduction in the anchovy population hypothetically caused by the combination of man-induced pressure in an area of relatively localized spawning area, together with changes in production processes. Within the SESAME EU project, one case study tackles the analysis of EA changes in abundance through environmental and human forcings in the Alboran Sea. Through the combination of Individual-based models coupled to circulation models, we try to understand the underlying processes regulating mid and long-term fluctuations in the populations. Gathering in situ data like vertical migration or growth is one step towards building and validating these models. The objective of this work was to analyse the vertical distribution of anchovy early stages in a coastal area where it spawns, and to interpret the results in the frame of existing dispersion models and vertical distribution data.

Material and Methods

A first excercise to identify the zones in the North Alboran Sea with higher retention probability was perfomed using the outcome of a 3D ROMS (www.myroms.org) ocean climatology of 30 years averaged each 8 days (2 km resolution in the Alboran Sea, MFS used as boundary conditions and ERA-40 meteorological forcing). The package Ichthyop (www.ecoup.ird.fr/projects/ichthyop) was used to simulate the transport of inert particles from 13 different areas during 12 climatological months. Each monthly run consisted on 65000 particles released between the 50 and 100 m isobath, which drifted for 30 days. They were set to recruit if they spent over 1 day over the 50 m isobath at ages older tan 14 days. To obtain vertical distribution data, an ichthyoplankton-oceanographic survey was conducted in 2008 over the potential spawning zone of EA (Fig. 1). From the 27 stations, preliminary data from the vertical distribution of anchovy eggs and larvae was analysed from 12 stations located at the areas of higher retention, close to Malaga Bay. Vertical distribution was derived from a multinet (HydroBios, 50x50) equiped with 200 microns mesh and set to operate at 25m intervals from 100 m to surface. Plankton samples were preserved in seawater with 4% formalin buffered with Borax. All fish species were sorted and EA eggs and larvae were kept separate for later analysis. The preliminary results shown here correspond to mean abundances per stratum of stations collected during daytime, using stations for which at least the top 2 depth ranges were available.

Results and Discussion

The results of the dispersal model showed that 1) the area close to Malaga Bay showed a significantly higher probability of retention than adjacent zones in the N Alboran Sea, and 2) that this retention was higher from April to September, coinciding with the spawning period of the EA. The surveyed area area was characterised by the presence of mixed Mediterranean-Atlantic waters of 36.6-37at surface, and of Mediterranean waters at deepre layers (Fig.1 A). The signal of the Western Atlantic Gyre, was visible at station 6 from the coast (Fig. 1 A). A strong shallow thermocline at ca. 25 m was present in the area. From the 10987 larvae found, anchovy represented only 1.23 % (135 ind). Eggs were found in low numbers (54) in the vicinity of Malaga Bay, suggesting a very local and patchy spawning, which confirms earlier works [4]. Eggs and larvae agregated in the top 25 m, diminishing sharply afterwards (Fig. 1 B), in relation to the presence of the strong thermocline. The data for Fig. 1 were collected during daytime: although these results are preliminary, there was no evidence to suport the view that larvae performed significant type I migration. We provide the first data on vertical distribution of anchovy in the Alboran Sea. Further analysis of size-based data, and diel rithms will shed more light into the mechanisms driving vertical behaviour in this area, and will be an added value for the spatially-explicit IBM excercises that are being implemented.

Fig. 1. (A) Salinity (contour) superimposed on a temperature profile (shaded) from a transect of the N Alboran Sea. (B) Median vertical abundances and IQ ranges of anchovy eggs and larvae from positive stations. In A, the stations (dots), transect (rectangle) and the aproximate location of the thermocline (horizontal dashed line) are indicated

PHENOTYPIC VARIABILITY OF THE KILLIFISH APHANIUS FASCIATUS (NARDO, 1827)

Francesco Cavraro^{1*}, Vyron Georgalas¹, Stefano Malavasi¹ and Patrizia Torricelli¹ ¹University Ca' Foscari, Venice - cavraro@unive.it

Abstract

Samples of the cyprinodontid *A. fasciatus* from the Northern and Central basins of the Venice lagoon were compared in terms of phenotipic variability. Results suggest that fishes inhabiting the two basins differ in some life history traits and in the fluctuating asymmetry of lateral bars.

Keywords: Teleostei, Adriatic Sea, Brackish Water, Life Cycles, Conservation

Introduction

Estuaries and coastal lagoons represent important natural areas for fish communities. The Venice Lagoon is the largest lagoon in the Mediterranean basin, covering an area of about 540 km². It is characterized by a complex patchwork of shallow water habitats. Among them, saltmarshes offer many different ecological niches and resources to nektonic community. The extension of these habitats is subject to a progressive reduction due to human activities. For these reasons, the European Directive 92/43/EEC ('Habitat' Directive) lists these habitats in Annex I as natural habitats of community interest. Aphanius fasciatus (Pisces: Cyprinodontidae) has been considered by previous studies [1] as a typical species characterizing the nektonic community of salt marsh creeks. It is also listed in Annex II of the Habitat Directive as a 'species of community interest whose conservation requires the designation of special areas of conservation'. Other species belonging to the order Cyprinodontiformes have been used in many studies of environmental monitoring of salt marsh systems [2, 3, 4]. In the present study, first results of the variation of some phenotypic traits between fishes inhabiting two main basins (Northern vs Central) is reported, in order to assess the health of natural populations of A. fasciatus and in the perspective of its potential use as "biomonitor" of ecological status and variability of saltmarshes in the Venice lagoon.

Material and Methods

Samples of *A. fasciatus* were collected in the Northern and Central basin of the Venice lagoon using a beach seine. For each specimen a set of phenological traits were collected: Standard Length (SL), Total Weigth (TW) and number of vertical bars on each body side. A Condition Factor CF=(TW*100)/SL³ was calculated for each individual.

Fig. 2. Cumulative frequencies values of fluctuating asymmetry (FA) in males and females of *A. fasciatus* collected in the Northern and Central basin of the Venice lagoon

The difference in the number of vertical bars between the two body sides was used to assess the absolute values of fluctuating asymmetry (FA) [5] and to test for its variability between the two basins. The degree of FA may be used as indicator of developmental instability due to environmental stress [6]. Males and females were analyzed separately, due to the sexual dimorphism of this species.

Results and Discussion

The mean values of CF of fishes in the Central basin were higher than that of the Northern one within the smaller and intermediate size classes, whereas they were similar or slightly higher in the Northern basin for larger size classes (Figure 1). This suggests the presence of different life history traits, especially in size/age-specific growth rates, or in the level of reproductive and somatic investment. Also the degree of FA changed significantly between the two basins, with higher frequencies of asymmetry in the Central basin (Figure 2). Although further studies are needed to properly explain the patterns of phenotypic variability observed in this species, the differences found between the two basins suggest the potential use of this species as "biomonitor" for the variation of saltmarsh habitat quality.

DETERMINATION OF OXIDATIVE STRESS PRECURSORS OF BLEACHED AND NON-BLEACHED ANEMONES FROM TURKISH COASTLINES

Sevilay Cengiz¹ and Levent Cavas^{1*}

¹ Dokuz Eylul Uni. Faculty of Arts and Sciences, Department of Chemistry, Izmir-Turkey - lcavas@deu.edu.tr

Abstract

The antioxidant enzyme activities and the lipid peroxidation levels of bleached and non-bleached *Anemonia viridis* from Turkish coastlines were determined in the present study. *Keywords: Aegean Sea, Cnidaria*

Introduction

Sea anemones, a group of the order Actinaria, show a symbiosis between cnidarian and an alga commonly known as zooxanthellae. This association is considered to be mutualistic as the two side of the association acquire some benefits from the presence of other side. Despite its benefits to each side, this mutualism must be carefully balanced. If this balance shifts towards to alga, the anemones will be destroyed by the excess O2 and also the increased reactive oxygen species (ROS) from photosynthesis [1]. Due to their unpaired electrons, the reactive oxygen species react rapidly with some molecules in the body which may cause DNA injury, lipid peroxidation and protein carbonylation [2]. In order to protect themselves against the excess ROS, the anemones expel the alga from their bodies to reconstitute the balance between two sides of symbionts or the photosynthetic pigments of alga are removed. This alga or pigment loss cause whitening which is named "bleaching" in the anemone. There are some reports in the literature that elevated temperature, UV exposure, cold shock, pathogenic infections, reduced salinity, unfavorable light conditions or pollution may also be the other factors of bleaching [3]. To the best of our knowledge, this is the first report on the bleaching event of anemone species from the Turkish coastlines. The antioxidant enzyme activities and lipid peroxidation levels of the bleached and non-bleached anemones which were collected from the same locations were investigated in order to see the differences between these individuals.

Materials and Methods

The animals were collected from Dikili-Turkey in May 2009. 0.10 gram of samples was homogenized in 1 mL of phosphate buffer (pH 7.2, 50 mM) with Ultra-Turrax T8 IKA-Werke homogenizator. The homogenates were centrifuged in a refrigerated centrifuge (Hettich 32R) at 10,000 rpm for 10 min at +4°C to remove the cell debris and the supernatants were used in experiments. Total protein concentrations were determined by the Bradford Method using bovine serum albumin (BSA) as standard [4]. SOD activity was assayed by using a commercial kit produced by Randox (SD 125). CAT activity was determined by Aebi's method [5] that measures the decrease in absorbance of H₂O₂ at 240 nm. GSH-Px activity was assayed by using a commercial kit produced by Randox (RS 505). LPO level was measured by measuring the concentration of thiobarbituric acid reactive substances (MDA). The LPO level was calculated by using an extinction coefficient of 155 mM⁻¹cm⁻¹ as nmol MDA/g fresh weight of anemones [6]. Student t test was used to evaluate the experimental data. The statistical significance was considered as p<0.05.

Fig. 1. Antioxidant enzyme activities of bleached and non-bleached anemones. NBT, BT, NBC and BC identify the non-bleached tentacles, bleached tentacles, non-bleached columns and bleached columns, respectively. * shows the statistical differences between the enzyme activities observed in the non-bleached and bleached tentacles. Letter (a) shows the statistical differences between the enzyme activities observed in the non-bleached and bleached columns. The results are the means of three different experiments and the error bars show \pm S.E.M

Results and Discussion

In order to evaluate if there is a connection between the bleaching of sea anemones and increased oxidative stress, the antioxidant enzyme activities were determined. The results were presented in Figure 1. SOD activities of non-bleached tentacles were statistically higher than the SOD activities of bleached ones (p<0.05). The excess H_2O_2 is scavenged by the activities of CAT. There was a statistically difference between the CAT activities of non-bleached and bleached columns (p<0.05). There was no statistical difference between the GPx activities of all species. No statistical differences were observed between the LPO levels of these species. According to the results of present study, there is no correlation between the antioxidant enzyme activities and the bleaching event.

Fig. 2. LPO levels of bleached and non-bleached anemones. NBT, BT, NBC and BC identify the non-bleached tentacles, bleached tentacles, non-bleached columns and bleached columns, respectively. The results are the means of three different experiments and the error bars show \pm S.E.M

Abstract

Les prospections dans le milieu naturel ont montré que le cycle de *Proctoeces maculatus* s'effectue entièrement dans la lagune de Bizerte. Il comporte comme premier hôte intermédiaire, le mollusque lamellibranche, *Mytilus galloprovincialis* et comme second hôte, *Sabella pavonina* et *Clamys varia*. Ce dernier hôte présente un taux maximal de parasitisme. *S. pavonina* montre une valeur maximale de l'intensité moyenne. L'hôte définitif est représenté par 3 espèces de Sparidés (*Diplodus vulgaris, Lithognathus mormyrus, Sparus aurata*). *S. aurata* semble être l'hôte préférentiel de ce parasite *Keywords: Lagoons, Larvae, Life Cycles, Parasitism*

Introduction

Les travaux de recherche concernant les digènes parasites des organismes aquatiques provenant des côtes tunisiennes ont concerné, en particulier, la diversité, la morpho-anatomie et la dynamique évolutive des communautés parasitaires infestant les Poissons et les Mollusques [1], [2]. Mis à part les travaux effectués sur le cycle évolutif de *Bucephalus anguillae* parasite de l'anguille et celui de *B. labracis* parasite du loup [3], [4], aucune autre étude se rapportant à cette thématique n'a été entreprise sur les côtes tunisiennes. *Proctoeces maculatus* semble présenter, à l'état larvaire, un danger potentiel élevé pour la mytiliculture (baisse de la vitesse de croissance des moules (1.5 à 2 fois) et mortalité massive de ces mollusques dans le cas d'une hyperinfestation [5], [6]). Dans ce travail, nous nous sommes intéressés, à la détermination du cycle biologique de ce parasite dans la lagune de Bizerte, biotope privilégié de la culture des moules.

Matériel et méthodes

Les moules examinées proviennent de Menzel Jemil (1402 individus) et de Menzel Bourguiba (650 spécimens), stations conchylicoles situées dans la lagune de Bizerte (Nord-est de la Tunisie). La faune associée à ces mollusques est triée, déterminée et maintenue vivante pour la recherche des métacercaires. Cette faune regroupe des Polychètes errants (60 Nereidae, 5 Aphroditidae, 20 Eunicidae, 4 Cirratulidae, 5 Syllidae, 5 Phyllodocidae), des Polychètes sédentaires (59 Sabellidae, 5 Terebellidae, 120 Serpulidae), des Bivalves (39 Pectinidae, 114 Limidae) et des Gastéropodes (170 Muricidae). La dissection de ces animaux est effectuée sous la loupe binoculaire. Les différents organes de chaque animal sont examinés pour détecter la présence éventuelle de parasites. La place, le nombre et l'état de développement de chaque larve sont notés. Les parasites récoltés sont observés au microscope pour être déterminés. Pour la recherche du parasite adulte nous avons examiné 480 sparidés, regroupant 13 espèces (Boops boops, Diplodus annularis, D. puntazzo, D. sargus, D. vulgaris, Lithognathus mormyrus, Pagellus acarne, P. erythrinus, Pagrus auriga, P. pagrus, Sarpa salpa, Sparus aurata, Spondyliosoma cantharus) évoluant dans la lagune de Bizerte. Après la dissection de ces poissons, les trématodes sont recherchés dans les différentes parties du tube digestif. Les observations des parasites ont été effectuées in vivo et à partir d'individus fixés dans le bouin Hollande, colorés avec le Carmin Boracique, déshydratés puis éclaircis dans l'essence de Girofle et montés entre lame et lamelle dans une goutte de Baume de Canada. La nomenclature appliquée pour la détermination des valeurs épidémiologiques est celle utilisée habituellement [7], [8].

Résultats et discussion

Jusqu'à présent seules les moules provenant de Menzel Jemil ont montré la présence des larves de digènes. Il s'agit de sporocystes et de cercaires de *Proctoeces maculatus*. La fréquence globale de cette infestation ne dépasse pas 0.35%. Les sporocystes infestant la moule colonisent, au début de l'infestation, l'hépatopancréas. A la fin de l'infestation la totalité du manteau se trouve colonisé par les sporocystes ; cet organe présente, alors, l'aspect d'une fine membrane transparente vidée de ses substances de réserves et de ses cellules germinales actives. Une constatation semblable a été faite par d'autres auteurs [6] sur la côte ouest du Cotentin. Les sporocystes récoltés contiennent, selon l'état de maturation, des cellules germinales, des sporocystes fils et des cercaires ou seulement des cercaires. Les cercaires émises de ces sporocystes, peu actives et ne présentant pas de queue, vont, se fixer sur des animaux vivant en association avec les moules. En effet, l'examen de la faune associée a permis de récolter la métacercaire de *P. maculatus* chez

une annélide polychète, sédentaire, Sabella pavonina et chez un mollusque bivalve, Clamys varia, avec respectivement une prévalence de15.25% et 28.20% et une intensité moyenne de 4.88 et 1.36. Ces larves se déplacent librement dans le cœlome des premiers segments des sabelles parasitées. Les métacercaires récoltées chez C. varia se trouvent, par contre, enkystées au niveau de la masse viscérale. La métacercaire de P. maculatus, récoltée chez des hôtes appartenant à des familles distinctes, présente une large spécificité. Des résultats semblables ont été mentionnés par d'autres auteurs [9], [10] qui ont signalé la présence de ces métacercaires chez des Annélides Polychètes, des Bivalves et des Gastéropodes. L'examen du tube digestif des sparidés nous a permis de détecter le stade adulte de Proctoeces chez 3 espèces (Diplodus vulgaris, Sparus aurata, Lithognathus mormyrus), parmi lesquelles, S. aurata semble être l'hôte préférentiel (prévalence globale : 15.73%, Intensité moyenne : 2.78). La fréquence de ce parasite est relativement faible chez les deux autres hôtes ; les valeurs de la prévalence et de l'intensité moyenne sont respectivement 6.25% et 1 chez L. mormyrus et 4.76% et 1.66 chez D. vulgarus. La distribution de P. maculatus, au sein du tube digestif, varie selon les espèces ; ce parasite occupant l'intestin antérieur et postérieur chez S. aurata, colonise l'œsophage et la partie antérieure de l'intestin chez L. mormyrus; chez D. vulgaris, ce parasite se limite à l'intestin postérieur.

COMPOSITION BIOCHIMIQUE D'UN MOLLUSQUE BIVALVE : MACTRA CORALLINA DU GOLFE DE TUNIS (KALAAT EL ANDALOUS)

I. Chetoui ¹*, I. Rabeh ¹, K. Telahigue ¹, N. Ghazali ¹, D. Boussoufa ¹ and M. El cafsi ¹ ¹ Faculté des Sciences de Tunis, 2092, Tunisie - chetouiimene@gmail.com

Abstract

Dans ce travail, nous avons procédé à l'analyse des composés biochimiques des muscles adducteurs et de l'ensemble glande digestive-gonade d'un mollusque bivalve marin *Mactra corallina*. Nous avons relevé une quantité relativement importante d'acide palmitique (C16 :0), d'acide eicosapentaénoîque (EPA, C20 :5n-3) et d'acide docosahexaénoîque (DHA C22 :6 n-3) dans les deux organes étudiés. La teneur en glycogène est plus importante au niveau des muscles adducteurs qu'au niveau de la glande digestive-gonade.

Keywords: Bivalves, Physiology

Introduction

Mactra corallina (Linné, 1758) est un mollusque bivalve qui colonise les sables fins de l'étage infralittoral à faible profondeur allant de 3 à 100 m. Pour la plupart des bivalves, les muscles adducteurs, les glandes digestives et les gonades constituent des organes de stockage de glycogène et de lipides [1]. Dans cette étude, nous avons analysé la composition biochimique des muscles adducteurs et de l'ensemble glande digestive-gonade (acides gras totaux et glycogène).

Matériel et méthode

Les analyses ont été effectuées sur des échantillons de *Mactra corallina* de taille comprise entre 30 et 40 mm dont le poids total est compris entre 19 et 26 g. Ils ont été prélevés durant le mois de mars. Les lipides totaux sont extraits par un mélange de solvants chloroforme méthanol (2/1) selon la méthode de Folch *et al.* [2] et analysés par chromatographie en phase gazeuse (HP 6890). Nous avons utilisé pour nos analyses statistiques un logiciel Statistica 5.0 (ANOVA- MANOVA). Le glycogène total a été analysé par la méthode enzymatique Dubois *et al.* [3].

Résultats et discussion

Cette étude nous a permis d'identifier les acides gras saturés : C14 :0, C16 :0, C18 :0 et C20 :0; les acides gras monoinsaturés C16 :1, C18 :1n-7 et le C20 :1n-7 et les acides gras polyinsaturés C18 :2n-6, C18 :3n-3, C18 :4n-3, C20 :3n-6, C20 :4n-6, C 20 :5n-3 et C22 :6n-3. L'ensemble glande digestive-gonade se caractérise par une teneur élevée en lipides totaux (51,63%) par rapport au muscle adducteur (18,48%). Ces deux organes présentent des pourcentages rapprochés en acide palmitique (C16 :0). L'acide eicosapentaénoîque (EPA, C20 :5n-3) présente un pourcentage élevé au niveau de l'ensemble glande digestive-gonade égal à 27,05%, alors que l'acide docosahexaénoîque (DHA, C22 :6n-3) dépasse les 12% au niveau des muscles adducteurs. Le muscle adducteur est l'organe qui permet l'ouverture et la fermeture des valves, ce qui explique la quantité importante de glycogène (3,44mg/1g) qui constitue chez les bivalves la première source d'énergie utilisée [4] et le seul glucide utilisé pendant la contraction musculaire [5].

EVALUATION OF MARINE VERTEBRATE BIODIVERSITY OF NORTH CYPRUS COASTAL ZONE ACCORDING TO NATURA 2000 HABITAT TYPES

Burak Ali Çiçek 1*

¹ EASTERN MEDITERRANEAN UNIVERSITY - burak.cicek@emu.edu.tr

Abstract

In this study, species belong to marine vertebrate biodiversity of Akdeniz, Alagadi, Tatlisu, North Karpaz and South Karpaz Special Environment Protected Areas (SEPA) are listed according to "Natura 2000 Network" habitat types with applying underwater visual census (UVC) method. When compared with previous studies done at the area, it is determined that although covering many of the species, Natura 2000 marine habitat types need to be reevaluated to cover other habitat types and biodiversity in the Mediterranean. *Keywords: Biodiversity, Coastal Waters, Conservation, Eastern Mediterranean, Fishes*

Introduction

Over the last 25 years, European Union built up a vast network of over 26,000 protected areas covering all the Member States and a total area of around 850.000 km2, representing more than 20% of total EU territory. It is known as the Natura 2000 network - the largest coherent network of protected areas in the world. The legal basis for the Natura 2000 network comes from the Birds Directive which dates back to 1979 and the Habitats Directive from 1991. Together these Directives constitute the backbone of the EU's internal policy on biodiversity protection [1]. This study is done under EU project "Technical assistance for management and protection of potential Natura 2000 sites in the northern part of Cyprus (Ref No. EuropeAid/125695/C/SER/CY/7)" which is funded by the European Union under the Aid Regulation for the economic development of the Turkish Cypriot community (Council Regulation (EC) No 389/2006) in order to determine marine habitat types and biodiversity in relevant sites located at the coastal zone.

Materials and Methods

This study has been conducted in the marine area of Akdeniz, Alagadi, Tatlisu, North Karpaz and South Karpaz SEPA's of North Cyprus. Cyprus Island is located in the northeastern part of the Mediterranean at 32-34 meridian and 34-35 north latitudes. The island is the only land in the Levantine Basin, which is also the third biggest island in the Mediterranean after Sicily and Sardinia. In order to identify the quantity and the quality of the species, underwater visual census (UVC) method has been utilized for this study. UVC, in simple terms, means that the diver collects quality and quantity based data using equipment, which would assist the researcher to breathe. Using the same method, there have been researches conducted at different locations and different habitats [2, 3, 4, 5]. Transects with different habitat (biotope) structures have been identified at every station. The length of these transects were limited with habitat boundaries. The dives on the transects were conducted to and back directions. On the "going" direction, fast swimming vertebrates were recorded through visual documentation. On the same direction, pelagic, benthic and forms in between the two have been counted. On the "back" direction, especially cryptic and small individuals were recorded. On this direction, sampling work has been conducted as well. During the dive, the researcher carried water-proof PVC notebook and a guide book for identification of the species - especially the ones, which can swim fast. After the dive, the notes taken at the PVC notebook would be transferred to the "area registration form". As much as the technical and environmental conditions permit, the species were recorded visually. Canon S-80 digital camera was used for recording the underwater visuals. In April - May 2009, UVC diving were conducted for 23 transects. During the field works species were recorded according to Natura 2000 habitat types as: "1110 Sandbanks which are slightly covered by sea water all the time", "1120 Posidonia beds", "1140 Mudflats and sandflats not covered by seawater at low tide", "1150 Coastal lagoons", "1160 Large shallow inlets and bays", "1170 Reefs" and "8330 Submerged or partially submerged sea caves" In order to better evaluate the habitat diversity cluster analysis was conducted. The cluster analysis for this research was conducted using the PAST package program. Bray-Curtis similarity analysis was used to identify the similarity levels and the results were drawn using the "Bray-Curtis Dendogram" [6].

Results

A total of 50 vertebrate species were recorded during the field works. Types 1120 (n:30), 1160 (n:28) and 1170 (n:39) are found to be biodiversity-rich habitats which cover rocky and/or macrophyte dominated substratum related species. Habitat type 8330 (n:6) includes similar but less number of species in comparison with rocky and/or macrophyte dominated substratum habitat

types because of the extreme conditions. Habitat types 1110 (n:8), 1140 (n:2) and 1150 (n:10) covers mainly soft substratum related benthic species except transitory visitors. According to species abundance, cluster analysis showed that habitat type 1140 is dissimilar with all other types. It is observed that, habitat type 1110 which covers bare substratum with sandy bottom is dissimilar with the group of habitats covering high relief rocky and/or macrophyte covered substratum types like 1120, 1170 and 1160 where 1150 and 8330 placed between these two main substratum types. Bray-Curtis Dendogram given in Figure 1.

Fig. 1. Bray-Curtis Dendogram.

Conclusion

In this study, vertebrate biodiversity of 7 different Natura 2000 marine habitat types under protection are determined, however in a previous study which was done at similar locations, 83 vertebrate species at 37 different habitat types had been reported [7]. In addition, it is observed that, some habitat definitions appear to be too general, which create difficulties to distinguish and to determine boundaries and organize them in a classification system. It is suggested that, marine habitat classification system of Natura 2000 Network needs to be re-evaluated and the context should be extended in order to cover more habitat types and biodiversity in the Mediterranean.

ASSESSMENT OF SEA TURTLES MONITORING AND RESEARCH STUDIES AT KARPAZ PENINSULA, NORTH CYPRUS

Burak Ali Çiçek 1*

¹ EASTERN MEDITERRANEAN UNIVERSITY - burak.cicek@emu.edu.tr

Abstract

Sea turtle conservation and monitoring studies in North Cyprus started in 1992 in Alagadi Special Environment Protected Area (SEPA) and the scope had been increased to other sites especially the coasts of Karpaz Peninsula which also cover Karpaz SEPA and South Karpaz SEPA. At the field works in 2007, in Karpaz Peninsula, totally 123 sea turtle nests, 73 of them belonging to *Chelonia mydas* and 42 to *Caretta caretta* with 8 unidentified were determined at 13 nesting beaches, with average nest success percentages of 66.1% and %53.9 in order. In this study, consequences of efforts given to protection and monitoring of sea turtles in the area evaluated in general. Additional protection measures that must be taken at nesting habitats and conservation activities are discussed.

Keywords: Conservation, Monitoring, Turtles, Eastern Mediterranean, Biodiversity

Introduction

All sea turtle species (Chelonioidea) considered as threatened species, where the Mediterranean population of *Chelonia mydas* have been determined as critically endangered [1, 2]. Environment Protection Department (EPD) is in charge of any activities related to the protection and monitoring of the sea turtles at the Karpaz Peninsula in North Cyprus.

Materials and Methods

Nesting habitats in the Karpaz Peninsula are given in Figure 1. The data collection has been conducted in three phases. During the nesting period, nest parameters has been recorded with locations and conservative measures has been taken. In the second phase, an "indirect counting method", this is based on counting the remaining egg-shells and traces of the hatchlings after they emerge; predated eggs during the incubation and emerging periods; and the remaining under-developed eggs at the control opening of the nests, has been employed. The eggs, which have been carried to new locations (hatchery) against flood have been controlled, and checked and their success rates have been recorded with same method. During the last phase of the study, the hatchlings are monitored in the sea. The hatchlings were monitored for three hours in the marine environment to obtain information through measuring the breathing frequency in seconds, identifying directions in the sea and observing predation situation as well as behavioral patterns.

Fig. 1. Study sites in Karpaz Peninsula

Results

In this study, 42 C. caretta and 73 C. mydas nests have been identified. Additional to the identified species in nests, there are also 8 other nests (unidentified species), which have been located after hatchlings emerge or predation signs have been observed. After the field works conducted, the average success rate of the nests in the Karpaz Peninsula for C. caretta has been calculated as 53.9% and 66.1% for C. mydas. The data on the behaviors of the hatchlings in the marine environment have been obtained from 7 C. caretta and 24 C. mydas individuals. The average breathing frequency for the hatchlings of C. caretta has been measured at 13.4 seconds per breath, and diving depth at 0.5m. During the observation, apart from one individual, all the others swam towards the open seas. All the monitored C. caretta followed a natural process (incubation, emerging and entering the sea) and have managed to reach the sea; however 7 of the C. mydas were found in control openings and brought to the sea by researchers. C. mydas hatchlings were observed having an average frequency of 14.8 seconds per breath and diving to 0.4m. It was also observed that the two of the seven juveniles monitored did not behave in the normal pattern, furthermore these two hatchlings, in attempt to move forward were doing somersaults. It is suggested that, based on the under-developed nervous systems for balance and directions, their behaviors were distorted.

Conclusions

It was reported [3, 4] that the number of nests fluctuate throughout the years. Based on these data, it is possible to state that the number of nests

found in 2007 is within the regular fluctuation ratio. In terms of successful hatchling, the ratio of the total number of eggs laid and the success rate of these eggs are provided in order of year for 1999 to 2006: %58, %65, %66, % 68, %62, %71, %62, and %72 [3]. In this research, C. mydas and C. caretta species have been evaluated separately. The current situation and the ratio is believed to be as a result of the C. mydas, which is more critically endangered and which lays eggs on Ronnas and Ayfilon more often, conservation efforts such as protection-caging and cover against predation, to be more rigorous and more effectively managed. The conservation measures cannot be implemented as effectively as in the northern beaches, which has an effect on the C. caretta species because these species frequent those beaches. There is a direct ratio between the less controlled beaches and a higher percentage of predation or hidden nest cases. In this research, the control openings (in order to take the stuck hatchlings, dead ones and removing the eggs) were conducted a day or two after the first emerging time. The live juveniles, in control openings, were put in the sea. Another method for control openings would be that after the natural emerging time, the nest would be controlled for juveniles stuck on the tip of the nest but left without any interference. The control opening should be conducted one week after the last observed hatchling. Even the juveniles are free from the egg shells, their developmental process continues [6]. As this research observed, the two hatchlings, which were found after a control opening, did not swim properly and the others surfaced more frequently for breathing. Even though there could be other reasons for these observations, but it is being thought that the reason for the juveniles' behavior is based on the control openings and the fact that the iuveniles were left in the sea before they could complete their physical development. Hatchery operations have been carried out in the Karpaz coasts - especially in Ronnas for a long time to avoid the nests getting flooded [3, 4]. Moreover, this work is carried out by carrying the eggs from different locations of the beach to one spot. However, it is known that, the different temperatures at different points of the beach have an effect on determination of the sea turtle sex ratio [5]. There is a high probability of effecting the male-female ratio if the eggs that have been carried from several nests to one point. Furthermore, it would be safer in view of other risks not to carry all the eggs to one point only. In this respect, the recommended method would be to carry the eggs to higher ground, which is above the water-flood levels and parallel to the original nests.

Abstract

In the Mediterranean Sea, the richest coastal marine ecosystems are the *Posidonia oceanica* beds (endemic Mediterranean species). This species is a key ecosystem in the Mediterranean sea and strictly protected (classified list "species strictly protected" in the Bern International Convention). The aim of this study is to better know the distribution of *P. oceanica* in the northeastern boundary (Dardanelle straits and the Sea of Marmara). The lower and upper limits of *Posidonia oceanica* at the Dardanelle Strait was between 0-17 m deep and covered approximately 30 km long at both sides of the Dardanelle Strait. *Posidonia oceanica* is covered the coastline of 3,13 km at Pasalimani Island and 8 km at Kapidag Peninsula. *Keywords: Posidonia, Mapping, Dardanelles, Marmara Sea*

Introduction

Posidonia oceanica (L.) Delileis an endemic and the most abundant species in the Mediterranean Sea. It is a protected species (classified list "species strictly protected" in the Bern International Convention). This endemic species forms very dense beds between 0 and 40 m deep. P. oceanica growthis very slow (3 cm.y-1) and its reproduction by seeds is very rare. Posidonia oceanica beds are very sensitive to disturbances caused by human activity (e.g. coastal development, pollution, turbidity, anchoring...) and their loss has been observed in a number of regions. Due to its ecological role and to growing concern about its decline, P. oceanica is now a protected species in Turkey by the laws. [1; 2; 3; 4,5]. Since the years 1970, repetitive surveys of the seagrass beds became an important way to check on a long term basis the general health of littoral water. They led to stress the relative importance of different causes of the major negative impacts. More recently the effects of the global change on the hydrologic conditions of the Mediterranean Bassin (temperature, salinity, currents, introduced species) can affect the deepest and geographical boundaries of the P. oceanica beds and need a particular survey. About the Northeastern Mediterranean Bassin boudaries of the Posidonia beds contradictory informations are available in the general descriptions of the repartition of this seagrass. It is mostly checked absent in the Dardanelle straits and in the Marmara sea [6, 7, 8]. In 2005 an isolated bed of P. oceanica has been checked in the middle and southern part of the Sea of Marmara [5]. This region is under extreme hydrologic conditions in comparison for most of the ecological condition of P. oceanica development in the Mediterranean Bassin with low salinity and low temperatures dues to the flow of brakish waters coming from the Black Sea [5]. The aim of this study is to better know the distribution and mapping of P. oceanica in the northeastern boundary (Dardanelle straits and the Sea of Marmara). Also there are two monitoring stations established at Dardanos (Dardanelle Strait) and Pasalimani Island to monitor the changes about the meadows.

Material and Methods

In 2004 all bibliographical informations on the distribution of *Posidonia oceanica* meadows in the strait of Dardanelles and the Marmara Sea was collected. After that an investigation has done with the professional fishermen and diving clubs around Dardanelle and Marmara Sea with personal communications and questionnaries. The surveys were continued with beamtrawls and dredges. Afterwards field work has done by scuba and skin diving for determinig the upper and lower limits of the *P. oceanica* beds with the help of an GPS. All these data prosesed and put in the digital maps.

Results and Discussion

The distribution of *Posidonia oceanica* beds in Dardanelle and Marmara Sea were; at the Europe side of Dardanelle strait (Seddulbahir, Morto bay,Havuzlar, Kilya bay); at the Anatolian side (Odunluk port, Youth Camp, Dardanos, Kepez, Çanakkale Underwater sports club, at Marmara Sea; Pasalimani Island and Erdek Gulf, Kapidag Peninsula. The lower and upper limits of *Posidonia oceanica* in these stations were between 0-17 m deep. *Posidonia oceanica* covered approximately 31 km long with low density at the Europe side of the Dardanelle Strait and 35 km long at the Anatolian side of the strait. The density of the *P. oceanica* at the Europe side was weaker than the Anatolian side because of the surface currents. *Posidonia oceanica* has seen only at Pasalimani Island and the coastline between Ocaklar and Narli at Kapidag Peninsula at the depth of 2-7 m. In these areas the meadow structure

is patchy. The total length of the coastline which is covered with *Posidonia* oceanica is 3,13 km at Pasalimani Island and 8 km at Kapidag Peninsula. All *P. oceanica* rhizomes at the lower limit are plagiotrophic at the monitoring stations. Monitoring of the meadows are still continuing at two station (Dardanos and Pasalimani Island).

Introduction The aims of our study were (i) to review available estimates of Mediterranean marine biodiversity, and update previous checklists, (ii) to depict the main spatial and temporal patterns of biodiversity, including innovative ways of describing marine diversity, and (iii) to summarize the main drivers of change and threats to marine biodiversity.

Material and Methods We used an extensive bibliographic search combined with the participation of several experts on Mediterranean biota to update publicly available estimates of major taxa, from microscopic organisms to vertebrates. This effort included new estimates of less conspicuous organisms. The new estimate was then compared with previous efforts within the region (1-4), and with online databases, and the state of knowledge by groups was assessed.

We used information available by region or sub-regions and by taxonomic group to depict spatial patterns of marine biodiversity. Patterns of primary producers and most invertebrate species could only be explored at the scale of large regions or basins. Detailed spatial patterns of vertebrate diversity (fish, marine mammals, marine turtles, and seabirds) were analyzed using Geographical Information System software (ArcView by ESRI) covering the Mediterranean basin after available data were digitized (e.g. 5). For each 0.1 degree grid cell, species richness was estimated as the sum of the species cooccurring. We also used the global species distribution model Aquamaps (www.aquamaps.org) to generate standardized range maps of occurrence for marine species. We then compared results with local distribution maps.

To describe temporal changes of diversity over time, we summarized information from several studies (e.g. 6-7) that dealt with the challenge of analysing and integrating diverse data. For the North Adriatic Sea, we included results from Lotze et al. (6) who used a multi-disciplinary approach to assess the ecological changes and overall shift in diversity over historical time scales. We finally identified main current threats to diversity by large taxonomic groups, while special attention was given to climate change scenarios.

Results and Discussion Our analysis identified >17,000 species occurring in the Mediterranean Sea and updated previous estimates that were in the order of 8,000-12,000 species. However, our estimate is still incomplete as more species are likely to be described, especially of smaller and less conspicuous biota. Deep sea areas and portions of the southern region are also still poorly known for several taxonomic groups. In addition, the invasion of new species, especially through the Suez Canal, is a crucial factor that will continue to condition several aspects of Mediterranean marine biodiversity.

Spatial patterns confirmed a general decreasing trend in biodiversity from west to east and north to south, with exceptions. Biodiversity is higher in coastal areas and continental shelves, and decreases with depth. We provide a comprehensive set of species richness maps that represent a baseline for future analysis of biodiversity changes and trends, an important task within the context of global change and associated species' range shifts. The first attempt to depict hotspot areas for vertebrate species in the Mediterranean Sea may be useful for conservation planning (8).

Temporal trends indicate that exploitation and habitat loss where the main drivers of historical changes in biodiversity. More recently, habitat loss and degradation, pollution, climate change, over-exploitation and invasions are the most conspicuous threats that also impact the greatest number of taxa.

An important remaining task is the free distribution of publicly available data from national and regional research initiatives to facilitate updates and enable scientific discussion. We envision the need to continue the collaborative research effort that this work illustrates to further update marine biodiversity registries and narrow down the unknowns.

INTERANNUAL VARIATION (2003-2008) OF CALYCOPHORAN SIPHONOPHORES IN THE BAY OF CALVI (CORSICA)

Amandine Collignon ^{1*}, Anne Goffart ¹ and Jean-Henri Hecq ¹

¹ Université de Liège - Océanologie, Centre MARE - Amandine.Collignon@doct.ulg.ac.be

Abstract

The interannual variation of the calycophoran siphonophores was investigated in the Bay of Calvi (Corsica) from 2003 to 2008. The dominant species, *Chelophyes appendiculata* was present throughout the year, with a maximum of reproduction during the summer. Large variations of abundance occur from year to year.

The study of the developmental stages along the year allows us to establish its life cycle, which seems to be correlated with the temperature and mesozooplancton abundance. The cycle takes place each year with a similar seasonal pattern throughout all the study. Other species as *Abylopsis tetragona*, *Lensia* sp., were also present in lower abundance. *Keywords: Zooplankton*, *Medusae*, *Western Mediterranean*

Calycophoran siphonophores are widely distributed in the seas all over the world and are planktonic carnivorous predators which could have a major impact on the structure and dynamics of the zooplankton. They may represent up to 20 % of the zooplankton biomass. Copepods are their principal types of prey [1]. *Chelophyes appendiculata* represents the most common species of calycophoran living in the upper layers and is very dominant throughout the northwestern Mediterranean, especially in the area of Ligurian divergence [2] [3]. That species seems to be less abundant or absent in Gibraltar Straight, Alboran sea, in the South Western Mediterranean [1], in the Thyrenean Sea [4] and in the Gulf of Tigulio [5] [6] and finally in the Adriatic where *Muggieae* sp. or *Lensia* sp. are dominant.

A weekly time series of wp2 zooplankton horizontal sampling were carried out at 5 m depth in the Bay of Calvi from 2003 to 2008. The calycophoran siphonophores species have been counted and identified up to the developmental stage according to taxonomic criteria from Bouillon *et al.* [7] and Patriti [8].

In Calvi, the dominant species, *Chelophyes appendiculata* (Eschscholtz, 1829) was present throughout the year, with a maximum of reproduction during the summer. The different developmental stages (nectophores - asexual stage and the eudoxids - sexual stage) appear and follow each other during all the year.

Nectophores are present all the year with a mean density of 12.2 ind/100m³ but are less abundant in winter. Two peaks of abundance were observed one in spring and a larger in autumn. They were dominant in 2006 with a maximal value starting in July (647 ind/100m³).

Fig. 1. Interannual variation of zooplancton fresh weight (A) and *C.appendiculata* necotophores (B) in the Bay of Calvi from 2003 to 2008

Eudoxids were less abundant during the winter and maxima occurred from the beginning of spring to the end of summer. The mean density was 0.74 ind/100m³. The highest abundance was noted in the beginning of June (64 ind/100m³).

The early larval stages coming from the sexual reproduction appeared only in a short time during summer.

These results agree with previous investigations made in the northwestern Mediterranean basin concerning the presence and temporal variation of *C. appendiculata* in Villefranche sur Mer [3]. The breading reproduction occurs in summer. The main difference between these studies is that *C. appendiculata*, in Calvi, occurs in larger abundance throughout the year.

This species is a species characteristic of the central waters of the Ligurian divergence [1] and its dominance in Calvi could be explained by the strong influence of offshore waters input Corsican occidental coast [9].

The comparison of the abundance of nectophores of *Chelophyes appendiculata* with the mesozooplankton biomass (fresh weight /m³) shows a good correlation (Fig.1). We have noted that the maximum values of abundances in 2006 and 2008 correspond to years when invasions of *Pelagia noctiluca* were important.

Abylopsis tetragona, was less abundant than Cheophyes appendiculata and only the nectophores were counted. This species occurred throughout the year (mean: 1.87 ind/100m³) but was less abundant during winter. The maximum of abundance was observed in May 2004 (27 ind/100m³).

More than other plankton species, siphonophores present variability in composition in different regions of the Mediterranean probably due to local hydroclimatic conditions. Actual data aren't enough to explain these variations. A integrate study of the calycophoran diversity and its variability should be carry out between the different laboratories.

AN INTER-REGIONAL COMPARISON OF THE DIET OF EUROPEAN ANCHOVY JUVENILES IN THE ADRIATIC SEA AND IN THE GULF OF LIONS

D. Costalago Meruelo ¹*, D. Borme ², V. Tirelli ², I. Alvarez ¹, A. De Olazabal ² and I. Palomera Laforga ¹ ¹ Institut de Ciències del Mar (CMIMA-CSIC), Passeig Marítim de la Barceloneta, 37-49 - 08003 Barcelon - costalago@icm.csic.es ² Dipartimento di Oceanografia Biologica, Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Via Piccard 54, 34151 Trieste, Italy.

Abstract

This work was carried out in the framework of SARDONE project to assess and compare the ecology of juveniles of *Engraulis encrasicolus* (L.) in two important fishing areas of the Mediterranean Sea. Although in the Adriatic Sea the mean zooplankton biomass was much higher than in the Gulf of Lions during autumn 2007, the diet of the anchovy juveniles was based mainly on small copepods in both areas. Anchovy prey selectivity seems to point out the preference for few genera: *Temora, Oncaea, Euterpina* in the Adriatic and *Temora, Microsetella* and *Corycaeus* in the Gulf of Lions. *Keywords: Diet, Pelagic, Gulf Of Lions, Adriatic Sea, Zooplankton*

Introduction

Small pelagic fish are essential mid trophic levels of the food web and play a major role in the ecosystems in terms of trophic flows and biomasses in the Mediterranean Sea [1, 2]. European anchovy, *Engraulis encrasicolus* (L.), can be found throughout the Mediterranean Sea, being the most important fishery of small pelagic fish in two of the major stocks (North-western Mediterranean and Adriatic Sea). Since the fishing pressure exercised over *E. encrasicolus* is exceptionally high in these areas [1], different studies have been carried out in order to improve the knowledge on the trophic ecology of this species [3, 4]. However, differences in the diet of anchovy juveniles between the Adriatic and the Gulf of Lions have never been studied. Here we present the first work that compares the trophic behaviour of anchovy in these two regions.

Materials and Methods

Two cruises were carried out in the Gulf of Lions (Northwestern Mediterranean) and in the Po river Delta (Northwestern Adriatic Sea) in December and November 2007, respectively. Plankton samples were collected by vertical tows with a standard WP2 net (mesh size of $200 \,\mu\text{m}$) for mesozooplankton, and by means of a modified Calvet net (mesh size of $53 \,\mu\text{m}$), for microplankton. Juveniles of *Engraulis encrasicolus* were captured with a small pelagic trawling net. The total length and the weight of the individuals were measured. The feeding preferences were assessed using the Ivlev's dietary selectivity index [5].

Results and Discussion

In the Adriatic Sea mean microplankton biomass was 67.04 mg*m⁻³ and mesozooplankton biomass was 29.04 mg*m⁻³ while in the Gulf of Lions mean biomass was 11.38 mg*m⁻³ and 7.04 mg*m⁻³ of microplankton and mesozooplankton respectively. Anchovies total length ranged between 45 and 86 mm in the Adriatic Sea, and between 48 and 110 mm in the Gulf of Lions. The composition of the stomach contents in the Adriatic and in the Gulf of Lions was basically made-up of small copepod (adults and copepodites). Ivlev's selectivity index (Fig. 1) pointed out a preference for *Temora* spp. *Oncaea* spp. and *Euterpina acuiffrons* in the Adriatic. In the Gulf of Lions, the most highly selected preys were mainly *Microsetella rosea*, *Temora* spp.and *Corycaeus/Farranula*, but decapod larvae and other crustaceans were also positively selected. *Temora spp.* was preferred in the same proportion in both the areas, but , in the Gulf of Lions the feeding selectivity covered a wider range of prey.

Fig. 1. Ivlev's diet selectivity index of juvenile anchovies

ASSESSMENT OF MORPHOMETRIC PARAMETERS OF TUNA *THUNNUS THYNNUS* (LINNAEUS, 1758) BASED ON MUSEUM EXHIBITS, DUBROVNIK NATURAL HISTORY MUSEUM

Marija Crncevic 1, Marijana Cukrov 2 * and Katarina Ivanišin-Kardum 1 ¹ Dubrovnik Natural History Museum, Androviceva 1, 20000 Dubrovnik, Croatia - mcrncevic@dubrovnik.hr ² Croatian Biospeleological Society, Demetrova 1, 10000 Zagreb

Abstract

The natural objects of the Dubrovnik Natural History Museum, such as the head and the caudal fin of tuna *Thunnus thynnus* (Linnaeus, 1758.), which as species is listed on the Red list of threatened plants and animals of Croatia, are a valuable source of data of this threatened species in the Adriatic Sea. These Museum objects, as well as the relevant existing written historical documents and existing scientific knowledge regarding tuna were used to assess the morphometric characteristics. The parameters will be used in construction of a credible complete model of tuna that will form part of the Museum permanent collection, with emphases on its educational aspects.

Keywords: Adriatic Sea, Pelagic, Fishes

Introduction

The dermoplastic preparations of the head (Figure 1) and the caudal fin of tuna *Thunnus thynnus* (Linnaeus, 1758) belong to the particularly valuable natural objects of the Dubrovnik Natural History Museum. According to the written data it was caught near the small town Ston in 1897 and it weighed around 275 kg [1].

Fig. 1. The dermoplastic preparation of the head of tuna *T. thynnus*, Dubrovnik Natural History Museum

Tuna is a large and high migratory species. Usually they school by size. This fast swimming bony fish occurred in almost whole Adriatic Sea: along the coast, in channels and especially in open sea, rare along the Istria coast [2]. Tuna fishing have a long tradition in Croatia.

Due to its economic value the population of tuna in the Adriatic Sea has been significantly reduced. According to the IUCN categorisation, these species have been included in the Red book of sea fishes of Croatia [2]. In line with the legislation of the Republic of Croatia, tuna is a protected species [3], and fishing is regulated by the catch quotas in accordance with recommendations of the International Commission for the Conservation of Atlantic Tunas [4].

Material and Methods

On the basis of morphometric characteristics of the Museum exhibits: diameter of the eye, length of the head and the preorbital length, as well as on the information supplied on the weight of the caught tuna and the scientific knowledge of tuna, mathematical methods were used to calculate its overall morphometric values and to define its meristic properties (Table 1) [2, 5, 6]. The same data will be used for construction of the model of life size tuna that will, as a Museum exhibit, form part of the Museum permanent collection.

Results and Discussion

Tab. 1. Morphometric and meristic characteristics of tuna Thunnus thynnus

Morphometric characteristics	Length (cm)
Total length	258.0
Standard length	230.0
Fork length	235.0
Pre-anal length	146.5
Pre-dorsal length	71.2
Pre-pelvic length	78.1
Pre-pectoral length	71.9
Body depth	74.0
Head length	66.5
Eye diameter	10.6
Pre-orbital length	18.6
Wide caudal fin	67.2
Meristic characteristics	Number
D ₁ first dorsal fin	XIII
D ₂ second dorsal fin	I + 13
A anal fin	II + 12
V pelvic fin	1+5
dorsal finlets	10
ventral finlets	9

Construction of the complete Museum object and accompanying, organised educational programmes, will contribute to indication of the status of these threatened species: the need for preservation and the necessity for enforcement of measures of the protection and the economy.

Abstract

Alien species Ficopomatus enigmaticus was recorded on two locations along the eastern Adriatic coast, Krka River Estuary and Neretva River Delta. It is probably introduced as ship fouling.

Keywords: Adriatic Sea, Brackish Water, Species Introduction, Polychaeta

Introduction

Ficopomatus enigmaticus (Fauvel, 1923), previously know as Mercierella enigmatica, is sedentary suspension-feeding polychaete belonging to family Serpulidae. These polychaete worms build and live in upright white calcareous tubes that have distinctive collar like rings at irregular intervals. It is reproducing successfully on temperatures around 18°C [1, 2]. It is cryptic species probably invaded the Mediterranean Sea as ship fouling during the First World War [3]. The first record in Europe was in the Channel de Caen in the northern France in 1921. In the Adriatic Sea, F. enigmaticus was recorded for the first time in the Venice Lagoon, the Northern Adriatic [4]. Today, it builds huge aggregate "reefs" in the Po River Delta [2].

F. enigmaticus was recently recorded at two new locations along the eastern coast of the Adriatic Sea, Krka River Estuary and Neretva River Delta (Fig. 1). The investigations of both records were performed by scuba divers. The first location, Krka River, is situated in the karst region and its estuary, with total length of 22 km, was formed during the Holocene transgression. In the lower part of estuary, the Port of Šibenik is located. It is a typical example of a stratified estuary which bottom gradually deepens from 2 m to 42 m.

Fig. 1. Locations of the F. enigmaticus appearance

Around the shores of the lower part of the Krka River Estuary F. enigmaticus occurs as single tubes or as large dense fouling aggregations mostly on artificial substrates like cement (seawalls) and iron construction (Fig. 2). It exists at depths up to 3 m, but the largest settlements are up to 0.5 m. Hull encrustations are up to 25 cm thick reaching the water surface during the low tide. We have found larger fouling aggregations only at three sites. Also, it makes fouling in community with Mytilus galloprovincialis. The intertwined tubes are often coated with bryozoans. Additionally, along the coast we have observed dead fragments of fouling aggregations with domination of F. enigmaticus tubes. Probably, that fouling aggregates collapses due to excess weight or mortality during the winter due the exposure to low temperatures for long period, low

salinity and flow intensity

Fig. 2. Photo of F. enigmaticus from the Krka River Estuary (July, 2009.)

The second location, Neretva River Delta, covers about 20 000 ha of which 12 000 ha are in Croatia. It is constituted of numerous channels. The Port of Ploce is situated near the river mouth, and it is one of the main Croatian ports. In this area, F. enigmaticus occurs in two delta's channels as single specimens or in small aggregates regularly in communities with Balanus sp. It mostly occurs at depths of 0.7 m. The fishes from genus Syngnathuswere observed as main predators on fouling tubeworm in this area.

Conclusion

The fact that populations of F. enigmaticus appear near the ports suggests that the probable mechanism of introduction was ship fouling. Also, appropriate environmental factors on these locations enable growth of the species.

MARINE MOLLUSC FAUNA OF KASTAMONU AND SINOP COASTS (THE SOUTHERN BLACK SEA, TURKEY)

Mehmet Culha 1*

¹ COMU, Fisheries Fac., Hydrobiology dept., Terzioglu camp. 17100. C.kale - msculha@gmail.com

Abstract

The study was carried out to determine Mollusca fauna of Kastamonu and Sinop coasts. A seasonal sampling procedure was performed in the area from a variety of biotops in 0-0.5 and 5m depths at 4 stations between July 2007 and May 2008. A total of 11 species and 16823 specimens belonging to Bivalvia; 15 species and 5482 specimens belonging to Gastropoda and 1 species and 1 species and 1 specimens belonging to Polyplacophora classes were encountered during the study. Also, the seasonal distribution of the physicochemical parameters measured on site as in-situ. In addition to, analytical procedure and minimum and maximum ranges with (Mean±SD) are shown.

Keywords: Mollusca, Black Sea, Biodiversity

Introduction The biodiversity of the Black Sea ecosystem includes some 2,050 species of animals including Arthropoda, Molluscs (206), Echinodermata, Fish and Mammals (1). As far as Turkey is concerned, the investigations on mollusk biodiversity of the Black Sea are quite scanty and limited to information depth of finding and other details, except for Russian, Ukraine and Romania, some another countries coasts of the Black Sea. There have been some studies on Mollusca in Turkish coasts of the Black Sea. These studies have begun since years of 1960'. 11 by Caspers (1968); 49 by Bacescu et al. (1971), 37 by Fisher et al. (1987), 37 by Mutlu et al. (1993), 49 by Kocatas et al. (2000), 108 by Ozturk (1998), 50 by Ozturk and Cevik (2000), 16 by Culha et al. (2000), 99 by Demir (2003), 23 by Demirci and Katagan (2004), 28 by Culha (2004), 8 species by Luth (2004), 26 by Ozturk et al. (2004), 33 by Demirci (2005), 14 by Culha et al. (2007), 15 species of the et al. (2007) were reported. As a result of the studies in Turkish coasts of the Black Sea carried out up to now, 183 Mollusca species have been identified.

Material and Methods Mollusk specimens were obtained by sampling during July 2007 and May 2008 at 4 stations (2 stations from Sinop [Ayancik, Türkeli] and 2 stations from Kastamonu [Abana, Çatalzeytin] chosen at the Middle Black Sea, Abana: 41o58'51"N, 34o00'01"E; Çatalzeytin: 41057'20"N, 34011'58"E; Türkeli: 41056'59"N, 34020'37"E; Ayancik: 41056'46"N, 34034'41"E (Figure). A total of 32 (16 x 2 replicate) samplings were performed with 4 samplings for seasonaly. Sampling at the 4 stations was conducted seasonally at various biotopes at depths of 0.5m -5m. A spatula or shovel was used to collect specimens from a 20X20 cm area using a quadrate sampling methodology. Sampling was carried out by free or scuba diving. Additionally, the physico-chemical parameters of the sampling stations were measured seasonally from the surface to ~1-2m depth using a WTW 340i multi Set water quality meter (Table). The collected material was fixed in 4% formalin solution to be examined in the laboratory. Species identification was performed according to shell characteristics and several reference sources, including Nordsieck (1968), Cachia et al. (1996, 2001), Graham (1971), Barash and Danin (1992), Butakov et al. (1997), Culha (2004), Dogan (2005). Sabelli et al. (1990, 1992) and Clemam (2008) were followed for the systematic index of the species.

Fig. 1. The position of four selected stations at Kastamonu and Sinop coasts St. 1) Ayancik, (St. 2) Türkeli, (St. 3) Çatalzeytin and (St. 4) Abana

Results and Discussion The aim of the present study is to determine the marine mollusk species on Kastamonu (Abana, Çatalzeytin) and Sinop (Ayancik, Türkeli) coasts. A total of 27 species was detected: 1 of these species belonged to the class Polyplacophora, 15 belonged to the class Gastropoda and 11 belonging to the class Bivalvia. In previous studies, Pusillina radiata and Heleobia stagnarum (Demirci, 2005); Gibbula adriatica, Hydrobia acuta and Mangelia costata (2), and Abra segmentum were reported as new records for the Black Sea coasts of Turkey. On the other hand,

Hemilepton nitidum (Turton, 1822) is one of the new species reported for Molluscan fauna from Turkey (3). Previous studies carried out in Sinop peninsula and neighbouring areas analyzed in different biotopes. Demirci and Katagan (2004), collected the samples from rocky substrates and reported 23 species in Ulva facies. Çulha et al. (2000) carried out several studies in sandy bottoms of the same area, but the same authors found 8 species that were not reported by Demirci (2005). Similarly, Çulha (2004) reported 28 Gastropoda. Among these, 13 species were not reported during the study performed by Demirci (2005). In study of Öztürk et al. (2004) from sandy and hard substratum, 26 Bivalvia species were detected. In a deep water study carried out in Inebolu district (Central Black Sea), Luth (2004) found 3 Gastropod and 5 Bivalvia species. Consequently, different results were obtained in previous studies carried out at various periods and localities of the central Black Sea region. This is due to different biotopes, different zones (Supralittoral, infralittoral, mediolittoral etc.), different sampling methods such as grab, dredge, quatrate and different depths. In addition, the utilization of updated publications (e.g. 3Öztürk and Çevik, 2000; 4Clemam, 2008; 5Sabelli et al., 1990, 1992) by researchers who study in this area will reduce potential errors that may arise.

DEMERSAL ICHTHYOFAUNA OF THE CENTRAL AEGEAN SEA: DECLINING TRENDS IN SPECIES RICHNESS

Dimitrios Damalas¹ and Vassiliki Vassilopoulou¹* ¹ Hellenic Centre for Marine Research - celia@ath.hcmr.gr

Abstract

Data collected from 462 commercial bottom trawl hauls in the central Aegean Sea, during 1995-2006, indicated that species richness of the local ichthyofauna has significantly decreased. It is most likely that while the fishery was driven by the most resilient target species, at the same time it had a dramatic effect on numerous other less robust species. Our findings identified certain warning signs reflecting ecosystem degradation and further study through longer monitoring will contribute to the clarification of trends. *Keywords: Aegean Sea, Biodiversity, Fisheries*

Introduction

The bottom trawl fishery represents some 20% of the total marine production in Greece with almost 45% of the catch being usually discarded at sea [1]. In order to estimate the long-term impact of commercial fishing on the ichthyofauna diversity of the central Aegean Sea, 462 records of bottom trawl hauls were collected on board commercial vessels between 1995 and 2006 (2001-2002 excluded).

Material and Methods

Fish species identification was done on board by trained scientific personnel, who did not interfere with the normal fishing practices of the crew. An annual biodiversity index was constructed by calculating the number of species by year, in 1000 repetitions of randomly selected predefined number of hauls, so that to exclude spatial and effort effect in the biodiversity trend [2]. The annual trend was then expressed by the slope of a linear regression when regressing number of species upon year.

Results and Discussion

Overall, a total of 171 species were recorded (138 bony and 33 cartilaginous fish), belonging to 79 families and 28 orders [Table 1]. More than three quarters of the bony-fish species encountered were perch-likes (Perciformes), flatfish (Pleuronectiformes), cods (Gadiformes) and scorpionfishes (Scorpaeniformes). These were also the groups of fishes exhibiting some of the higher abundances (Catch Per Unit of Effort > 300 individuals per hour of trawling). Skates and rays (Rajiformes) accounted for almost half of the chondrichthyans. Our results revealed that certain species were absent from the catches during the last 4 years of the study; these were the bony-fishes: Acantholabrus palloni, Anthias anthias, Arnoglossus imperialis, Arnoglossus rueppelli, Argyropelecus hemigymnus, Callionymus risso, Centrolophus niger, Deltentosteus quadrimaculatus, Echelus myrus, Epigonus telescopus, Hymenocephalus italicus, Stomias boa, Spondyliosoma cantharus, Symphurus nigrescens, and the chondrichthyans: Centrophorus granulosus, Chimaera monstrosa, Dalatias licha, Myliobatis aquila, Raja circularis, Squatina aculeata, Sauatina oculata,

Tab. 1. Number of species encountered and fishery dependent abundance (CPUE) by family and order taxon

The observed decline in the number of species caught in the central Aegean in recent years is further illustrated by the negative and highly significant (P < 0.001) slope of the linear regression, relating number of fish species

encountered with year [Fig. 1], and suggesting that species richness was reducing by an average of 1.83 species per year, during the studied period. Analogous declining trends were also observed for certain phylogenetic indices in the Greek seas [3], and can be accredited to a series of reasons associated to fishing impact on particular vulnerable species and habitats [4], as well as environmental impact and specifically climate change causing the 'tropicalization' of Eastern Mediterranean [5] which exacerbate biodiversity loss. In fact, specific marine species may be more vulnerable to exploitation and/or changing conditions owed to a number of factors such as older age at maturity, lower reproductive rate, poor adaptation capabilities [6].

Fig. 1. Annual trend of fish species richness as inferred by a linear regression of Average number of species upon Year

Hence, although our findings identified certain warning signs reflecting ecosystem degradation, further study through longer monitoring will contribute to the clarification of trends.

BIOLOGY OF CALLISTA CHIONE (L., 1758) IN THERMAIKOS GULF (N AEGEAN SEA)

Panagiotis Damianidis ¹*, Paraskevi K. Karachle ¹ and Chariton-Charles Chintiroglou ¹

¹ Aristotle University of Thessaloniki, School of Biology, Department of Zoology, Box 134, 54124, Thessaloniki, Greece -

damian@bio.auth.gr

Abstract

The biology of smooth callista [*Callista chione* (Linnaeus, 1758)] was explored from two sites in Thermaikos Gulf, N Aegean Sea. L infinity, K and total mortality were found to be higher in Platamonas (81.38, 1.4, and 2.6474, respectively) compared to those from Sani (76.13, 0.66, and 1.174, respectively). No significant differences were found in the condition index (range: 43.95-51.67), both between stations and seasons.

Keywords: Bivalves, Growth, Mortality, Biometrics, Aegean Sea

Introduction

Smooth callista [*Callista chione* (Linnaeus, 1758)] is commercially exploited throughout the range of its distribution in the Mediterranean. In Greece, despite its great importance, the information regarding its biology is limited (Evvoikos Gulf: [1], Thasos Island: [2]). In the present study, the biology of smooth callista was examined in Thermaikos Gulf. This research was conducted in the framework of a research project (Operational Programme for Fisheries Sector 2000-2006).

Materials and methods

Seasonal samples (spring 2007-winter 2008) were collected from professional fishers (divers with constant air supply), from two different sites in Thermaikos Gulf, Sani (N40° 07,509' E23° 18,149') and Platamonas (N39° 56,741' E22° 42,888'). Shell length (L, in mm) and total weight (W, in 0.1 g) were measured and related using the allometric model W=aL^b [3]. The slopes of the seasonal regressions were compared using analysis of covariance (ANCOVA, [4]). For the estimation of growth parameters L_{inf} (length infinity) and K, and total mortality, FISAT II software [5] was used. Condition index (CI) was estimated as follows [6]:

CI=[MW/(W-SW)]*100

where MW= net body weight and SW= shell weight. CI values were compared using two-way ANOVA and Fisher's least significant difference (LSD) test [4].

Tab. 1. Parameters of the von Bertalanffy equation (L_{inf} = length infinity, in mm; K=parameter of the von Bertalanffy growth function (also known as growth coefficient; in yr⁻¹), total mortality (Z) and seasonal values of condition index (mean value±standard deviation) for *Callista chione*, Thermaikos Gulf, Greece.

Parameter	Platamonas	Sani		
Length range (in mm)	47.31-75.28	29.53-73.02		
Weight range (in g)	20.76-104.64	5.99-97.87		
Lint (in mm)	81.38	76.13		
K (in yr ⁻¹)	1.4	0.66		
Z	2.6474	1.1740		
Condition index Spring 2007		49.77±3.39		
Summer 2007	43.95±7.51			
Autumn 2007	45.45±7.96	47.95±16.33		
Winter 2008	51.67±2.15	49.84±3.51		

Results and Discussion

Overall, 319 individuals (140 from Platamonas and 179 from Sani) were examined. Shell length range was 47.31-75.28 mm in Platamonas, and 29.53-73.02 mm in Sani (Table 1). Seasonal length-weight relationships were all significant (p<0.01, R²>0.71; Fig. 1). The values of b of the relationships ranged from 2.7431 to 3.5548 (3.0063±0.28), whereas no significant differences in their values with season and between the two sites (ANCOVA: all cases p>0.05) were found. The von Bertalanffy growth parameters (L_{inf} and K), as well as total mortality (Table 1) were highest in Platamonas than in Sani. Linf values in the study area are similar to those from Evvoikos Gulf (Linf = 93mm, [1]) and higher than that from Thasos (L_{inf} = 57.8 and 62.7 mm, [2]). Additionally, K values were found to be higher than any previously reported ones from Greek waters ([1]: Evvoikos Gulf. 0.24, [2]: Thassos island, 0.24 & 0.26), indicating that the species in the study area shows very high growth rate. This could be attributed mainly to the environmental conditions prevailing in Thermaikos Gulf [7]. This species is known to have a fast growing rate in its first years of life, a rate that is progressively reduced [8]. CI ranged from 43.95 to 51.67 (Table 1). Two-way ANOVA revealed that CI values were not affected by sampling site (F-value= 0.02, p=0.8992) and season (F-value= 1.51, p=0.2221). In addition, Fisher's LSD showed no differences between the two sites and seasons. The fact that no spatiotemporal differences in CI values were found could be mainly attributed

to the reproduction cycle of the species. In general, spawning is prolonged from spring till the beginning of winter [1]. Given that our samples were collected during spawning season, no differences were anticipated.

Fig. 1. Seasonal length-weight relationships for *Calliste chione*, in Platamonas (left) and Sani (right), Thermaikos Gulf, Greece

SPATIAL DISTRIBUTION OF ICHTHYOPLANKTON IN THERMAIKOS AND CHALKIDIKI GULFS DURING JUNE 2004

Maria Danelli¹, Apostolos Siapatis²*, Athanasios Machias² and Marianna Giannoulaki²

¹ Hellenic Center for Marine Research - siapatis@ath.hcmr.gr

² Department of Marine Sciences, University of the Aegean

Abstract

The spatial distribution of fish larvae was studied in Thermaikos and Chalkidiki gulfs during June 2004. Samples coming from the 500mesh size Bongo net were analyzed and 42 taxa belonging in 29 families were identified. Spatial heterogeneity depended on the combined effects of topography and hydrographic features of the region. Classification of stations into groups established three distinct groups of stations, which basically corresponded to the bathymetry of the study area. <u>Keywords: Aegean Sea, Ichthyoplankton</u>

Introduction

Marine fish larvae play an important role in understanding the ecology and evolution of fishes and their populations [1]. The interpretation of spatial patterns in the ichthyoplankton involves consideration of many factors pertaining to the biology and early life history of fish species and the environment in which they live and reproduce. A complex suite of environmental factors interacts with the biology of fish populations at different temporal and spatial scales to influence the occurrence, distribution, and abundance of the larvae.

Materials and methods

A grid of 13 stations (Fig. 1) was sampled in 15-20 June 2004, with a 60 cm bongo-net (0.250 and 0.500 mm meshed nets) towed obliquely from just above the sea bottom to the surface (maximum to 200 m). Hydrographic profiles were collected on a denser grid of 42 stations. The early life stages of fishes were sorted and identified into families and species. To define ichthyoplankton assemblages, a hierarchical cluster analysis of a Bray-Curtis similarity matrix calculated between species by ranked larval abundance was performed [2], considering only those species or groups that represented 1% of the total catch.

Fig. 1. Map of the study area showing the location of sampling stations

Results and discussion

A total of 3,617 fish larvae were sorted from the 0,500 mm cod-end of the net that were categorized under taxonomy levels of 38 species, 7 genera, and 1 family. European anchovy (28%) composed the highest level in larval distribution and *Sardinella aurita* (14%) was in the second place. The myctophids *Ceratoscopelus maderensis* (14%) and *Hygophum hygommii*(10%) were the most abundant mesopelagic taxa. Other taxa caught at high percentages were *Gobiidae* (5%), *Trachurus mediterraneus* (4%), *Serranus. hepatus* (3%), *cepola macrophalma* (3%) and *Arnoglossus sp.* (2%). Using cluster analysis three different groups of taxa were classified (Fig. 2). The first group contains bathypelagic specie/families like *Mychtophidae, Sternoptychidae* and *Paralepididae* whereas their larvae caught mainly at the offshore stations of Chalkidiki gulfs. The second group contains neritic species like *Diplodus*

annularis, Coris julis, Chromis chromis and Symphodus sp.exhibit an inshore distribution in the coastal band of Thermaikos gulf. Finally, the last group contains taxa characterized by wide dispersal patterns like the pelagic *Engraulis encrasicolus, Sardinella aurita, Trachurus mediterraneus,* the demersal Serranus hepatus, Gobiidae Cepola macrophalma and mesopelagic Ceratoscopelus maderensis and Hygophum hygomi whereas their larvae caught in extremely high densities and distributed over the majority of the sampling stations. The presence of mesopelagic fish larvae over the shelf, occasionally in quite shallow water, therefore, may be the result of some passive mechanism or of shore wards migration by the larvae themselves [3].

Fig. 2. Dendrogram of similarities (cluster analysis, group-average linkage, fourth root transformation) of the taxa sampled in June 2004

STRUCTURE OF INFAUNAL COMMUNITIES UNDER VARIABLE TRAWLING DISTURBANCE

Silvia De juan mohan¹, Montserrat Demestre^{1*} and Pilar Sanchez¹ ¹ Intituto de Ciencias del Mar (CSIC) - montse@icm.csic.es

Abstract

Macroinfaunal communities subjected to different gradients of trawling disturbance were analysed to investigate responses related with trawling effort. Results showed a decrease of abundance and richness with increasing effort, highlighting the benefits of effort restriction to protect marine communities.

Keywords: Biodiversity, Coastal Management, Continental Shelf

Introduction

Fishing activities impacts marine communities and habitats [1], being necessary the incorporation of ecosystem protection in management [2]. We need to gain knowledge on the extent of commercial trawling impact in order to develop actions to reduce disturbance [3]; however pristine areas within trawling grounds are rare, and we have little knowledge about unexploited situations [4]. Aiming to understand the effects trawling intensity on communities we compared the macroinfaunal community at 4 soft bottoms subjected to different regimens of trawling disturbance.

Material and Methods

The 4 sites are located within soft bottoms around 50m depth from the NW Mediterranean. The first study area (A) is located in a fishing ground. This fishing ground includes a portion of undisturbed seabed due to the remains of an abandoned oil platform (area B). The area C is located adjacent to Medes Islands MPA, north from the previous two areas, where occasional trawling takes place. The area D is located inside the MPA where trawling is prohibited. Each area was sampled with a 0.1 m² van Veen grab at 5 stations, with 5 grabs randomly collected at each station to obtain the minimum sampling size. Samples were sieved over 1 mm, and organisms were identified to the lowest taxonomical level recording number of individuals. A one-way ANOVA and a Tukey post-hoc test were performed to identify differences between areas.

Results

Abundance is significantly different at all sites (p>0.01); being higher at B and D sites (Fig. 1a). Species richness is significantly higher at D (p>0.001), whereas it is similar at the other three areas (A, B, C) (Fig. 1b).

Fig. 1. Abundance and richness (number of species) at the four study areas

70 taxa were collected at area A, 84 at B, 63 at C and 105 at D. Polychaetes is the most abundant group at either area: A, 74%; B, 73%; C 68%; and D 39% (Fig. 2). The second most abundant group at A and B is crustaceans (16%). C holds 6-8% of abundance of each of the groups crustaceans, bivalvia, sipunculida and cnidaria; and D: 26% of sipunculida, 13% bivalvia, 8% crustacean and 6% ophiurids.

Fig. 2. Percentage of taxonomic groups at the four study areas

Discussion

Trawling reduces the faunal abundance by eliminating the most vulnerable organisms [4]. This pattern is observed in the results with higher abundance at both the MPA and the undisturbed area within the fishing ground. Moreover, trawling might reduce the species richness by increasing dominance of opportunists and species with low vulnerability to trawling [1]. Our results agree with this as the MPA holds higher richness. The four communities are dominated by polychaetes, however the MPA presents lower dominance with higher abundance of other groups. The less disturbed areas maintain more structured communities, suggesting that trawling intensity must be reduced to protect marine habitats from degradation [3, 4].

Abstract

Fishing pressure was evaluated using side scan sonar at 5 Mediterranean coasts subjected to different levels of trawling disturbance. The work evidences that trawling effort can be accuratedly estimated using an indirect method. These results have been compared with fishing effort data from commercial fishery and discussed in the context of its implications for management *Keywords: Fisheries, Acoustics, Zoobenthos, Biodiversity*

Introduction

Bottom trawling is one of the major sources of damage to the benthos and habitats. Thus, there is an urgent need for developing tools focussed on achieving efficient management of fishing effort and to reduce its impacts [1, 2]. It is difficult to estimate the fishing effort of the trawl fleet both at a small scale and consistent with commertial fishing activities around the wold [3]. Furthermore, this information is essential to analyse both the response of benthic communities and the levels of bottom disturbance in relation with gradients of fishing effort [4]. This study has been developed in the framework of the project COMSOM (CTM2008-04617).

Methods

Five coastal areas located over Mediterranean continental shelves were selected: two in Spain, Cataluña and Murcia coasts, one in Italia, Tyrrhenian coast, and one in Greece, Ionian coast. Each area, that is located between 40 and 70 m depth, subjected to the trawling activity of commercial fishing fleets, and under variable level of fishing effort, were sampled with side scan sonar (SSS) [2]. The images obtained by SSS were analysed by a computer-aided planimetric analysis to determine the density of trawl marks. In a parallel way, information on commercial fishing activity was obtained from data gathered by the fishermen's' association of each selected fishing port.

Results & Discussion

Information on fishing activity and in situ evaluation of the daily activity of the trawl fleet in each coastal area permited the identification of three levels of fishing presure at each area: high, medium and low activity. On the other hand, the densities of trawl marks were estimated by 75 m range sonographs and between 5-7 m above the bottom Both results offer a reliably estimation of the fishing effort at a small scale. The results are presented only in the case of the Ionian coast, as an example. The number of trawlers and GT *hours devoted to fishing activity during the period Oct2008-May2009 suggest 3 sites with different level of fishing activity (Tab1)

Tab. 1. Distribution of fishing effort in three sites of Ionian coast								
IONIAN COAST	Site A - Patra Medium effort	Site B - Killini High effort	Site C- Katakolo Low effort					
Nº trawlers/year	18	17	11					
GT*days/month	10.603	17.255	5.593					
Trawl tracks density	23 trawl tracks	39 trawl tracks	13 trawl tracks					

The images of SSS follow the same pattern: in a line of 150 m range the number of trawl tracks showed higher number of trawl tracks in site B, less number in site A, and few in site C (Tab.1;Fig 1).

Fig. 1. Trawl marks at the three sites off the Greek Ionian Coats. From right to left: medium, high, and low fishing effort counted along 150m range

From these results we can generalise patterns of trawling disturbance over different habitat types and regions which effort restriction patterns must be applied to reduce benthic ecosystem disturbance [2,4]. The use of indirect methods to adequatedly determine the trawling effort would provide with the potential to develop tools for properly managing fishing activity. In this context, a methodology for determining the level of ecosystem disturbance that can be standardised over different community types would be very useful to allow a comparison of the state of soft-bottom communities from continental shelves.

MARINE SPONGES FROM DATÇA-BOZBURUN PENINSULA - A SPECIALLY PROTECTED AREA IN THE SOUTH EASTERN AEGEAN SEA (TURKEY)

Volkan Demir^{1*} and Erdogan Okus¹

¹ Istanbul University Institute of Marine Sciences and Management - volkandmir@yahoo.com

Abstract

The Sponges were studied at the largest Specially Protected Area (SPA) of Mediterranean basin, Datca Bozburun SPA, in 2002-2004 periods. The samples were collected from all area at depth of 0 to 55 metres both diving by Scuba, freestyle and coastal researchings. As a result, 20 species, belonging to 17 families were found from the Datça Bozburun SPA. One of these taxon is a new record for the Turkish Sponge Fauna (*Ciocalypta carballoi*).

Keywords: Porifera, Eastern Mediterranean

Introduction

Sponges are ecologically and economically important group of marine invertebrates [1]. Each species are an integral part of marine benthic communities with a high-impact role in benthic-pelagic coupling processes [2]. Also Sponges have some of the characteristics of good bioindicators and are convenient tools for characterizing the state of a marine ecosystem [3].

Material and Methods

This study is based on the project "Coastal and Marine Biological Diversity Assessment of Datça-Bozburun Specially Protected Area" [4]. 831 SCUBA and 382 skin dives have been performed in 148 days in 7 cruises to determine the marine biodiversity at the Datça-Bozburun SPA [Fig.1].

Fig. 1. Location map of the sampling stations

The samples were collected from all area at depth of 0 to 55 metres both diving by Scuba, freestyle and coastal researchings. All sampling stations were situated in the upper infralitoral zone. Samples were fixed by ethanol solution (80%). Following fixation, spicules were isolated by Rützler's standart method and identified to species level.

Results and Discussion

A result of this study, totally 20 species belonging to 17 families were determined from Datça Bozburun Specially Protected Area. These species were as follows: Sycon raphanus Schmidt, 1862, Cliona celata Grant, 1826, Spirastrella cunctatrix Schmidt, 1868, Suberites domuncula (Olivi, 1792), Tethya aurantium (Pallas, 1766), Chondrilla nucula Schmidt, 1862, Chondrosia reniformis Nardo, 1847, Crambe crambe (Schmidt, 1862), Axinella cannabina (Esper, 1794), Axinella damicornis (Esper, 1794), Axinella polypoides Schmidt, 1862, Acanthella acuta Schmidt, 1862, Ciocalypta carballoi Vacelet, Bitar, Carteron, Zibrowius & Perez, 2007, Agelas oroides (Schmit, 1864), Haliclona (Reinera) mediterranea Griessinger, 1971, Petrosia (Petrosia) ficiformis (Poiret, 1798), Calyx nicaeensis (Risso, 1826), Sarcotragus foetidus Schmidt, 1862, Dysidea avara (Schmidt, 1862), Aplysina aerophoba Nardo, 1843. One of these species is as follows.

Halichondriidae- Ciocalypta carballoi Vacelet, Bitar, Carteron, Zibrowius & Perez 2007

The samples were 0,5-8,5 cm high for 3-10 mm basal in diameter. Colour is deep yellow to orange yellow alive, basal incrustation between the papillae, when visible, yellow to yellow green. The spicules are $300-750 \times 2,5-15 \mu m$ oxeas, most often curved along the whole length. Styles of same size, rare or absent, with intermediates with true oxeas [5].

In study area, rich variety of species have been identified [Fig. 2]. *S. foeditus* and *P. ficiformis* showed the most extensive distribution and all species diversity has a maximum range in Karabük region.

Fig. 2. General distribution of the sponge diversity

This is the first systematical study on sponge fauna in the Datca-Bozburun SPA area. For some areas of the Mediterranean Sea, like those of the Aegean sea, our knowledge on the composition, diversity and abundance of the sponge fauna is limited [6].

PRELIMINARY RESULTS ON REPRODUCTIVE BIOLOGY OF TRACHURUS MEDITERRANEUS (STEINDACHNER, 1868), IN THE NORTHEASTERN SEA OF MARMARA

Nazli Demirel¹* and Ahsen Yüksek¹

¹ Institute of Marine Sciences and Management, Istanbul University - ndemirel@istanbul.edu.tr

Abstract

Mediterranean horse mackerel, *Trachurus mediterraneus*, is one of the most important commercial species in Turkish territorial waters. Results from March to October 2009 show that spawning season of Mediterranean horse mackerel starts at early May and ends at early September in NE part of the Sea of Marmara. Mean GSI values and b parameters show similar variations with synchronized opposition of CF values in monthly results.

Keywords: Reproduction, Fishes, Marmara Sea

Introduction

Trachurus mediterraneus is distributed throughout the Mediterranean, the Black Sea, and the Northeastern Atlantic [1; 2]. Mediterranean horse mackerel is the most abundant commercial fish species after anchovy in the Sea of Marmara [3]. The aim of the present study is to determine the reproductive cycle of the species in the Sea of Marmara. The Sea of Marmara is an enclosed basin where Atlantic-Mediterranean originated commercial pelagic fishes spawn while migrating from the Mediterranean and the Aegean Sea to the Black Sea [4].

Materials and Methods

Samples were obtained randomly from catches of commercial fishing vessels from March to October 2009, caught from 60 to 100 m depths. A total of 523 specimens (232 males, 230 females) were measured. Body weight (W) and total length (TL) were measured (W to the nearest 0.1 g and TL to the nearest mm), to analyse the length–weight relationship. Sex was determined macroscopic aspect of gonads. Gonads of all specimens were dissected and weighed to the nearest 0.001 g in order to calculate the gonosomatic index (GSI).

In addition for further analysis: 1-) Gonads were fixed in 10% buffered formaldehyde solution for determining batch and annual fecundity estimation and histologic studies [5], 2-) Otoliths were sampled for age determination, 3-) Water salinity and temperature profiles were recorded by a CTD system prior to the water quality monitoring project in the northeast part of the Sea of Marmara.

Results

Total length ranged from 11,3-22,5 cm (Fig. 1). The mean GSI reached its maximum values in June and July. Studies on macroscopic aspects of gonads indicated that mature specimens (stage IV in VI maturity classes) were over 11.3 cm for males and 11.7 cm for females (TL).

Fig. 1. Frequency of length classes

According to mean GSI values (Fig. 2) and macroscopic aspects of gonads reproductive period appeared to last from early May to late September. Seasonal variations of the parameter b for determining the isometric-allometric growth, shows similarities to GSI variations. From April to August positive allometry was determined while negative allometry was observed in March, September and October.

Fig. 2. Monthly variations of mean GSI, CF and b parameters value

Discussion

The total length of specimens sampled in northeastern Marmara (11,3-22,5 cm) does not correspond with the maximum length size up to 50 cm [6; 7]. The lack of bigger specimens could be a characteristic of the local population, overfishing and temperature ranges.

The maximum values of mean GSI were found 5,4% in females in August and 5,2% in males in July. Limited data results are compatible with recent researches on reproductive biology of *T. mediterraneus* in Mediterranean basin [8; 9] although it was reported that values of 10% for mean GSI was common during the reproductive period [8].

MATURITY AND REPRODUCTIVE CYCLE OF THE COMMON GUITARFISH, RHINOBATOS RHINOBATOS (LINNAEUS, 1758), IN ISKENDERUN BAY (NORTHEASTERN MEDITERRANEAN)

Sefa ayhan Demirhan¹, Sehriban Çek¹, Asiye Basusta² and Nuri Basusta²*

¹ Mustafa Kemal University, Fisheries Faculty, Iskenderun -Hatay Turkey

² Firat University Fisheries Faculty, Elazig Turkey - nbasusta@hotmail.com

Abstract

In this study, maturity and reproductive cycle of *R. rhinobatos* was investigated in the Iskenderun Bay. Lengths at 50% maturity were 70.0 cm for males, and 86.0 cm for females. In the 2005 breeding season, there was one major period of spawning which lasted approximately 3 months, from April to July. In November and December, gonads of females were almost empty. The peak GSI was recorded in May $(4.29 \pm 1.19 \text{ g})$ for females and in November $(1.97 \pm 0.148 \text{ g})$ for males. Hepatosomatic index (HSI) was found to fluctuate widely in males and females. The annual HSI cycle in female *R. rhinobatos* begins with an increase in liver weight in January and February just prior to maximum GSI levels in May, followed by a decrease in September, October and November at the onset of mating.

Keywords: Fisheries, Fishes, Reproduction, Eastern Mediterranean

Introduction

Elasmobranches are generally long-lived with long gestation period, low fecundity and late maturity that make them susceptible to over fishing [1;2]. *R. rhinobatos* is an ovoviviparous fish having a gestation period of about nine months and a mean reproductive rate of 8 to 14 progeny per pregnancy [3]. If shark, skate and ray fishing is to be sustainable, management must be driven by the biological capacity of the sharks themselves. This will require better knowledge of the biology, ecology and the life history of the populations being exploited, and of rarer species that may be taken as bycatch [4]. The aim of this study was to investigate and gain additional information on the maturity and reproductive cycle of *R. rhinobatos* in Iskenderun Bay.

Material and Methods

A total of 114 common guitarfish were caught and examined. Fish ranged in size from 41 to 146 cm (TL). The sizes at 50% maturity for male and female *R. rhinobatos* were 70 cm and 86 cm in TL respectively (Figure 1). The GSI and the HSI were estimated from 114 specimens, measuring between 41 and 147 cm in total body length, sampled during the study period.

Fig. 1. Proportion of maturity against total length (cm) for males ([]) and females (O)

Results and Discussion

Results of the GSI and HSI calculations for females and males, from January 2005 to December 2005 are represented in Figure 2a, b. The peak GSI was recorded in May $(4.29 \pm 1.19 \text{ g})$ for females and in November $(1.97 \pm 0.148 \text{ g})$ for males. An increase in the average value of this index is interpreted as beginning of sexual maturation, while a sudden drop in this index is indicative of a spawning event. Changes in GSI in females and males did not follow a similar pattern during gametogenesis in R. rhinobatos. This founding is similar to that reported for other elasmobranches species, e.g. [5]. R. rhinobatos seems to spawn during the spring season as the GSI of females was the highest in May. As vitellogenessis proceeds in female R. rhinobatos GSI increases to a peak in May while HSI declines. This decline in HSI, continue throughout gestation (March, April, May, June) recovering to pre-ovulatory levels after parturition. This means that, R. rhinobatos devotes the resources to gonadal development. Hepatosomatic index was found to fluctuate widely in males and females. Similar fluctuations in female HSI are reported for the lesser sand shark, Rhinobatos annulatus [6] and spiny dogfish, Squalus acanthias [7]. Seasonal variation in HSI of the R. rhinobatos has been attributed to fluctuations in lipid

content of the liver, which has been correlated with reproductive condition in female lesser sand shark R. annulatus [8]. The pattern of HSI was not consistent in female and male R. rhinobatos over the reproductive cycle may indicated that liver reserves (such as lipids and proteins used for oocytes growth) were stored and metabolised during different times of the reproductive cycle. This is in agreement to other ovoviviparous species such as D. sabina [5] and spiny dogfish, Squalus acanthias [7]. In elasmobranches, males and females are not sexually mature at the same size [8;9]. This knowledge is supported by the observation that, females matured lager sizes than males in this study. In addition the length at first maturity of R. rhinobatos in the recent study were similar for both males and females in some previous studies. The present result showed that, total body length ranged from 72 to 89 cm in 10 specimens, in which clasper lengths (mean 6.0 cm, ± 1.13) were smaller than expected clasper length (mean 10.3 cm, ±0.67) in 5 specimens (total body length ranged from 71 to 89 cm) in the same length groups. It has suggested that, smaller clasper length in large specimens was not a sign of hermaphroditism, but was a sign of late maturity [10].

REPRODUCTION DU SAR TAMBOUR *DIPLODUS CERVINUS CERVINUS* (SPARIDAE) DES COTES DE L'EST ALGERIEN

Farid Derbal ¹* and Mohamed Hichem Kara ¹

¹ Laboratoire bioressources marines, Université Badji-Mokhtar, Annaba, Algérie - mfderbal@yahoo.fr

Abstract

Divers aspects de la reproduction du sar tambour *Diplodus cervinus cervinus* (Lowe, 1838) sur les côtes de l'Est de l'Algérie sont abordés. La valeur moyenne annuelle du sex-ratio (29,12%) est en faveur des femelles. La fraction hermaphrodite reste insignifiante et ne représente que 2% de la population échantillonnée. Cette espèce se reproduit entre mars et août, à partir d'une longueur totale de 25 cm.

Keywords: Algerian Basin, Fishes, Reproduction, Teleostei

Introduction

Malgré l'étendue de son aire de répartition dans les eaux atlantique et méditerranéenne, le sar tambour *Diplodus cervinus cervinus* (Lowe, 1838) est rarement signalé ou est absent des inventaires ichtyologiques. Les informations sur sa biologie et son écologie sont éparses [1], [2]. En Afrique du Nord, seuls Derbal et Kara [3] se sont intéressés à son régime alimentaire. Nous fournissions ici des données nouvelles sur sa reproduction sur les côtes de l'Est de l'Algérie.

Matériel et méthodes

Ce travail a été réalisé sur 230 individus de longueurs totales comprises entre 9,8 et 52,7 cm. Les poissons ont été pêchés mensuellement entre janvier et décembre 2001. Le sex-ratio a été exprimé par la relation suivante: SR = (nombre de mâles / nombre total) x 100. L'écart des valeurs observées du sex-ratio par rapport à la proportion théorique 50 % a été déterminé par un test de khi-deux [4]. Le sex-ratio a été d'abord établi pour la population globale, puis en fonction du développement ontogénétique et des saisons de capture. La période de reproduction a été déterminée d'après les variations mensuelles du rapport gonado-somatique (RGS). La taille à la première maturité sexuelle correspond à la taille à laquelle 50% des individus sont matures et présentent des gonades développées (stade III de l'échelle de Buxton) [5].

Résultats

La population échantillonnée de *D. cervinus cervinus* est structurée de la manière suivante: juvéniles (26,38%), mâles (20,83%), femelles (50,69%) et hermaphrodites (2%). Avec une valeur annuelle moyenne de 29,12%, le sexratio n'est pas différent de la proportion théorique 50% ($\chi^2 = 2,22$; P $\leq 0,05$). Le tableau 1 indique les variations saisonnières du sex-ratio. D'une manière générale, les femelles dominent numériquement dans les prises au cours des quatre saisons ($22,72 \leq SR \leq 33,33\%$; P $\leq 0,05$). L'évolution ontogénétique du sex-ratio montre que la proportion des femelles domine nettement dans les catégories de taille comprises entre 20 et 50 cm (52,63 - 100%). En revanche, les mâles sont plus nombreux au-delà d'une longueur totale de 50 cm (83,3%). Le suivi mensuel du rapport gonado-somatique (Fig. 1) permet de situer la période de reproduction entre mars et août. La longueur totale des poissons à leur première maturité sexuelle est de 25 cm. L'intervalle de maturité sexuelle (I_m) relatif à cette taille est comprise netre 21,5 et 27 cm.

Fig. 1. Evolution mensuelle du RGS et période de reproduction de *Diplodus cervinus cervinus* des côtes de l'Est algérien

Discussion

Dans l'Est algérien, *D. cervinus cervinus* se reproduit entre le printemps et l'été, à partir d'une longueur totale de 25 cm, comme dans l'archipel des Canaries où cette espèce se reproduit à partir de 26 cm pour les mâles et de 22 cm pour les femelles [2]. Chez *D. cervinus hottentotus* des côtes de l'Afrique du Sud, cette taille de première maturité sexuelle est de 28 cm [6]. La population que nous avons échantillonnée est dominée nettement par des femelles avec une fraction hermaphrodite négligeable. L'insuffisance des effectifs dans les classes de taille limites (petits et grands) ne permettent pas de préciser la stratégie reproductive emprutée par le sar tambour sur les côtes Est de l'Algérie. Dans l'archipel des Canaries, *D. cervinus cervinus* est hermaphrodite protogyne et son sex-ratio est aussi en faveur des femelles (1 : 2,16) [2], alors que sur la côte Sud-est du Cap (Afrique du Sud), la proportion relative des deux sexes chez la population de *D. cervinus hottentotus* ne présente pas de différence significative par rapport à 1 (χ ²= 1,15; P > 0,05) [6].

PRELIMINARY DATA ON A NEW STRAIN OF ARTEMIA (CRUSTACEA, BRANCHIOPODA) FROM EL-BAHIRA LAKE (NORTHEAST ALGERIA)

Farid Derbal ¹*, Mounia Amarouayache ¹ and M. Hichem Kara ¹

¹ Laboratoire bioressources marines, Université Badji-Mokhtar, Annaba, Algérie - mfderbal@yahoo.fr

Abstract

Artemia from El-Bahira lake (northeast of Algeria) has been studied in point of view of its biometrics, its dynamics and its cyst hatching quality. Adults are only represented by females. Those measure between 9.04 and 12.15 mm length and produce between 3.75 and 18.43 offspring/brood, according to the sampling period. Cyst diameter is 277.26 μ m and freshly hatched nauplii are 549.12 μ m length. Population density varied during the wet period of 2009 between 12.38 and 107.7 ind.L⁻¹. Hatching percentage of cysts is 63.45 %.

Keywords: Aquaculture, Biometrics, Crustacea, Reproduction, Zooplankton

Introduction

In Algeria, *Artemia* (L., 1819) (Crustacea, Branchiopoda) made the object of some ecological and biological works. The aim of these investigations is to understand the dynamics of the different populations and to check their quality for aquaculture purposes. Three bisexual strains are well known, that of Sebkha Arzew [1], that of Chott Marouane [2, 3, 4] and that of Sebkha Ez-Zemoul [4]. We describe here for the first time an Algerian parthenogenetic population, in point of view of its biometrics, some aspects of its dynamics and its cyst hatching quality.

Materials and Methods

El-Bahira is a seasonal saline lake of 10 ha, situated in the semi-arid high table land of Constantine in the northeast of Algeria ($35^{\circ}50'19''N 05^{\circ}15'04''E$, 1000 m altitude). The salinity varied during the study period between 80 and 120 g.L⁻¹. Samples of *Artemia* have been taken between February and June 2009, using a plankton net of 125 µm mesh vacuum, and fixed in 3 % formalin. Diameter of hydrated cysts has been determined. Adults and freshly hatched nauplii have been measured from the naupliar eye to the anus. Individuals have been counted under a binocular, using Dollfus cells, and gathered, according to their developing stage, into nauplii and metanauplii, juveniles and adults [5]. Cysts have been incubated in standard conditions recognized by [5], after hydrogen peroxide treatment used for diapause's deactivation. Cyst hatching percentage has been determined.

Results and Discussion

Artemia population from El-Bahira lake is represented only by females and should be parthenogenetic. The latter are big in size (Tab. 1) in comparison with bisexual Mediterranean populations [3, 6, 7, 8] and are little fertile $(3.75 \pm 1.06$ and 18.43 ± 9.67 offspring/brood). The oviparity is the dominant mode of reproduction as it is the case for the other Algerian populations (4). That mode occurs when conditions are harsh. Thus, it is a way to unsure the perennial continuity of the species [9]. Hydrated cysts and nauplii are relatively big in size (Tab. 1) [2] and are close to those of parthenogenetic origin [5].

Tab. 1. Biometrics of adults, cysts and nauplii of *Artemia* sp from El-Bahira lake, Algeria (values between parentheses represent the number of observations)

Mean adult	's size (n	nm±S.D)	Mean cyst's	Mean naupliřs		
February	April	June	diameter (µm± S.D)	size (µm± S.D)		
9.06	9.06 9.72 12.15		277.26	549.12		
±0.83	±1	±1.13	±22.36	±60.32		
(88)	(200)	(347)	(100)	(100)		

In February 2009 (the beginning of the wet period), nauplii and metanauplii dominated while adults were present at a low percentage (Fig. 1). The same demographical structure was observed in April. In June, adults dominated while nauplii and metanauplii presented less than 10 % of the population. Total density was 63.8 ± 3.22 ind.L⁻¹ in February, attained a maximum of 107.7 ± 7.78 ind.L⁻¹ in April and decreased to 12.38 ± 1.6 in June. According to [10], a natural density of 100 ind.L⁻¹ is considered as very high. Hatching percentage of cysts is 63.45 ± 21.18 %, which should be acceptable of their use in aquaculture.

Abstract

The metazoan parasites of 20 species of invasive and native fish species along the Israeli and Turkish Mediterranean coasts were studied. A total of 648 fish were examined for branchial and alimentary tract parasites. The parasite groups found were Nematoda (25.5% of examined fish), Cestoda (18.7%), Monogenea (15.3%), Digenea (11.9%), Copepoda (7.3%), Isopoda (4.5%) and Acanthocephala (0.5%). The combined prevalence of all taxa was very similar amongst native and invasive species. Although information on the invasive parasite species in their native Red Sea are not as well studied as in their new Mediterranean target area, analysis of our data suggested that the success of invading host populations was not unequivocally linked with reduced parasite loads. *Keywords: Parasitism, Fishes, Eastern Mediterranean, Red Sea, Suez Canal*

Introduction

One of the most significant factors to impact the eastern Mediterranean over the last few decades is the massive invasion of tropical Red Sea faunal elements via the Suez Canal.Despite numerous research efforts of this extraordinary phenomenon, we still have relatively little knowledge on the role parasites have in this arena. Several authors have attempted to explain the extraordinary success of some invader species that have created large populations and spread over large areas, while others appear to be limited and only marginally successful. The "Enemy Release Hypothesis" has been suggested as a possible explanation.

Materials and methods

In the present study, we studied the metazoan parasites of 20 species of invasive and native fish species along the Israeli and Turkish Mediterranean coasts. All together, a total of 648 fish were examined for branchial and alimentary tract parasites.

Results

The most prevalent parasite groups were Nematoda (25.5% of examined fish) and Cestoda (18.7%); Monogenea (15.3%) and Digenea (11.9%) were less common, and least abundant were Copepoda, Isopoda and Acanthocephala (7.3%, 4.5% and 0.5%, respectively). The prevalence of all taxa combined was very similar amongst native and invasive species (65.6% and 61.3%, respectively; χ^2 p=0.348). Digenea are a distinctive heteroxenous group of parasites, which possess complex, multiple-host life cycles. Somewhat unexpectedly, no statistically significant difference (p=0.093) was found between their prevalence in invasive (13.1%) and native (8.1%) fish host species.

Overall infection prevalence values were higher in samples taken from the Israeli coast as compared to those taken in Turkey (67.4% vs. 52.7% respectively, p<0.001). This difference may reflect warmer waters prevailing on the Israeli coast that would accelerate parasite development rates and possibly enhance survival of larval stages.

The most abundant invasive fish species in our samples was *Saurida undosquamis* (Synodontidae), which occurred in >80% of the trawl nets. This long established species was heavily infected with larval cestodes (mostly Tetraphyllidae and Trypanorhynchae). It also hosted the digenean *Lecitochirium* cf. *manicaudatus* (Hemiuridae), larval nematodes, Monogenea (Capsalidae) and *Gnathia* sp. (Isopoda). A recent invading species, *Apogon smithi*, which occurred in 35.5% of the trawls, supported a high prevalence (52.1%) of cestodes (mainly Pseudophyllidea and Diphyllidae), as well as an unidentified digenean probably belonging to the Lecithasteridae.

The bluespotted cornetfish, *Fistularia commersonii*, another recent invader species, supported high prevalence infections with larval cestodes and two digeneans, *Allolepidapedon* sp. and *Neoallolepidapedon* sp. (Lepocreadidae). *Allolepidapedon* has recently been reported from bluespotted cornetfish on the Italy coast (Pais et al., 2007). Both lepocreadids are known from cornetfish in the Pacific Ocean and are therefore presumed to be invasive Indo-Pacific species.

The Hemiuroidea were by far the most prominent and speciose digenean suborder in our samples. These parasites typically have low host specificity and most occupy the stomach, a relatively harsh environment. These group attributes may have facilitated the relatively wide distribution and abundance amongst the invading fish species.

Discussion

Although in recent years we are steadily accumulating knowledge on parasitic infections of the Red-Med species in their new environment, we still lack fundamental data on parasite infections of the invasive species in their native Red Sea. The available information suggests that while parasite richness is reduced upon invasion, abundance levels of some host species fluctuate and the success of invading host populations may not be unequivocally linked with reduced parasite loads.

Abstract

Stable isotope ratios in muscle (C, N) and otolith (C, O), and otolith microchemistry were analysed in common soles when they entered a coastal lagoon in spring and when they returned to the sea in autumn. Fingerprints of lagoonal life were observed both in muscle and otolith, but were fixed for the whole life of fish in otoliths only. *Keywords: Coastal Systems, Fishes, Migration, Chemical Analysis, Gulf Of Lions*

Introduction

In the Gulf of Lions (NW Mediterranean), population dynamics of the common sole, *Solea solea* (L., 1758), are positively correlated to the Rhone River inputs [1]. Juveniles recruit in shallow waters in spring. Part of this population then enters coastal lagoons shortly after recruitment and migrates back to the sea only in autumn [2]. This raises the question how time spent in coastal lagoon nurseries early in the lifespan influences common sole population dynamics. To address this question, we analysed changes in potential fingerprints of lagoonal life (in particular, C, N, and O stable isotope ratios and otolith microchemistry) in sole populations entering and leaving the same coastal lagoon.

Material and Methods

Soles were sampled in Mauguio lagoon in April and May 2004 (n = 47) when they entered the lagoon and in September and November 2004 (n = 42) when they returned to the sea. C and N (dorsal white muscle) and C and O (otoliths) stable isotope ratios were analysed by isotopic mass spectrometry [3] and the microchemistry of their whole otoliths was determined by LA-ICPMS [4].

Results and Discussion

Entering soles measured 10.6 ± 1.2 cm TL. They had doubled their size (20.9 \pm 1.0 cm TL) when they left the lagoon in autumn. Muscle C and N stable isotope ratios increased during lagoonal life. The same trend was observed in otolith C and O stable isotope ratios (Fig. 1). Concerning otolith microchemistry, significant changes were oberved for the Sr/Ca, Mg/Ca and Fe/Ca ratios. Sr/Ca was higher in leaving than in entering soles, whereas the reverse was observed for Mg/Ca and Fe/Ca (Fig. 2).

In summary, isotopic and chemical signatures significantly differed in soles leaving Mauguio lagoon in autumn compared to individuals entering in spring. This indicates that the time spent in coastal lagoons left distinct fingerprints in different sole components.

Fig. 1. Stable isotopic signatures in common soles entering (open symbols) and leaving (black symbols) Mauguio lagoon

Fig. 2. Otolith chemical fingerprints in soles entering and leaving Mauguio

A likely explanation lies in the particular environmental conditions in lagoons (e.g., salinity, temperature, energy sources, contaminants). In particular, the high values in the ratio ¹⁵N/¹⁴N observed in leaving soles may be related to strong eutophication of the lagoon of Mauguio. In addition, comparison of muscle signatures with those of primary producers in the Mauguio system (own unpublished data, not shown) indicates that seagrasses (Ruppia, Potamogeton), which were formerly common in Mauguio Lagoon but have declined precipitously [5], do not play a role as base of the common sole foodweb in the lagoon. Finally, the increase in otolith $^{18}\mathrm{O}/^{16}\mathrm{O}$ and Sr/Ca ratios suggests that salinity and temperature were higher in the lagoonal habitat than in the coastal habitat inhabited prior to migration. It is interesting to note that istotopic ratios in fish muscle change in a few months, which means that lagoonal signatures will disappear soon after moving back to the sea. In contrast, isotopic and chemical signals recorded in the otoliths would persist during the whole fish life, and are therefore best suited to analysing fish migrations between different environments.

Abstract

Due to insufficient data on physiology, haemathology and immunology of *Muraena Helena*, L. 1758 a field study was conducted to measure the blood parameters of wild caught specimens from eastern Adriatic Sea, Elaphite islands, near Dubrovnik, Croatia. *Keywords: Adriatic Sea, Fishes, Physiology, Cell*

Introduction

Blood cell analysis is an indicator of physiological condition and health status of fish engaged in aquaculture or ecotoxicological studies. Spotted moray eel, *Muraena helena* L.1758 is biologically and commercially interesting species. To our knowledge data on physiology, haemathology or immunology of this species are insufficient [1, 3]. In august 2009 a field study was conducted to establish the blood parameter values of wild caught Morays from eastern Adriatic Sea, Elaphite islands, near Dubrovnik, Croatia.

Materials and Methods

Morays (n=9) were caught with 300 m long line hooks on a depth of 20-30 meter. The hooks were set at 03:00 at night with squid chunks as bait, and collected two hours later. The average length was 72.37 ± 13.41 body weights were 1296.33 ± 804.45 . All fish were collected alive and proceeded to blood collection immediately on spot. Each fish was sedated for 15 minutes with MS222 in a 100 L plastic barrel in oxygenated sea water (dose of MS222=250 mg/L). After sedation blood was collected from the heart with a 10 ml syringe washed with anticoagulant heparin. Blood was immediately diluted 1:200 with Nett-Harricks dye. Cell parameters were evaluated in blood by standard non-automated haemathology assays using Bürker-Turk haemocytometer.

Results

Average red blood cell (RBC) count and platelet count was 3.513 ± 1.471 x 10^{11} / L. Average white blood cell (WBC) count was 9.33 ± 4.72 x $10^{10}/$ L. Mean hematocrit values were 23.22 ± 8.13 .

Tab. 1. Average biometric and selected hematology parameters of wild caught Spotted Moray eels

	Body lenght (cm)	Body weight (g)	RBC and platalet (x 10 ¹¹ / L)	WBC (x 10 ¹⁰ / L)	Hematocr te	
Mean	72.37	1296.33	3.513	9.33	23.22	
SD	13.41	804.45	1.471	4.72	8.13	

Discussion

Shape, size and structure (Fig.1) of erythrocytes were similar as in majority of other fish species [2].

Fig. 1. Blood cells of Spotted Moray from eastern Adriatic Sea, Elaphite isalnds, near Dubrovnik, Croatia

Similarly, all leukocyte types typical found among variety of fish species were also recorded in Moray's blood, as same as trombocytes of round, spindle and oval shapes [1].

MONOFILAMENT GILLNET SELECTIVITY FOR THE RED MULLET (MULLUS BARBATUS) IN THE EASTERN BLACK SEA COAST OF TURKEY, TRABZON

Ahmet Cemal Dinçer ¹* and Mustafa Bahar ²

¹ Karadeniz Technical University, Faculty of Marine Sciences, Trabzon-Turkey - cdincer@ktu.edu.tr

² General Directorate of Coastal Safety, Province Directorate, Trabzon, Turkey.

Abstract

The mesh size selectivity of monofilament gillnets for red mullet (*Mullus barbatus*) was investigated using four different stretched mesh sizes (32, 36, 40 and 44 mm). Experimental fishing operations were carried out in Trabzon (Turkey) coasts of the Black Sea in springtime of 2002 and 2003. Fifteen trials were conducted giving a total catch of 303 red mullet. Selectivity on *M. barbatus* was assessed using the Holt's method. The optimum lengths (100% retention probability) were 13.16cm, 14.8cm, 16.44cm, and 18.09cm for the nets of 32, 36, 40 and 44 mm mesh respectively with a common selection factor of 4.11. Considering the minimum allowable landing size (13 cm) in force, 36 mm mesh is advised to be the best as it result more conservative approach in terms of size selectivity. *Keywords: Fisheries, Black Sea*

Introduction

M. barbatus is an important fish species of the Black Sea and its catch has recently been recorded to diminish [1]. There are some evidences that overfishing and illegal fishing are mainly responsible for this decrease [2]. Gillnets are the main fishing gear to catch red mullet in Turkish Black Sea coasts. Gillnets are very size selective and therefore the mesh size may be considered to be the most important characteristic of a gillnet [3]. Gillnets are made of monofilament, multifilament or multifilament nylon. Despite the importance of this fishing gear little is known about its selectivity especially in the eastern coasts of the Black Sea in Turkey. Thus, this study aims to investigate the selectivity features of this gillnets to enable the necessary data for Turkish fisheries management.

Materials and Methods

The study was performed in May to June 2002 and in April to June 2003 in the Black Sea, Trabzon coasts with monofilament gillnets of 32 mm, 36, 40 and 44 mm mesh sizes. Fifteen valid hauls were obtained during the study period. The net configuration was in four sheets attached together, each having 50 m length and 2 m depth with a constant hanging ratio of 0.50. Experimental trials were carried out on boards of a commercial fishing boat of 9 m long and 28 hp, at depths ranging from 10 to 20 m. Sample sizes were measured to the nearest cm in terms of total length. The selectivity analysis was done by Holt's method [4], which is based on standard linear regression. The calculations were carried out in Excell package.

Results and Discussion

The total number of fish caught during the experimental fishing operations was 303, of which 26% from 32 mm, 35% from 36 mm, 18% from 40 mm and 21% from 44 mm mesh sizes. The mean lengths caught by each mesh sizes were 13.72 cm, 14.54 cm, 15.92 cm and 16.85 cm. Regression and selectivity calculations are shown in Table 1. The common selection factor (SF) is found to be 4.11 and corresponding optimum lengths (L_{opt} =SF x mesh size) are calculated as 13.16 cm, 14.80 cm, 16.44 cm and 18.09 cm for 32 mm, 36 mm, 40 mm and 44 mm meshes. The selectivity curves for the four mesh sizes are presented in Figure 1.

Tab. 1. Regression and selectivity paramaeters for the red mullet obtained by Holt's method for monofilament gillnets of four different mesh sizes

Smallest mesh size	32 mm	36 mm	40 mm	Overall mean
Largest mesh size	36 mm	40 mm	44 mm	
Intercept	-7.56	-12.97	-24.57	
Slope	0.540	0.796	1.493	
Selectivity factor	4.12	4.29	3.92	4.11
Variance	3.05	2.16	1.05	2.09
Standard deviation	1.75	1.47	1.02	1.41

Fig. 1. Selectivity curves for the red mullet caught by monofilament gillnets of four different mesh sizes

The optimum lengths for *M. barbatus* for all meshes were over minimum landing size of 13 cm [5]. These values are also well over length at first maturity, which was reported in a previous study [6]. The ratio of undersized fish caught by each mesh were17.9%, 10.4%,1.8% and1.5% for 32 mm, 36 mm, 40 mm and 44 mm meshes, respectively. Among these four mesh sizes the 36 mm mesh had the highest catch efficiency (35%). The selectivity results show that the most recommended mesh size would be 36 mm, in behalf of being more conservative with regards to fishing management policies.

HEAVY METAL CONCENTRATIONS IN DIFFERENT TISSUES OF MULLUS BARBATUS AND MULLUS SURMULETUS FROM ISKENDERUN BAY, EASTERN COST OF MEDITERRANEAN, TURKEY

Meltem Dural ¹*, Esra Bickici ¹ and Meltem Manasirli ²

¹ Faculty of Fisheries Mustafa Kemal University 31200 Iskenderun, Hatay, Turkey - duralmeltem@yahoo.com ² Faculty of Fisheries University of Cukurova 01330 Balcali, Adana, Turkey

Abstract

Along the cost of Iskenderun Bay, there are agricultural lands and industrial plants (iron-steel plants, LPG, plants, oil transfer docks and cargo ship's ballasts water). Due to heavy industrial and agricultural activities in the region, the Bay is under stress of the many polutants. In this investigation, muscle was generally, accumulated the lowest levels of metals for two species. The results showed that metal accumulation in *Mullus surmuletus* was higher than *Mullus barbatus* tissues. *Keywords: Metals, Fishes, Monitoring*

Introduction

The pollution of aquatic ecosystems by heavy metals is an important environmental problem as heavy metals constitute some of the most hazardous substances that can bioaccumulate [1]. Fish species are often the top consumers in aquatic ecosystems and thus metal concentrations in fish can act as an environmental indicator of the state of the environment [2]. Iskenderun Bay, in which there are large quantities of untreated industrial and domestic sewage, has one of the polluted coastal waters of Turkey and also has high economic importance for fishery. The aim of this work was to evaluate selected metal (Fe, Zn, Al, Cu, Pb, Mn, Ni, Cr, Cd) concentrations in different tissues of fish from two demersal species collected from Iskenderun Bay, which is situated on the eastern Mediterranean coast of Turkey.

Material and Methods

Red mullet (*Mullus barbatus*) and striped red mullet (*Mullus surmuletus*) samples were caught by fishermen's nets in 2009 from Iskenderun Bay. Total size and weight of fishes were for *M.barbatus* 36.05 ± 2.45 g, 14.08 ± 0.27 cm; for *M. surmuletus* 60.76 ± 2.30 g, 16.32 ± 0.23 cm, respectively. The sample preparation and analysis were carried out according to the procedure described by UNEP reference methods [3]. The tissues digested with concentrated nitric acid and percholoric acid (2:1, v/v) at 60° C for 3 days. All samples assayed using ICP-AES. The accuracy of analytical procedure was checked by analyzing the Standard reference materials (National Research Council of fish samples digested. Recovery rates ranged from 93% to 100% for all investigated elements.

Result and Discussion

For skin; the highest Al (17.21 µg/g dw), Fe (20.28 µg/g dw), Cr (10.47 µg/g dw) concentration were detected in *M. barbatus*; the highest Pb (11.87 µg/g dw), Zn (5.58 µg/g dw), Ni (1.99 µg/g dw) concentration was detected in *M.surmuletus* from Iskenderun Bay . For muscle tissue; the highest Al (7.52 µg/g dw), Pb (8.10 µg/g dw), Fe (4.51 µg/g dw), Zn (0.77 µg/g dw), Ni (1.51 µg/g dw) concentration were detected in *M. surmuletus*; the highest Cr (6.56 µg/g dw), concentration was detected in *M. barbatus* from Iskenderun Bay. For liver tissue the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay. To result the highest Al (13.94 µg/g dw), Pb (15.18 µg/g dw), Fe (161.41 µg/g dw) was detected in *M. surmuletus* from Iskenderun Bay (Tab. 1, 2).

Mn	0.01±0.01	0.01±0.00	nd						

Generally the levels of metals found in tissues of the *M. surmuletus* were generally higher than those found in *M. barbatus*. Our results show that generally metal accumulation is highest in liver and skin, while it is low in muscle in two species. This is probably due to their physiological roles in fish metobolism. It is well known that large amount of metallothionein induction occurs in the liver tissue of fishes, therefore the liver tissue is highly active in the uptake and storage of heavy metals [4, 5, 6, 7]. Turkish legislation establishes maximum levels for four of the metals studied, above which human consumption is not permitted as; 0.1 mg/kg for Cd, 1.0 mg/kg for Pb, 20.0 mg/kg for Cu, 50 mg/kg for Zn [19]. Food and Agricultural Organization limits for Cd and Pb 0.5 mg/kg, for Cu and Zn 30 mg/kg [20].

In conclution, the concentrations of these metals measured in the muscle of the three species studied were generally lower than the levels issued by FAO and Turkish legistation. Yet, Pb concentrations in the muscle tissues were higher than the maximum levels set by law.

ECOLOGIC AND TAPHONOMIC TRENDS IN MOLLUSCAN DEATH ASSEMBLAGES OF HUMAN-IMPACTED AREAS: ISRAELI EASTERN MEDITERRANEAN

Yael Edelman-Furstenberg ¹*

¹ Geological Survey of Israel - yael@gsi.gov.il

Abstract

Man-induced changes in the Israeli Mediterranean shore had a strong ecological imprint on the biota. Molluscan death-assemblage results from near a sewage outlet show that species richness and number of specimens/gram sediment are considerably lower than those from peripheral stations. Unexpectedly, there is a considerable difference in species richness and total abundance/gram sediment between summer and winter in death assemblages from the treated sewage outlet station. This may point to extremely high sedimentation rates for this station and/or extremely strong impact of the sewage on the fauna. *Keywords: Sediments, Sewage Pollution, Mollusca, Eastern Mediterranean*

Introduction

During the past decades man-induced nutrients were introduced to the eastern Mediterranean. These man-induced changes in the Israeli Mediterranean shore had a strong ecological imprint on the biota. This is especially true for the area of Palmahim, in the vicinity of the treated sewage sludge outlet. Recent foraminifera and polychaete studies [1] show great variations along the eastern Mediterranean shore tracking eutrophication trajectories. Macrobenthic invertebrates such as shelled molluscs are known to be sensitive indicators of seafloor oxygen levels, water energy and sediment mass properties. After death, skeletal macrobenthic material is buried and preserved in the sediment record. Investigating the death assemblage record of these organisms should capture the composition and community structure of the living community better than a short-term or single biological characterizations based on macrobenthic death assemblages can be considered as a more complete "modern" picture than information based on live censuses alone.

Material and Methods

A sub-sampling of box core sediment samples were examined from an alongshore transect that crosses the treated sewage sludge area but also includes areas peripheral to the main impact area, parallel to Hyams [2] study area. Molluscan death assemblages from summer (07.03) and winter (01.04) from three stations were analyzed and species richness, evenness, relative and total abundance were calculated. Also, taphonomic characteristics (shell state preservation) of the dominant bivalve shells from the different stations were scored.

Results ans Discussion

Thirty five gastropod species were identified and 45 bivalves. Assuming that the molluscan death assemblages average out the seasonal and annual variations, each sampling site should have yielded similar data for samples taken during summer and winter. Yet, molluscan results from the area of the sewage outlet (station PL3-summer) show that species richness and number of specimens per gram sediment are considerably lower than those from the same location during winter as well as from the peripheral stations PL29 and AS1. Twenty two species (Margalef's richness index of 8.9) and 0.4 mollusc abundance/gram sediment were recorded for the summer station at PL-3 as opposed to 39 species (Margalef's index of 13.1) and 4.3 molluscs abundance/gram sediment recorded for the winter sampling of the same station. The expectation was that the sewage sludge, which enters the water year-round, would affect the faunal assemblage of both sampling periods in the same way, by suppressing the fauna. However, the removal of the sludge during the winter (strong water currents, biological churning of the sediment, [1]) inhibits a long-term effect on the faunal composition and assemblage community structure, which is only seen as a local and direct result during the summer sampling, when the sludge covering accumulates.

This unexpected difference in species richness and total abundance between summer and winter in death assemblages from the treated sewage outlet station (PL3) is similar to that seen in the <u>live</u> benthic foraminifera data (Fig. 1). The number of foraminifera specimens per cc in station PL3 was low during summer sampling and high during winter sampling [1]. In the figure both the foraminifera and molluscan measurements are shown against the sludge accumulation thickness, which is thick during the summer, ~10 cm, and non-existent during the winter. This may point to extremely high sedimentation rates for this station on the one hand and extremely strong impact of the sewage on the fauna on the other hand. It seems that under extremely stressful environmental conditions, such as anthropogenic impacts on marine environments, the time-averaged death assemblage is skewed, and acts more like a "snapshot" assemblage [3]. Thus, even a time-averaged death assemblage carries effects of the anthropogenic

impact on the community structure of the molluscs.

Fig. 1. Molluscan differences between summer and winter in the sewage area (this study) are similar to those seen in the live benthic foraminifera [2]. Bar graphs: total standing stock of living (stained) individuals/10 cc from PL29, summed over the top 0-10 cm of the sediment; PL3, summed over the 0-5 cm; and AS1, summed over the top 0-5 cm. Sludge accumulation thickness is shown for PL3. Circles: total molluscan abundance

ON BOARD TRAWL SAMPLING IN THE THERMAIKOS GULF. SEASONAL QUANTITATIVE AND QUALITATIVE COMPOSITION OF THE CATCH

Kostantinos Efthimiadis¹, Erotokritos Chairistanidis¹, Pavlos Vidoris¹ and Argyris Kallianiotis¹* ¹ NAGREF – Fisheries Research Institute - akallian@inale.gr

Abstract

The purpose of this work is to describe the qualitative and quantitative composition of the catch in Thermaikos Gulf, using a special bottom trawl. It is also tested if there is a statistically important differentiation in the abundance between the inner gulf, where the fishing with trawlers is not allowed and the outer gulf, where the fishing with trawlers is allowed. *Keywords: Aegean Sea, Trawl Surveys, Fisheries*

Introduction

Thermaikos Gulf is the biggest gulf of the Aegean Sea. The Rivers Axios, Aliakmonas, Loudias and Galikos, and several smaller, are flowing into Thermaikos, contributing to its strong productivity. The existence of 23 ports on the shores of the four counties that surround Thermaikos, with a total of 1453 vessels (30 purse seiners, 68 trawlers, 12 boat seiners and 1343 coastal) of coastal and open sea fisheries, reveals the intensive fishing activity within the limits of the bay.

Materials and Methods

The experimental sampling was conducted with professional trawler. Twenty hauls took place, each lasting 30 minutes in each sampling period, in default stations, on May, on July, on September and on December of 2008. The depth of the stations ranged between 16 and 90 meters. The abundance index was calculated for each season. By using ANOSIM, the statistical differentiation of two different areas of Thermaikos was estimated, according to the access or not of trawlers in these areas. Specifically, the access of trawlers is not allowed to the inner part of the gulf. The remaining part of the gulf where the access of trawlers is allowed, is referred as outer Thermaikos. The SIMPER analysis revealed which species mainly contributed to the differentiation between the two areas of Thermaikos. All the above mentioned analyses were conducted using the PRIMER software [1].

Fig. 1. Map of stations sampled.

Results and Discussion

In all four samplings 122 species were recorded, of which 94 (77%) were fishes, 12 (10%) were cephalopods and 16 (13%) were crustaceans. Specifically, on May, 88 species were recorded, of which 65 (74%) were fishes, 8 (9%) were cephalopods and 15 (17%) were crustaceans. On July, 94 species were recorded, of which 71 (76%) were fishes, 10 (11%) were cephalopods and 13 (13%) were crustaceans. On September, 91 species were recorded, of which 70 (77%) were fishes, 10 (11%) were cephalopods and 11 (12%) were crustaceans. Finally, on December, 87 species were recorded, of which 68 (78%) were fishes, 9 (10%) were cephalopods and 10 (12%) were crustaceans. The species that occurred only in one sampling seasons were 64 (52%), while the species that occurred only in one sampling season were 25 (20%). The most abundant species in all four sampling seasons are the following: 1) *Liocarcinus depurator* (12007,9 individuals/km²), 2) Serranus hepatus (8836,0 individuals/km²), 3) Trachurus mediterraneus (5949,1 individuals/km²), 4) Mullus barbatus (5226,7)

individuals/km²), 5) Arnoglossus laterna (4689,0 individuals/km²), 6) Pagellus (4345,8 individuals/km²), 7) Diplodus annularis acarne (3056.2 individuals/km²). ANOSIM was used in order to test if there is a statistically important differentiation in the abundance between the inner gulf and the outer gulf. The resulting value R=0,659, shows that the stations of inner Thermaikos are statistically different from the stations of the outer Thermaikos on May. This is also the case for the other sampling months, where the values of R are R=0,636, R=0,658 and R=0,53, for July, September and December, respectively. The SIMPER analysis showed that the species which mainly contribute to the statistically important differences are the following: A. laterna, L. vulgaris, G. niger, L. depurator, T. minutus, D. annulariska, P. longirostris. This result is attributed to the fact that in inner Thermaikos the trawlers are not allowed and the concentration of nutrients is higher due to the outfall in Thermaikos of the rivers. However, there is only little knowledge of the effects of fisheries with trawlers on marine organisms in the Mediterranean [2].

FROM THE TETHYS OCEAN TO THE MEDITERRANEAN SEA, HOW TECTONICS SHAPED ECHINOCARDIUM CORDATUM EVOLUTION.

Emilie Egea ¹*, Gwilherm Penant ¹, Jean-pierre Féral ¹ and Anne Chenuil ¹ ¹ UMR6540-DIMAR - egea@univmed.fr

Abstract

Irregular echinoids constitute one of the most important groups of the Mediterranean benthic fauna. The genus *Echinocardium* is well represented but its diversity seems to have been underestimated. Genetic analyses of *E. cordatum* highlighted a complex of at least five cryptic specieswhich appearance seems to have been greatly driven by the paleontological history of the Mediterranean Sea. *Keywords: Biodiversity, Biogeography, Echinodermata, Ocean History*

Introduction

Echinocardium [Loveniidae, Spatangoida] is a widespread genus of irregular sea urchins, presently composed of six nominal species. Three of them can be observed in sympatry in the Mediterranean Sea: *E. cordatum* (Pennant, 1777), *E. mediterraneum* (Forbes, 1844) and *E. capense* (Mortensen, 1907). Genetic studies [1] revealed that *E. cordatum* is a complex of at least five different cryptic species encountered in the Atlantic (A, B1), Pacific (NP, SP) and Mediterranean (B1, B2) basins (Fig 1). Its antitropical distribution raises the question of the formation of these cryptic species complex with respect to paleogeography.

Fig. 1. Distribution of the cryptic species in E. cordatum

Material and Methods

A 430 bp portion of the 16S ribosomal gene and a 560 portion of the cytochrome oxidase subunit I (CO1) of the mitochondrial genome were amplified for several Spatangoida species (Species in bold Fig1). Sequences of 16S and CO1 for 12 additional Spatangoid species and one Echinolampadidae were retrieved from genebank (Fig 1). The phylogenetic tree was constructed using Bayesian inferences as performed in MrBAYES software [2], under the GTR+I+G evolutionary model as determined by MODELTEST [3] Topology within E. cordatum was confirmed by the intronic region of the Elongation Factor a (EF1) of the nuclear genome. Molecular estimates of divergence times were calculated using the Bayesian method of Thorne et al. (1998) [4] as implemented in the Multidivtime package of PAML [5]. Paleontological data from the litterature were used to calibrate the topology. Hence, the divergence of E. cordatum and the other species of the genus of the tree are estimated to be 12 to 40 MYR old [6], and the appearance of the Schizasteridae family, 95MYR old [7]. Conolampas sigsbei (Cassiduloida, Echinolampadidae) was used as outgroup for the study establishing the root age at about 200MYR [7].

Results

Bayesian inferences allowed generating a satisfying phylogeny of the studied species, and in particular, of *E. cordatum* nominal species as well as aging its cryptic lineages. The split between cryptic specie A and the remaining lineages is estimated to have occurred some 13MYR ago, and the split between B1 and B2 is dated to 5 MYR.

Discussion

These data are consistent with geological information about the evolution of the Tethys Ocean and Mediterranean Sea under the following scenario. Geographic isolation in the two basins resulting from the closure of the Tethys around 10 MYR ago leaded to allopatric differentiation of the species A in the Atlantic-Mediterranean basin and the common ancestor of lineages P (NP & SP) and B (B1 & B2) in the Pacific basin. Between 13 and 5 MYR ago, this common ancestor evolved to create two modern species in the Pacific Ocean, NP and SP and migrated back to the Mediterranean Sea [via South Africa (where the nominal species *E. cordatum* is found)] to diverge in two others species, B1 and B2, around 5 MYR ago. Despite the fact that these species are now found in sympatry, they might have been formed by allopatric speciation, as their divergence time concords with the Messinian crisis (6MYR ago) during which the Mediterranean Sea experimented extensive desiccation and sea level changes[8]. The salinity increase that results from the Messinian crisis might have caused the extinction of lineage A into the modern Mediterranean Sea. This hypothesis could be tested via salinity tolerance experiments on lineages A and B.

Fig. 2. ML tree obtain from 16S and CO1 concatenated genes using Bayesian inferences with datation of nodes and 95% confidence interval for *Echinocardium cordatum*. * Nodes with fossil records. Cryptic species NP not shown

Long thought to be a single cosmopolitan species, *E. cordatum* revealed to be a complex of cryptic species which evolution has been extensively intertwined with the evolution and history of the Mediterranean Sea.

REPARTITION DES CRUSTACES DECAPODES DANS LE GOLFE DE GABES

Henda El lakhrach ¹* and Abdallah Hattour ²

¹ Institut National des sciences et technologies de la mer. BP .1035- 3018 Sfax. - hendalak@yahoo.fr ² Institut National des Sciences et Technologies de la Mer- Salammbô

Abstract

La répartition des crustacés semble occuper l'ensemble du golfe de Gabés (côtes sud-est de la Tunisie). La présente étude a ciblé les crustacés décapodes du golfe de Gabès. Elle a permis d'inventorier 35 espèces et permis aussi de comparer la richesse spécifique de ces crustacés dans les différentes aires de distribution. Le traitement statistique des données a permis de dresser la répartition spatiale de ces derniers.

Keywords: Gulf Of Gabes, Crustacea

Introduction

Le golfe de Gabès, large échancrure situé sur le littoral sud de la Tunisie, constitue le golfe le plus important du littoral tunisien ([1], [3]). L'étude de la répartition des crustacés sur les fonds du golfe de Gabès s'inscrit dans le cadre d'une étude bionomique du plateau continental. Ce dernier a fait l'objet de très peu de travaux de recherches.

Matériel et méthodes

Durant le printemps 2009, une campagne de pêche expérimentale a été effectuée à bord du navire océanographique et de recherche le « N/o Hannibal » au niveau de la région du golfe de Gabès. Quarante stations ont été échantillonnées, couvrant une grande partie du golfe. Les traits sont répartis entre 20 et 260 m de profondeur. Deux types d'engin ont été utilisé :

- un chalut de fond du type « crevettier » pour les faibles profondeurs (< à 50 m)

- un chalut à grande ouverture verticale (GOV) pour les grandes profondeurs (de 60 à 260 m).

Pour étudier la répartition des crustacés décapodes, nous avons calculé la richesse spécifique de chaque station, qui est définie par le nombre d'espèces recensées à une échelle d'espace bien déterminée. La cartographie des crustacés décapodes a été réalisée à l'aide d'un système d'informations géographiques (SIG). Le SIG permet de croiser les données cartographiques avec d'autres données spécialisées par le biais de requêtes et d'outils de traitements [2].

Résultats et discussion

La détermination des espèces prises par chalutage nous a permis d'identifier 35 espèces de crustacés décapodes (Tab 1) dont les plus importantes sont : *Penaeus keratherus, Metapenaeus monoceros, Medorippe lanata, Inachus sp et Pagurites ermita.* Ces espèces sont inégalement reparties sur toute l'aire investiguée par les chaluts. Les espèces appartenant à la famille des Penaeidae sont dominantes. La courbe de la richesse spécifique en fonction de la position montre une répartition irrégulière des crustacés décapodes. Les stations G8, G10 et G14 se caractérise par une richesse élevée (12 ou 13 espèces). Par contre, les stations G9, G38 et G39 présentant une richesse nulle (Fig. 1). La différence de la richesse spécifique pourrait être due aux conditions environnementales ; paramètres physico-chimiques (température, PH, salinité) et également à la nature du fond (vaseux, sableux, sable-vaseux, vaso-sableux).

Fig. 1. Variation de la richesse spécifique en fonction de la position (G)

INTRODUCED SPECIES AND THEIR IMPACTS IN THE BLACK SEA

Naciye Erdogan ¹, Ertug Duzgunes ²*, Hamdi Ogut ² and Nazli Kasapoglu ² ¹ ODÜ University Faculty of Marine Sciences ² KTU Faculty of Marine Science(2) - ertug@ktu.edu.tr

Abstract

In the last half of the 20th century, many forms of marine organisms, belonging to various levels of food chain, native to Indian Ocean and the Mediterranean Sea have been unintentionally introduced into the Black Sea mainly by the means of shipping vessels or water exchange through Sea of Marmara. Along with the changes in the climate due to the global warming, a process namely "Mediterreneanisation" has been taken place in the Black Sea, leading to collapse of fisheries i.e impact of Comb jellyfish on anchovy stocks, and Rapa whelk *Rapana venosa* on mussel banks.

Keywords: Black Sea, Bivalves, Gastropods

Introduction

Hundreds of species from various flora and fauna have been introduced to the Turkish seas since the beginning of 20th century. For instance, more than 85 species of macrophytes including "killer algae" introduced to the Mediterranean, nine of them are considered as invasive, i.e., playing a conspicuous role in the recipient ecosystems. The Black Sea biodiversity has become extremely more sensitive to immigrants' expansion than those in other seas. Rich diversity of biotopes and the poor local species diversity provide favorable conditions for some exotic invaders finding naïve ecological niches with no competitors or predators (Gomoiu, 2001). Unfortunately, the data generated from controlled experiments are very limited; therefore, observations will be presented here.

Invasive Species The number of invasive species penetrations into the Black Sea peaked during 2000s (Fig. 1) (Gomoiu 2001). The main invaders establishing and having the most dramatic impacts on species diversity are Rapa whelk *Rapana venosa, Scapharca cornea*, Comb jelly fish *Mnemiopsis leidyi*, Pacific Mullet *Mugil soiuy. Rapana venosa,* introduced during 1940s, spread all over the Black Sea due to lack of predators ie sea stars (Duzgunes and Feyzioglu, 1994; Saglam et al, 2009).

Fig. 1. Number of new species accumulated for years (redrawn, Gomoiu, 2001)

It has devastatedmajority of mussel banks *Mytilus galloprovincialis* and baby clam *Chamelina gallina* stocks (Table 1). At present, mussels only survived at habitats having steep slopes and high currents. Mussels are essential organisms to slow down or prevent eutrification by filter feeding in the Black Sea. Another introduced species *Scapharca cornea*, a filter feeder bivalve, become established and spread due to the fact that they are less exposed to predation owing to thicker shell (Duzgunes, 1995). Comb jelly fish *Mnemiopsis leidyi*, feeding on eggs and larvae of small pelagics e.g. anchovy, caused to collapse of fisheries in the Black Sea during the late 1980s. Total anchovy catch in the Black Sea dropped sharply from 526000 metric tonnes to 85000 from 1988 to 1991 (Dumont et all, 2002).

Tab. 1. Impact of major introduced species in the Black Sea

Species	İmpact	Remarks		
Rapana venosa	Destroyed mussel and baby clam stocks	No predator in the Black Sea and due to its resistant egg cysts reproduction rate is too high		
Anadara cornea	Replaced Mytilus galloprovincialis	Have no economical value and under predation of <i>Rapana</i> <i>venosa</i> at present		
Mnemiopsis leidyi	Predating on fish eggs and larvae of small pelagics	Decreased overall biodiversity in the Black Sea		
Mugil soiuy	Food competition with native mullet species	Majority of the native mullet species are now out of fisheries		

Pacific mullet, introduced into Azov Sea in 1985, was first observed in the Black Sea in 1989 (Ünsal,1992; Okumus and Bascinar, 1997). It successfully competes with such native mullet species as *Mugil cephalus*, *M. auratus* for food. As a result of this competition, catch quantity of native mullet species declined from 14189 tones to 1518 tones during the period 2000-2008. At present commercial catch shifted from native to the pacific mullet. Establishment of both *Rapana venosa* and *Mugil soiuy* was so efficient, as a result the species were able to increase their numbers significantly allowing an economically feasible fishery towards their harvest.

Conclusions

Species abundance and diversities changed significantly as a result of introduced species.

THE PRESENCE OF INDO-PACIFIC PUFFER FISH *TORQUIGENER FILAVIMACULOSUS* HARDDY & RANDALL,1983 IN THE ISKENDERUN BAY, THE EASTERN MEDITERRANEAN COAST OF TURKEY

Deniz Erguden ¹* and Mevlut Gurlek ¹

¹ Mustafa Kemal University Faculty of Fisheries - derguden@gmail.com

Abstract

The first record of the lessepsian pufferfish (*Torquigener filavimaculosus* Hardy & Randall, 1983) in coast of Iskenderun Bay, Eastern Mediterranean Sea, is given in the present paper. A single young specimen was sampled with the research trawler "Mustafa Kemal I" in June, 2008, and morphological characteristic and fin formulas are described with detail. *Keywords: Fishes, Species Introduction, Teleostei, Eastern Mediterranean*

Introduction

The family Tetraodontidae is represented in the Mediterranean Sea by four genera and nine species [1,2]. *Torquigener filavimaculosus* is distributed in shallow waters and found on sand-muddy bottoms at depths of 3 to 57 m. It is carnivorous feeding on small benthic invertebrates. *T. filavimaculosus* has a distribution throughout Indian Ocean Red Sea, Persian Gulf and eastern Africa to Seychelles [1,3]. The puffer fish *T. filavimaculosus* was recorded for the first time in the Mediterranean Sea from Haifa Bay, Israel [4]. Following, Bilecenogu [5,6] based on two specimens observed from the south western Mediterranean coast of Turkey (off Fethiye shore), expanded the westward distribution range of the species. Lately this species is recorded by Corsini-Foka [7] from Rhodes island.

Material and Methods

On 26 June 2008 a 52.0 mm total length (*Lt*), 48.2 mm fork length (*LF*) and 42.6 mm standart length (*Ls*), specimens of puffer fish *T. filavimaculosus* Harddy & Randall, 1983 was caught by the research trawler "Mustafa Kemal I" from Iskenderun Bay (36^0 33' N- 36^0 03' E) at a depth of 24 m (Fig. 1). The single specimen has been deposited at the ichthyological collection Museum of Faculty of Fisheries, Mustafa Kemal University. Some morphometric and meristic characteristics of the specimen are given in Table 1.

Fig. 1. Torquigener filavimaculosus caught off Iskenderun Bay, Eastern Mediterranean Sea, Turkey (52.0 mm L_t)

Results and Discussion

Body elongate, somewhat compressed laterally and inflatable. The chin distinct, mouth small and terminal with conspicuous lips, covered with short papilllae. Eyes elongated. Origin of dorsal fin slightly in front of anal fin origin. Dorsal and anal fins were elongated and pointed. Caudal fin truncated. Pectoral fin rounded with wide base. Pelvic fins absent. The skin had numerous londitudinal pleats. *Colour:* The body is lightbrownish with regularly distributed grey dots dorsally and white ventrally. A mid lateral line with longitudinal series of yellow to olive-green spots. Caudal fin with brown spots, dorsal fin spotted, anal and pectorals fin transparent. Measurements, counts and body coloration of puffer fish *T. filavimaculosus* agree with described from the Red Sea and adjacent waters by Hardy & Randall [8]. *T. filavimaculosus* further differ from *T.brevipinnis* inhaving caudal fin markings less regular andmore numerous on

each ray andthe dorsal fin arises above the vent. Both species differ from *Torquigener hypselogeneion* in the relative eye diameter, caudal pedunclelength (smaller dimensions in *T. hypselogeneion*), and in having more dense ventral spination [9]. The present record is caught the first of the species from the coast of Iskenderun Bay, Eastern Mediterranean Sea. While a single specimen does not necessarily indicate an established population. This species may be capable of colonization in the Mediterranean in the future, like other this species.

ETUDE DU PLANCTON DE LA ZONE FNIDEQ-OUED LAOU (MEDITERRANEE OUEST MAROCAINE)

O. Ettahiri¹, A. Berraho^{1*}, A. Orbi¹, K. Hilmi¹, L. Somoue¹, S. Zizah¹ and S. Charib¹

¹ Institut National de Recherche Halieutique, 02, Rue Tiznit Casablanca 20 000 Maroc - amina_berraho@yahoo.fr

Abstract

L'analyse du plancton (phytoplancton et chlorophylle 'a', mésozooplancton et ichtyoplancton) dans la zone d'étude a révélé la présence d'une grande richesse planctonique dans la partie Nord comprise entre Fnideq et Cabo Nigro avec une variabilité spatiale des foyers de forte concentration en relation avec la circulation générale dans la zone. *Keywords: Phytoplankton, Zooplankton, Ichthyoplankton, Western Mediterranean*

Introduction

Le phytoplancton et le zooplancton jouent un rôle primordial dans le transfert d'énergie vers les niveaux trophiques supérieurs. Certains groupes sont considérés comme indicateurs biologiques des masses d'eaux [1], des changements climatiques [2] ou encore du degré de salubrité des milieux marins [3]. La répartition spatiale de ces deux composantes est généralement synchrone et constitue un milieu favorable pour le développement de l'ichtyoplancton, surtout les larves de poisson. Cette répartition est liée aux conditions hydrodynamiques du milieu, gouvernées par la présence du tourbillon anticyclonique dans la partie occidentale Sud de la Méditerranée [4].

Matériel et Méthodes

Des échantillons d'eau ont été prélevés (du 27 janvier au 07 février 2009) pour le dosage de la chlorophylle 'a', selon un dispositif CTD. Trois niveaux ont été échantillonnés : la surface, à 10 m et le fond. D'autres échantillons d'eau d'un volume de 100 ml ont été prélevés à la surface pour l'étude du phytoplancton. Le zooplancton et l'ichtyoplancton ont été collectés sur toute la colonne d'eau à l'aide d'un filet Bongo de 145µm de diamètre de maille.

Fig. 1. Distribution de la chlorophylle 'a' à différents niveaux

Résultats et Discussion

L'étude biologique durant cette campagne de mesures a montré que la productivité du milieu, illustrée par la concentration de la chlorophylle 'a', présente une richesse relativement importante, à la fois en surface et au fond de la zone côtière (<50m), comprise entre Fnideq et l'oued Negro, dominée généralement par les eaux atlantiques. Au-delà de l'isobathe 75 m, les concentrations chlorophylliennes diminuent et le sont davantage dans les couches profondes, du fait de l'existence à ce niveau de deux masses d'eaux : l'une en surface d'origine atlantique et riche en chlorophylle 'a' et l'autre méditerranéenne, plus profonde et pauvre en chlorophylle 'a' (Figure 1). Cette

situation se reflète également dans l'étude de la densité du phytoplancton de surface dont le maximum de cellules se situe à moins de 75m dans la partie nord de la zone d'étude (Fnideq - oued Smir). De plus, l'accumulation des eaux superficielles au niveau du tourbillon, implique une large épaisseur des eaux pauvres en nutriments (oligotrophes) et une grande pénétration de la lumière. Par conséquent la profondeur à laquelle s'établit le maximum superficiel de chlorophylle (DMC : Depth Maximum Chlorophyl) est importante impliquant une faible productivité biologique [5].

Généralement, la distribution du zooplancton est en relation avec celle du phytoplancton. Toutefois, on observe un certain décalage entre les foyers à fortes concentrations de phytoplancton et ceux à fortes biomasses zooplanctoniques, surtout au nord de la zone d'étude. Etant donné que la composante zooplanctonique est échantillonnée sur toute la colonne d'eau, cette situation est plus justifiée, tenant compte des distributions de la chlorophylle 'a' aussi bien au nord qu'au sud de la zone. La zone d'étude peut être également qualifiée de zone de ponte pour un certain nombre d'espèces, dont la sardine qui représente à elle seule plus de 60% du nombre total des œufs et larves recensés dans la région (Tableau 1). La sardine est une espèce dont la ponte principale se déroule en hiver, ce qui explique la forte abondance des œufs et larves dans la zone (échantillonnage fin janvier). Ainsi, la proximité de la zone d'étude du détroit de Gibraltar, confère surtout à sa partie nord des caractéristiques hydrologiques optimales pour une forte productivité et la ponte des espèces halieutiques. En effet, l'effet fertiliseur du flux d'eau d'origine atlantique est en faveur d'une grande diversité du phytoplancton et aussi du mésozooplancton qui se compose à la fois d'espèces néritiques, pélagiques et celles d'origine atlantique [6]. Toutes ces conditions sont en faveur d'une ponte et de développement larvaires d'espèces halieutiques assez diversifiées.

REDISCOVERY OF LIVE GIBBULA NIVOSA (GASTROPODA: TROCHIDAE)

Julian Evans¹, Joseph A. Borg¹ and Patrick J. Schembri^{1*} ¹ Department of Biology, University of Malta - patrick.j.schembri@um.edu.mt

Abstract

Live animals of the trochid gastropod *Gibbula nivosa*, which is endemic to the Maltese Islands, have not been recorded for over 25 years despite recent intensive searches in localities where good populations used to be found. Sampling carried out at Marsamxett Harbour and Comino has yielded live individuals from accumulations of cobbles and pebbles, showing that this is an important habitat for *G. nivosa* and confirming that this species is not extinct, although it should still be regarded as 'critically endangered'. *Keywords: Biodiversity, Conservation, Endemism, Gastropods, Mollusca*

Introduction

The Maltese Topshell *Gibbula nivosa* is a critically endangered [1] trochid gastropod endemic to the Maltese Islands [2,3]. Although this species has been reported many times from Malta, it is rare and the last record of live individuals dates back to 1981 [4] despite recent intensive searches for the species in many localities [1]. Given its restricted geographical distribution and rarity, *G. nivosa* is protected under both local and international legislation. Proper conservation and management of this species is necessary to safeguard it but very limited information on its current status exists, a situation that can only be addressed by intensive sampling of the coastline where reported habitats of *G. nivosa* occur. The main habitat for the species is regarded to be leaves of the seagrass *Posidonia oceanica* at depths down to 10m [5], but the gastropod has also been reported from under stones in shallow water [4,6] and fresh empty shells were recently (2006) collected from such a habitat in Marsamxett Harbour, suggesting that live individuals may have been present.

Material and Methods

Surveys of the infralittoral cobble beds in Marsamxett Harbour (Fig. 1) were made in September 2006 and December 2007. Stations were established along the long axis of the cobble beds and three replicate samples were randomly collected from each station at depths of 5-12m, using a 0.1m^2 circular quadrat. The cobbles and pebbles within the quadrat were carefully handpicked and transferred to a 0.5mm mesh-bag, whilst a small hand net was used to scoop the basal layer of finer granules into a separate mesh-bag. In the laboratory, the sediment was sorted by hand, and the collected molluscs were identified and counted. Any *G. nivosa* found were kept alive and returned to their original site of collection. Searches for this species were subsequently carried out at sites in Comino, Qawra Point and St. Thomas Bay, where similar infralittoral cobble and pebble beds occur.

Results and Discussion

Live individuals of G. nivosa were collected during both surveys at Marsamxett, with mean abundances of 37.3±78.6SD and 17.6±25.0SD individuals/m² recorded in September 2006 and December 2007, respectively. The large variation in abundance, reflected by the high standard deviation, was probably due to the patchy distribution of the species within its habitat, which had a low cover (ca 0.005km² only) within the area. The relatively restricted habitat area would support a small total population of G. nivosa. The habitat at Marsamxett was characterised by a gently sloping bottom of gravelly sand and silt with overlying accumulations of cobbles and pebbles (modal size: 16-64mm diameter; maximum thickness of pebble layer: 10cm) (Fig.1). This vertical stratification enabled the two layers to be sampled separately, and significantly higher densities of G. nivosa were recorded from the upper pebble stratum than from the gravelly sand below (Mann-Whitney U-test, p = 0.018). Two live individuals were collected whilst searching at Comino on a similar bottom type, albeit with a much sparser cover of cobbles and pebbles, at a depth of 18-20m. However, no live animals were found at the other two sites, where the cobbles and pebbles occurred interspersed with P. oceanica beds. It is interesting to note that one of these sites, St Thomas Bay, has been regarded as the main locality for G. nivosa [4.6].

The present record is the first of live individuals of *G. nivosa* in over 25 years, showing that this species is not extinct and suggesting that other as yet undiscovered populations may exist in some places. Although the main habitat of *G. nivosa* is considered to be *P. oceanica* leaves, in this study live animals have been recorded from infralittoral cobbles and pebbles within Marsamxett Harbour, where the seagrass is not present, indicating that cobble beds may be a more important habitat for *G. nivosa* than previously thought. It is possible that individuals collected from seagrass leaves in the past were only foraging there and actually retreated to the accumulations of cobbles and pebbles

(assuming this habitat was interspersed with seagrass beds) when not feeding. However, during this study, no *G. nivosa* were found in either accumulations of cobbles and pebbles interspersed with seagrass beds, or on the *Posidonia* leaves, so more work is required to test this hypothesis. Searches in cobble habitats are necessary for a better knowledge of the current status of *G. nivosa*, which is still regarded as 'critically endangered' under the 2001 IUCN Red List criteria [7].

MITOCHONDRIAL DNA SEQUENCE VARIATION IN TUNISIA SARDINE (SARDINA PILCHARDUS) STOCKS

Karima Fadhlaoui-Zid ¹*, Soumaya Oueslati ¹, Lotfi Ben Abdallah ¹ And Othman Jarboui ¹ ¹ Institut National Des Sciences Et Technologies De La Mer - Karimafadhlaoui@Yahoo.Fr

Abstract

The genetic diversity and population genetic structure of the Tunisian sardines Sardina pilchardus were investigated. A total 92 individuals were sampled from 3 localities of the coastal zones of Tunisia. Genetic variation in DNA sequences were examined from the cytochrome b (cytb) gene of the mitochondrial DNA. High levels of haplotype diversity were detected, indicating a high level of genetic diversity. Phylogenetic trees demonstrated a divergence between the populations examined in the present study. The knowledge on genetic diversity and genetic structure will be crucial to establish appropriate fishery management stocks for the species.

Keywords: Genetics, Fishes

Introduction

The sardine, Sardina pilchardus (Walbaum, 1792), is an important fish species of great economic importance to Tunisia, as well as to many other countries [1] [2]. For the management and sustainability of fish populations, studying genetic diversity is critical. Nevertheless, studies on the geographic distribution and genetic population structure of many commercial fish species stocks have not been completed [3]. Data concerning sardine populations inhabiting Tunisia coastal waters are currently very limited [4]. To the best of our knowledge the genetic diversity of Tunisia's sardine populations has yet to be investigated using modern DNA technology which is provides suitable markers to examine genetic structure such as mitochondrial DNA.

Mitochondrial (mt) DNA has many attributes that make it particularly suitable for population genetic studies, including its rapid rate of evolution, lack of recombination, and maternal inheritance.

The aim of the present study was to determine whether there is genetic diversity among the sardine populations inhabiting the coastal zones surrounding Tunisia.

Materials and methods

A total of 3 samples of Sardina pilchardus were collected from representative regions along the coastal zones of Tunisia (Gulf of Tunis, Sahel and Gulf of Gabes). For each sample, a fragment of cytochrome b (cytb) gene was amplified by PCR analysis and subsequently sequenced. Sequences of the 307-bp cytb region were aligned using the BioEdit v.7.0.7 program. Haplotype frequencies, gene diversity (h) and pairwise genetic distances (Fst) were calculated with ARLEQUIN vers. 3.01 [5].

Pairwise FSTs genetic distance was used to construct the population phenogram using the neighbor-joining algorithm [6] implemented in Phylip v3.6.1 [7].

Results and discussion

This work provides the first molecular data for the species Sardina Pilchardus along the coast of Tunisia.

Among the 92 specimens studied, 24 different haplotypes were defined by 45 polymorphic sites. Significant heterogeneity in the distribution of haplotypes was revealed between the three populations analysed.

Of the 24 haplotypes, 5 were singletons and of the remaining 19 haplotypes, one was shared among populations.

Haplotype diversity (h) within populations ranged from 0.827 at Gulf of Tunis to 0.910 at Gulf of Gabes. This result demonstrates that Gulf of Gabes is the most diversified.

FST values calculated between populations indicated significant difference (p < 0.05) in each pairwise combination of these 3 sampled areas.

The phylogenetic tree constructed using neighborjoining and maximum likelihood methods indicated that population from Gulf of Tunis was closely related to the Adriatic and Ionian sardine samples [8], whereas the two other populations were most divergent. The result suggested that the sardine stocks investigated in the present study were from different populations.

Besides the possible contribution of the history and hydrographic barriers, evolutionary processes such as genetic drift and founder effect, and or selection, may have produced the observed genetic differentiation between the populations analysed.

FOOD WEB STRUCTURE OF DEEP-SEA COMMUNITIES IN THE BALEARIC BASIN: EVIDENCE FROM D¹³C AND D¹⁵N ANALYSIS

E. Fanelli ¹*, J. E. Cartes ¹, V. Papiol ¹, F. Maynou ¹, P. Rumolo ² and M. Sprovieri ² ¹ ICM-CSIC - efanelli@icm.csic.es

² IAMC-CNR

Abstract

Food web structure of deep-sea communities off the Catalan Sea (NW Mediterranean) was investigated using carbon and nitrogen stable isotope tracers on a total of 124 taxa. Samples were collected close to Barcelona, between 650 and 1600 m depths, from January 2007 to February 2008. The higher trophic levels were occupied by benthic fish (Nezumia aequalis and Bathypterois *mediterraneus*, $d^{15}N=11.30\%$ and 11.36%, respectively) and infaunal species (carnivores polychaetes such as *Nephthys* spp. and the deposit feeder Molpadia musculus). At the lower trophic levels we found Salpa maxima, and the pteropod Cymbulia peroni (TL=2). The overall range of d¹³C values was indicative of more than one source of carbon sustaining deep-sea communities: from different kinds of sinking particles to sedimented and frequently recycled POM. Keywords: Deep Sea Ecology, Food Webs, Western Mediterranean

Introduction

The use of stable nitrogen and carbon isotopes for the study of trophic interactions is now common in aquatic ecosystems. However studies of the trophic web structure of deep-sea organisms are very limited [1,2] and only few were appied to lower trophic levels (benthos, suprabenthos, zooplankton) [3,4]. As part of the Spanish funded BIOMARE project, this study is aimed to identify the trophic levels of bathyal communities' dominant species, with particular respect to benthic and zooplanktonic organisms as resources for megafaunal species and to determine the origin of the primary food source and the different sources of food of bathyal ecosystems.

Materials and methods

Samples were collected from cruises sampling megafauna, benthos, zooplankton and suprabenthos off the Catalan Sea slope (Balearic Basin, NW Mediterranean) at depths ranging from 651 to 1600 m. Samples of megafauna and megabenthic, invertebrate epifauna were obtained by trawling the sea floor with a semiballoon otter trawl (OTSB-14). Macrobenthos (infauna) was collected with box corers, suprabenthos by a MACER-Giroq sledge, while macroplankton, micronekton fauna was obtained by a WP2 net with a system of closure. Once collected samples were frozen at -20°C on board, then sorted in the laboratory, identified to species level and prepared for stable isotope analysis (see [4] and [5] for details on the methodology). A hierarchical cluster analysis was carried out on $\delta^{13}C$ and $\delta^{15}N$ mean values per species and per survey. An ANOSIM test was performed on the same matrix to compare groups identified based on knowledge of gut contents, and then a pair-wise comparison was done on the average δ^{13} C and δ^{15} N values of these groups.

Results and discussion

Overall the nMDS analysis separated samples as a function of the trophic level: on the right mainly species belonging to epi/infauna and to megafauna were found, while on the left suprabenthic and macroplankton/micronekton species occurred (Figure 1).

Fig. 1. NMDS plot of the mean $d^{15}N$ and $d^{13}C$ values of 124 taxa

A high complexity were found among each compartment. Epibenthic, invertebrate fauna was organized in three trophic levels based on a 15Nenrichment factor of 2.54‰ per level [6]. d¹³C ranges were particularly wide

among surface deposit feeders (ranging from -21.0‰ to -16.4‰), suggesting exploitation of POM of both terrigenous and oceanic origins.

The same organization was found among macroplankton/micronekton: the lowest values were found for filter feeders which feed on particulate organic matter. Only two trophic levels were found in the zooplanktonic community off Cabrera (Algerian Basin, [4]). d¹³C ranges were particularly wide among carnivores (from -20.7‰ to -16.6‰), suggesting predation on a variety of prey from gelatinous zooplankton to small fishes and decapods. Three trophic levels were also found among suprabenthos according to [3] and [4], while megafauna occupied TL 3 and 4 with few fish species located at TL=5 (Bathypterois mediterraneus, Phycis blennoides, Mora moro, Nezumia aequalis, Coryphaenoides guentheri, Lepidion lepidion). Generally decapods occupied a lower trophic level than fish, according to [8] and [9], though 2 levels have also been identified.

MORTALITE MASSIVE DANS LES PARCS CONCHYLICOLES DE LA LAGUNE DE BIZERTE

Mouna Fartouna Bellakhal¹*, Meher Bellakhal¹ and Hechmi Missaoui¹

¹ Institut Supérieur de Pêche et d'Aquaculture de Bizerte. Unité de recherche Exploitation des Milieux Aquatiques, 7003 Tunisie - nephertitim@yahoo.fr

Abstract

Suite à une mortalité massive de moules et d'huîtres au niveau des parcs conchylicoles de la lagune de Bizerte au nord de la Tunisie, un échantillonnage des paramètres physico-chimiques pendant 48 heures, a révélé une élévation inhabituelle de la température de l'eau (29,8°C) et une baisse drastique de l'oxygène dissous (0,64 mg/l). Des expériences en laboratoire ont montré que le facteur déterminant dans cette mortalité est la température.

Keywords: Global Change, Lagoons, Bivalves

Introduction

La lagune de Bizerte, couvrant une superficie de 150 km^2 et située au nord de la Tunisie, constitue un plan d'eau très important du point de vue écologique et économique. Elle est particulièrement propice à la conchyliculture qui ne cesse de se développer, en parallèle avec l'activité de pêche. Les conséquences du changement climatique, qui a touché beaucoup d'écosystèmes sur le globe, ont commencé à se faire ressentir au cours de ces dernières années dans cette lagune. C'est ainsi que des épisodes de mortalité massive de moules et d'huîtres sont devenus assez fréquents notamment pendant la saison estivale. Différents agents, tels que les prédateurs, les parasites, les maladies ou même les conditions environnementales, pourraient également intervenir dans cette mortalité. Cette étude a porté sur l'identification du facteur déterminant dans la mortalité de *Mytilus galloprovincialis*, espèce autochtone de cet écosystème.

Matériels et méthodes 5 stations ont été prospectées toutes les 5h dont 3 (S1, S2 et S3) au niveau de la Société Tunisie Lagune (STL), située au nord-est de la lagune de Bizerte et 2 stations (S5 et S6) au niveau de CUTIMER du côté du canal au nord-ouest de la lagune de Bizerte (37°12′14′′N; 9° 55′79′′E). Le monitoring des paramètres physico-chimiques de l'eau a été réalisé toutes les 5 heures durant 48 heures, à l'aide d'un multi-paramètres type VWT.

Résultats et discussion: La température movenne de surface au niveau de la STL est de l'ordre de 27,7 °C, alors que celle du fond est de 26,9 °C. Tandis que les maxima atteints durant la campagne prospective sont respectivement de 29,8°C en surface et de 28 °C au fond. Au niveau de CULTIMER, on a constaté un gradient nettement important entre surface et fond, en effet, la moyenne en surface est de 29 °C, celle du fond est de 24,9 °C. Les teneurs halines sont inférieures à celles citées dans la littérature pour les années précédentes, avec une valeur moyenne de 33 psu au niveau des deux sites d'échantillonnage en surface. Au fond, la salinité est de 33,3 psu. Les valeurs du pH sont homogènes en surface ainsi qu'au fond avec une valeur de l'ordre de 8,3 témoignant d'une influence marine. Toutefois, les concentrations en oxygène au fond sont très fluctuantes et ont atteint une valeur de 0,64 mg/l. Quant aux concentrations en oxygène en surface, elles ont une valeur moyenne de 4.2 mg/l. La teneur moyenne en ammonium est de 0,3 µM et celle en phosphate est 0,6 µM au niveau de la STL. Ces teneurs sont respectivement de 0,2 et 1 µM au niveau de CULTUMER. Des expériences ont été menées au laboratoire, afin d'identifier le facteur déterminant dans la mortalité des moules et des huîtres, Des lots de 100 moules chacun ont été placés dans des aquariums identiques avec une première phase d'acclimatation, un renouvellement total de l'eau toutes les 24 heures, une aération comprise entre 5 et 6 mg/l d'oxygène dissous et des températures croissantes à partir de 25 ° C. La mortalité est apparue au bout de 60 H pour des températures de 27 °C (±0,5 °C). La mortalité totale est survenue après 10 H.

Conclusion : La température élevée et prolongée constitue un stress qui a affecté la capacité de tolérance des moules ce qui a conduit à un affaiblissement physiologique. À cela s'ajoute la forte densité de naissains, les premières mortalités qui accentuent le confinement et favorisent l'activité bactérienne. Ainsi, le concours de tous ces facteurs a abouti à la mortalité des moules. La gestion environnementale des projets aquacoles, de la conception jusqu'à la désaffectation, est une responsabilité partagée par l'industrie, le gouvernement et la recherche.

BENTHIC ASSEMBLAGES ON CONCRETE ARTIFICIAL REEFS IN THE NORTHERN ADRIATIC SEA: COMPARISON BETWEEN TECNOREEF® PYRAMIDS AND CUBIC BUNDLES OF TUBES

Federica Fava ¹*, Massimo Ponti ¹, Otello Giovanardi ² and Marco Abbiati ¹

¹ University of Bologna - federica.fava8@unibo.it

² Istituto Superiore per la Protezione e la Ricerca Ambientale

Abstract

Benthic assemblages colonising two typologies of concrete artificial reefs (Tecnoreef® pyramids and cubic bundles of tubes), characterised by different shape and material, were investigated three years after their deployment offshore to Po River Delta (northern Adriatic Sea). On both reef types large areas were covered by fine sediments, assemblages where characterised by reef building polychaetes and zoantharian. Assemblages differed among reefs but not between reef typologies, both in term of species abundance and cover percentage.

Keywords: Adriatic Sea, Artificial Reefs, Fouling, Po Delta, Zoobenthos

Introduction

Artificial reefs are manmade structures deployed on sea bottoms with the main aims: protecting and increasing biotic resources by preventing trawling, supporting sessile filter feeders, which can colonise the hard substrata and exploit water column resources, providing nourishment and refuges for motile species, attracting bentho-nectonic fishes ([1], [2]). Sessile and motile species colonise artificial reefs according to complex ecological processes affected by seasonal larval supply, water circulation, turbidity and nutrients, depths, orientation and material of the substrata ([3], [4], [5], [6], [7], [8]). The macrobenthic assemblages colonising two types of concrete artificial reefs modules, Tecnoreef® pyramids and cubic bundles of tubes differing in shape and concrete type, were investigated 3 years after their deployment in the northern Adriatic Sea.

Material and methods

The investigated artificial reefs were deployed in autumn 2006 on muddy bottom 2 nautical miles offshore of Scardovari (Po River Delta, northern Adriatic Sea, 44° 54' N 12° 33' E) at 13-14 m in depth, close to a long-line mussel farm. Reefs included a few dozen of Tecnoreef® pyramids (2 and 3 floors, 1.8 and 2.4 m height), made by 'sea-friendly' certified reinforced concrete manufactured using only natural components without synthetic additives, and cubic bundles of tubes, made by common building reinforced concrete tubes laid on a concrete slab (1.8 m height). The macrobenthic assemblages were investigated during the summer 2009 by means of destructive (scraping off 20x20 cm by hammer and chisel) and digital photographic (17x23 cm) sampling. Four reefs per typology were randomly chosen. For each reefs, 4 destructive and 8 photographic samples were collected. Species were identified to the lowest possible taxonomic level and their abundance was estimated as number of individuals per sample and/or covers percentage estimation, excluding from the pictures dark and blurred zones or portions covered by motile organisms. On pictures percentage cover of sediment was also estimated. Differences between reefs and reef typologies were assessed by uni- and multivariate permutational analysis of variance (PERMANOVA, [9]).

Results

The vertical surfaces of all the reefs were mainly covered by muddy sediments (mean percent cover 57%). Overall, 58 invertebrate taxa were identified in the destructive samples. The most abundant sessile taxa were the reef builder polychaetes (*Sabellaria spinulosa*, *Pomatoceros triqueter* and *Serpula vernicularis*), the zoantharians *Epizoanthus* sp. and the bivalve *Anomia ephippium*. In particular, *Sabellaria spinulosa* colonies, with up to 51 ind. dm² (means 16.1±5.3 ind. dm⁻² ± e.s.), built thin crusts of fused tubes from mud, send or shell fragments. Motile fauna was dominated by the muddy tube building amphipod *Corophium acherusicum* and the fossorial polychaetes *Polydora ciliata*. Assemblage structures significantly differed between single structures but not between reef typology (i.e. shape and concrete types), both in term of species abundance and cover percentage. Similar patterns were observed in the distribution of the most abundant species.

Discussion

Both destructive and photographic samplings were able to assess the dissimilarity among single reefs and between reef typologies. No differences in density and/or diversity of the assemblages were detected between Tecnoreef® pyramids support and cubic bundles of tubes. Bio-construction processes on artificial reefs, mainly supported by calcareous algae, is generally favoured under good light conditions and low sedimentation rate ([7]). Here,

under high sedimentation rate and reduced lighting conditions, *Sabellaria spinulosa*, with its sand-muddy agglomerates seem to play a relevant bioconstruction and strengthening role.

Acknowledgments Research funded by the "Consorzio di bonifica Delta Po Adige" (www.deltapoadige.it).

UTILISATION DES PARASITES COMME MARQUEURS BIOLOGIQUES POUR LA DISCRIMINATION DES STOCKS DE SARDINELLA AURITA DES CÔTES EST DE LA TUNISIE

Mariam Feki 1*, Lassad Neifar 2, Lobna Boudaya 2 and Abderrahmen Bouain 2

¹ Faculté des Science de Sfax, Tunisie

² Faculté des Sciences de Sfax, 3018 Sfax, Tunisie - mariamfeki1@yahoo.fr

Abstract

Une étude a été menée afin de déterminer l'utilité des parasites comme marqueurs biologiques pour la discrimination des stocks de l'allache *Sardinella aurita* des côtes Est de la Tunisie. Un échantillonnage de 329 poissons de taille comprise entre 170 et 210 mm a été effectué au niveau de trois stations : Mahdia, Gabès et Zarzis. Des analyses discriminantes, non paramétriques, utilisant quatre taxons parasites, *Parahemiurus merus, Aphanurus stossichi, Lechithocurium* sp. (Digenea) et les larves de Tetraphyllidea (Eucestoda) ont permis de séparer les allaches du golfe de Gabès (Gabès et Zarzis) de celles du golfe de Hammamet (Mahdia). *Keywords: Stock Assessment, Parasitism*

Introduction

Sardinella aurita est une espèce migratrice dont la distribution varie selon les saisons et les stations [1]. C'est une espèce d'une grande importance économique et commerciale en Tunisie. Elle représentait 25% de la production totale des petits pélagiques en 2006 [2]. Pour une gestion durable de cette ressource, l'identification des stocks est indispensable. Au cours de ce travail, les parasites ont été utilisés comme marqueurs biologiques. Ils ont montré leur efficacité pour l'étude des petites et délicates espèces de poissons comme les Clupeidae [3].

Matériel et méthodes

Durant 3 saisons, automne, hiver et printemps, 329 individus de *S. aurita* ont été échantillonnés aux points de débarquements à Mahdia, Gabès et Zarzis. Les coordonnées de pêches ont été soigneusement prélevées avec la collaboration des pêcheurs. Chaque poisson a été examiné afin de rechercher les ectoparasites et les endoparasites. Pour chaque espèce parasite, la prévalence et l'abondance moyenne ont été calculées [4]. Les variations saisonnières et géographiques de ces deux paramètres ont été aussi testées par une analyse discriminante non paramétrique.

Résultats et discussion

Des larves de Tetraphyllidea, au niveau des ceaca pyloriques, trois espèces de Digenea, Parahemiurus merus, Aphanurus stosssichi, au niveau de l'estomac, et Lechitochiurim sp. dans la vessie gazeuse ont été récoltées. L'étude des variations saisonnières de la prévalence et de l'abondance a montré des différences significatives. Les larves de Tetraphyllidea sont plus prévalentes $(97,61\%, (X^2=29,5; ddl=2; p<0,05))$ et abondantes $(110,45, (X^2=28,03; ddl=2))$ ddl=2; p<0,05)) en automne pour S. aurita en provenance de Gabès. P. merus présente une prévalence importante pendant l'automne (62,5%) et le printemps (65,85%) au niveau de Mahdia (X²=26,4 ; ddl=2 ; p<0,05). Ce Digenea est complètement absent en automne à Gabès. A. stossichi est plus prévalent au printemps chez les individus en provenance de Gabès (57,14% $(X^2=7,03 ; ddl=2 ; p<0,05))$ et de Mahdia (60,97% $(X^2=63,3 ; ddl=2 ; p<0,05))$ p<0,05)). En hiver, il est plus prévalent à Zarzis (66,66% (X²=6,8; ddl=2; p<0,05)). Ces variations de la prévalence et de l'abondance moyenne pourraient être dues à la migration et au changement du régime alimentaire de S.aurita. Cette espèce peut effectuer des migrations saisonnières pouvant atteindre des centaines de Km. Ces poissons qui vont se déplacer ont plus de chance d'être en contact avec des parasites [5]. Lechitochiurim sp. est complètement absent chez S. aurita en provenance de Gabès et Zarzis. On le trouve chez les spécimens en provenance de Mahdia pendant l'hiver et le printemps. Des variations géographiques de la prévalence, sont aussi enregistrées. En effet, P. merus est plus prévalent (90%) chez les individus de Zarzis (X2=111,05; ddl=2; p<0;05). A. stossichi est plus prévalent dans le golfe de Gabès (Gabès :52,74% et Zarzis : 58,77%) qu'à Mahdia (20,16%) (X²=41,56; ddl=2; p<0,05). Lechitochiurim sp. n'est présent que chez S. aurita en provenance de Mahdia. Les variations géographiques de la prévalence de ces trois Digenea pourraient être expliquées par l'existence de plus d'une population entre le golfe de Gabès et le golfe de Hammamet.

Abstract

Our recent observations made on gut contents of *Diplodus sargus*, have highlighted that the algal pest *Caulerpa racemosa* represents an important component of the fish diet along the coast of the Salento Peninsula (SE Italy). Here, we demonstrated that one of *C. racemosa* secondary metabolites, caulerpin, enters in trophic chains and accumulates in fish tissues. Providing a new perspective in the understanding of the effects of biological invasions, the present study represents the starting point for future investigations aimed at evaluating both the potential hazard for long-term effects on the fish, and risks for human health deriving from *D. sargus* consumption.

Keywords: Alien species, Bio-Accumulation, Fishes, Food Webs

Introduction

Secondary metabolites of *Caulerpa* species have been previously investigated to evaluate their ecological role both in chemical defence against herbivores [1] and as allelochemicals in interspecific competition [2]. Our recent observations made on gut contents of *Diplodus sargus*, have highlighted *C. racemosa* as a very important component of the fish diet along the coast of the Salento Peninsula (SE Italy). This study aimed at measuring whether and to what extent the presence of an invasive species in the diet of an endemic fish species can determine accumulation of the algal secondary metabolites in the fish tissues.

Material and Methods

This study is based on a collection of 18 specimens speared in June-September 2008, a period of the year when the abundance of *C. racemosa* reaches its maximum. Each individual was dissected and white and red muscle, liver, skin and the gastrointestinal tract separated. Stomach contents were observed under magnification to assess the abundance of *C. racemosa*. Animal tissues were lyophilized and then exhaustively extracted first with acetone then with ethyl acetate. RP-HPLC-MS analyses were carried out on organic extracts to quantify the accumulation of algal metabolites in fish tissues.

Results and Discussion

The only algal metabolite we were able to detect in D. sargus tissues was caulerpin which is the main component of the C. racemosa lipophilic extract. The concentrations range between: $0-5.4 \,\mu g/g$ (white muscle), $0-38.2 \,\mu g/g$ (red muscle), 0-14.4 µg/g (skin) and 0-16.3 µg/g (liver). Even though we still do not know if the accumulation of caulerpin is responsible of toxic effects and/or other physiological alterations in the fish, it is reasonable to hypothesize harmful effects on non-adapted fish populations, such as those typical of the invaded systems. This study has represented a baseline on which we have designed an ad-hoc experiment, which is based on an integration of chemical, physiological and ecological approaches. Forty-five specimens of D. sargus (15 individuals for each of the three locations considered along the Apulian Coasts) have been speared in September-October 2009. Analysis of wide battery of molecular and cellular biomarkers, namely Cat, GPx, TOSC assay, Na⁺-K⁺-ATPase, VTG, Micronucleus and Comet assay, are currently evaluating the health status of these fishes and their reproductive potential. At the same time, chemical investigations on fish tissues are in progress to value algal metabolites accumulation and to correlate these data with fishes physiological responses. Therefore, through the analyses in progress, we should provide a better understanding of how the C. racemosa spreading in the Mediterranean Sea can affect the population dynamics of a single species. Also, we should provide essential information for an effective evaluation of possible risks for human health, deriving from D. sargus consumption.

Abstract

For a 10 year period two Western Mediterranean zooplankton time series (Mallorca Channel and Gulf of Naples) have been analyzed and compared. The environmental seasonal patterns in relation to their main zooplankton groups have been described. No trends were found for temperature, but a salinity increasing trend was observed in the Balearic Sea. Zooplankton was dominated by copepods which, together with cladocerans and appendicularians contributed more than 84% to total. Copepods and cladocerans were more important in Naples, while siphonophores and ostracods were only found in the Balearic Sea. Other minor groups occurred in both areas but during different seasons. Although the period considered may be too short to investigate climate effects, the synchronies observed in the zooplankton suggested common responses to basin-scale signals.

Keywords: Zooplankton, Copepoda, Balear Sea, Tyrrhenian Se, Western Mediterranean

Introduction

The Mediterranean plays a critical role in the global climate system and is one of the most sensitive areas on earth in a global warming context, particularly due to its location at the boundary of two different climate cells and regimes of the temperate and sub-tropical zones (1). On a large scale the Mediterranean could be considered to be a uniform basin representative of the warm temperate region, however it is far from being biogeographically homogeneous, due to its complex morphology with many orographic features and a complex sea floor. The Western Mediterranean (WM), in connexion with the Atlantic through the Straits of Gibraltar, forms a small semi-enclosed basin in which processes are similar to those in the neighbouring ocean, where to study climate or warming effects (2).

Sampling sites and methodology

The sampling sites (St. PA, in the SW of Mallorca island and St. MC in the inner Gulf of Naples) are located at similar latitudes (39°28'59 and 2°25'63; 40°48.5 and14°15, Baleares and Naples respectively), depths (~75m) and coastal proximity (2 nm). However, st. PA is exposed to more offshore waters, located in a boundary area between northern and southern WM waters, st. MC has more coastal character, being heavily influenced by land run-off and a densely populated region at the border between the coastal and offshore waters. Comparable methods were used for sampling and analytical methods (3, 4).

Results and Discussion

Seasonal cycle-Temperature pattern was very similar at both sites and, with the exception of the summer period, was slightly lower in the Balearics (17.07 $^{\circ}$ C) than in Naples (17.24 $^{\circ}$ C). Salinity, even at the surface, was lower in the Baleares (37.6-37.8) than in Naples (37.9-38.1), excepting the surface during spring.

The pattern of total zooplankton showed that the main difference between the two sites was due to copepods (59% in Baleares and 68% in Naples) but also to cladocerans, (8 and 11%). Appendicularians followed them (17% and 11%) as may to correspond at both different ecosystems (3,4). In lower abundances doliolids and chaetognaths, were present during the first part of the year in Baleares, although mainly present in autumn in Naples. Siphonophores and ostracods were abundant only in the Balearic site as correspond to more oceanic area (3). The most important copepods were *Clausocalanus* and *Oithona* group, but *Acartia clausi, Centropages typicus, Paracalanus parvus* and *Temora stylifera* were abundant with peaks in different periods of the year. Their relative contributions of these copepods showed interesting differences at the two sampling sites, in relation to differences in the local environmental conditions.

Interannual variability- Temperature showed marked variability with no significant trends. Warmer conditions were observed during 1997 and 1998 in the Balearics and after year 2000 in Naples. Salinity increased in the Balearics during the whole period but no in Naples. The interannual variability of total zooplankton and copepod abundances showed an increasing trend in Naples, that was interrupted after the year 2000. No trend was observed in Baleares. Cladocerans showed marked interannual variability and excepting years 2000 and 2001, lower values in Baleares. Appendicularians did not show clear differences throughout the study period at either both sites. Doliolids and chaetognaths, decreased in Baleares and increased slightly in Naples.

Opposite trends were observed for the siphonophores and the ostracods. The most abundant copepods *Clausocalanus* spp., *A. clausi* and *C. typicus* exhibited marked interannual variability at both sites with no clear trend. *Oithona spp., T. stylifera* and *P. parvus* increased in Naples.

The differences recorded in the community composition at groups and species level indicated an strong adaptation to local conditions, nevertheless they had a clear oligotrophic character at the Balearic site and a marked coastal influence at the Naples site.

Although the period considered may be is too short to investigate zooplankton pattern in relation to climate forcing, the synchronies in the zooplankton patterns recorded at both sites points suggested responses of zooplankton to signals at the basin scale. Longer time-series and further analysis have to be encouraged in the Mediterranean as a potential tool to long term evolution of planktonic communities and their responses to climate change.

SPATIAL DISTRIBUTION OF HOLOPLANKTON ON THE ANATOLIAN COAST, NERITIC ZONE OF BLACK SEA DURING LATE AUTUMN 2005

Ali Muzaffer Feyzioglu¹* and Ilknur Yildiz¹

¹ Karadeniz Technical University, Faculty of Marine Sciences - muzaffer@ktu.edu.tr

Abstract

During the late autumn 2005, holoplanktonic community have been analyzed in Southern waters of the Black Sea. During the sampling period, totally 4 major taxa, which Copepoda, Cladocera Appendicularia and Chaetognatha, were identified. The copepods were the dominant group. Although similarity between the stations were higher than 70 %, three different community structure which fits the Black Sea general current regime were observed during the sampling period. *Keywords: Black Sea, Zooplankton*

Introduction

Zooplankton has an important role in aquatic environment in energy transfer to upper trophic level such as fish larvae and other planktivores organisms. Abundance of the zooplanktonic organism is important for efficiency of marine environments. So their abundance and distribution have been widely studied since they first discovered [1]. Zooplankton is divided into 2 main groups as holoplankton and meroplankton. Group spends only a part of their life as a plankton and settling to seabed are called meroplankton. Others, such as copepod and chaetognatha, complete their life cycle as plankton is called holoplankton [2]. They are the permanent members of the pelagic system not only larvae stage but also during the adult stage. In the temporal region like Mediterranean and the Black Sea during the winter period holoplankton are the main components of the zooplankton community. Holoplankton community structure is important component for comparing the regions and the efficiency of secondary production. The aim of the study is to determine the abundance and similarity of the holoplanktonic groups along the Anatolian coast (South Eastern Black sea) neritic zone during the late autumn of 2005.

Materials and Methods

Samples were collected from ten stations located along the South Eastern Black Sea coast during the eight days cruise of R/V DENAR in November 2005 (Fig. 1). Sampling tows were performed at each site using Hensen type closing net with 75 μ m mesh size; 70 cm mount diameter, and 220 cm long net. The plankton nets were towed vertically from 50 m depth to surface. The volumes of the sea water filtered were calculated by digital flowmeter (Hydro-bios Kiel, No 439115). The samples were preserved in borate-buffered 4% formaldehyde-sea-water solution until laboratory analysis. Zooplankton samples were removed from the solution and counted under the stereomicroscope [3].

Fig. 1. Sampling location

Result and Discussion

During the sampling period, totally 4 major taxa (Copepoda, Cladocera Appendicularia and Chaetognatha) were identified along the Black sea Anatolian coast. The main and the largest taxa in holoplankton were Copepoda. The most abundance copepod species belonging to the orders of Calanoida and Harpacticoida were *Calanus euxinus*, *Acartia clausii, Pseudocalanus elongatus*, *Paracalanus parus*, cyclopoid copepodlardan *Oithona sp.* and *Tigriopus sp.*, *Laophonte sp.* respectively. Other Crustacea was Cladocera. This taxa includes *Evadne tergestina*, *Evadne spinifera* and *Penilia avirostris* in the sampling area. In addition to above mentioned, *Oikopleura dioica* and *Sagitta setosa* were only representative for Appendicularia (*Oikopleura dioica*) was the second highest biomass in the near shore region. The maximum biomass was observed as 12763 organisms m⁻³ Although the similarities between the stations are higher than

70 %, three different regions distinguish in holoplanktonic community at the Anatolian cost of the Black Sea during the sampling period (Figure 2.B). These are west, middle and eastern Black Sea Regions. The distribution of holoplanktonic communities shows similarities with general Black Sea current regime which has two anti-cyclonic gyros located east and west part of the Black sea. in Ordu off (BL11). Appendicularia was also observed as high as 4837 organisms m⁻³ in Inebolu off (BL 4). It was the highest value for Appendicularia. However the maximum biomass of Chaetognatha was found as 1289 organisms m⁻³ in Unye off (BL 10). Although Cladocera were represented by three species in the region, it was the poorest group. The maximum number of the Cladocera was estimated as139 organisms m⁻³ in the sampling areas (Fig. 2.A).

Fig. 2. A. Abundance of holoplanktonic organisms B. Similarity between the stations

Although the similarities between the stations are higher than 70 %, three different regions distinguish in holoplanktonic community at the Anatolian cost of the Black Sea during the sampling period (Fig. 2.B). These are west, middle and eastern Black Sea Regions. The distribution of holoplanktonic communities shows similarities with general Black Sea current regime which has two anti-cyclonic gyros located east and west part of the Black sea.

Abstract

44 years after the discovery of living populations of deep corals in the « Lacaze- Duthiers » canyon, dense populations of corals were observed on its west side . These populations settled either on blocks or cliffs were associated with diverse organisms including sponges, brachiopods, tube worms, echinoderms, oysters, cephalopods and fishes. *Keywords: Biodiversity, Deep Sea Ecology, Western Mediterranean*

Altough living deep cold-water coral reefs are well documented in the world oceans (1,2) their presence in the Mediterranean sea has been scarcely reported (3,4). Considered as rare organisms and in decline (5) most of them were dredged dead or in bad shape. The first observation of Mediterrranean living corals was made in the Lacaze Duthiers canyon (1961 and 1963) using the submersible SP350 (Commandant Cousteau) (6) and since then, no more scientific investigations have been performed. During R/V MINIBEX (COMEX) cruises (« MINIBEX » (OOB/DIREN) May-July 2008 ; « MEDSEASCAN » (AMP) november 2008 and june 2009) video surveys using the ROV « ACHILLE » and the submersible « REMORA »(COMEX), have allowed the discovery of new sites colonized by dense living cold water corals populations (Lophelia pertusa, Madrepora oculata, Dendrophyllia cornigera, Desmophyllum dianthus) . Madrepora oculata was observed on blocks or vertical cliffs from 220 to 535m depth colonizing rocks with high densities and large colonies up to 50cm high . Lophelia pertusa with exceptional colonies up to 1m high appeared from 250 to 535m with main abundance between 360 to 535m. Desmophyllum dianthus was also often associated with both species .

Fig. 1. Lacaze-Duthiers canyon (MINIBEX, May 2008). Living Lophelia pertusa, Madrepora oculata and Desmophyllum dianthus on blocks, 340m.

The yellow coral Dendophyllia cornigera was present with other corals or isolated on rocks till 346m. The coral community was composed of a rich fauna of invertebrates including number of sponges, brachiopods, echinoderms, oysters, ascidians and bryozoans as well as vagil cephalopods and fishes. The populations are structured by both their nutrition with organic particles transported by currents and the sedimentation of mud. Among the identified species, 4 are protected by the French regulation (corals), 13 are cited in European directives 79/109/EEC (Art 4) and 92/43/EEC (Annexe 2), 2 are cited in the OSPAR convention and 13 are of commercial interest.

Fig. 2. Lacaze-Duthiers canyon (MEDSEASCAN, June 2009). Lophelia pertusa, Madrepora oculata well opened on a cliff, 363m.

Number of wastes, not observed in the first dives (1961 and 1963) were also observed including fishing nets and lines, boots, cans, glass bottles and plastic bags. These observations will allow to implement this canyon with a deep observatory dedicated to deep experiments. Habitat mapping and conservation programs will allow the long-term monitoring of these coral populations.

Acknoledgments : are due to H. Zibrovius for confirmation of the coral species and the « MINIBEX » , «ACHILLE » and « REMORA » crews.

³ Wilderness studi ambientali, via Cruillas 27 90146, Palermo, Italy

Abstract

A juvenile of the Canary drum *Umbrina canariensis* was caught in the Sicilian Channel extending the area of occurrence of the species. The specimen was found between 140 and 171 m depth on the eastern side of the Malta Bank. This finding represents the easternmost record of the species in the Mediterranean, confirming the role of the Sicilian Channel as the biogeographic boundary between the western and eastern Mediterranean. *Keywords: Fishes, Biogeography, Sicilian Channel*

The Canary drum *Umbrina canariensis* Valenciennes, 1843 occurs on the shelf and upper slope at 50 to 300 m depth on muddy and sandy bottoms in the

and upper stope at 50 to 500 in deput of maday and stardy bottoms in the eastern Atlantic Ocean and western Mediterranean Sea [1]. In the Mediterranean it has been recorded from the Alboran Sea, the Catalan Sea and off Maiorca [2], along the Algerian coast [3], and in north-western Tunisia [4]. Following [5], the presence of the Canary drum in Sicily was also reported [6], but a more careful reading of the Doderlein's paper allows us to interpret this finding as the specimen of *U. ronchus* Valenciennes, 1843, found off Messina by Giglioli [7]. Our fish was a juvenile male of 177 mm total length caught on June 19th 2004 (MEDITS trawl survey) between 140 and 171 m depth on the eastern side of the Malta Bank (approximate position 36 03.26 N; 15 16.63 E). Table 1 shows the main biometrics and meristics of the collected specimen.

Tab. 1. Main biometries and meristics of the examined specimen (L=length and D= depth)

TotalL	Standard L	Head L	Body D	E/e clame ter
177	145	42.2	49.5	12.5
Catdalpedtack D	inte ro doitaí widta	Lofilanaliay	1" dosalfh	2 rd dorsal fit
13	17	17.9	X	H28
Avaitin	Pe otoral fin	Petrbith	Caudain	G litrackers on 1° gli arch
148	16	6	18	16

This finding is the first documented occurrence of *U. canariensis* in the Sicilian Channel and the easternmost record in the Mediterranean, confirming the role of the Sicilian Channel as the biogeographic boundary between the western and eastern Mediterranean [8].

Abstract

The Enot Timsah spring system feeds an endangered wetland ecosystem at the foot of the Carmel Mountains. The site studied is isothermal, oligohaline (3-4 psu) and highly oligotrophic. Foraminiferal diversity consists of 15 live species and 3 more in the dead assemblage, reflecting a uniquely diverse marginal system. Richness is attributed to thermal stability, maturity dating to early Holocene, and position beneath bird migration routes. Low numbers, mainly of agglutinants, live in the top 4 cm. The dead assemblage is more numerous but records significant taphonomic loss of agglutinants and durability of hyalines; miliolid representation is unaffected.

Keywords: Biodiversity, Brackish Water, Eastern Mediterranean, Foraminifera

Introduction

The Enot Timsah nature reserve is located at the foot of the Carmel Mountains ~2.5 km from the Mediterranean. It constitutes the only significant natural outlet of the mountain aquifer system, and is the last remnant of the extensive Kebara wetlands, drained in the early 20th century. We here address the living foraminiferal assemblage that inhabited this ecosystem, as well as the dead assemblage that time-averages out patchiness and informs on taphonomic changes that allow comparison with the geologic record.

Material and Methods

The sampling station was located in an undisturbed spot in the Timsah reserve downstream from an active spring $(32^{\circ}33'9N/34^{\circ}55'41E)$. Foraminifera were sampled monthly over one year in 2002-3. Temperature, conductivity, pH, major ion and nutrient concentrations of the water were determined. Sediments were taken using a 100 ml syringe to 4 cm depth. Living foraminifera were stained with Rose Bengal and preserved in 95% ethanol. Living and dead foraminifera >63µm were counted from 5 sets each from 8 sampling events.

Results and discussion

Enot Timsah is a unique ecosystem representing a ground/surface water interaction zone with very stable water properties. The system is nearly isothermal with temperature averaging 23.98±0.42 °C. It is oligohaline, with total dissolved solids (TDS) averaging 3,213.6±118.5 mg/l. pH averaged 7.05 \pm 0.15, in equilibrium with the carbonate aquifer source. PO₄³⁻ is the limiting nutrient in concentrations indicating oligotrophy. Organic carbon averaged 8.8±2.8 wt% with C/N ratio of ~14. Sediment is silty sand and % CaCO3 is ~40%. Living foraminiferal abundance was 3 to 32 specimens/10 cc in the top 4 cm, much lower than in other oligohaline environments. Low numbers reflect the extremely low salinity, at the lower range for survival for most foraminifera, and the extreme oligotrophy, reflected by the high N/P, that limited phytoplankton production. 15 living and additional 3 dead species were recovered, comprising 8 agglutinants, 6 miliolids and 4 calcareous hyalines. This number of species is significantly higher than other environments of low salinity (Fig. 1). Occurrence of hyaline and miliolid taxa in oligohaline systems is atypical, and probably reflects the warm water and the high, stable Ca²⁺ and HCO₃⁻ concentrations contributed by the carbonate aquifer source. This wetland is located along the main migratory route of water fowl between Eurasia and Africa, so repetitive avian transport of cosmopolitan brackish foraminifera explains the high diversity. Also contributory is the long-term stability of temperature and salinity compared to marginal marine environments, as no significant change took place during the Holocene. Agglutinants comprise 49-80% of the living assemblage, hyalines 10-43%, and miliolids, 5-13%. The most common species are Haplophragmoides manilaensis, H. wilberti and Trochammina inflata that are low salinity indicators known from brackish environments. Others include Birsteiniolla macrostoma and Pseudothurammina limneti. Among miliolids, the shallow marine species Affinitrina eburnea is most common. Hyaline forms include Cribroelphidium cf. C. vadescens and Trichohyalus aguayoi. Ammonia tepida is present in small numbers. Noteworthy is relative abundance of Bisaccium imbricatum, a species recorded to date only from Louisiana. Foraminifera in the dead assemblage are more numerous. Hyalines are 2-6 times more abundant than in the living assemblage, while agglutinant numbers are sharply reduced. Among hyalines A. tepida abundance rises significantly. Miliolids comprise 5-13% of dead forms, similar to the living assemblage. The main control on taphonomic change is not the pH of 7.1, as calcareous miliolids and hyalines are more susceptible to dissolution than organic-cemented agglutinants. Selective preservation of calcareous tests is due mainly to the high HCO_3^- content and the CaCO₃-rich sediments, while decrease in agglutinants is due to extreme fragility of some tests, combined with microbial degradation of the organic cement.

Fig. 1. Comparison of species richness in selected oligohaline (0.5-5 psu) and mesohaline (5-18 psu) settings. Values are high at Timsah, Black Sea, and Sea of Azov where salinity is more stable than in salt marshes and estuarine settings. Records were [1] for the lower Mississippi delta; [2] for the Black and Caspian seas and Sea of Azov; [3] for New Zealand brackish environments; [4] for UK intertidal zone; [5] for Mexican sinkholes

IN LESS THAN 10 YEARS THE SQUAT LOBSTER MUNIDA RUTLLANTI HAS REPLACED M. INTERMEDIA IN THE WESTERN POMO PIT (CENTRAL ADRIATIC)

Carlo Froglia ¹*, Maria Emilia Gramitto ¹ and Elisabetta Betulla Morello ¹ ¹ ISMAR - CNR - c.froglia@alice.it

Abstract

Munida rutllanti was recorded for the first time in the central Adriatic in 2003 and today has almost completely replaced *M. intermedia*, ranking second by weight in the benthic decapod crustacean assemblage of the western Pomo pit. *Keywords: Decapoda, Adriatic Sea, Global Change*

The "meso-Adriatic depression" (Pomo pit) is an important trawling ground for the Adriatic fishing fleet. Munida intermedia was, initially, the only squat lobster recorded in benthic decapod crustacean assemblage of the area, ranking second by weight after Nephrops norvegicus [1]. Munida iris rutllanti Zariquiey Alvarez 1952 was first described from the Alboran Sea (off Melilla). Since then, in the Mediterranean, it has been reported from the Alboran, Catalan and Northern Aegean Seas only, despite its distinctive characters and the numerous fishery surveys carried out throughout the western and central Mediterranean since the 1970s. In 2000 it was first collected in small numbers in the Southern Adriatic [2] and Eastern Ionian Seas [3]; and in June 2003 it was recorded for the first time in Pomo Pit when, already, it outnumbered M. intermedia [4]. Since 2003, the population of M. rutllanti has been opportunistically monitored and some aspects of its biology investigated and compared with information already available for M. intermedia [5]. Munida intermedia was absent in most of the hauls of the May 2009 trawl survey, the ratio M. intermedia / M. rutllanti was 1: 150 (TAB 1) whilst the overall abundance of squat lobsters in the decapods assemblage remained substantially unchanged. In the Pomo pit the two species reach similar maximum sizes and the smallest ovigerous females are around 8 mm CL for both; despite this, their reproductive strategies are different. Munida rutllanti spawns in late-spring and summer and is a multiple spawner, as shown by the large number of females carring embryos ready to hatch, and having mature turquoise ovaries visible trough the cuticle. Munida intermedia, on the contrary, spawns in winter and is a single spawner The fecundity of the single batch of a female of M. rutllanti is higher than that of M. intermedia of the same size. Furthermore M. rutllanti is far less subject to parasitization by Rhizocephalans compared to M. intermedia (TAB. 1). Most Rhizocephalans are known to alter the reproductive success in a population by inducing castration of the host. Fishing trials carried out in 2004 [6] revealed that creels selectively caught M. intermedia compared to M. rutllanti (4:1) whilst the opposite was true for bottom trawl catches (1:4). This is suggestive of the fact that the two species may also have different feeding strategies.

Tab. 1. Composition of the squat lobsters popolation in the Western Pomo pit in the period 1997-2009 and percentage of parasitization by Rhizocephalans in the two species of *Munidia*

Year	1977	1993	1998	2003	2004	2005	2009
N. Squat lobster examined	786	2943	3174	733	8049	1206	1951
M. intermedia / M. rutllanti	1/0.0	1/0.0	1/0.0	1/3	1/5	1/12	1/150
M. intermedia % parasitized	35.2	14.5	X	26.6	37.6	40.2	39
M. rutllanti % parasitized	-	-	-	0.6	0.3	< 0.1	0.1

The capacity of *M. rutllanti* to outcompete *M. intermedia* is probably related to its life history, but climate warming and the effect of the Eastern Mediterranean Transient on overall Mediterranean circulation [7] could be at the origin of this recent spreading.

CONTRIBUTION TO THE DIETARY ANALYSIS OF THE SQUID *ILLEX COINDETII* (CEPHALOPODA, OMMASTREPHIDAE) AT THERMAIKOS GULF (NORTH AEGEAN-GREECE)

K. Fryganiotis ¹*, M. Margaritis ¹, C. Antoniadou ¹, P. Damianidis ¹ and C. C. Chintiroglou ¹ ¹ Department Of Zoology, School Of Biology, Aristotle University, Thessaloniki,Greece - kfrygani@bio.auth.gr

Abstract

The dietary analysis of the squid *Illex coindetii* was carried out at Thermaikos Gulf. Samples were collected seasonally by bottom trawl during one permitted fishing period. The species preyed mostly on crustaceans, cephalopods and fishes. The composition of its diet differed according to the season and the animal's sex and size. Female and large-sized individuals preferably consumed crustaceans. Similar results have been reported from *I. coindetii* populations at the same geographic area, but the dietary composition of the squid is different at other Mediterranean populations. These results reveal the increase variability of the species' trophic habits. *Keywords: Diet, Cephalopods, Aegean Sea*

Introduction

The squid *Illex coindetii* (Verany, 1839) is an Atlanto-Mediterranean species, inhabiting various soft substratum types, mostly muddy bottoms, with a broad vertical distribution, from shallow waters up to 1000 m depth [1, 2]. The species is very common throughout the Mediterranean and in several areas of the Aegean Sea [1]. Due to its commercial interest and also to its wide range of distribution, there are many studies about the species' biology, fisheries and natural stock management [2]. In particular, the diet of the squid has been described revealing significant differences according to the geographic area, the sex, the season and the size of the animal [2]. Therefore, the present study aims at describing the trophic habits of *I. coindetii* at Thermaikos Gulf, by presenting preliminary data about the influence of sex, season and mantle length to its diet.

Materials and Methods

The study was carried out at Thermaikos Gulf (north Aegean Sea, Eastern Mediterranean). Seasonal samples were collected using commercial bottom trawl, during one permitted fishing period (October 2005 to April 2006). 21 hauls were carried out (mesh size of the net: 40 mm) at depth ranging from 32 to 96 m. All the collected squids were measured for mantle length and their stomach content was examined. The trophic level of the squid [3] and two trophic indices ([4], [5]) were estimated: the frequency of occurrence, F and the percentage of prey, P, calculated as follows F=n*100/N_s and P=n_1*100/N_p, where n= number of stomachs containing a certain prey, N_s= total number of stomachs examined, n₁= total number of individuals of a certain prey andN_p= total number of prey items. According to N values, prey categories were distinguished as preferential (N>50%), secondary (10% <N<50%) and occasional (N<10%) [3, 4]. ANOVA analysis was used to test for the effects of sex, season and size to the stomach content of the squids.

Results and Discussions

In general, 200 specimens of *I. coindetii* were collected, almost exclusively in daytime, and examined. According to the calculated indices, these squids prayed preferably on crustaceans (F=29.5%, N=54,13%), cephalopods (F=13%, N=23,85%) and fishes (F=12%, N=22,02%), whereas a significant percentage of squids presented empty stomachs (up to 50%). The percentage of each food item is given at Table 1. The trophic level of *I. coindetii* was estimated at 3.94 (S.E=0.59). ANOVA results showed that prey composition differed among seasons, sex, and size (P<0.05). Large sized individuals and females consumed increased amount of all three food items. With respect to the seasonal differences, the consumption of Crustace adecreased in autumn, whereas that of Cephalopoda and Pisces increased in spring.

Tab. 1. Ratio of stomach content of Illex coidetii by sex, season and size (ML=mantle length of cuttlefish)

Stomach content		Percentage of prey (%)							
	Male	ale Female Autum Winter Spring ML≤69,3							
crustaceans	25.7	33.3	20.4	33.8	32.1	24.8	34.7		
cephalopods	10.9	15.1	11.1	5.9	20.5	9.5	16.8		
pisces	8.9	15.1	9.3	11.8	14.1	8.6	15.8		
Empty	55.1	63.7	66.7	61.8	52.6	64.8	53.7		

The above results conform to other studies conducted at the north Aegean Sea [1]. In contrast, the main prey items at the western Mediterranean populations of the squid are fishes, followed by crustaceans and to a much lesser extent, cephalopods [2]. Also, at these areas the predominance of fishes over crustaceans is higher in spring and autumn than in winter. At the present study a very high percentage of cephalopods in prey composition was observed. This

result may be attributed to the relatively small size of the collected squids, since cephalopods are considered as occasional prey for *I. coindetii*, being consumed mostly by juveniles [1, 2]. It seems therefore, that the species can utilize a variety of food items, according to prey availability, size, sex and season.

PATTERNS OF BIOINVASION IN THE MEDITERRANEAN SEA – MANAGEMENT AND MISMANAGEMENT

Bella s. Galil ¹*

bella@ocean.org.il

Abstract

The synthesis of data on Mediterranean alien species' native region, human-mediated transfer mechanisms and spatial and temporal occurrence, generate "apparent patterns" of invasion: (a) most species have been introduced through the Suez Canal; (b) most species occur in the Levant; (c) their native region and vector differ greatly among basins; (d) more rapid and extensive geographical spread in the past two decades; (f) apparent rate of invasion corresponds to shifts in vectors, alterations of recipient regions, and sporadicity of research efforts. Climate change is a significant factor. The challenges for environmental management are discussed. *Keywords: Alien species, Global Change, Suez Canal*

Six hundred-and-twenty metazoan species are recorded as alien in the Mediterranean Sea [1]. All are littoral and sublittoral benthic or demersal species (or their parasites). Their native range is most commonly the Ind- Pacific Ocean, Indian Ocean, and the Red Sea. The majority entered through the Suez Canal (54%), with additional 10% primarily introduced through the Canal and then transported by vessels. The means of introduction differ greatly among the phyla and among basins. The numbers of alien species which have been recorded in the Mediterranean each decade over the past century have increased in recent decades. The figure reflects political crises, economic development and scientific interest in recording marine alien species. The inventory of the alien species in the Mediterranean provides us with data that allows examination of the efficacy of regulatory instruments and environmental management options either in place or soon to be. Due to the high permeability of aquaculture facilities, transport and transplantation of farmed alien species in the 1970s and 1980s markedly increased the number of intentionally and unintentionally introduced species. The impact of the voluntary guidelines, the restriction of importation due to self-sustaining spat production and the realization by the industry that the imported species may arrive with their complement of parasites and pathogens, led to institution of "zoosanitary precautions" that have already contributed to a reduction in the numbers of mariculture-associated alien species. Still, segments of the industry resort to illegal importations: a bilaterally ablated female banana prawn, Fenneropenaeus merguiensis, was collected in the Bay of Iskenderun, Turkey, in late 2006 [2]. Because eyestalk ablation is commonly used in aquaculture to induce maturation of gonads, there is no doubt that specimen escaped or was released from a nearby aquaculture facility. However, neither the Turkish authorities nor FAO have been aware of the importation of that species. A great number of alien species in the Mediterranean Sea have been vessel-introduced and vesseldispersed. The International Maritime Organization (IMO) sponsored an international instrument to regulate ballast water management which was adopted by a Diplomatic Conference in 2004, but only 20 contracting states have signed on (www.imo.org). Assuming that the Convention will be ratified and implemented, the number of ballast-transported aliens maybe reduced. However, hull fouling, long acknowledged as a dominant vector of transport of alien biota, may soon be on the increase as a result of the implementation of another IMO Convention: the International Convention on the Control of Harmful Anti-Fouling Systems on Ships, which calls for a global prohibition on the application of organotin compounds, entered into force in 2008 (www.imo.org). Alternative ship coating recently introduced as a substitute to TBT based antifouling paints may not be as effective, possibly resulting in more species being transported, and the number of introductions by hull fouling may increase significantly [3]. The increasing role of the Mediterranean as a hub of international commercial shipping has been reflected in the growing number of vessel-introduced aliens in the past 20 years. Unless ballast- and hull transport are strictly controlled, shipping-mediated introductions of alien species are set to increase. Climate change and biological invasions are key drivers affecting biodiversity, yet their impacts are rarely considered in tandem. As Erythrean aliens make their way northwards and westwards across the Mediterranean Sea, the most invasive of the lot attract attention for their realized or potential impacts on the native biota, or as health hazards. The result of the ongoing climate change is an increasing discrepancy between the requirements of native species and altered environmental conditions. In climate-facilitated invasions, the occurrence of alien species depends on change in the receiving environment that drives native species to become increasingly ill adapted to the local environment, whereas the aliens are better adapted to the new conditions. The Erythrean aliens are thermophilic species and it is likely that the rising sea-water temperature favour their colonization, reproduction, growth, persistence and

spread, and provide them with a distinct advantage over native temperate Mediterranean taxa. Their presence alters population dynamics of native biota, the structure and composition of communities and functioning of ecosystems. However, no implicit or explicit management strategies has yet been discussed to curb the influx of Erythrean aliens that impact the already teetering fisheries, mariculture, and tourism through proliferation of alien parasitic, noxious and poisonous species, displacement of commercially- important native species. The changes in biodiversity patterns in the Mediterranean are linked to climate change and invasive species, as well as to the well-established drivers of habitat change, overexploitation and pollution, and pose complex challenges for the maintenance of biodiversity and ecosystem function. Thus far, we have failed to assess the cost of environmental damage, and ignored the depletion of resources, environmental degradation and health impacts caused by alien invasion. There is a need for better Mediterranean marine governance. The EU recently introduced the Marine Strategy Framework Directive (MSFD, EU Commission 2008), which aims at achieving good environmental status in European Waters. The peri-Mediterranean countries need to develop their own optimal marine management capacity to avoid irreversible negative outcomes. While researching, defining and agreeing on management strategies and governance by the diverse communities of scientists, stakeholders and policymakers have barely began, native and alien communities re-assemble and establish under a new climate regime in the Mediterranean Sea

HIGHER TAXA SURROGATES OF MARINE BIVALVIA (MOLLUSCA) AND POLYCHAETA (ANNELIDA) DIVERSITY IN THE EASTERN MEDITERRANEAN (GREEK WATERS)

Abstract

Higher-taxon richness as a surrogate for species was used to estimate the species richness of marine bivalvia and polychaeta in the Greek waters of the Eastern Mediterranean. In both these classes, significant and positive relationships between generic and species richness were found. Family richness is also strongly related to the number of species. This suggests that identification to the family level may be sufficient in many routine surveys. At the generic or family level, this surrogate method may be a valuable tool for locating and designing representative systems of protected areas for the well-documented zoobenthic communities that occur in Greek waters.

Keywords: Biodiversity, Bivalves, Polychaeta

Introduction

The assessment of biodiversity usually relies on a proxy, such as species richness or diversity [1]. However, the use of lower taxonomic resolution has also proved promising in environmental monitoring and impact studies [2-3]. A series of studies have demonstrated good congruence between species richness patterns and higher-taxon richness, indicating that this approach could be a promising tool in conservation biology for the rapid estimation of species richness [4-5]. In the present study 753 species of marine polychaeta and 308 bivalvia were considered and using regression techniques were tested for whether higher taxons are a good surrogate for species diversity.

Materials and Methods

According to the comprehensive checklist of Simboura and Nicolaidou (2001) [6], 753 benthic polychaete species have been recorded in Greek waters. Data 308 species of bivalvia [7] were used. The data were aggregated to higher taxonomic levels and correlations were made between species richness, genus and family richness. Four models (linear, polynomial of power 2, polynomial of power 3 and exponential) were fitted so as to be able to investigate the predictive power of higher order diversity on species richness. The best-fitting model was chosen on the basis of the highest correlation coefficient values. The univariate method applied was that of linear regression (Pearson and Spearman correlation coefficients). Correlations were used to relate the number of species to the number of genera and families in the two datasets.

Results and Discussion

All relationships between species, genus and family were significant for both taxa studied (P < 0.001) (Tab1).

These correlations show that it is possible to use higher taxa as a surrogate for species in surveys of richness. Cross taxon correlations of the richness at the different taxonomic levels were positive and strong (Tab 2). The analyses performed in the present study showed that generic and family levels could be used as a reasonable surrogate for species richness in eastern marine bivalvia and polychaeta. Surrogacy can be seen both as a preliminary approach, in cases when it is not possible to quickly identify all for conservation purposes, or as an end in itself, in regions where most species are unknown, or when insufficient resources are available to further pursue the identification process [8].

DIFFERENTIATING DAILY GROWTH STRATEGIES WITH STABLE ISOTOPE ANALYSIS FOR TROPHISM OF ALBORÁN SEA SARDINE LARVAE

Alberto Garcia¹, Jose M. Quintanilla¹, Raul Laiz-Carrion^{1*} and Jesus Mercado¹ ¹ Instituto Español de Oceanografia - raul.laiz@ma.ieo.es

Abstract

A combined study of Alboran Sea sardine larval growth which differentiated two different growth strategies with stable isotope analysis for trophism yielded no trophic differences between both the two populations. The faster growing larvae showed higher C:N relationship in relation to the slower growing larvae.

Keywords: Larvae, Alboran Sea, Growth, Trophic Relations

Introduction

Sardine is a key species of the neritic ecosystem off the Alboran Sea coasts, constituting its major small pelagic resource. Its economic and ecological interest has been manifest through studies focusing on early life daily growth [1] and larval condition [2]. This study intends to provide new insights in larval growth variability with stable isotope analysis.

Material and Methods

A single catch of schooling post-flexion sardine larvae was sampled to study trophic influence on daily growth variability. The larval school was sampled at night time by means of a surface Bongo 90 tow off the nearshore coasts of Málaga. Larvae were sorted on board and stored in liquid nitrogen. Sampling and laboratory procedures are described in [3]. In the laboratory, larvae were thawed, measured for standard length (SL) and dry weighed (DW) after dry freezing during 24 hours. Otolith microstructure analysis allowed estimating the daily growth of larvae as described in [3] while natural abundance of ^{15}N ($\delta^{15}N$, %) and ^{13}C ($\delta^{13}C$, %) were measured using an isotope-ratio spectrometer (Thermo-Finnigan Delta-plus) coupled to an elemental analyser (FlashEA1112 Thermo-Finnigan). The determinations were calibrated against atmospheric nitrogen and PeeDee Belemite, respectively. using acetanilide as standard.

Results and Discussion

The sardine larval school comprised exclusively post-flexion larvae ranging from 12.2-19.0 mm standard length (SL). The SL vs DW relationship of the larval cohort differentiated two relative growth relationships originating from different growth strategies, that is, a normal growing population (N) in contrast with a slower growing larval population (S) investing growth energy in gaining somatic weight rather than length (Fig. 1). Their respective LnAGE vs LnSL and LnDW relationship is significantly different. LnSL and LnDW telationship is significantly different. LnSL and LnDW the N growing population is greater than the S larvae (ANCOVA F_{1, 176}=142.8, p<0.001). δ^{15} N averaged 7.07‰ (± 0.50), indicating trophism within the phytoplankton size fraction around the 200mm threshold, while δ^{13} C averaged -17,9‰ (± 0.63). A previous study indicates that the values of δ^{15} N and δ^{13} C for the particulate organic matter fraction <200 mm, which is mainly phytoplankton in the study area during spring- is 3.71‰ (± 1.07) and 21.93‰ (± 0.58), respectively.

Fig. 1. Dry weight vs SL

The isotopic enrichment of the N from the particle pool <200 mm to sardine larvae was about 3.8‰. The relatively low nitrogen enrichment indicates that this plankton fraction constitutes the main diet of the sardine larvae. Nevertheless, the N and S populations did not show significant differences (ANOVA, p>0.05) in respect to $\delta^{15}N$ and $\delta^{13}C$, and therefore, no dietary difference. A greater gain in somatic mass with age in the S population is corroborated with a significantly greater Nitrogen percentage (N%) (ANCOVA $F_{1, 135}$ =9.7, p<0.01), while the greater growth potential of the N population is in agreement with its significantly greater Carbon percentage (C%). The Fulton index, indicative of energy storage in individuals showed significant linear increase with age in both populations (r²=0,72 and 0.92, respectively), whereby the S larvae showed significantly higher values than the N larvae (ANCOVA F1. 176=461.1, p<0.001). Lastly, the C:N relationship showed a significant decrease with age/size of both populations (Fig. 2) similar to the growth rate decline with age/size. N larvae presented a greater C:N ratio than the S larvae (ANCOVA F1 135=63.6, p<0.001) demonstrating a greater investment of the N larvae in the structural development of larvae with time rather than energy reserve components.

INFLUENCE OF ABIOTIC FACTORS IN THE BIOMASS OF DEEP WATER SHRIMPS, P. LONGIROSTRIS AND A. ANTENNATUS, OFF CATALANO-LEVANTINE MEDITERRANEAN COAST OF SPAIN

Mariano Garcia Rodriguez¹*, Angel Fernandez Gonzalez¹ and Antonio Esteban Acon¹ ¹Instituto Español de Oceanografia - mariano.garcia@md.ieo.es

Abstract

Deep-water shrimps show large inter-annual fluctuations in biomass. We analysed the influence of some abiotic factors in these fluctuations using survey data (2006-2009). While *Parapenaeus longirostris* biomass was feebly affected by the T-S of the water masses, these factors, particulary salinity, seemed to have a significant effect on *Aristeus antennatus*, a species considered to be stenothermal and stenohaline, whose biomass distribution showed a direct relationship with the Levantine Intermediate Water. *Keywords: Biomass, Decapoda, Western Mediterranean*

Introduction

The deep-water rose shrimp (*Parapenaeus longirostris*) and the red shrimp (*Aristeus antennatus*) are demersal species found on sandy and muddy bottoms in the Mediterranean Sea and South Atlantic Ocean of the Iberian Peninsula. Both species are among the most valuable resources for the trawl fishery. They show high inter-annual fluctuations in landings, despite the fishing effort applied remains almost constant, which suggests that these fluctuations do not completely dependent on fishing activities. Here we present an exploratory study of the influence of some abiotic factors in the biomass fluctuations of these two species.

Materials and Methods

Data are from the MEDITS_ES International spring trawl survey (2006-2009), performed according to a standard methodology [1]. Depth, temperature and salinity were recorded by means of a CTD SBE-37 probe located in the mouth of the gear. For each of these factors, the average of the data recorded during the effective trawl (when the gear is in contact with the bottom) was estimated for each haul and included in the analyses. Time period (2006-2009) and latitude were also considered as factors. Species biomass per haul was calculated as the catch in weight by sweep area and expressed in kg/km². G.I.S. was used to represent yearly distribution maps by kriging. Data were normalised by transforming to Ln (n+1), and the relationship between the different factors and species biomass was analysed by means of linear and multiple regressions (GLM), applying a simple model without interactions.

Results and Discussion

Analyses comprised data from 293 hauls (33-816 m depth) collected over a period of four years (2006-2009). Both salinity and temperature were highly correlated with depth, showing a gradient on both the continental shelf and the upper slope, with colder and saltier waters in depth, corresponding to the Modified Atlantic Water (MAW) and Levantine Intermediate Water (LIW) in the shelf and the slope, and to the Western Mediterranean Deep Water (WMDW) in depth, especially in the Ibiza channel. Average biomass of both species seemed to increase over the four years. Overall, P. longirostris was more abundant in Southern latitudes while A. antennatus' presence increased towards the North. P. longirostris appeared in 52 hauls comprising a depth range 370 m wide, with maximum biomass values in the 200-500 m depth interval. A. antennatus appeared in only 25 samples, showing a depth range 698 m wide, with maximum values in the 500-800 m interval. Despite both species biomass decreased with temperature and increased with salinity, we found remarkable differences between them in this sense. Thus, P. longirostris biomass appeared distributed in ranges of temperature and salinity 1.2442 C° and 0.5378 psu wide, respectively, with averages of 13.2010 C° (± 0.2383 S.D.) for temperature and 38.5191 psu (±0.1505 S.D.) for salinity. On the other hand, despite its depth range was almost two-fold wider, A. antennatus showed a narrower range for temperature (0.3135 C°)and salinity (0.0859 psu), with 13.1569 C° (±0.099 S.D.) and 38.5054 psu (±0.0242 S.D.) as averages respectively. According to these observations, full model (all factors included) explained only 21% of the variance in P. longirostris biomass, none of the factors being significant for α = 0.05. In the case of A. antennatus, full model explained 44% of the variance, with depth and salinity being significant factors. These results suggest that P. longirostris fluctuations may be due to factors different from T-S, such as recruitment strength, food availability or others. In contrast, A. antennatus biomass seems to be significantly affected by T-S of the water masses, specially salinity, which reinforces its stenothermal and stenohaline character [2] as well as its direct relationship with the LIW [2] [3].

MEDUSIVOROUS FISHES OF THE LIGURIAN SEA 2. THE SPECIALIST, SCHEDOPHILUS MEDUSOPHAGUS COCCO, 1839

Fulvio Garibaldi 1*, Lidia Orsi Relini 1 and Giulio Relini 1

¹ Università di Genova, DIP.TE.RIS., Centro di Biologia Marina del Mar Ligure - garibaldi.f@libero.it

Abstract

From 2004 onwards, several adult specimens of the cornish blackfish *Schedophilus medusophagus* were sampled in the Ligurian Sea: these fish represent first adult captures in the whole Mediterranean. The presence of the mauve stinger *Pelagia noctiluca* in the stomach contents of one specimen is described. The fish was eating a large number of entire jellyfish and showed in the caudal portion of the stomach a coloured concentrate of this food.

Keywords: Medusae, Fishes, Pelagic, Ligurian Sea

Schedophilus medusophagus was described by Cocco [1] in Sicily. The specific name was questioned by Günther [2] because "the fish could draw but little nourishment from jellyfish". Only one century later, the value of pelagic cnidarians as food for vertebrates was fully understood. Ates [3] was able to list 75 species of medusivorous fishes; 15 of them were reported to have their stomach filled solely, or for a considerable part, with jellyfish remains. Fish belonging to the family Centrolophidae are recognized as specialists in the association with jellyfish during their juvenile and young adult phases, so that the term "medusafish" was coined for them [4].

Four species are present in the Mediterranean: *Centrolophus niger* (Gmelin, 1789), *Hyperoglyphe perciformis* (Mitchill, 1818), *S. ovalis* (Cuvier, 1833) and *S. medusophagus* Cocco, 1839. The latter was recorded in Western Mediterranean [5] and Adriatic Sea [6; 7; 8], but it is still a poorly known species because most specimens collected to date are juveniles [4] and sometimes larvae. Past Mediterranean literature and iconography [9; 10], always relate to juveniles as well as the records, until the beginning of the millennium. In recent times, and especially from 2004 onwards, an important sampling of *S. medusophagus* was carried out in the Ligurian Sea. This abundance could be related to jellyfish (*Pelagia noctiluca*) blooms that occurred in the last few years in the Western Mediterranean. At the best of authors knowledge, a collection of many adult fish is unprecedented both in Mediterranean and in the adjacent Atlantic.

Fig. 1. The adult female Schedophilus medusophagus caught off Sanremo on $28^{\rm th}$ June 2006

One of these specimens, a female, 64 cm TL, caught off Sanremo on 28th June 2006 (Fig. 1), gave the opportunity to observe the stomach content consisting solely of *P. noctiluca*, for a total volume of 400cc (Fig. 2).

The cephalic portion of the stomach showed several complete individuals of *P. noctiluca* (umbrellas plus manubrium with oral arms). An ink-like liquid completely filled the caudal part of the stomach, showing evidences that, during the digestion, the pigments of *P. noctiluca* are transformed into a violet fluid that colours the entire gut.

Fig. 2. Stomach content of the adult *S. medusophagus* from the Ligurian Sea, showing entire undigested *P. noctiluca* specimens and product of digestion (black spot at the bottom of the picture)

ON THE REPRODUCTION OF *ACANTHEPHYRA EXIMIA* S. I. SMITH, 1884 IN THE CENTRAL WESTERN MEDITERRANEAN

Alice Gastoni¹*, Ivan Locci¹, Antonello Mulas¹ and Maria cristina Follesa¹ ¹ Department of Animal Biology and Ecology – University of Cagliari - gastoni@unica.it

Abstract

Macroscopic and histological analysis were performed on the female gonads of *Acanthephyra eximia*. The macroscopic observation regarding the changes of the ovaries leads us to identify six stages of development, validated by histological analysis. *Keywords: Decapoda, Western Mediterranean, Reproduction*

Introduction

Acanthephyra eximia S. I. Smith, 1884 is a cosmopolitan nektobenthic species, common in waters below 1000 m [1, 2], where it represents the most abundant decapod of the lower-slope communities [3]. Nevertheless, the current knowledge on its biology, especially on the reproductive cycle, is scanty. Aim of this work is to provide some information concerning the reproductive pattern of this species.

Materials and Methods

Samples of *A. eximia* were collected from experimental trawl surveys carried out between 580 and 1598 m in the Sardinian waters from 2003 to 2009. Carapace length (CL, in mm), total and ovarian weight (TW, OW in grams) for each specimen were registered. The determination of stage's development maturity was performed using macroscopic descriptions validated by histological examinations. Preparation of ovarian tissues for microscopic analysis, performed following Dominici's method [4], included fixation, sectioning, oven drying and staining.

Results and Discussion

We analysed 478 females of *A. eximia*, the carapace length ranged from 8.2 to 38.0 mm CL, with a mean \pm SD of about 27.0 \pm 4.6. The range size of females carrying eggs was 22.1 - 35.4 mm CL. The smallest and the biggest spermatophores-bearing specimens measured 25.8 and 35.4 mm CL respectively. During the analysis, six developmental stages changing shape, dimension and colour, were identified (Tab.1).

Tab. 1. Developmental stages scale proposed for Acanthephyra eximia caught in the Sardinian sea

Stage	Macroscopical description
I, Immature	Ovaries thin and whitish. Eggs not visible
II, Developing	Ovaries yellow in colour, growing. Eggs start to be visible
IIIa, Maturing	Ovaries turgid and pale-orange in colour. Eggs achieving greater dimensions
IIIb, Pre-spawning	Ovaries bright-orange in colour and swollen in the cephalotoracic region
IV, Spawning	Ovaries vivid red in colour. Eggs ready for spawning
V, Post-spawning	Ovaries flaccid, thin and trasparent
Stage	Hystological description
I, Immature	Oogonia and primary oocytes in the germinative zone. Follicular cells appear
II, Developing	Lipidic vesicles oocytes appear, primary vitellogenesis starts (oocytes Y1)
IIIa, Maturing	Secondary vitellogenesis starts (oocytes Y2). Follicular cells flatten
IIIb, Pre-spawning	Tertiary vitellogenesis starts (oocytes Y3). Nucleus disappearing
IV, Spawning	Ovary entirely filled with oocytes. Nucleus disappears
V, Post-spawning	Empty follicles and atresic oocytes undergoing phagocytosis

In the present study, a complete macroscopic and histological description of the various maturity stages has been performed. During monthly samplings, carried out throughout the year (except in April, October and December), we observed a regular occurrence of females with different developmental ovarian stages. In particular mature females (stage IV) were found in March and September (28 out of 290 and 1 out of 65, respectively) (Fig. 1).

Fig. 1. Annual trend in percentage occurrence of different maturity stages of females of *Acanthephyra eximia* caught in the Sardinian sea

Eggs are carried in a big clutch among the pleopods, their colour matches with the pleon, likely a sort of camouflage, as observed for other middle-slope decapod crustaceans [5].

Abstract

Le suivi des réserves énergétiques de l'anguille européenne, acclimatée en eau douce et en eau de mer pendant un mois, au niveau des organes osmorégulateurs (branchies, œsophage, intestin et rein) montre que ce poisson utilise, probablement, le glycogène comme principale source énergétique.

Keywords: Fishes, Physiology, Salinity

Introduction

L'anguille européenne est une espèce très euryhaline. Comme tout poisson qui s'adapte aux différentes salinités du milieu, son osmorégulation suggère une variation dans sa demande énergétique. L'objectif de ce travail est d'étudier les réserves énergétiques (glycogène, lipides et protéines) au niveau des organes osmorégulateurs (branchies, œsophage, intestin et rein) chez l'anguille jaune *Anguilla* acclimatée en eau douce et en eau de mer.

Matériel et méthodes

L'anguille européenne est pêchée dans le lac de Tunis dont la salinité est de 21 ‰. Deux lots d'anguilles jaunes (*c.à.d* immatures) ont été acclimatés à deux salinités différentes : 0,5 ‰ et 35 ‰. Au bout de quatre semaines, une série de 8 individus sont sacrifiés de chaque lot et pour chaque analyse biochimique. Après anesthésie, les poissons sont disséqués et les organes osmorégulateurs : branchies, œsophage, intestin et rein sont conservés à -30°C pour être analysés. Les protéines sont dosées selon la méthode de Lowry [1]. Le glycogène est isolé, hydrolysé puis dosé sous forme de glucose par une méthode enzymatique en présence de glucose oxydase. Les lipides totaux sont quantifiés après extraction [2].

Les résultats sont analysés statistiquement par ANOVA en appliquant le test de Tukey. La différence statistique est considérée significative à p<0,05 (*) et hautement significative à p<0,01(**).

Résultats et discussion

Le tableau 1 montre la variation de la teneur en protéines, en glycogène et en lipides totaux au niveau des organes osmorégulateurs de l'anguille acclimatée en eau douce et en eau de mer. Les branchies sont probablement le principal organe osmorégulateur puisqu'elles sont en contact direct avec le milieu extérieur. La comparaison de la composition biochimique de cet organe en eau douce et en eau de mer montre qu'il y a une différence significative (p=0,0002) de la teneur en glycogène qui est plus importante en eau de mer. Il n'y a pas de différence significative de la teneur en protéines ni en lipides dans cette comparaison.

Le suivi des réserves énergétiques au niveau de l'œsophage de l'anguille jaune montre que le taux de glycogène est significativement plus élevé (p=0,0002) chez les poissons d'eau douce par rapport à ceux acclimatés en eau de mer. On peut déduire qu'il y a eu probablement consommation de cette réserve dans le milieu hyperhalin.

Pour l'intestin et en eau douce, nous remarquons une diminution significative de la teneur en protéines et de la teneur en glycogène.

Au niveau du rein, nos résultats ne montrent aucune différence significative pour les réserves énergétiques de l'anguille jaune acclimatée en eau douce et en eau de mer.

En conclusion nous pouvons déduire que, probablement, au niveau de ces organes osmorégulateurs, l'anguille, poisson particulier, utilise principalement le glycogène comme source énergétique, bien que chez d'autres poissons, en l'absence de glucides alimentaires, ce sont les protéines et les lipides qui sont rapidement et efficacement métabolisés afin de fournir l'énergie nécessaire à la couverture des besoins de l'organisme [3].

Abstract

Alien benthic species in the Straits of Messina have been monitored since 2001 and consequently reviewed. Established molluscs and crustacean decapods accounted for nine and two species respectively, all of Indo-Pacific origin, except for one decapod that has spread from the Atlantic region. The records of five mollusc and two decapod species were considered as "casual". *Keywords: Biodiversity, Biogeography, Species Introduction, Strait Of Messina*

Introduction

The effects of global warming and/or anthropogenic pressure on bioinvasion processes are emphasized in the Mediterranean, as a regional, highly anthropized sea which joins the Atlantic and Indo-Pacific regions [1]. Within the Mediterranean Sea, the Straits of Messina connects the western and eastern basins, thus representing a crossing node of migratory routes and human activities, favouring the spread of introduced species. In this paper original data on the occurrence of benthic alien species in the Strait is reported and examined in relation to their establishment.

Materials and methods

In order to detect the presence of alien species, quantitative samplings and specimen collections have been carried out in coastal (0-50m) and transitional waters (Capo Peloro lakes, Saline Ioniche harbour and salts) since April 2001 [2].

Result and Discussion

According to Zenetos et al.'s [3] criteria, 9 mollusc and 2 decapod established species have been identified: the lessepsian Brachidontes pharaonis (Fisher P., 1870), known in this area since 1974 [4]: Bursatella leachi De Blainvile, 1817 and Melibe fimbriata Alder & Hancock, 1864, both common locally since 2000; Pinctada radiata (Leach, 1814), sporadically recorded during 2000-2001 and regularly found since 2007; Aplysia dactylomela Rang, 1828, since 2008; Cerithium scabridum Philippi, 1848, since 2007, in all transitional waters; the Indo-Pacific Crassostrea gigas (Thunberg, 1793) and Ruditapes philippinarum (Adams & Reeve, 1850), that have been imported from the northern Adriatic to aquaculture farming since 1970 and 1980 respectively, together with Anadara demiri (Piani1981) (first recorded in 2007); Marsupenaeus japonicus (Bate, 1888), that arrived by natural dispersal; the Atlantic Percnon gibbesi (H. Milne Edwards, 1853), the only species which showed an invasive behaviour in the Strait, found since 2006. The arrival of other 5 "casual" species was related to the mussel and oyster trade. One specimen of the Indo-Pacific Rapana venosa (Valenciennes, 1846) was recorded in the Peloro coastal lakes in September 2008; the other species, although reported since 1982 [5], has never colonized this area, despite their regular introduction together with stalling shellfish; these species are the Indo-Pacific Anadara inaequivalvis (Bruguière, 1789), and the Atlantic Littorina littorea (L., 1758), Crepidula fornicata, (L., 1758) and Nucella lapillus (L., 1758). Finally, the occasional occurrence of the lessepsian Portunus pelagicus (L., 1758) and of the Atlantic P. hastatus (L., 1767)in coastal waters has been noted.

Conclusion

A prevalent Indo-Pacific origin, compared to the warm-temperate Atlantic one, connotes the established alien species in the Straits of Messina, whilst no western European species has thrived to date. Mollusc farming determined a remarkable colonization of transitional waters, whilst the coastal environment was colonised by introduced species which spread their Mediterranean areal northwards.

DESIGNING A NETWORK OF MARINE RESERVES SUBJECTED TO DIFFERENT HUMAN CONSTRAINTS: THE CYCLADES ARCHIPELAGO CASE STUDY

Sylvaine Giakoumi^{1*}, Hedley Grantham², Giorgos D. Kokkoris¹ and Hugh P. Possingham²

¹ University of the Aegean, Department of Marine Sciences, 81100 Mytilene, Lesvos island, Greece - sylvaine@marine.aegean.gr ² University of Queensland, The Ecology Centre, St. Lucia, Queensland 4072, Australia

Abstract

Best practice dictates that the design of networks of marine reserves follows the principles of systematic conservation planning which includes information about cost of making a reserve. Our study, which has taken place in the Cyclades archipelago (Greece), aims at detecting the sensitivity of reserve network configuration with respect to different ways of calculating cost. We discovered that the choice of priority areas for protection is greatly influenced by the cost definition and components. *Keywords: Cyclades Islands, Eastern Mediterranean, Marine Parks, Coastal Waters*

Worldwide, marine reserves have been increasingly used as management and conservation tools for the protection of marine ecosystems from rapid and radical degradation. Marine reserves cover only the 0.01% of the total surface of the Mediterranean Sea [1]. At the same time, most marine protected areas in the region have been established in an *ad hoc* way with little or no scientific information [2]. Systematic conservation planning provides an efficient and transparent approach, guiding the location, configuration and management of socioeconomic costs [4].

Our study area covers the coastal area of 26 Kyklades islands in the Central Aegean Sea, North – Eastern Mediterranean Sea. Our conservation objectives are to protect: a) enough critical habitats for endangered and vulnerable species b) places with higher fish biomass to replenish adjacent areas. To identify priority areas for conservation we used the latest version of Marxan [5]. This software aims at achieving explicitly a set of conservation targets while minimizing the cost and the boundary length of the reserve system. Our aim was to create a reserve system from amongst 223 planning units. Each contains a stretch of the coastline and extents 1 km into the sea. We set high targets (50%) for priority habitats and species (*Posidonia oceanica, Cystoseira* spp., breeding caves for the Mediterranean monk seal *Monachus monachus*) and lower targets for other conservation features (abundance of 60 fish species and other habitat types). We produced 3 different scenarios considering different cost aspects: 1. fishing pressure and exposure to prevailing winds, 3. fishing

As we expected, the priority areas, which should be included in a network of marine reserves, vary according to different ways of including cost in the analysis (fig.1 & 2). In this study, we incorporate, for the first time in the relevant literature, the level of physical exposure to the cost of our planning units. We consider that planning units with high levels of wind and wave exposure have less opportunity cost regarding competitive uses of the coastal area (coastal fisheries, tourism).The results of our study are consistent with the current literature; all available information that affects the distribution of economic activities in a region should be included in marine conservation planning.

Fig. 2. Priority areas for cost scenario 2: fishing pressure and wind exposure and scenario 3: same as second scenario but reduced by tourism benefits

Abstract

The occurrence of two females of *Ocythoe tuberculata* Rafinesque, 1814, during June 2006 and April 2009, in the Strait of Messina (Central Mediterranean) is reported. *O. tuberculata* is a pelagic octopod species rarely reported in the Mediterranean Sea. *Keywords: Cephalopods, Strait Of Messina*

O. tuberculata is known to be cosmopolitan in tropical and temperate seas ([1], [2]).It was reported along the Mediterranean ([3],[4]), in the Greek waters [5], in the Catalanas coasts [6], and in the Sicilian Channel [7]. It has been reported off the Azores and Canary archipelagos and in Peruvian waters [8], in the west of Portugal and north-west of Spain [9]. Few informations are available about the biology and behaviour of this species. It shows a strong sexual dimorphism with males that are usually smaller than 3 cm in mantle length while females are larger with a maximum mantle length reported of 3,5 cm [10]. Females of *Ocythoe* are one of the few known cephalopods with a true swimbladder and the only known cephalopods that are ovoviviparous.

An interesting feature of the species is the mode of locomotion that occurs through the enormous funnel, considered one of the greatest of cephalopods, and the powerful cloak which provide great strength in the expulsion of water from the palleale cavity. The two specimens were caught at few metres by the falcate zone of S. Raineri (Strait of Messina): one of the two specimens was caught inside a group of Salps. The main morphological data of the two specimens are recorded and reported. The female caught in June 2006 was sexually mature, with a total length of 410 mm, total weight of 320 g, mantle length of 225 mm, mantle perimeter of 240 mm, mantle wide of 100 mm, eye diameter of 18 mm and funnel length of 44 mm. The female caught in April 2009 were a juvenile with a weight of 82,4 g, total length of 231 mm, mantle length of 84 mm, mantle perimeter of 148 mm, mantle wide of 55 mm, eye diameter of 17mm and funnel length of 35 mm. The presence of O. tubercolata in the Straits of Messina is probably in relation to the hydrodynamics phenomena of the Straits. The main characteristics of the Messina Straits are the strongest tidal currents reaching 300 cm/s or more, with the addition of other effects (wind for example). Strong turbulence is present mainly nearby the northern mouth, but in the whole Straits the currents are turbulent, with large internal waves. In fact other pelagic cephalopods as Thysanoteuthys rhombus were caught in the same area.

Fig. 1. Female of O. tuberculata caught in April 2009

RE-APPEARANCE OF *CAULERPA SCALPELLIFORMIS* (R. BROWN EX TURNER) C.AG. WEBER VAN BOSSE (CAULERPACEAE, CAULERPALES) IN THE GULF OF ANTALYA, TURKEY

Mehmet Gökoglu ¹*, Beylem Banbul Acar ¹ and Halil Çolak ¹ ¹ Akdeniz University, Faculty of Fisheries - gokoglu@akdeniz.edu.tr

Abstract

Caulerpa scalpelliformis is an alien species for Turkish coastline. Its first record was reported in 1995 from the Gulf of Antalya. At that time it was not considered as a serious thread for Antalya coastlines due to its disappearance from observed areas. However, it's more distribution and re-appearance in the same area was observed in summer 2009. The present study provides new and more data related to *Caulerpa scalpelliformis* invasion in the Gulf of Antalya-Turkey in 2009. *Keywords: Alien species, Eastern Mediterranean, Phytobenthos*

Introduction

The first record of *Caulerpa scalpelliformis* (Brown ex Turner) C. Agardh 1817 from Turkey coastline was reported from Antalya Marina in summer 1995 [1]. Subsequently, presence of this species at the same area was investigated by Aysel et.al. (2002). In that study, it was also found locally out of the Marina [2]. *C. scalpelliformis* is orginated from tropical waters of Syria, Israel, Lebanon, Palestine and Egypt in the Mediterranean [3]. Its indo-Pacific distribution [4][5] in the Indian Ocean are reported in Aldabra Islands, Australia, India, Kenya, Madagascar, Mauritius, Mozambique, Oman, Pakistan, South-Africa, Sri Lanka, Tanzania and Yemen [2]. Local announcement of *C. scalpelliformis* from out of the Antalya Marina supports the belief that this species is transported by means of the ships or their hoes. This green algae species has only been reported from the coasts of Turkey, however there is no study except two papers. Therefore, event of *C. scalpelliformis* is not known until yet. The purposes of this study is to determine distribution of *C. scalpelliformis* and its ecological parameters.

Materials and Methods

Distribution of *Caulerpa scalpelliformis* in the Gulf of Antalya was investigated by SCUBA dives. Two SCUBA equipments were used for dives. Depth and temperature of the water were measured using the underwater computer (Suunto Stinger). Skimmer net with 5 mm mesh size was used to collect the samples; SONY Cyber-Shot 40 m/132 ft marine pack housing and SONY DSC-T9 6.0 mega pixels camera were used to record the underwater movies and pictures. Many dives were conducted between the depths 0-40 m from Side (36°46'22."N,31°23'21."E) to Çirali (31°24'56."N,30°29'08."E) in the Gulf of Antalya.

Results

Caulerpa scalpelliformis was found exclusively in the areas between Antalya Marina (36°53'01"N, 30°42'02"E) and Antalya Great Harbour (36°50'16"N, 30°37'05"E). Species has covering and spreadable characteristics. The lowest water depth recorded for the species was 15 m outside the Yacht Harbour. Distribution of the species in the other area (Konyaalti beachs) ranged from 15 to 30 m depth. Species was not found on rocky bottoms. It was determined that C. scalpelliformis was available on the gravelly, sandy, slimy and gravelly-sludgy bottoms. However it was abundant on gravelly-sludgy and silty compact bottoms and frequently found at 2-10 m intervals. It has been also determined that stolons were aggregated in the area of 1-10 m², but the encounter frequency of C. scalpelliformis was decreased to 20-50 m on the sandy bottoms (Antalya Great Harbour). Aggregation on the sandy bottoms occurs with accumulation of a few stolons in 1-2 m². Species on sandy bottoms has poor vegetation and underdeveloped fronds. The peak vegetation was observed in the period of May-June. Deaths of the stolones of C. scalpelliformis were observed in July with increase in water temperature (26.5-27°C). In August at 28-30°C, the species completely died in certain areas while disappearance of 50% of stolons was observed at some areas. Distribution of the species was maximum at a depth of 20-22 m. Abundance of Udotea petiolata at the same depth is remarkable.

Discussion

The first record for *Caulerpa scalpelliformis* from the coasts of Turkey has been reported by Ertan et al. (1998). In that study this species has been found in the entrance of Antalya Marina. Ertan et al. (1998) collected the samples from though substrate at 0.5-2m between August and September at the same area in the period which water temperature declined and reported disappearance of the species. Reduction of water temperature has been shown as a possible reason of this situation and it was considered that the species was temporarily detected [1]. Similar results have been reported by Aysel et al. (2002). Disappearance of C. scalpelliformis has been associated with water pollution by these researchers [2]. Notification for record of this species from entrance of a harbour for the coasts of Turkey supports the possibility of transportation by bottom and anchors of vessels. In the present study this species was detected on rockless substrate at 15 m. It demonstrates that the species is still available in this area. The species was found not only in entrance of the marina but also distributed around the Great Harbour. Therefore it can be marked that it is a spreading species. In the present study it was determined that the species died in July at 26.5-27°C. It is estimated that the reason of detection of this species in February and March in Konyaalti Beaches is due to increasing of water temperature. Caulerpa scalpelliformis was not detected in more than 15 m depth along the coast of 7 km between Marina and Great Harbour. Presence of this species in shallow waters may be arisen from increase of water temperature (30-31°C) in the coast and movement of coast sediment by waves. The reasons of aggregation and poor growing in the region until Great Harbour are sandy bottom structure of the Gulf, movements in benthic by wave and difficulty in cling of organism onto the sediment. It is occured that the species spreads towards the west from first recorded area because of the currents. It indicates that the species may spread from Antalya to Kemer after this time. Although C. scalpelliformis has unfairable properties like coverable and cytotoxicity, it possesses the good developed rhizomes to avoid the underwater erosion. Monitoring of this species will provide the elaborate data about C. scalpelliformis.

Abstract

Preliminary results of distribution and abundance of anchovy (*Engraulis encrasicolus*) and sardine (*Sardina pilchardus*) eggs and larvae in the northern Aegean Sea was studied during the period of August 23-29, 2008. The spawning areas for anchovy are located in the northern coast of Foca (Izmir), Edremit Bay, and the area between the Saroz Bay and the north of Gökceada Island. Anchovy eggs and larvae were mainly distributed over the continental shelf. Few sardine eggs and larvae were collected. *Keywords: Ichthyoplankton, Larvae, Pelagic, Aegean Sea, Fishes*

Introduction

Due to the rich nutrient content of the northern Aegean Sea which is becoming seawater rich with nutrients from the Black Sea and the Sea of Marmara, many rivers bringing $1000 \text{ m}^3/\text{s}$ of fresh water flow into this part of the Aegean Sea [1]. This area is an important fishing ground for sardines, anchovy, chub and Atlantic mackerel. 62.5% of the sardines (13 088 t) and 2.2% of the anchovy (8390 t) catch in Turkish waters comes from the Aegean Sea [2].

Ichthyoplankton-based methods are increasingly being used around the world to estimate the biomass of fish stocks and monitor trends in fish abundance [3]. Ichthyoplankton researches conducted in the Turkish waters of the Aegean Sea are concentrated in Izmir Bay (central Aegean Sea). The aim of this paper is to give the results of ichthyoplankton research on the distribution and abundance of the anchovy and sardine eggs and larvae in the northern Aegean Sea.

Material and Methods

The samples were collected during an ichthyoplankton cruise onboard the R/V Yunus S in August 2008 in the northern Aegean Sea. A total of 13 sub-surface plankton horizontal tows with a Bongo net of 60 cm inlet diameter equipped with 250 μ m mesh for oblique tows. The net was geared with general oceanic flowmeter for filtered volume estimates. All tows were fixed at 10 minutes duration. In each of the stations covered, a CTD (Seabird19+) was cast. All samples were preserved in 5% formaldehyde solution buffered with sodium borate.

In the laboratory all egg and larvae were removed, identified to the lowest possible taxon, counted and measured (diameter for eggs and standard length for larvae). The absolute number of eggs and larvae per haul was recorded and the relative number per 100 m³ filtered water was calculated.

Results and Discussion

Survey area surface seawater ranged from 20.0 to 26.0° C, salinity from 34.7 to 39.4 psu, oxygen from 3.59 to 6.88 mg/l, and bathymetry from 40 to 330 m.

Anchovy eggs were found in three areas; namely in the northern coast of Foca (Izmir), Edremit Bay, and the area between the Saroz Bay and the north of Gökceada Island (Fig.1). Throughout the entire study area they were mainly located at the shelf (≤ 100 m). Maximum egg abundance of 324 eggs/100 m³ was recorded. The longitudinal diameter of the eggs varied between 0.91 and 1.32 mm, and the transverse diameter between 0.48 and 0.57 mm. Peak larval abundance was 125 larvae/100 m³ and the size ranged from 2.50 to 9.02 mm SL. Eggs were more abundant than larvae. This is in agreement with existing knowledge of the reproductive period of this species which occurs from April to September with peaks usually in the warmest months [4].

Few sardine eggs and larvae were collected on this cruise (Fig.2). Maximum egg abundance of 14 eggs/100 m³ was recorded. The diameter of the eggs varied between 0.67 and 1.13 mm. The length of the sardine larvae was 4.88 - 7.10 mm SL.

In a research conducted in the northern Aegean Sea (Greek waters), anchovy larvae were highly abundant in June 1996 [5]. According to our results, in the northern Aegean Sea (Turkish waters), anchovy egg and larvae were highly abundant in August 2008. The restriction of the Turkish Ministry of Agriculture and Rural Affairs of fish catch by purse seiners in the summer period (between 15 April and 1 September) is an appropriate regulation for the protection of the anchovy population. In the Mediterranean Sea, the anchovy is caught also by other nations. Therefore, a common fishing legislation should jointly be regulated with other fishing partners.

Abstract

In 2002 CIESM published the first in its series of Atlases of Exotic Species in the Mediterranean, first on Fishes and on Decapods, then two years later on Molluscs. The Atlases provide user-friendly access to detailed and authoritative information on Mediterranean biodiversity to both amateurs and experts and raise the level of awareness of these important issues. A survey of electronic databases has revealed that the CIESM Atlas of Exotic Species: Fishes has been cited by close to 200 scientific articles. *Keywords: Alien species, Fishes, Eastern Mediterranean, Western Mediterranean*

In 2002 CIESM published the first in its series of Atlases of Exotic Species in the Mediterranean, first on Fishes and on Decapods, then two years later on Molluscs.

Whereas the original and main goal was to document the existing situation concerning the dynamics of biodiversity in the Mediterranean, in light of ongoing changes, the very fact of the publication of the Atlases, and of the online Atlases via the CIESM website in the Internet, raised the level of awareness of these issues to the public. The Atlas provides user-friendly access to detailed information on Mediterranean biodiversity to both amateurs and experts.

Since the publication of the CIESM Atlases, there has been a notable increase in the number of exotic species in the Mediterranean, in all three taxa, but especially in molluscs. This dramatic increase may be attributed to the significant augmentation of collection activity, both by scientists and by amateur naturalists. In addition, most molluscs have hard shells which remain after their death, thus allowing detection of abortive colonization attempts; this is not possible concerning other taxa.

However, concerning fishes, there are other means of detecting the presence of exotic fish species in the Mediterranean. The fishery industries and fishermen, both commercial and amateurs, assist in the recognition of the arrival of species previously unknown in their new distribution areas. Furthermore, the quantitative biology and ecology of many fish species are well known, which is conducive to monitoring of the number and distribution of exotic fish species.

The Atlas of Exotic Species: Fishes [1] has become a known and leading authoritative baseline for researchers and others searching for accurate and updated information on the dispersal and distribution of exotic fish species in the Mediterranean Sea. A survey of electronic databases has revealed that the Atlas of Fishes has been cited by no less than 197 scientific articles. We the authors and members of the CIESM Fish Group estimate that the actual or local interest and distribution may not necessarily be indexed by the standard databases and most popular online search engines.

The number of known citations of the Atlas has risen from 3 in the first year of its publication, 2002, to at least 45 in 2009. The citing publications have first authors from many nationalities, from no less than 23 different countries; the country with the most citations of the Atlas is Italy (with 38), then Greece (31), Israel (28), Tunisia (20) and Turkey (17).

In the future, the CIESM Atlas of Exotic Species, in its online format on the CIESM website, can continue to inform the scientific and general community of the presence of new exotic species that may constitute a threat to the health and safety of the public. For example, there are exotic fish species that are poisonous, such as *Lagocephalus sceleratus*, the Elongated Pufferfish [2, 3] or venomous, such as *Plotosus lineatus*, the Eel Catfish [4]. It is hereby suggested that the CIESM website add a page of recent scientific publications, including grey literature, on invasive species in the Mediterranean.

A CONTRIBUTION ON THE DISTRIBUTION OF THE GIANT RED SHRIMP ARISTAEOMORPHA FOLIACEA (RISSO, 1827) ALONG THE AEGEAN SEA AND MEDITERRANEAN PART OF TURKEY

Onur Gönülal¹*, Tahir Özcan² and Tuncer Katagan³

³ Department of Marine Biology, Fisheries Faculty, Ege University

Abstract

The aim of this study is to provide information on the distribution of *Aristeomorpha foliacea* in the Aegean Sea and Mediterranean coast of Turkey. Samples were collected during surveys at various stations in South Aegean and North-East Mediterranean Sea from 2005 - 2008.

Keywords: Decapoda, Deep Waters, Aegean Sea, Eastern Mediterranean

The giant red shrimp is a commercially important, valuable species for deep water fisheries in Turkish coasts. It is heavily exploited in Western Mediterranean, and is currently fished in the Central Mediterranean; its stocks are pristine in the Eastern Mediterranean [1]. *A. foliacea* is more common than *A. antennatus* in the Eastern Mediterranean [2]. The species was rarely recorded in the Eastern Mediterranean while in The Aegean Sea, it appears in a few reports. Biological surveys were carried out in Marmaris 650 m (one male; 2005), Mersin Bay (20 male; 15 female; 2008) and Iskenderun Bay (103 male; 125 female; 2005); the species was also collected from the north of Ikaria Island (29 male, 43 female, 480 m, 2007), (Fig. 1).

Fig. 1. Sampling areas along the Turkish coast

In some areas of the Aegean Sea their exploitation has recently started. The mean biomass indices recorded at the Mediterranean basin showed that *A. foliacea* was least abundant in the Aegean Sea [3]. A total of 336 specimens of *A. foliacea* were measured and sexed throughout the sampling area (Table 1). A prevalence of females can be generally observed, representing 55% of the sampled total, except for the Mersin Bay, where only 42% out of all individuals were females.

Tab. 1. Minumum, maximum and mean Carapace length (mm) and weight (g) for male and female in The sampling areas

Geographic	Significant (n<0.05)	Carapace Length (mm)				Weight (g)			
Area	Significant (p<0.05)	Sex	Min	Max	Mean	Sex	Min	Max	Mean
Morsin Bay	North of Ikaria island (0,001)	03	27,7	53	41,7	°?	9	16,9	13
Wershi'l Day	lskenderun Bay (0,760)	9	38,8	48,1	44,2	9	11	17	13,9
lskenderun	Mersin Bay (0,760)	103	24	49	35,7	O_3	6,6	29,7	19
Вау	North of Ikaria island (0,000)	9	33	67	54	9	13,9	71,2	41,1
North of	Mersin Bay (0,001)	0_3	24,3	49,6	32,3	0 ³	8,1	27,2	15,3
lkaria island	lskenderun Bay (0.000)	2	32,4	48,5	41,1	2	11,2	38,8	22,5

Anova tests and Tukey test were used to compare the differences in the average carapace length for each geographic area; the median value of carapace length for A. foliacea differs significantly between North of Ikaria island (Aegean Sea) and Iskenderun Bay (Eastern Mediterranean) (Table 1). The differences in size may be attributed to one or more factors: the effects of different areas such as abiotic factors, fishing depth and fishing pressure. Sizes of giant red shrimp in deeper areas was relatively larger compared to the shallow depth zone [4]. For its

population at commercial fishing depths (usually from 400 to 600 m) in Iskenderun Bay (Eastern Mediterranean), the total CPUE ranged from 0.94 kg/hr to 8 kg/hr, and the mean CPUE (\pm SD) and its variation coefficient were calculated as 4.76 \pm 2.41 and 50.73% respectively; the ratios of giant red shrimp in the total catch and in the total shrimp catch were calculated as 22.45% and 64.61% respectively [5]. According to these data, it can actually be concluded that variability, both in the yields and in the sizes, appears particulary high for the species. These facts need to be more studied in order to clarify the causes that induce these differences.

Abstract

A study of the near-shore fauna (to 40 m depth) in the eastern Mediterranean has revealed the domination of the fish fauna by Erythrean aliens in the south-east Levantine Sea. The number of alien species and their relative abundance decline with increasing distance from the Suez Canal. Some of the recently arrived species have established large populations and comprise a significant component of the Levantine marine biota.

Keywords: Levantine Basin, Fishes, Biodiversity, Alien species

The continuous invasion of biota into the Mediterranean through the Suez Canal (Erythrean invasion; Galil, 2008) and the recent rise in sea water temperature (European Environment Agency, 2007), have accelerated the expansion of Indo-Pacific fishes in the eastern Mediterranean. A study of the soft-bottom, shallow-water fish fauna (to 40 m depth) conducted in the south-eastern Levantine Sea (Ashdod, Israel) and along the northern Levantine Sea (Iskenderun Bay, Antalya, Turkey) compares the Erythrean alien fish fauna at the three sites. The preliminary results, based on examination of more than 250,000 specimens, have shown a domination of the fish fauna by Erythrean aliens along the south-east Levantine Sea, and a decline in their numbers with their increasing distance from the mouth of Suez Canal (Fig. 1). The proportions of alien species, (individuals and biomass) decrease between Israel, Iskenderun, and Antalya, whereas the average fish size increase: the smallest specimens were found in Ashdod and the largest in Antalya. A comparison of the fish communities at depths of 9-20, 20 and 40 m at Ashdod, revealed a depth gradient in the dominance of the alien species. In the shallower water the alien species comprise ca. 80% of the biomass and ca. 90% of individuals; at a depth of 20 m ca. 60% of the biomass and ca. 70% of individuals; and at 40 m the alien species comprise ca. 40% of the biomass and ca. 25% of individuals. The most abundant alien species (comprising over 5% of the total catch: biomass or/and individuals) are Decapterus russelli (Rüppell, 1830), Nemipterus randalli Russell, 1986, Plotosus lineatus (Thunberg, 1787), Apogon smithi (Kotthaus, 1970), Lagocephalus suezensis Clark & Gohar, 1953, Saurida undosquamis macrolepis (Richardson, 1848), and Callionymus filamentosus Valenciennes, 1837. The first four species have been recorded in the Mediterranean only in the past decade. Seasonal changes in abundance of the alien species were detected during the 18 months of the study. Their abundance were low during spring and early summer, and peaked during November and December. However, a comparison between the early stages of the study (spring and summer 2008) and the same months in the second year of the study reveals an increase in the proportion of aliens and significant changes in the proportions of the various species.

Fig. 1. A comparison of the number of Erythrean alien species, individuals and biomass at three sites in the Eastern Mediterranean.

Abstract

Zooplankton is a key link between primary producers and larger predators and most zooplankton population changes can be attributed to environmental causes. Multi-year zooplankton time series provide an important tool for examining climate-ecosystem interactions. The CIESM Zooplankton Indicators program developed comparative studies of bio-geographical variations across the sea basins through international co-operation and through the constitution of networks of institutes and experts. *Keywords: Zooplankton , Biogeography, Time Series, Sampling Methods, Global Change*

Mediterranean Sea is oligotrophic with low fisheries production, similar to the subtropical part of the North Atlantic; nevertheless the extraordinarily rich variety of singularities driving ocean life and biogeochemical dynamics of this enclosed sea makes more critical its sustainable use by the surrounding human populations. The North Atlantic encompasses several highly productive sea areas around its continental shelf margins that provide work and living to local communities. While there are important differences between these two ecosystems, they also share several common features and belong to the same ecosystem type or biome as defined by Longhurst (1998, The Ecological geography of the Sea), given that the greatest number of species in the Mediterranean Sea are of Atlantic origin.

Fig. 1. World map long-term series of zooplankton from COPEPOD's analytical and data processing www.st.nmfs.noaa.gov/plankton. In green, the Mediterranean series, structured through the CIESM Zooplankton Indicators Program.

Both areas have a strong history of plankton research. In the Mediterranean and the Black Sea, the Mediterranean Science Commission's (CIESM) Zooplankton Indicators Program supports a network of marine researchers from 23 member states, applying the latest scientific tools to better understand, monitor and protect their fast changing and highly impacted sea areas. In the North Atlantic, The ICES Working Group on Zooplankton Ecology (WGZE), reviews sampling and analysis technologies, and monitors zooplankton sampling activities. In the framework of their activities both groups developed interactions with the aim to mutually enrich the marine zooplankton research activities (fig. 1).

The terms of reference of this collaboration were:

a) review and consider comparison of zooplankton ecology of the Mediterranean and the North Atlantic, with emphasis on common species and size structure using common numerical methods;

b) review and consider overview of on-going time-series programmes;
c) review and consider harmonization of methods, overview of experimental work;

The web page (http://www.wkzem.net/), hosted at the NOAA-NMFS, Science and Technology gives detailed information on the activity undertaken in a form of a workshop organized in Heraklion, Crete, in October 2008. The zooplankton time series results are expressed in a consistent form (see fig. 2 and the site address in the legend of fig 1).

Fig. 2. Standard analysis plots (distrograms, histograms, means and anomalies) of the Villefranche Point B dataset consists of more than 30 years of samples collected off Villefranche at 43°41 N 07°19 E. Samples were collected by a vertical tow from bottom to surface (75-0 m), using a Juday-Bogorov net (330 μ m mesh). Copepod abundance was counted from ongoing and historical samples using the wet-bed image scanning technique of ZooScan (Gorsky et al., in press). Copepod abundance was highest during the well-mixed winter period, followed by a general decline, with rising water temperatures and increasing stratification.

The different activities undertaken in the framework of the CIESM program on Zooplankton Indicators and the main achievements will be presented.

NUMERICAL SIMULATIONS OF SMALL PELAGIC FISHES EGGS AND LARVAE IN THE ADRIATIC SEA

R. Gramolini¹, A. Russo¹*, A. Coluccelli¹, M. La mesa², M. Panfili², E. B. Morello² and E. Arneri³

Abstract

An Individual Based Model (ICHTYOP) was applied in the Adriatic Sea with the aim of studying the mechanisms regulating spawning and recruitment success of small pelagic fishes. ICHTYOP numerical simulations have been driven by realistic current fields derived by an hydrodynamic model, and outputs were analyzed in a GIS environment. Preliminary results indicate that most recruits are along the western Adriatic coast and that the total interannual variability could be low compared to monthly variability. Specific simulations driven by position and ages of larvae caught in the Gulf of Manfredonia provide interesting insights for this important nursery area.

Keywords: Adriatic Sea, Spawning, Recruitment, Larvae, Models

Introduction.

The fishery for small pelagic, particularly for anchovy (*Engraulis encrasicolus*) and sardine (*Sardina pilchardus*), is important in the Adriatic Sea, being the largest of the Mediterranean Sea. Anchovy and sardine are species with a short life cycle, so a key factor regulating their abundance is recruitment success which in turn is considerably influenced by the passive transport from spawning areas to recruitment areas.

Materials and Methods.

Transport of small pelagic fishes eggs and larvae has being studied within the framework of the EU project "SARDONE" by using an Individual Based Model (IBM), ICHTYOP [1], already used in similar studies conducted in other areas with relevant small pelagic fisheries like the Benguela Current and the Peru upwelling systems. Realistic environmental conditions (in particolar 3-D currents and temperature over the whole Adriatic Sea) were provided to ICHTYOP as daily averages of the Regional Ocean Modelling System (ROMS; [2]) outputs. The Adriatic ROMS implementation is adequate to resolve mesoscale features (two numerical grids are being using, one with a resolution variable between 3 and 12 km and the other with constant spacing of 2 km; both having 20 *s*-levels in vertical). ROMS deduces fluxes of momentum, heat and atmospheric model, COSMO-17, managed by the Hydro-Meteo-Clima Service of ARPA Emilia-Romagna (Bologna, Italy), in agreement with the Meteorological Office of the Italian Air Force and Piemonte Region.

The whole Adriatic basin was arbitrarily divided into 36 regions according to morphology, bathymetry and general circulation. For a preliminary trial aiming to investigate the general behavior of the basin, eggs were released in ICHTYOP from each of the 36 regions (in a number proportional to the respective areal surface) and their trajectories followed for 60 days, representing the maximum duration of the passive larval transport. Eggs were released every 10 days during two years characterized by contrasting environmental characteristics (in terms of Po River runoff and wind stress). After 3 days, larvae hatch from eggs, and larval diel vertical migration was considered in the ICHTYOP run. The numeric outputs have been collected in a database for subsequent analysis in GIS, allowing for rapid and extensive result summaries and for more detailed studies.

Results and Discussion.

The GIS analysis of the ICHTYOP simulations provided the following main results: sea currents transport larvae ready to recruit in high concentration along the western Adriatic coast, especially in the central area, whilst very low concentrations are present on the eastern part of the basin (fig. 1); monthly variability is relevant; overall there are almost no differences between the two contrasting years, but there are differences in the monthly distributions.

ICHTYOP was applied also in "backward" mode to carry out a data-driven study. During two surveys conducted in the Gulf of Manfredonia (southern Adriatic Sea, Fig. 1), anchovies and sardine larvae were caught and their ages estimated by otholith microincrement counts. The Gulf of Manfredonia is known as an important recruitment area, hosting a valuable larval fishery, but it is not considered a spawning area. ICHTYOP integrations starting from date and position of anchovy and sardine larvae catches going backward up to their spawning date demonstrate a full consistency with known spawning areas.

Fig. 1. Percentage of total recruits in the 36 regions chosen for the Adriatic Sea as resulting from two years of ICHTYOP exploratory simulations

FEEDING HABITS OF THE SMALL-SPOTTED CATSHARK SCYLIORHINUS CANICULA (L., 1758) IN THE CENTRAL MEDITERRANEAN

Francesca Gravino¹, Mark Dimech² and Patrick J. Schembri^{1*}

¹ Department of Biology, University of Malta, Msida MSD2080, Malta - patrick.j.schembri@um.edu.mt

 2 Ministry for Resources & Rural Affairs (Capture Fisheries), Fort San Lucjan, Marsaxlokk, Malta

Abstract

Scyliorhinus canicula collected from 45 stations during the MEDITS annual bottom trawl survey had a Total Length range of 14-52 cm; males were more abundant than females. Of 532 stomachs sampled, 74.4% had identifiable prey material that indicated opportunistic feeding on a wide range of macrobenthic fauna. Teleosts and crustaceans were the most important prey groups (58.7 %/w and 19.3 %/w respectively). Cannibalism was also observed. There were significant differences in diet composition between the sexes and between different size classes for males and females combined. *Keywords: Elasmobranchii, Fisheries, Food Webs, Sicilian Channel*

Introduction

The catshark *Scyliorhinus canicula* is a common demersal elasmobranch in the Mediterranean. It has a wide geographical distribution and a bathymetric distribution ranging from shallow water to 550 metres depth, and is found primarily over sandy, muddy or gravelly bottoms [1]. Studies on the feeding habits of *Scyliorhinus canicula* have been made in various regions but not to date in the Central Mediterranean; the present study addresses this gap by presenting information on the diet of the species for this region, for the first time.

Material and Methods

The study was conducted in the General Fisheries Commission for the Mediterranean's Geographical Sub-Area (GSA) 15. Samples were collected in June 2006 from 45 stations as part of the ongoing MEDITS (Mediterranean International Trawl Survey) annual bottom trawl survey (Fig.1). For each specimen, total length, weight, sex and maturity stage were recorded. For males, the maturity stage determination was based on the length and degree of calcification of the pterygopods, while for females, determination was based on the degree of development of the distal part of oviducts and of the shell gland, on the presence of embryos, and on the dimensions of the eggs in the ovary [2]. In all, 532 stomachs were extracted; these were weighed, dissected and rinsed with 70% ethanol to ensure that all contents were removed and the emptied stomachs were re-weighed to estimate the fullness of the stomach. The prey items were identified to the lowest possible taxon then weighted separately to the nearest 0.001 grams. Individual catsharks were checked for any signs of regurgitation. Stomach contents were analyzed using numerical percentage (N%) and percentage by weight (W%). Statistical differences in feeding habits in relation to size and sex were assessed using the Kruskall-Wallis and Mann-Whitney tests.

Results

A total of 652 catsharks were caught from 25 of the 45 stations sampled. The fish ranged from 14 cm to 52 cm total length and from 6 g to 437 g in weight. Males were more abundant than females (sex ratio 1:0.75). Of the 532 stomachs examined, 33 (6.2%) showed signs of regurgitation, 103 (19.4%) were empty, and 396 (74.4%) contained prey. In all, 26 prey taxa were identified. The main prey items by weight were teleost fish (58.67%, dominated by Trachurus trachurus and Macroramphosus scolopax), crustaceans (19.25%, dominated by Alpheus glaber and Chlorotocus crassicornis), unidentified octopuses and cuttlefish (16.36%), polychaetes of the family Aphroditidae (3.89%) and a small percentage of Posidonia oceanica leaves (0.06%) and abiotic material (0.77%). One specimen had a juvenile S. canicula in a primary state of digestion in its stomach, which suggested cannibalism (1%/w). The abundance of food items by mass varied significantly between the different categories (One-way ANOVA, P < 0.001), and this was accounted for by the 'fish' category (Tukey post-hoc test, P < 0.05). Significant differences in the weight of the different stomach content items were observed between mature males and females (Mann-Whitney U-test, P < 0.05). Mature males consumed significantly more fish than did females, which consumed more crustaceans. Diet also differed between the different size classes (Kruskall-Wallis test, P < 0.05).

Discussion

Central Mediterranean *Scyliorhinus canicula* were found to have a high dietary diversity and to feed opportunistically on a wide range of macrozoobenthos and also on abiotic material, showing both predatory and a facultative scavenging, as reported by [3] for Isle of Man waters. The presence of small catsharks in the stomach contents showed that there is also some degree of cannibalism. The

composition of the diet varied significantly with size as the larger and more mature individuals showed an increasing preference for fish and cephalopods, while smaller individuals showed a preference for crustaceans, probably because large individuals are able to ingest larger food items such as fish. The preference for fish was more pronounced in mature males than in mature females, which may be related to sexual dimorphism in the shape of mouth and teeth at maturity [4].

Fig. 1. Map showing the position of General Fisheries Commission for the Mediterranean's GSA 15 (the square) and the 45 stations sampled (the dots). The 25 nautical mile Fisheries Management Zone around Malta is also shown.

Abstract

Diet of threadfin bream *Nemipterus randalli* was determined from the specimens collected in Iskenderun Bay, Eastern Mediterranean Sea. A total of stomach contents of 117 threadfin bream specimens with total lengths ranging from 7.0 cm to 26.6 cm were examined. Stomach content analysis revealed that this species is carnivorous, feeding on benthic crustaceans constituting the main food in the overall diet composition. Main food items found in the stomach were crustaceans (IRI%= 82.29). Other main prey items found were pisces (IRI%= 12.83) polychaeta (IRI%= 1.18) and mollusca (IRI%= 0.03). Therefore rapidly expanding population of *N. randalli* may damage crustacean biodiversity and fish stocks feeding on crustaceans. *Keywords: Diet, Teleostei, Eastern Mediterranean*

Introduction

The threadfin bream Nemipterus randalli is the first representative of the family Nemipteridae in the Mediterranean Sea, and recorded for the first time for the Mediterranean Sea by Bilecenoglu & Russel [1] based on a few specimen collected from the eastern coast of Iskenderun Bay, Turkey. This species has rapidly extended and now succesfully established in Eastern the Mediterranean Sea [2,3,4], N. randalli is very abundant in coastal waters. found on mud or sand bottoms in 5 to 80 m, usually in schools [5]. N. randalli has a widespread distribution found in the Indian Ocean and West Pacific. It is considered commercially important throughout its distribution, and one of the major species in the southern Red Sea and in the Gulf of Suez [6,7]. In the near future N. randalli may be a valuable commercial species in the Mediterranean Sea. Despite its abundance and new establishment along Turkish coast, no studies concerning the feeding regimes to the Mediterranean habit of N. randalli exists. In this study, the first time was to examine the feeding habits of threadfin bream caught in Iskenderun Bay, Eastern Mediterranean Sea.

Material and Methods

A total of 117 threadfin breams were collected during between 2009 from Iskenderun Bay (Eastern Mediterranean Sea). Specimens were caught by a R/V Mustafa Kemal I and commercial trawlers at a water depths ranging from 13 to 60 m under the project (TAGEM-09/AR-GE/11). After catching the fishes, stomachs were removed onboard, preserved in formalin and taken to the laboratory for analysis of the contents. In the laboratory, a total of 117 stomachs were dissected and then contents were identified to the lowest practical taxon (Table1). Prey were counted under a stereomicroscope and weighed to the nearest 0.01 g. Stomach contest was analyzed using the percentage frequency of occurrence (F%), percentage numerical abundance (N%), percentage gravimetric composition (W%) and index of relative importance; [IRI = (N%+W%) x F%] were determined [8]. IRI was expressed as a percentage; [IRI% = (IRI x 100) / Σ IRI].

Results and Discussion

Stomach contents of N. randalli specimens with total lengths ranging from 7.0 cm to 26.60 cm were examined (average total length= 13.12 cm). Of the stomach examined, 105 (90%) were full and 12 (10%) empty. A total of 305 prey items belonging to four taxa were determined. Crustacea were the most important group in the diet of N. randalli with IRI% 82.29, followed by pisces were second in importance, IRI% 12.83. Other main prey items found in the stomach were polychaeta (IRI%= 1.18) and mollusca (IRI%= 0.03) (Table 1). Diet composition of N. randalli from Iskenderun Bay revealed that this species carnivorous, expecially consuming benthic decapod crustaceans as primary food. The results demonstrated that N. randalli feed primarily on crustaceans, particularly Processa sp. N. randalli stomachs contained crustaceans (W=70%) and small fishes (W=18%). Similar result were obtained for the other Nemipterus species (Nemipterus marginatus)in the South China Sea, where mainly consumed crustaceans (70%) in particular Penaeus sp. constitued the major proportion of the diet composition (59.1%) [9]. The results demonstrated that N. randalli prefers crustaceans (Copepoda, Decapoda, Natantia, Brachyura, and Stomatopoda) as the main food, followed by teleost prey and polychaeta. The results suggested that the rapid extension of this fish species could be high the availability and distribution of food crustaceans. Therefore rapidly expanding population of N. randalli may damage crutacean biodiversity and fish stocks feeding with crustaceans. This information is very important in the management of fishery resources as well

as for the efficient utilization of this species.

Abstract

L'étude de la variabilité morphologique de trois échantillons lagunaires de *Lithognathus mormyrus (Linnaeus*, 1758) nous a permis de mettre en évidence une nette hétérogénéité morphologique entre ces échantillons. Cette hétérogénéité est liée principalement à la forme de la tête qui semble être en relation avec le régime alimentaire ainsi que la disponibilité, la taille et le type de proies. L'analyse de la variabilité allozymique de ces mêmes échantillons n'a montré de différences qu'entre les deux échantillons des lagunes d'El Biban et de Bizerte.

Keywords: Fishes, Lagoons, Western Mediterranean

Lithognathus mormyrus est l'une des espèces les plus importantes de la famille des Sparidés. Il s'agit d'une espèce essentiellement marine, mais elle est fréquemment rencontrée dans les lagunes et les estuaires, considérés comme des nurseries pour les juvéniles.

Dans cette étude, nous nous proposons d'analyser la variabilité aussi bien morphologique que génétique de trois populations lagunaires des côtes tunisiennes de *Lithognathus mormyrus*. Deux lagunes sont situées dans le secteur Nord-est (lagunes de Bizerte et de Ghar El Melh) et la troisième est située dans le secteur Sud-est (lagune d'El Biban). L'étude morphométrique est basée sur l'approche de « Truss » [1]. L'identification de 18 points repères (landmarks), nous a permis d'établir un réseau de 41 mesures. L'étude génétique a concerné le polymorphisme de sept loci enzymatiques (EST-1, EST-2, GOT-2, IDH-2, MDH-3, PGM et SOD).

L'analyse de la variance des données morphométriques, après transformation allométrique [2], a montré des différences hautement significatives entre les trois échantillons lagunaires étudiés et ce, pour 29 variables parmi les 41 choisies. L'analyse factorielle discriminante a permis de mettre en évidence une nette discrimination des trois échantillons analysés selon l'axe 1 qui explique 56% de la variabilité totale. Les plus fortes contributions ont été apportées par des mesures liées principalement à la longueur de la partie antérieure (la Tête). Cette différenciation s'expliquerait par l'hétérogénéité environnementale de ces lagunes. L'alimentation constituerait un important facteur pouvant influencer la morphologie de la tête [3], [4].

Fig. 1. AFD des variables morphométriques selon le plan formé par DF1 et DF2. LGM : lagune de Ghar El Melh ; LBIZ : lagune de Bizerte ; LBIB : lagune d'El Biban.

L'estimation de la diversité génique de Nei (Hnb) montre que l'échantillon de la lagune d'El Biban présente la valeur la plus faible. La valeur du F_{IS} global montre un déficit significatif en hétérozygotes (f = 0.3522; p < 0.001)

principalement généré par le locus IDH-2. Le calcul de l'estimateur du F_{ST} de Wright montre une hétérogénéité entre les échantillons des lagunes de Bizerte et d'El Biban ($\theta=0.0445\ p<0.01$) qui s'explique par des différences de fréquences alléliques au niveau des loci GOT-2 et EST-2. Ainsi, les différences morphologiques observées entre les échantillons des lagunes de Bizerte et d'El Biban reflèteraient à la fois les différences génétiques et la variabilité des facteurs environnementaux.

Abstract

Une campagne cartographique réalisée au printemps 2009 dans la lagune Nord de Tunis nous a permis de décrire la répartition spatiale de deux espèces de la famille des syngnathidés, le syngnathe de lagune *Syngnathus abaster* Risso, 1827 et le siphonostome de Méditerranée *Syngnathus typhle rondeleti* De la Roche, 1809. Cette répartition est étroitement liée à la nature des herbiers ainsi qu'à la profondeur de l'eau.

Keywords: Fishes, Lagoons, Mapping

Introduction

La lagune Nord de Tunis, peu profonde, est située au fond du golfe de Tunis entre les parallèles 36° 45' et 36° 52' de latitude nord 10° et 10° 20' de longitude est. Après les travaux de restauration, menés en 1985, cet écosystème lagunaire a montré une diversification biologique appréciable [1], [2], notamment pour les syngnathidés ; différentes espèces y ont été décrites telles que : *Syngnathus abaster* Risso, 1827, *Syngnathus typhle rondeleti* De la Roche, 1809, *Syngnathus acus* Linnaeus, 1758 et *Nerophis ophidion* Linnaeus, 1758 [3]. Ce travail porte sur la répartition de *Syngnathus abaster* et *Syngnathus typhle rondeleti* dans la lagune Nord de Tunis.

Matériel et méthodes

La campagne de cartographie réalisée au printemps 2009 avait pour objectif de décrire la répartition spatiale des deux syngnathidés Syngnatus abaster et Syngnatus typhle rondeleti. Leurs distributions ont été étudiées en rapport avec les macrophytes benthiques, notamment les deux espèces dominantes dans le milieu d'étude : la Magnoliophyte Ruppia cirrhosa (Petagna) Grande et la Chlorobionte Chaetomorpha linum (O.F. Müller) Kützing. Cette répartition a été étudiée suivant 19 transects distants de 500 m répartis sur l'ensemble du milieu lagunaire, moyennant un petit chalut benthique ayant un maillage de 1 mm.

Résultats et discussion

La répartition spatiale de Syngnathus abaster montre une présence importante dans la lagune Nord de Tunis et surtout dans la partie Sud de la lagune (fig. 1). Cette espèce est également rencontrée à l'est de la lagune et plus particulièrement au nord-est, zone fortement influencée par les échanges avec la mer. Ayant une taille ne dépassant pas les 12 cm, Syngnathus abaster est l'espèce la plus fréquente dans la lagune. Toutefois la répartition de Syngnathus typhle rondeleti, fragmentaire, est limitée à l'est de la lagune. Cette espèce, peu fréquente, est plus présente au sud-est de la lagune. Cette distribution est étroitement corrélée à celle des macrophytes benthiques et à la profondeur de l'eau. Les deux espèces de Syngnathidés ont été observées dans les herbiers à dominance Chaetomorpha linum et au niveau des zones à faibles profondeurs (inférieures a 0,8 m). La diversité et la fréquence des syngnathidés n'ont cessé d'augmenter dans la lagune Nord de Tunis après son assainissement. Ces espèces ont trouvé dans les herbiers à Magnoliophytes marines et dans les touffes à Chaetomorpha linum un refuge et un lieu de ponte. D'autres campagnes doivent être réalisées pour étudier l'évolution saisonnière de cette répartition. Par ailleurs, il est important, également, de comparer les variations saisonnières de la répartition des syngnathes à celles des macrophytes benthiques, particulièrement Ruppia cirrhosa et Chaetomorpha linum qui dominent dans la lagune Nord de Tunis.

PROBLEMATIC OF THE PELAGIA NOCTILUCA OUTBREAKS IN THE BAY OF CALVI (CORSICA)

J. Hecq ^{1*}, A. Goffart ¹, A. Collignon ¹, M. Garrido ², P. Lejeune ³ and V. Pasqualini ² ¹ Université de Liège- Océanologie, Centre MARE - jh.hecq@ulg.ac.be ² University of Corsica Pasquale Paoli, Corte (Corsica), France

Abstract

The interannual variations of the Schyphozoan jellyfish Pelagia noctiluca is estimated by weekly measurements in the Bay of Calvi (Corsica) from 2003. The mean annual abundance reaches a dramatic maximum in 2006. The medusae appear by migration of active swarms on the shelf and at the external limit of the Bay. Degraded individuals drift as passive swarms, throughout inner side of the Bay and embayments.

Keywords: Ligurian Sea, Zooplankton, Medusae, Coastal Systems, Time Series

The cyclic outbreaks of the holoplanktonic jellyfish Pelagia noctiluca have been extensively described in the Western Mediterranean, where the seasonal progression of the P. noctiluca blooms commences in late autumn- winter. High densities are maintained throughout the winter and the blooms end in the summer after a maximum of reproduction [1]. In the Ligurian Sea, P. noctiluca characterizes generally the offshore waters and develops actively at the level of the Liguro-Provençal Front [2].P. noctiluca develops in swarms, mostly observed at the level of the pycnocline and which can migrate to the surface [3]. The swarms occasionally drift to the shelf and seem to be regulated by macroscale hydrography and the hydroclimatic environment [4], local upwelling [5] or oscillations of Liguro-Provençal [6].

Actually, many processes related to the causality and dynamics of outbreaks remain unknown, especially those concerning swarm formation, migration and drift, at the scale of coastal embayment. In order to enhance our understanding of the factors controlling the dynamics of *P. noctiluca*, its abundance has been estimated weekly during 7 years (2003 - 2008) in the Bay of Calvi (Corsica) by visual observations, scuba diving and WP2 zooplankton sampling.

Fig. 1. Variation of a jellyfish Pelagia noctiluca swarm in the Bay of Calvi from 8 till 10 November 2006. Points represent the positions of counting by an onsurface diver. The concentrations express themselves in number of individuals counted on a radius of 10 m. Scale varies from 0 to 300 ind

The mean annual P. noctiluca abundance shows a progressive increase from 2004 to 2005 and reaches a dramatic maximum in 2006, followed by a progressive decrease during the summers 2007 and 2008. The P. noctiluca outbreaks start generally in late autumn-winter, maintain throughout the winter and disappear in spring. However, some years (e.g. 2005 to 2007), the seasonal progression continues during the late spring and large populations maintain during the summer. The outbreaks of P.noctiluca in 2006 could be correlated to the very intense mesozooplankton bloom in 2005

The distribution of swarms in the Bay of Calvi has been studied by scuba visual observations. Active swarms of 200 m of length and 50 m of wide appear on the shelf and at the external limit of the Bay by vertical migration, following some days of North-East (Fig.1). The swarms maintain in the same area for a few days. In these active swarms, 5 to 10 P. noctiluca per m³ were observed between 10 to 60 meters depth. The individuals were equidistant, swimming actively with the extended tentacles and capturing the food. In certain cases, individuals partially destroyed, dying or at the end of their biological cycle, escape from active swarms and derive passively in the first meters of the water column towards the coastal zones and embayments under the effect of the wind and the movements of the water. The degraded individuals which have lost tentacles or manubrium, move slowly and accumulate in large number (sometimes more than 200 m⁻²), edge to edge, in passive patches limited to the first three meters of water column. These swarms undergo an active predation by numerous sparid fishes. They disappear in a few hours, reduced by this predation or by massive sedimentation of the dead animals.

Acknowledgments: The study was done in the programme MEDUSE granted by the Agence Française de l'Eau (Rhone- Méditerranée- Corse). We thank Sylvain Plazza and the STARESO staff for sampling operations. JH Hecq is Senior research associate to the FRS-FNRS (Belgium).

ASSESSING THE IMPACT OF FISHING AND PROTECTION ON THE DYNAMICS OF THE SEA BREAM POPULATION IN THE NORTH-WESTERN MEDITERRANEAN SEA USING A SIMULATION MODEL

Chirine Hussein^{1*}, Marion Verdoit-jarraya¹ and Philippe Lenfant¹

¹ Postre - chirine.hussein@voila.fr

Abstract

We used ISIS-fish model to evaluate the impact of spatial and seasonal management measures on the dynamics of the sea bream population *Diplodus sargus sargus* (L., 1758) of the French Catalan fishery (North-Western Mediterranean). First, in order to identify the most significant parameters of model, a sensitivity analysis were carried out according to a fractional factorial experimental design. The method used consists in modifying some input parameters of the model by \pm 20% around its initial value. Second, we attempted to disentangle the effects of several measures jointly implemented; as marine protected areas MPAs, changes in gillnet mesh size and fishing effort reduction.

Keywords: Biodiversity, Coastal Management

Introduction

Over-exploitation of marine fisheries resources remains a serious problem worldwide. The traditional management measures (quotas, limiting fishing effort, size minimum capture) does not ensure the sustainability of fisheries [1], marine protected areas MPAs have been strongly advocated as an ideal tool and a central element of many marine resource management plans. In the study area, the legislative framework focused on marine protected areas (Cèrbère-Banyuls reserve) and on the minimum landing size. In the present paper, our interest is twofold. First, study the influence of uncertainty model on a sensitivity analysis, which is to identify, quantify and analyze how to react exits from one model to disturbances on the variable entry. Second, we present the results of the simulation numeric to assess quantitatively the impact of various management measures of fishing and protection on the sea bream population.

Materials and methods

In this paper, we used ISIS- fish model to evaluate the impact of spatial and seasonal management measures on the dynamics of the sea bream population Diplodus. Sargus Sargus, of the French Catalan fishery . In our model, numerous parameters are fixed as they present a range of variation. This is the case of the fecundity rate [2], recruitment [3], growth [2], [4], catchability [5], mortality [6]. Then, uncertain parameters were identified and grouped into 9 groups: length range, fecundity coefficients, migration coefficients, natural mortality, catchability coefficients, gears standardisation factors, target factors and the number of inactivity days for each strategy. Analysing the effect of several parameters simultaneously makes it possible both to show their possible interactions and to rank them according to their importance of the model. The method used consists in modifying each input parameter of the model by \pm 20% around its initial value. The effect of each operated modification is analysed on 5 outputs of the model (biomass at the last time step. last year catches, five last year's cumulative catches, last year nominal effort and five last year's cumulative nominal effort).

Results

The outputs considered showed particularly sensitive to some parameters such as natural mortality, length stage, gears standardisation factors, fecundity and catchability coefficients. Various management measures of commercial and recreational fisheries were simulated during 10 years in order to evaluate potential impact of fishing and to reduce over exploitation of the fishery, including for example, the imposition of AMPs in the nursery areas and in the spawning areas. An increase in gillnet minimum mesh size, from 60 to 80 mm were adopted to improve gear selectivity in the groundfish fishery. Finally, we attempts to reduce effort by 50% during the 5 first years and during the simulation duration. According to our model assumptions, the fishery has been overfished. In the model simulations carried out to explore the impact of possible management intervention:(a) MPAs nursery zones which would be an alternative management tool for conserving marine resources and ecosystems, (b) a change in the minimum mesh size to 80mm would cause an increase of 33% in the total catch (kg) and 51% in the gillnet catch in the long term, and (c) Limiting the fishing effort current levels resulted in higher levels of biomass and catches for the fishery (from the current 779t. up to an average 1766t in the 10 year horizon: a 226.65% increase.

Discussion

Our study has evaluated a broad range of assumptions concerning the status of the area being protected (spawning ground and (or) nursery ground), and fishing selectivity. The experiments and analyses presented in this paper have clearly demonstrated the potentials for ISIS-Fish. This enabled us to carry out preliminary explorations the impacts of these measures and to make a general diagnosis about the significance of the impact and finally to group them with respect to the consequences on both biomasses and catches of sea bream population. Results of the analysis in two different areas of the no-take zone indicate that the seasonal closure (Jan.-Jun.) of the nursery zones is beneficial for fish stock recovery, thereby increasing the biomass of fishes , it will result in an about 50% increase of the total catch and an about 76% reduction of juvenile catches (about 25 t.). A change in the minimum mesh size to 80mm would cause an increase of 33% in the total catch (kg) and 51% in the gillnet catch in the long term, providing that the minimum landing size of sea bream was simultaneously raised from 23 cm to 23.65 cm. Limiting the fishing effort current levels resulted in higher levels of biomass and catches for the fishery where the stock size responses are likely to occur on two distinct time scales associated with growth of existing fish and future recruitment. In conclusion, in the present situation of existing management policy and with the knowledge currently available, we recommended a potential framework of a project aimed at evaluating the potential of a novel co-management approach adopted at the actual situation along the French Catalane coastline.

SIGNATUS JAVUS, A NEW RECORD FROM THE SYRIAN WATERS, WITH A REFERENCE TO GROWTH & FEEDING OF TWO LESSEPSIAN FISH

A. Ibrahim¹*, M. Lahlah¹, M. Y. Kassab¹, W. Ghanem¹ and S. Ogaily¹

¹ High Institute of Marine Research, Tishreen University, Syria - a.ibrahim@aloola.sy

Abstract

One specimen of *Siganus javus* was caught during Oct. 2009 from the Syrian marine water. It is the first record in the Mediterranean Sea and may be a potential invader to the area. The study of feeding habits of two other lessepsian species from the Syrian waters revealed growth rates comparative to other local fish species and strong signs of starvation & food completions. *Keywords: Lessepsian migration, Competition, Growth*

Introduction

Colonization of the eastern Mediterranean by Red Sea and indo-pacific species has started after Suez Canal opening in 1869 [1]. So far, fish species entered the Syrian water are mostly Lessepsian (42 species) and, to a lesser extent, western Med. migrants (14 species) [2], [3], [4], [5]. The family Siganidae in the eastern Med. is represented by two species, *S. luridus & S. rivulatus*, migrated through Suez Canal (CIESM 2002). Exotic fish are likely to influence the local fish community in many ways such as competition for food and space and the consequence effect on growth. Identifying the level & extent of such effects are important for the proper management measures. This paper presents the characteristics of a new lessepsian Siganids record and estimations of growth rates (for the age groups 1 + - 5 +) and feeding habits (food composition, stomach fullness...) of two already established lessepsian fish species in the Syrian waters; Lizardfish, *Saurida undosquamis* and Squirrelfish, *Sargocentron rubrum*.

Results and Discussion

An Indo-Pacific originated fish species, Streaked spinefoot *Siganus javus* (L., 1766), was recorded for the first time in the Syrian waters and in the Mediterranean sea. It was captured on 10 Oct. 2009 by a trammel-net at night in a water depth of \approx 20m above a rocky & muddy bottom facing to Lattakia port (N35 31 425 E35 44 893). Water properties (at 1m depth) were: Temperature (26.4°C), Oxygen conc. (5.14mg/l), Salinity (39.34), Turbidity (0.056) and Chlorophyll conc. (0.52µg/l).

The fish (Fig. 1) was identified and kept as a reference at the High Institute of Marine Research. The body is oval & compressed with 13 dorsal fin spines (preceded by a forward projecting 2.6mm spine); 10 dorsal soft rays; 7 anal spines, 9 anal soft rays; ventral (2 spines separated by 3 soft rays) and 16 pectoral soft rays. Its measurements (cm) are: total length 18.4, standard length 15.5, fork length 17.9, body depth 7.5, head length 3.9 and eye diameter 1.1.

Fig. 1. Siganus javus from the Syrian waters

This species can be found in the Gulf of Oman, Pakistan, Thailand, southern China and down to Australia [6]. By recording this species, Siganidae would be represented by 3 species in the Syrian marine waters. However, this species is so far represented by a single specimen and its establishment has still to be proven and the introduction pathway has to be confirmed. To confirm the active migration, some future records in Suez Canal and in the south-eastern Med. sea are needed. Anyway, the survival in the Syrian waters and the recent sea warming make s. javus a potential eastern Med. invader.

Growth rate of the studied fish species was higher during the earlier life stages of life. Growth rate by length (cm) of *Sargocentron rubrum* for example was 5.5, 4.6, 2.2, 2.1 and 1.9 cm/y for the 5 age groups respectively. These estimations are comparative with other existing species such as *Pagrus coeruleostictus* and *Sardinella aurita*. The food of the Lizardfish consisted mostly of fish (mainly *S. aurata & B. boops* (and that of the Squirrelfish was of

Crustacea (maily Amphipoda, Isopoda and Decapoda). Both fish species had a clear food competition with many coexisting fishes. Stomach fullness rarely exceeded 50%; indicating that both fish species do not feed well in the study area.

Acknowledgement: The authors would like to thank Prof. Frederic Briand for his valuable help in the identification verification and tracking any previous records. Thanks also go to Mr. M. Shammat, whose fishing gears facilitated this work.

Abstract

The Levantine populations of Erythrean invasive swimming crab *Charybdis longicollis* have been parasitized by the rhizocephalan *Heterosaccus dollfusi*, itself an Erythrean alien, since 1992. The parasite affects the host morphology, moulting, behaviour, causes its sterilization, and induces mortality. The high prevalence of *H. dollfusi* can be ascribed to the dense population of the host, the year-round reproduction of the parasite that promotes recurrent re-infection. Despite the high prevalence of the parasite and its injurious impact on the host reproduction, the invasive host-parasite pair has reached an apparent *modus vivendi*. *Keywords: Levantine Basin, Decapoda, Parasitism*

Instances of rhizocephalans accompanying their invasive hosts are few. Yet among the hundreds of alien species that have entered the Mediterranean through the Suez Canal such an invasive host-parasite pair was identified: the portunid crab *Charybdis longicollis* (Fig. 1) with its parasitic barnacle *Heterosaccus dollfusi* (Fig. 2).

Fig. 1. A male specimen of Charybdis longicollis Leene, 1938.

Fig. 2. Charybdis longicollis parasitized by 6 externa of Heterosaccus dollfusi Boschma, 1960.

A significant percentage of the host population along the Levant coast has been parasitized [1]. The parasite causes sterilization, morphological and behavioral feminization, cessation of molting and by placing high energetic demands on the host, induces mortality [2], [3]. Aspects of the biology, ethology and population dynamics of the invasive host-parasite pair along the Mediterranean coast of Israel have been studied since 1992. Nearly 19,000 crabs were examined, among these, over 10,000 were either externae-bearing, or internally-

parasitized morphologically-modified crabs. The incidence of parasitization has been high and fairly stable over the past 15 years. The number of specimens and the incidence of parasitizationwere higher in the spring (May-June) than in the fall samples (August-October). The abdomen of both sexes of infected C. longicollis is modified to such an extent that the sexual apertures remain the only reliable character. Infection of the females causes the loss of the swimmerets, whereas in males the copulatory appendages are lost or reduced, and the abdomen broadens to such a degree that it closely resembles that of an uninfected female. In post-parasitization host populations the average and maximal size of non-parasitized males is larger than parasitized males whereas average and maximal size of non-parasitized female crabs are smaller than those bearing externa. It is proposed that H. dollfusi mayregulate the female host size to best endure the significant metabolic costs of the reproductive externa. Modifications of grooming, burying, courtship and mating, and agonistic behaviour have been observed in parasitized C. longicollis. The feminized agonistic behavior of male crabs parallels the feminization of the secondary sex characters and size range of H. dollfusi-parasitizedC. longicollis (see above). It is also suggested that the presence of the parasite reduces belligerence in male crabs, enhancing injury avoidance [4]. Multiple parasitization has been common: nearly 40% of the externae-bearing hosts sampled between 1994 and 2009 harboured more than one externa, and over 17% bore three externae or more. The percentage of specimens bearing three or more externae is five times as high in spring as in fall samples. The pattern that emerges from the examination of the percentage of externae-bearing hosts bearing more than a single externa is that it increases when the incidence of parasitization rises above 50%. Almost without exception multiple externae occur among smaller crabs, presumably because they survive more poorly than single parasites. By placing an unacceptably high nutritional demand on the host, multiple externae weaken it and in many cases cause its untimely death.

Abstract

The Erythrean crab *Charybdis longicollis* had established populations in the Levantine basin of the Mediterranean Sea in the mid 20th century, that were parasitized, in the last decade of that century, by the rhizocephalan *Heterosaccus dollfusi*, itself an Erythrean alien. In May 2008 the host populations were sampled at the southern (Israel) and northern (Turkey) limits of its introduced range. The prevalence of infection and multiple externae-bearing hosts were higher in Israel than in Turkey. It seems that off the Israeli coast the water temperature permits the synchronous ontogenetic development of both host and parasite ensuring availability of plentiful young, recently-molted prospective hosts for infection by the short-lived parasite cypris. *Keywords: Crustacea, Temperature, Parasitism*

Absence of natural enemies, be it competitors, predators, or parasites, is one of the explanations given for the success of alien biota. Yet, though parasite species richness may be lower in alien hosts in their new range, the prevalence of infection may be many times higher. The Levantine populations of the Erythrean invasive swimming crab *Charybdis longicollis* have been parasitized by the sacculinid rhizocephalan *Heterosaccus dollfusi*, itself an Erythrean alien [1]. An earlier study that examined the temporal variability of *H. dollfusi* prevalence at Palmahim, Israel, a site at the southern end of its introduced range, found that despite the high prevalence of the parasite and its injurious impact on the host, there was "no noticeable reduction in the host population"[2]. We sought to examine the spatial variability of the parasite's prevalence along a latitudinal gradient within its introduced range. To that end we sampled the host populations off Ashdod (Israel) and

Antalya (Turkey) in May 2008 and July 2009.

Fig. 1. Map of the investigated area: *=Antalya, **=Ashdod.

The prevalence of infection in Ashdod was more than three times higher than in Antalya. Multiple parasitization was common in the Ashdod population of *C. longicollis*: over half of the externae-bearing hosts harboured more than one externa. In contrast, most of the externae-bearing hosts (84.2%) collected off Antalya bore a single externa, and only few more than three. Multiple externae are related to prevalence of infestation, as the parasite avoids settling on an already infected host, and does so only when the chances of encountering an uninfected host are diminished. The small number of externae-bearing hosts bearing more than a single externa off Antalya (15.8%), though the density of the host population is high, is further proof that the infection rate off Antalya is

indeed a fraction of that in Ashdod and not a fortuity of the sampling.

Fig. 2. Incidence of parasitization and carapace width (mm) in *Charybdis longicollis* respectively collected off Antalya, Turkey, and Ashdod, Israel, in May 2008 and July 2009. M, F: unparasitized males and females, MI, FI: internally parasitized males and females, ME, FE: externa-bearing males and females.

What then could constrain the parasitization of *C. longicollis* in the northern part of its introduced range? Could it be a biological response of a thermophilic alien to a latitudinal gradient of temperature? Data from the population off the Israeli coast suggest that this critical stage takes place in spring. Off the Israeli coast the water temperature permits the synchronous ontogenetic development of both host and parasite ensuring availability of plentiful young, recently-molted prospective hosts to the short-lived parasite cypris. The lower water temperature off Antalya may affect the timing of ontogenetic stages of one or the other, or increase the mortality of infected hosts, resulting in a sharply reduced infection success.

ZOOPLANKTON COMMUNITY STATE IN THE ADJACENT REGIONS OF THE BLACK AND MARMARA SEAS

Melek Isinibilir ¹*, Leonid Svetlichny ² and Elena Hubareva ² ¹ Istanbul University, Faculty of Fisheries - melekisinibilir@hotmail.com ² Institute of Biology of the Southern Seas, Sevastopol, Ukraine

Abstract

During 2005-2008 species composition and abundance of mesozooplankton collected in the Bosphorus regions of the Black and Marmara Seas were studied taking into account the number of live and dead individuals. In the direction of the Marmara Sea from the Black Sea through the Bosphorus, the abundance of the Black Sea originated species reduced and the proportion of carcasses increased. On the contrary, the abundance of the Mediterranean species diminished toward the Black Sea. High number of their carcasses was found in the Black Sea near the Bosphorus. *Keywords: Zooplankton , Mortality, Black Sea, Marmara Sea*

The Black and Marmara Seas are connected with the narrow Bosphorus Strait (31 km). Due to positive water balance in the Black Sea, its water masses are transferred into the Marmara Sea through the Bosphorus forming a brackish surface layer (15-20 m) with a salinity of 18-24 ‰ and temperature ranging from 20-24 0 C in summer to 8-9 0 C in winter. Below this brackish layer lies more densely saline (about 39 ‰) Mediterranean Sea water with a constant temperature of about 15 0 C throughout the year. These dense and warm water masses enter from the Bosphorus with deep countercurrent and mix with overlying cold (6-8 0 C) intermediate layer of the Black Sea. The aim of the study was to analyze spatial and vertical distribution of alive and dead components of mesozooplankton community in view of spatial and vertical structure of the water masses in the adjacent regions of the Black and Marmara Seas.

Zooplankton samples were collected with a closing Nansen net seasonally during 2005 – 2008 at the permanent stations in the Marmara Sea near the Prince Islands and Bosphorus, in the northernmost part of the Bosphorus Strait and in the Black Sea near the Bosphorus. The samples were preserved with 4% borax-buffered formaldehyde. In the laboratory species composition and numbers of individuals being alive before sampling and their carcasses with destructive changes in muscles and internal organs were determined under a dissecting microscope.

During all periods of the study the tendency to diminish from the Black Sea toward the Marmara Sea for abundance and biomass of the Black Sea originated zooplankton species was found. This trend was due to decrease in total abundance and biomass of mass Black Sea copepod. The mean annual biomass of the Black Sea copepods decreased from 3696.9±2008 mg.m⁻² in the Black Sea to 832.8±453.9 mg.m-2 in the northern Bosphorus area and 329.8±265.7 mg.m⁻² near the Prince Islands in the Marmara Sea. The abundance of dead organisms of the Black Sea origin increased toward the Marmara Sea. Maximum mortality of the Black Sea copepods was observed in the Bosphorus region of the Marmara Sea. In this area mean values of nonconsumption mortality for the Black Sea copepods varied in limits of 8-60%increasing dramatically up to 80% in Acartia clausi. On the contrary, the mortality of Cladocera was low near the Bosphorus and reached 35% near the Prince Islands. In the Marmara Sea, the Black Sea species aggregate mainly in upper brackish or mixed layers whilst the Mediterranean organisms inhabit deep strata with high salinity. Usually the mortality in the Black Sea species increases with depth. In the northernmost part of the Bosphorus only 6 species of the Mediterranean origin were found. The main part of population of dominative O. minuta was attributed to the lower-layer flow where the mortality did not exceed 8 %, whereas in the upper layers the mortality of this species reached 42 %.

According to [1] and [2], mass mortality of copepods penetrating into the Marmara Sea from the Black Sea is connected with low tolerance to sharp salinity increase in the intermediate layer of the Marmara Sea. High mortality of warm-water Mediterranean species transferred to the Black Sea with the Bosphorus deep countercurrent may be due to both low salinity and temperature of their new environment.

NON-DESTRUCTIVE DISTANCE SAMPLING SURVEYS FOR POPULATION DENSITY AND ABUNDANCE ESTIMATIONS OF BENTHIC FAUNA

Yiannis Issaris¹* and Stelios Katsanevakis¹

¹ Hellenic Centre of Marine Research, Institute of Marine Biological Resources - issaris@ath.hcmr.gr

Abstract

Conventional Underwater Visual Census (UVC) methods assume total detection of all individuals in the surveyed areas. However, when counting small taxa or cryptic species, this assumption is not usually met, leading to the underestimation of species abundance. Distance Sampling methods that account for the detectability of the animals surveyed have been applied successfully and are hereby proposed as efficient and unbiased tools for estimating the abundance of benthic species. *Keywords: Conservation, Monitoring, Sampling Methods*

For estimations of population density and/or abundance of protected benthic species or surveys in protected habitats (e.g. seagrass beds, coral reefs), non-destructive methods are preferred than fisheries surveys. The most commonly used method in shallow waters is strip transect sampling with SCUBA diving. In strip transects, the observer travels along long narrow strips and records all animals of interest within the strip. The survey design comprises *k* randomly positioned strips or a grid of *k* systematically spaced strips randomly superimposed on the study area. Abundance in the study area A is estimated by where *n* is the number of detected individuals, A_c is , the surface area covered by the survey, (coverage probability).

 $\hat{N} = \frac{nA}{A_c} = \frac{n}{P_c}$

In strip transect sampling, the critical assumption is that all individuals present in the surveyed areas are detected. However, this assumption cannot be tested using the survey data, and to ensure that it holds to a good approximation in all habitats and environmental conditions, it may be necessary to use narrow strips, which is problematic for scarce species and increases the variance of density estimators [1]. When designing a strip transect survey, there is no way to estimate the maximum strip width for certain detection of the target species. If the assumption that all individuals present in the surveyed areas are detected is not met, there is underestimation of abundance, which is not uncommon in underwater surveys especially when counting small taxa or cryptic species [2]. One of the most active areas of biometric and wildlife research is the development of methods and models to properly account for detection probability. One such widely used method that properly accounts for detection probability is distance sampling with line transects [1]. Distance sampling has been used extensively in terrestrial ecology and for marine mammals, as the standard method for abundance estimations of many species, but it has only rarely been used for underwater surveys of benthic fauna. In line transect sampling, a standardized survey is conducted along a series of lines searching for the animals of interest. For each animal detected, the distance from the line is recorded. The probability that any particular individual that is in the covered region is detected, i.e., the 'detection probability', is denoted by P_a . If n animals were detected in a distance sampling survey, then an estimation of the mean density and the total number of animals in the study area is given by

$$\hat{D} = \frac{n}{A_c P_a}$$
 and $\hat{N} = \frac{n}{P_c P_a}$ respectively.

The main task of the analysis of distance sampling data is to estimate the detection probability P_a by the set of collected distances. This is done by modeling the detection function g(y), i.e., the probability of detecting an individual that is at distance y from the line or point. Having estimated g(y), the detection probability is given by $\hat{P}_{\alpha} = \frac{\int_0^w \hat{g}(y) dy}{g(y) dy}$

The function g(y) is estimated from the distance data with a semi-parametric approach, as described in detail by Buckland et al. [1]. Detectability and the shape of the detection function in an underwater benthic survey may depend on various factors such as habitat type, water turbidity, weather conditions, sun position, the ability of the surveyor, the target species and its contrast, sex, or size. To illustrate how detectability may differ by species, four different species (the fan mussel Pinna nobilis, the Mediterranean scallop Pecten jacobaeus, the purple sea urchin Sphaerechinus granularis, and a sea cucumber Holothuria sp.) were surveyed with line transects in the same site (Lake Vouliagmeni, Greece) in the summer of 2004. Habitat, water conditions, and the observer were the same and thus the differences in the detection function may be mainly attributed to the species characteristics (Fig.1). We should note the key assumption in line transect sampling which is that all animals that are located on the line are detected with certainty, i.e., g(0) = 1. In practice, detection on or near the line should be nearly certain and survey design must consider ways to assure that this assumption is met [1]. However, when studying the populations of highly

cryptic species, this assumption may be violated. In these cases, the imperfect detectability near the center line has to be properly accounted for. To achieve that, a mark-recapture distance sampling methodology has been developed [3].

Fig. 1. Variability of the detection functions of four benthic species as estimated by surveys conducted with line transects

Under the mark-recapture distance sampling (MRDS) methodology, two independent observers undertake the counting of animals and the common detections are treated as recaptures. With this approach, g(0) < 1 is estimated and accounted for in the estimation of P_a . MRDS was applied to estimate abundance of a seahorse (Hippocampus guttulatus) population in a 34.5 hectares site of northeastern Korinthiakos Gulf, Greece. Twenty-eight line transects were surveyed under a stratified sampling scheme by two independent observers. The estimate of average seahorse detection probability, in transects of 4 m half-width, was 0.41 (Fig.2). Average population density (in individuals per hectare) was 42.9 (95% CI: 25.8–71.3) and the estimated abundance in the study area was 1478 individuals (95% CI: 890–2455).

Fig. 2. Detection function of *Hippocampus guttulatus* using single and double observer data

IDENTIFYING DRIVERS OF ACCELERATING SEAGRASS LOSS IN THE MEDITERRANEAN: CAUSAL CHAIN AND SCENARIO ANALYSES

E. Jackson ¹*, O. Langmead ¹, S. Fowell ¹, M. Attrill ¹ and L. Mee ² ¹ Marine Institute, University of Plymouth - e.jackson@plymouth.ac.uk ² Scottish Association for Marine Science

Abstract

The primary causes of loss and degradation of Mediterranean seagrass beds were examined within a Driver Pressure State-Change Impact Response (DPSIR) framework as part of a larger EU project on European Lifestyles and Marine Ecosystems (ELME). Total losses were estimated at over 45 000 ha of seagrass over the last 100 years, with rates of change in the Mediterranean higher than recent global trajectories. Evidence gathered on the causes of loss (of seagrass habitat was used to produce Bayesian belief network (BBN) models to explore impacts of future changes in socio- economic drivers and policy. *Keywords: Posidonia, Coastal Management, Models*

Introduction

Mediterranean seagrass meadows (primarily Posidonia oceanica) play a crucial role in stabilising sediments, maintaining water quality, protecting sedimentary shores from erosion and represent important fish production areas [1]. However, they are often disregarded during economic and social development, despite a wealth of studies illustrating declines due to anthropogenic pressures [2], and this trend is accelerating [3]. Including marine ecosystems components in policies for sustainable development requires a better understanding on the causal connections between human pressures (and their socio-economic drivers) and the changing state of the systems. This is particularly important at a time when the European Community is expanding, re-examining its agricultural and chemical policies, reforming its fisheries policy and exploring new ways to protect marine systems using an ecosystem-based approach (Marine Strategy Framework Directive). Here we assesses the causes of historical seagrass habitat loss in the Mediterranean and the evidence gathered is used to produce Bayesian belief network (BBN) models to explore the impact of plausible alternative human development scenarios on seagrass habitats.

Methods

The study presented here summarises the information on loss (dates, amount and causes) of seagrass habitat in the Mediterranean over the last 100 years. Data gathering was carried out via three main methods; searching published material, an online questionnaire and via direct contact with key organisations and experts. Results of metadata analyses were used to construct a BBN model of the Driver, Pressure and State-change pathways (using probability density functions derived from data to describe causal relationships between variables). The model was trialled under different scenario outcomes based on plausible future development patterns, policy options and likely social changes at European Community level. The scenarios employed in this study were designed to provide a general overview of alternative states of the world to highlight the differences that result from divergent pathways of socioeconomic development [4]. A baseline scenario projecting future trends based on the current situation was contrasted with four Alternative Scenarios. defined at the extremes of two dimensions: governance and values. Each scenario comprises a description of the underlying values and policies that define it, and their broad socio-economic implications [5]. From these characterisations, narrative description of changes in basic socio-economic variables and activity in Driver sectors were developed for each scenario and translated into a simple categorical representation to indicate the direction of change in each of the Driver sectors, which were used to condition the BBN (full description see [6]).

Results and Discussion

We estimated total losses of over 45 000 ha of seagrass over the last 100 years, and identified rates seagrass loss for the Mediterranean which accede recent global trajectories. The causes of loss of seagrass habitat and the activities driving these pressures show patterns over time. The most numerically dominant activity causing past losses throughout the Mediterranean was input of urban sewage. However, there are indications that this activity pressure has been decreasing in frequency since the 1970s, perhaps due to improved wastewater treatment. The second most frequently observed pressure is from the fishing sector. There has been a gradually increasing trend in the loss of seagrass due to trawling, despite bans in the vicinity of seagrass beds in many parts of the Mediterranean. Other activities that are of growing concern are aquaculture (fish cages), tourism and shipping (anchoring, port construction). The BBN model (see Figure 1) was used to

examine levels of seagrass loss and degradation under different combinations of pressures observed under different scenarios. Alarmingly under the baseline scenario (and assuming that there is full compliance to policy) the decline of Posidonia continues, despite improvements in urban wastewater treatment and a decline in the trawling and dredge fleet, mainly due to increases in finfish aquaculture and coastal urbanisation (affecting turbidity and organic matter enrichment). Continuing upward trends in livestock production and fertiliser carry on loading coastal systems with nutrients indirectly affecting the light received by Posidonia. Of the alternative scenarios only local responsibility leads to an improvement in Posidonia state, due to a steep decline in destructive fishing practices and a decrease in the drivers of nutrient enrichment and turbidity. National enterprise has devastating effects on the Posidonia with all of the major causes of seagrass loss and degradation showing an increasing trend or stabilising at current levels but not declining. The outputs of this study, in terms of transdisciplinary scenario models, are intended to provide scientific support for the implementation of the ecosystem approach in Europe.

Abstract

Le chalutage benthique, les palangriers (de fond et de surface) et les filets maillants engendrent des captures accidentelles de la tortue marine *Caretta caretta* dans le golfe de Gabès. Les taux de captures sont relativement importants induisant une mortalité souvent élevée. La mortalité induite par les filets maillants ciblant les requins est de loin la plus élevée. *Keywords: Mortality, Gulf Of Gabes, Turtles*

Introduction

Les populations de tortues marines sont menacées d'extinction dans les différentes régions du monde. L'activité de pêche est considérée parmi les problèmes les plus menaçants et les plus urgents à résoudre pour assurer leur survie. Dans le golfe de Gabès, les tortues marines entrent en interaction avec la plupart des engins de pêche. Cette région, zone de pêche numéro 1 en Tunisie, est considérée par ailleurs comme une aire d'alimentation et d'hivernage des tortues marines en Méditerranée [1]. Ayant pour objectif la conservation, nous estimons dans ce travail les taux de capture et de mortalité des tortues marine par le chalut benthique, les palangriers de surface et de fond et les filets maillants côtiers opérant dans cette région.

Matériel et méthodes

Dans cette étude du golfe de Gabès, qui abrite environ 50% de la flottille de pêche du pays, nous avons réalisé 198 sorties en mer (73 avec des chalutiers, 80 avec des palangriers et 45 avec des embarcations côtières). Des observateurs à bord ont relevé les données suivantes : caractéristiques des engins de pêche, dates et heures, position géographique des opérations de pêche et des observations de tortues, espèce, Longueur Carapace Courbe (LCC), état physique de la tortue (vivante, morte, en coma). Les données sur les efforts de pêche déployés dans la région, fournies par l'administration des pêches, ont permis l'extrapolation des estimations des taux de capture et de mortalité des tortues à toute la flottille.

Résultats et discussion

Toutes les tortues marines, capturées accidentellement au cours de ce travail, étaient des caouannes *Caretta caretta*. Il s'agit, en effet, de l'espèce la plus abondante et qui nidifie sur certaines plages du pays. Les captures sont plus importantes dans les faibles profondeurs (en deçà de 50 m). Les tortues capturées sont essentiellement des juvéniles (LCC<70 cm). Les tailles moyennes des tortues capturées à la palangre de surface et au chalut benthique sont plus importantes que celles des tortues capturées à la palangre de fond (58,5 cm et 57,46 cm contre 48,7 cm). Le tableau 1 illustre les estimations des taux de captures et des mortalités directes (tortues trouvées mortes durant les opérations de pêche) pour les différents engins étudiés.

Engins de pêche	Espèces cibles	Taux de capture	Taux de mortalité
Chalut benthique	Crevettes et céphalopodes	0,006 t/l.d 0,822±0,249 t/sortie	3,33%
Palangre de surface	Requins et espadons	1,437±0,059 t/1000h 2±1,012 t/sortie	0%
Palangre de fond	mérous	0.633±0.040 t/1000h 1,142±0,79 t/sortie	12,5%
Filets maillants	requins	0.527±0.02 t/km²f.j 0.8±0.308 t/sortie	69,44%

t : tortue ; l.d : l est la longueur de la corde de dos du chalut/30,5m et d est la durée du trait de chalut/60mn ; h : hameçon ; f : filet et j : jour

Fig. 1. Taux de capture et de mortalité des tortues marines par les différents engins de pêche étudiés

Les taux de captures enregistrés sont relativement élevés et parmi les plus importants enregistrés en Méditerranée [2]. La mortalité est faible avec les chalutiers et les palangriers mais très élevée pour les filets maillants.

Conclusion

Les interactions de la caouanne avec l'activité de pêche dans le golfe de Gabès sont importantes. Cette espèce y est en effet relativement abondante et l'activité pêche y est également intense. L'atténuation du "by-catch" s'avère donc urgent dans cette région. La sensibilisation des pêcheurs, l'utilisation des "dehookers,"

l'essai d'hameçons circulaires, la manipulation adéquate à bord des tortues et la pêche plus au large, contribueraient à résoudre, en partie, le problème de ces interactions.

Abstract

Le régime alimentaire de *Dipturus oxyrinchus* a été étudié à partir des contenus stomacaux de 520 individus capturés dans le golfe de Gabès. Cette espèce se nourrit principalement de poissons téléostéens et de crustacés. D'autres invertébrés constituent toutefois des proies accessoires. Des variations dans le régime alimentaire ont été observées et sont liées à la taille et au sexe des individus. *Keywords: Food Webs, Elasmobranchii, Gulf Of Gabes*

Introduction

Dipturus oxyrinchus est une espèce atlanto-méditerranéenne quasi-menacée en Méditerranée [1]. Aucune étude sur la biologie de cette raie n'a été fournie dans cette zone. Dans ce travail, nous contribuons à la connaissance du régime alimentaire de *D. oxyrinchus* dans le golfe de Gabès, selon des aspects quantitatif et qualitatif par l'analyse du coefficient de vacuité et de certains indices alimentaires.

Matériel et méthodes

Les contenus stomacaux de 520 individus (LT: 25 - 105 cm), capturés dans le golfe de Gabès entre septembre 2006 et juin 2008 ont été examinés. Pour chaque individu le sexe, la LT (cm) et l'état de réplétion (estomac vide ou plein) sont notés et les proies des estomacs pleins sont identifiées, dénombrées et pesées au 0.1 g prés. Le coefficient de vacuité (Cv%) a été analysé en fonction de la taille et des mois. L'aspect quantitatif du régime alimentaire a été décrit, l'indice de l'importance relative (IRI%) combinant les pourcentages d'occurrence (F%), numérique (N%) et pondérale (M%) a été déterminé pour évaluer l'importance relative des différents items alimentaires identifiés [2].

Résultats et Discussions

520 estomacs de D. Oxyrinchus ont été examinés. 87 estomacs étaient vides, soit un coefficient de vacuité de 16.7% indiquant la voracité de l'espèce. La période préférentielle d'alimentation se situe en automne et en hiver (Fig. 1). Ce coefficient ne varie pas significativement avec le sexe (P: 0.05), par contre il a une variation significative avec les tailles des individus (P: 0.05); ceci est probablement lié aux changements des besoins énergétiques et à la mise en place d'une stratégie de prédation plus élaborée chez les individus de grande taille. Le bol alimentaire (Tab. 1) montre que D. oxyrinchus a un large spectre alimentaire et un comportement de prédation aussi bien pélagique que benthique. L'importance pondérale ainsi que la fréquence des proies sont en faveur des Téléostéens. Numériquement, les crevettes sont les plus nombreuses alors que les taxons restant sont faiblement représentés. Les variations numériques et pondérales observées indiquent le caractère opportuniste du prédateur. Nos résultats corroborent avec ceux d'autres auteurs [3] qui soulignent que le régime alimentaire de D. oxyrinchus est surtout constitué de crustacés, téléostéens et des céphalopodes.

Abstract

Temporal and spatial variation in density, biomass and size of littoral fish associated with *Posidonia oceanica* meadows were studied throughout an annual cycle. Approximately 109350 littoral fish were collected, belonging to 34 families and 88 species. Highest values of density were observed during August due to high densities of juveniles. Four functional guilds were created in order to describe the habitat use for each species encountered including juvenile migrants, seagrass residents, seasonal migrants and occasional visitors. Among the species encountered, eleven were found to be non-indigenous. *Keywords: Fishes, Posidonia, Aegean Sea, Levantine Basin, Biodiversity*

Introduction

The ecological importance of *Posidonia oceanica* meadows, for the littoral zone of the Mediterranean, is from various aspects well sustained. *P. oceanica* meadows are highly productive and diverse communities and considered the high spot of soft bottom substrata [1]. They promote sediment stability [1], and their high complexity provides a habitat for food, shelter and nursery for several fish populations [4, 6]. This is the first study with the aim to quantitatively assess the fish assemblage associated with *Posidonia oceanica* meadows in eastern Mediterranean. We investigated the temporal and spatial dynamic, assemblage structure and functional guilds of the fish fauna. In addition, the role of newly and former non-indigenous species of Indo-Pacific origin was studied in this habitat.

Materials and Methods

In order to study temporal and spatial variations in fish assemblages, day samples were taken at five shallow (5-35 m) locations around the coasts of Rhodes Island with boat seining on four occasions over the year 2008: February (winter), May (spring), August (summer) and December (autumn). Fish species density, biomass and average size was seasonally recorded during an annual cycle and used to create functional groups. The functional guilds defined in this study consisted of similar to those described by Elliot and Dewailly [3], although modified depending on own data and observations. The definitions we use here are: SR - Truly seagrass residents, species which are stationary on Posidonia oceanica meadows and are highly dependent on them; JM - juvenile migrants, species which use seagrasses primarily as a nursery ground, but often returns as adults for spawning or feeding; SM - seasonal migrants, species which have seasonal visits to seagrasses, usually as adults for spawning or feeding and OV - occasional visitors, species that appear irregularly on seagrasses but have no apparent seagrass requirements.

Results

showed that Posidonia oceanica meadows from eastern Our study Mediterranean sustain a diverse fish community including 88 species within 34 families a number that accounts for 19% of the total number of species inhabiting eastern Mediterranean [7, 5). Density showed significant seasonal seasonal differences (p<0.01) which was as revealed from Tukev's HSD attributed to significant higher values during summer compared to all other seasons (p<0.01). Mean fish density showed approximately three times higher values in summer compared to any other season, while species richness showed slightly higher average values in spring and summer. Native planktivorous school forming species (e.g. B. boops, S. smaris, S. maena, C. chromis), were dominant in terms of abundance. Labridae and Sparidae families were found to be the two most diverse fish families, which is in accordance to previous studies from western Mediterranean [1, 2, 4]. The fish assemblage consisted of 24 seagrass resident, 17 juvenile migrants, two seasonal migrants and 45 occasional visitor species.Several species within seagrass resident guild were of commercial value (e.g. Spicara smaris, Spicara maena) and showed high contribution to total abundance (Table 1). Several species in the juvenile migrant guild were of commercial importance (Table 1). Most of the species within the diverse and dominating family Sparidae, were classified as juvenile migrants, indicating a habitat use mainly during their early life stages.

Tab. 1. Ranking of the 10 dominant species in terms of total biomass and density on *P. oceanica* meadows. Family, origin and ecological guild are indicated. * denotes species of commercial value

8	Sphyraena chrysotaenia*	Sphyraenidae	NI	JM	1325
9	Mullus surmuletus*	Mullidae	1	JM	1312
10	Sparisoma cretense*	Scaridae	I.	JM	1077
10	Sparisoma cretense*	Scaridae	I	JM	1077

Discussion

Seagrass resident species were widely represented within the dominant families of the fish assemblage (e.g. Centracanthidae, Labridae, Mullidae, Sphyraenidae and Syngnathidae). All juvenile migrants were found to use seagrass meadows during samplings in August and usually occurred in high densities. Spring was found to be the main season in seagrass for *Chromis chromis* and *Thalassoma pavo*, and due to their occurrence only as reproductive adults, they were classified as seasonal migrants.

FOOD AND FEEDING HABITS OF NINE ELASMOBRANCH SPECIES IN THE N AEGEAN SEA

Paraskevi k Karachle ¹* and Konstantinos i Stergiou ¹

¹ Aristotle University of Thessaloniki, School of Biology, Department of Zoology, Lab of Ichthyology - pkarachl@bio.auth.gr

Abstract

We present diet composition for nine elasmobranch species the N Aegean Sea. These species fed mainly on Crustacea, Cephalopoda and fishes, and to a lesser extent on Polychaeta. Based on their feeding habits, they form two distinct groups: one including species with streamline body shape and *Raja miraletus* and the other one all the remaining dorso-ventral flattened species. *Keywords: Elasmobranchii, Diet, Aegean Sea*

Introduction

In this study we present the feeding habits of nine elasmobranch species from the N Aegean Sea. Out of those nine species information from the Aegean Sea exist only for four species (i.e. Dasyatis pastinaca [1]; Raja clavata [2]; Raja radula [3]; and Scyliorhinus canicula [2]). These data are useful for studying the Mediterranean marine food webs and developing local ecosystem models.

Materials and Methods

Seasonal samples (spring 2001-winter 2006) were collected, using commercial fishing vessels (for a detailed account on samplings see [4]). Diet data were analysed with multivariate analyses ([5]) in order to identify groups of species with similar diets. Additionally, SIMPER analysis [5] was employed to identify food items responsible for group formation.

Results and Discussion

Overall, the stomach content of 172 individuals, belonging to 9 different elasmobranch species were examined (Table 1). The small number of individuals is attributed to the fact that many of these species are rare in the study area, or were caught in low abundances with the fishing gears used. Dalatias licha, Galeus melastomus and Scyliorhinus canicula fed mainly on Cephalopoda (97.3, 93.6 and 50.2%, respectively), T. marmorata on fish (99.3%), whereas all the remaining species preyed mainly on Crustacea (Dasyatis pastinaca: 74.6; Dipturus oxyrhinchus: 100.0; Raja clavata: 63.7; Raja miraletus: 68.7; and Raja radula: 53.3%) (Table 1). The diets of the species in the present study were similar to those reported from other areas ([1], [2], [3], [6]), except for D. oxyrinchus. The latter preys mainly upon fish [6], whereas in the present study we only caught one individual which fed on Natantia (Table 1).

Tab. 1. Food items and their contribution (expressed as % wet weight) for nine elasmobranchs in the N-NW Aegean Sea, Greece, spring 2001- winter 2006. N=number of individuals; TL=total body length; VC=vacuity coefficient

N	3	34	2	1	1	7	3	3	118
TL range (cm)	23.3-54.0	24.1-45.1	38.0-40.2	50.1	81.2	25.6-46.5	22.6-33.9	21.8-32.0	8.8-37.3

Multivariate analysis showed the formation of two distinct groups (cluster analysis: 11.56% similarity; multi-dimensional scaling: stress <0.01, figure not shown) (Fig. 1): one included Charcharhiniformes, Squaliformes and R. miraletus (average similarity=50.55%) and the other one the Torpediniformes and all the remaining Rajiformes (average similarity=34.23%). According to SIMPER, the food items responsible for the dissimilarity of these two groups (average dissimilarity=88.44%) were Cephalopoda and Natantia (average contribution=38.47% and 25.36%, respectively). The main food item for the first group was Cephalopoda (average contribution=94.95%). Cephalopoda were almost absent from the diet of the second group, in which the main prey items were Natantia (average contribution=59.44%) and not identified fish (average contribution=33.19%). Presumably, the consumption of such food items, with different morphological and ecological characteristics, requires swimming ability and morphological features (i.e., dentition, mouth position and large gape) that differ among the species of the two groups. Indeed, the streamlined body shape of the majority of species included in the first group probably allows them to attain higher speeds and accelerations. Conversely, the flattened body form of the species in the second group fit for movement by undulation [6] allowing them to lay on the sandy bottoms and prey upon organisms with low swimming ability. The fact that R. miraletus was included in the first group could be attributed to the large proportions of Cephalopoda in its diet, combined with the small number of individuals examined.

Fig. 1. Cluster analysis for seven flatfishes, based on their feeding habits, from the NW Aegean Sea, Greece, spring 2001- winter 2006. Fish drawings from FishBase (www.fishbase.org; [6])

The trophic level estimates of these species, based on the feeding habits presented here, are given elsewhere [4]. They ranged from 3.46 ± 0.53 , for D. pastinaca, to 4.50 ± 0.41 , for G. melastomus. Seven of these species had trophic levels >3.7, a fact that classifies them as carnivores [7], thus playing an important role in the trophic structure of marine ecosystems (see also e.g. [8], [9]).

AGE ESTIMATION OF ALBACORE (*THUNNUS ALALUNGA*) CAUGHT BY PURSE SEINE IN TURKISH WATERS BASED ON DORSAL SPINE READING

F. saadet Karakulak 1* and Taner Yildiz 1

¹ Istanbul University, Faculty of Fisheries, Ordu cad. No.200, Laleli, Istanbul, Turkey - karakul@istanbul.edu.tr

Abstract

Lengths of 151 albacore (*Thunnus alalunga*) were measured from 1999 to 2004 in the northern Levantine and Aegean Sea. Fork lengths ranged between 65.0 and 91.5 cm. Age and growth were estimated from seasonally formed bands on the first dorsal spines of 95 specimens. The parameter estimates for the combined sexes were $L_{\infty}=100.74$ cm, k=0.167 years⁻¹ and $t_0=-4.878$ years. Growth performance index Φ' was 7.435 of all individuals studied. The maximum age was 8 years. *Keywords: Fishes, Pelagic, Growth, Eastern Mediterranean*

Introduction

Albacore (*Thunnus alalunga*) is a highly migratory species, found in both subtropical and temperate waters of the three oceans, including the Mediterranean Sea. This species, which has been caught as a by-catch species from bluefin tuna fishery in the Turkish waters, has increasingly been caught by gillnets as the target species in recent years [1]. The catch quantity of albacore has increased remarkably from 73 t in 2006 to 852 t in 2007 [2]. The objective of our study was to estimate albacore age and growth in Turkish waters from growth rings on sections of the first dorsal spine.

Material and Methods

A total of 151 samples were collected during the 1999-2004 from catches by Turkish fishing fleets operating in the northern Levantine and Aegean Seas in bluefin tuna purse seine fisheries. Fishing area depth was 200-2400 m. The first spine of the first dorsal fin was removed from each specimen and fork length (FL), date and area of capture were recorded.

Mean length at age data were used to estimate the growth parameters of the von Bertalanffy growth function $L_t = L_{\infty}$ [1-e^{-K(t-to)}], where L_t is the total length of fish at time t; K is a growth constant; L_{∞} is the asymptotic length; and t_0 the theoretical age at length 0. Growth performance indexes (Φ '=lnk + 2 ln L_{∞}) were calculated to compare results obtained in this study with results published elsewhere [3].

Results and Discussion

Fork length of all individuals collected ranged from 65.0 to 91.5 cm FL (average value 80.23 ± 0.53 cm). Dominant length class in the total sample was 80-84 cm (Fig.1).

Fig. 1. The fork length distribution of albacore caught in Turkish waters

Age determination and back-calculation analysis was determined from 95 fish of 65.0 to 91.5 cm FL. The age range was between 2 and 8 years. 5- and 6-year-old fish were the most abundant in the samples from the albacore population studied (Tab.1A). The estimated von Bertalanffy growth parameters for sexes combined were L_{α} =100.74 cm, k=0.167 years⁻¹ and t_o=-4.878 years.

Growth performance index Φ' was 7.435 for all individuals. The comparison of growth parameters and growth performance indexes estimated in the present study and those obtained in previous studies are shown in Tab.1B. The mean growth performance index was significantly lower (P<0.05) for the Mediterranean than for Atlantic populations. Compared to Mediterranean sample, north Atlantic populations showed a higher fitted L_{∞} (134.4 -140.1

cm).

This study	dorsal spines	100.7	0.167	-4.878	7.435

The absence of 0- and 1-years-old individuals in the purse seine fisheries of the Turkish waters may be associated with the habitat and behaviour of these young fish. 5- and 6-year-old fish were the most abundant in the purse seine fisheries. However, 2 and 3 years old individuals are more dominant for the long-line fisheries in the Aegean Sea [6]. This situation may be attributed to the selectivity of the fishing gear.

ON A COLLECTION OF OPISTHOBRANCHS (MOLLUSCA, GASTROPODA) FROM THE LEVANTINE COAST OF TURKEY

S. Ü. Karhan ¹*, E. Kalkan ², M. B. Yokes ³, H. Balkis ¹ and C. Dalyan ¹

² Institute of Environmental Sciences, Bogaziçi University

³ Department of Molecular Biology and Genetics, Haliç University

Abstract

A small collection containing ten species of opisthobranch gastropods reported here from the Levantine coast of Turkey. Of these species *Facelina annulicornis* and *Pruvotfolia pselliotes* are new records for the Levantine Sea. *Keywords: Gastropods, Mollusca, Levantine Basin*

The knowledge of opisthobranch fauna of the Levantine Sea is very incomplete and needs to be improved when compared to the other parts of the Mediterranean. Although, some contemporary studies from Turkish coast [e.g. 1,2] have provided important insights into the Opisthobranch fauna of the region, most of the current knowledge is based upon some old studies from Turkish and Israeli coasts [e.g. 3,4].

The specimens reported here were obtained during a faunistic survey conducted on the coasts of Samandag and Yayladagi (Levantine coast of Turkey, close to the Turkish-Syrian border) between October 2008 and May 2009. Collection of the specimens was carried out by SCUBA diving. All specimens were photographed alive, were preserved in 70% ethanol and are stored in the Istanbul University Science Faculty Hydrobiology Museum, Turkey. Of the ten opisthobranch species identified *Facelina annulicornis* and *Pruvotfolia pselliotes* are new records for the Levantine Sea.

POPULATION DYNAMICS OF DEEP-WATER PINK SHRIMP PARAPENAEUS LONGIROSTRIS (LUCAS, 1846) AT MONTENEGRIN SHELF (SOUTH ADRIATIC)

Olivera Kasalica 1* and Slobodan Regner 2

¹ Institute of Marine Biology, P.O.Box 69, 85 330 Kotor, Montenegro - okasalica@yahoo.com ² Institute for Marine Biology, Kneza Viseslava 1, 11 030 Belgrade, Serbia

Abstract

The deep-weater pink shrimp Parapenaeus longirostris (Lucas, 1846) presents an economically significant species in Montenegrin trawling fishery. The objectives of this work were to investigate population dynamics. Population of this species on the shelf of Montenegrin coast is not threatened by high rate of trawler fishing. Keywords: Adriatic Sea, Continental Shelf, Decapoda, Population Dynamics

Introduction

Parapenaeus longirostris (Lucas, 1846) is a decapod species that is widely distributed on the Montenegrin shelf, and since late 1990-ties it is an object of especially big commercial importance. As for the Montenegrin coast there were no data that could be used to follow up the population dynamics of this species', the task was to study the population structure in this area for the first time, to determine the main population parameters (length-weight relationships, growth parameters, mortality rates), estimate of biomass (relative and absolute) as well as maximal biological sustainable yield (MSY).

Materials and Methods

The material was collected by commercial trawlers in period March 2003 -June 2004, at depths of 20 - 120 m, including one quarter of the total area of shelf. Data include catch from 13 trawling hauls, duration of which was from 1.17 to 4 hours. The weight of the total catch and the weight of deep-water pink shrimp catch was measured on the ships, while statistical analysis was performed in Institute of Marine biology in Kotor. The parameters of the length - weight relationship were determined. The growth parameters were obtained using the Von Bertalanffy growth equation and the Bhattacharya method [1] using FISAT computer program [2]. Two methods were used for the estimation of total mortality (Z): length converted catch curve method [3] and method which is based on the relationship between Z and the mean total length [4]. Natural mortality M was estimated using Pauly's formula [3]. Fishing mortality F was calculated as: F = Z - M and exploitation rate E as: E = F / Z. Yield per recruit was estimated using the Beverton-Holt model [5]. For estimating MSY we used Cadima's formula (MSY = 0.5 * Z * B) [6]. Beddington and Cooke [7] concluded that formula generally overestimates MSY 2 to 3 times, so we used 0.2 instead 0.5. to get better estimate of MSY.

Results and Discussion

Values of powers of length-weight relationships is b = 2.37 for the total sample, b = 2.41 for males and b = 2.33 for females; while values for total length (TL) are b = 2.9 for total sample, b = 2.84 for males and b = 2.89 for females. The estimated growth parameters are $L_{\infty} = 47$ mm and K = 0.7 for carapace length (CL), while for total length (TL) $L_{\infty} = 146$ mm and K = 0.9. The calculated mean value of rate of total immediate mortality (Z) is 3.48, while mean value of rate of natural mortality (M) is 1.5. Value of the fishing mortality is 1.98. The estimated mean value of relative biomass (Br) is 69.3 kg/km², while the total relative biomass of whole studied area is 67.6 tons. The calculated total relative biomass and coefficient of vulnerability q =0.6455 were used to estimate the absolute biomass, which yields (Ba) 112.63 tons, while MSY of the studied area is 78.39 tons per year. As the value of maximal allowed exploitation rate is $\mathrm{E}_{\mathrm{max}}$ = 0.564, and the real exploitation rate is E = 0.3, we may conclude that the population of Parapenaeus longirostris on the Montenegrin shelf is not yet threatened by the present fishing effort of the trawl fishery.

IMPACT OF MARINE LITTER ON SEA LIFE: A REVIEW

Stelios Katsanevakis^{1*} and Yiannis Issaris¹ ¹ Hellenic Centre for Marine Research - skatsan@ath.hcmr.gr

Abstract

Marine litter (i.e., any manufactured or processed solid material that enters the marine environment) is a greatly underestimated component of marine pollution. Herein the impact of marine litter on sea life is reviewed. The entanglement of marine species, especially marine mammals, seabirds, turtles, fish, and crustaceans has been frequently described as a serious mortality factor. Marine species may ingest litter items, which has many harmful effects on their physical condition and survival. Other impacts include toxic contaminants entering food webs, assistance of the invasion of alien species, altering the structure of benthic biocommunities, and damage to coral reefs and coral facies.

Keywords: Plastics, Pollution, Mortality

Marine litter (or marine debris) is any persistent, manufactured or processed solid material discarded, disposed of or abandoned in the marine and coastal environment from any source [1]. Although there are various types of litter, plastics (synthetic organic polymers) make up most of the marine debris worldwide. Most marine litter originates from land-based activities, and the main sources include storm water discharges, municipal landfills located near the coast, riverine transport of waste from landfills and other sources, discharges of untreated municipal sewage, unregulated disposal of litter due to absence of waste services or landfills, tourism, all types of vessels, offshore oil and gas platforms, and aquaculture installations. Litter densities that reach many thousands or even millions of items per hectare have been reported on the seafloor or along beaches [2]. Mediterranean is among the areas with the highest reported marine litter densities [2].

A direct threat to marine life is entanglement in loops or openings of floating or sunk marine litter. The most problematic marine litter for entanglement appears to be lost or discarded fishing gear, six-pack plastic rings, and packing strapping bands. Entangled animals may get killed by drowning, suffocation, or strangulation. Even if they manage to survive, entangled animals may suffer restricted efficiency of movement and swimming, and thus an impaired ability to catch food and avoid predators, whilst their demand for food may increase significantly due to elevated energetic costs [3]. Entanglement could cause lacerations and infections from the abrasive or cutting action of attached litter. In addition, entangled animals may exhibit altered behavior patterns that place them at a survival disadvantage [4].

The entanglement of marine species in marine litter, especially marine mammals, seabirds, turtles, fish, and crustaceans, has been frequently described as a serious mortality factor. Derelict or discarded fishing gear may continue to fish for years, a process that has been termed 'ghost' fishing. Many marine species interact with marine litter as a result of their normal behavior patterns and suffer by high rates of entanglement. Entanglement in marine litter has been reported for at least 20 pinniped species, i.e. 61% of existing species worldwide, at least 14 cetaceans: six species of baleen whales and eight species of toothed whales, and all seven species of marine turtles (Table 1).

The impact of entanglement in marine litter on marine populations is difficult to quantify as unknown number of marine animals die at sea and decompose without being recorded. Animals that become entangled and die may quickly sink or be consumed by predators at sea, eliminating them from potential detection. Some endangered species may be very rare and their detection quite difficult, so that entanglement incidents to marine litter are scarce and almost impossible to detect even with intense sampling efforts. Hence, the estimated mortality rates and the effects on the population dynamics of many affected species are probably underestimated [2].

Many marine species such as marine mammals, seabirds, marine turtles, and fish have been reported to ingest marine litter, especially plastics. Ingestion of marine litter may occur either because of misidentification of litter as natural prey or accidentally during feeding and normal behavior. The most serious effects of ingested litter are the blockage of the digestive tract and internal injuries by sharp objects, which may be a cause of mortality. Other harmful effects include blockage of gastric enzyme ingestion, diminished feeding stimulus, nutrient dilution, reduced growth rates, lowered steroid hormone levels, delayed ovulation and reproductive failure, and absorption of toxins [5]. At least 32 species of cetaceans (43% of existing species worldwide) and all species of marine turtles have been reported to ingest marine litter (Table 1).

All Mediterranean marine mammals and marine turtles have been reported to either ingest or get entangled in marine debris, i.e. the Mediterranean monk seal (entanglement), all three marine turtles, and all 14 cetaceans that either have permanent populations or are occasionaly observed in the Mediterranean (entanglement: 8/14; ingestion: 13/14).

Plastics may release toxic chemicals when ingested because of the chemical additives they contain. Several additives like nonylphenols, polybrominated diphenyl ethers, phtalates, and bisphenol A are used as plasticizers or are added to plastic during production to give it desirable properties. Furthermore, plastics have the potential to absorb hydrophobic pollutants like PCBs and DDT from seawater. There is great concern about the possible transfer of these toxic pollutants to marine organisms due to plastic ingestion [5], [6].

Other known impacts of marine litter include altering the structure of benthic communities [7], causing damage to coral reefs and coral facies [8], and assisting invasions of alien species [9].

Abstract

The aim of this study was the detection of DNA damage and repair efficiency, in hepatocytes of sea bream (*Sparusaurata*), under copper (Cu^{++}) and zinc (Zn^{++}) experimental exposure. The results illustrated a different cellular behaviour between metals' exposure, implying variant response mechanisms to stress. Moreover, the contribution of repair processes in DNA fragmentation of hepatocytes is discussed.

Keywords: Aquaculture, Ecotoxicology, Metals, Pollution, Trace Elements

Introduction

Zinc and copper are natural elements occurring in aquatic ecosystems. On trace amounts within a narrow optimal concentration range, they are essential to living organisms. However, metal concentrations can become toxic to hydrobionts due to anthropogenic load on hydrosphere. Both zinc and copper are common metal cofactors conducting an important role in a plethora of fundamental biological processes [1] especially in the metabolic pathway. The scope of the present work was to study sublethal metal genotoxicity in githead sea bream (*Sparus aurata*) hepatocytes. The selected concentrations were directly comparable to marine pollution levels.

Materials and Methods

Three hundred and twenty specimens of gilthead sea bream, Sparus aurata, (70±10g) were provided from a local breeding farm in northern Evoikos Gulf. They were acclimatized for one month at the University facilities in 500L tanks. Different replicates of fish were exposed to 0.1 and 0.5ppm of CuSO₄5H₂O and 0.2 and 1.0ppm of ZnCl₂ for 24 and 96 hours. Livers were dissected from three specimens per treatment. Hepatocytes' isolation protocol was conducted according to [2]. Cell counting was carried out using a Neubauer haemocytometer and their viability was determined with eosin staining. Cell suspensions were divided into two aliquots, referring for the direct damage assessment (first assay) and the estimation of repair efficiency (second assay). DNA fragmentation was assessed using a slightly modified protocol of the alkaline comet assay [3]. In order to estimate the involvement of repair mechanisms in DNA fragmentation, 1ml of isolated hepatocytes was placed in a 5ml culture medium and was incubated for 2h in room temperature (metal-free treatment). Two microscope slides per specimen and 100 cells per slide were analyzed for both assays. Comet-shape structure was examined using a fluorescent microscope and was scored with the open-source image analysis package CASP [4].DNA damage was evaluated by computing the tail moment (TM) parameter [5]. Kruskal-Wallis tests were adopted for the statistical analysis [6].

Results and Discussion

TM parameters are presented in Fig. 1. Significant DNA fragmentation was detected on specimens exposed to both zinc and copper, compared with the control ones. Incubated hepatocytes in the metal free medium showed higher DNA fragmentation compared to those directly assayed. This significant difference in the TM values denotes an increased repair activity leading to substitution of the damaged DNA segments [7]. DNA fragmentation of specimens exposed to copper for either 24 or 96h revealed a significant increase in the higher concentration in both assays. Regarding the incubation in the metal-free medium, specimens' exposure to low copper concentration was non-significant in comparison with the control ones. The fact that a time response to copper exposure was detected only in the second assay could be explained by a delayed activation of the detoxification mechanisms [8]. On the other hand, specimens exposed to the high zinc concentration presented maximum DNA fragmentation in either 24 or 96h, indicating elevated genotoxicity. Furthermore, a significant time response to zinc exposure, similar to copper exposure, was observed in the metal-free medium incubation. Only this time there was a significant decrease rather than the observed increased pattern in the TM values regarding copper exposure. A possible explanation is that exposure to high zinc concentrations directly affects DNA repair mechanisms. The different assayed cellular behaviour pattern between specimens exposed to copper and zinc could be explained by variant response mechanisms to each metal [8]. Fish exposure to copper seems to instantly

activate detoxification mechanisms. Adversely, zinc seems to inhibit their DNA repair activity.

Fig. 1. Median TM values for all treatments. Significancies among bars are noted with different letters (P < 0.05)

Abstract

This paper presents the results of the bottom trawl survey carried out in the Gulf of Antalya in the summer period of 2009 in order to determine the catch composition, abundance and biomass of the demersal fish stocks. A total of 84 fish species were identified. *Gymnura altavela* (Linnaeus, 1758), *Mullus barbatus* Linnaeus, 1758, *Dasyatis pastinaca* (Linnaeus, 1758), *Pagellus erythrinus* (Linnaeus, 1758) and *Epinephelus aeneus* (Geoffroy Saint-Hilarie, 1817) are the species that have the highest biomass index values. *Keywords: Trawl Surveys, Demersal, Fishes, Biomass, Eastern Mediterranean*

Introduction

The Gulf of Antalya locates in the Norteastern Levantine Basin and is characterized by high temperature, salinity and oligotrophy. Few studies concerning the demersal fish community of the shallow continental shelf area of the Northeastern Levant Sea are available [1,2,3]. This paper presents the first detailed information on the demersal fish community of the Gulf of Antalya.

Material and Methods

This research was carried out in August 2009, in the Gulf of Antalya, between the depths of 25-200 m, using a commercial bottom trawl net. The cod-end mesh size was 22 mm (knot to knot). The samples were collected day time with 2.5 n.m./h average trawling speed. The geographical coordinates of 30 trawling stations vary between N36° 52' 48.5 - 36° 23' 00.0'' - E31° 32 32.2' - E30° 31' 11.3''. The total catch from each haul was identified to species, counted, weighed and standardized to unit trawling hour. The stock amount is calculated according to the swept area method; the catch weight (Cw) divided by the swept area (a) for each species and for each haul [4]. The swept area (a) for each species and for each haul [4]. The swept area (a) for each species and for each shall of the head-rope, *D*: cover of distance, X: fraction of the headrope length which is equal to the width of the path swept by the trawl (accepted as 0.5).

Results

A total of 30 hauls were carried out at the depths of 25, 50, 75, 100, 150, 200 m. The average catch was 83.38 ± 15.54 kg/hour (±se), average biomass 4188.77 ± 797.93 kg/nm² (±se) or 1221.25 ± 232.64 kg/km² (±se) and average abundance 63049 ± 8181 ind./nm² (±se) or 18382 ± 2385 ind./km² (±se) (Tab.1).

Tab. 1. The number of hauls, average catch (kg/hour (\pm se)), biomass (kg/nm² (\pm se)), abundance (ind./nm² (\pm se)), and number of species at six depth levels in the Gulf of Antalya.

Depth (m)	Number of hauls	Average catch kg/hour (±se)	Average biomass kg/nm²(±se)	Average abundance ind./nm ² (±se)	Number of Species
25	6	122.8 ± 54.11	6294.99 ±2906.27	88997 ±22156	56
50	6	92.37 ±28.49	4641.18 ± 1452.14	54819 ± 13728	61
75	6	55.82 ± 7.99	2814.59 ± 389.04	54117 ± 11807	54
100	6	98.89 ±44.93	4838.31 ±2179.65	60775 ±25678	38
150	4	60.92 ± 27.82	3047.09 ± 1365.52	70345 ±22946	40
200	2	19.21 ±6.21	970.15 ± 310.00	28924 ± 5703	22
Total	30	83.38±15.54	4188.77 ± 797.93	63049 ±8181	84

Among the total of 84 fish species identified, 75 were osteichthyes, and 9 chondrichthyes. The 26 species, that have higher biomass index than 15 kg/nm² are given in Table 2. *Gymnura altavela* (Linnaeus, 1758), *Mullus barbatus* Linnaeus, 1758, *Dasyatis pastinaca* (Linnaeus, 1758), *Pagellus erythrinus* (Linnaeus, 1758) and *Epinephelus aneuus* (Geoffroy Saint-Hilarie, 1817) are the species that have the highest biomass index values and *M. barbatus* Linnaeus, 1758, *P. erythrinus* (Linnaeus, 1758), *Bothus podas* (Delaroche, 1809), *Citharus linguatula* (Linnaeus, 1758), and *Lepidotrigla cavillone* (Lacepède, 1801) have the highest abundance.

Discussion

This research was conducted in the "pre-fishing" season both in the fishingprohibited and open areas and will continue for four seasons. The aim of the research is to determine the seasonal and spatial distribution of the demersal species in the Gulf of Antalya. This paper presents the preliminary data of the research but this is the first detailed information on the demersal fish community of the Gulf of Antalya. In the Gulf of Antalya, the catch composition of bottom trammel nets at max.10 m depth was studied by [3] and 73 fish species were reported. The 84 fish species found in this study is far below the number of fish species (165), given by [1] for the Gulfs of Iskenderun and Mersin. Thus long-term approaches are required for the stocks, if the lack of relevant literature from this region is concerned.

DISTRIBUTION OF DEMERSAL FISH SPECIES IN THE BLACK SEA, SEA OF MARMARA AND NORTH AEGEAN SEA

Cetin Keskin¹*

¹ Fisheries Faculty Istanbul University - aydankeskin10@hotmail.com

Abstract

Fish species richness decreases from the Aegean Sea, Sea of Marmara to Black Sea. In this study, biogeographic differences between three areas were approved in terms of demersal fish species. Some endemic species such as *Mezogobius batrachocephalus* and *Neogobius melanostomus* obtained only less saline and temperate water in the Black Sea. <u>Keywords: Fishes, Biogeography, Eastern Mediterranean</u>

Introduction

Geologic history and hydrologic characteristics of Turkish Straits System (Bosphorus, Sea of Marmara and Dardanelles) are main factors indicating to the fauna and flora characteristics in the Northeastern Mediterranean from the Aegean Sea to the Black Sea. This system is important as a biological barrier or corridor and acclimatization zone for Mediterranean Sea and Black Sea species [1]. This study is a preliminary emphasis on the zoogeography of demersal fish species in the Black Sea, Sea of Marmara and North Aegean Sea.

Materials and Methods

Fish samples were collected with bottom trawl net. A total of 17 hauls was carried out during autumn periods in 2006 and 2007 on board the R/V *Yunus-S* in the North Aegean Sea (AS), Sea of Marmara (SM) and Black Sea (BS), depth ranging from 22 m to 72 m (Fig. 1). Species presence/absence matrix was used to classify hauls with similar species composition. Cluster based on Bray-Curtis similarity index. SIMPER analysis was applied in order to identify the percentage contribution of each species to the overall similarity.

Fig. 1. Samplings in the Black Sea, Sea of Marmara and North Aegean Sea during autumn periods in 2006 (dark circles) and 2007 (white circles).

Results and Discussion

A total of 67 fish species were collected during this study. Species richness showed a decrease from the AS, and SM to BS (38, 30 and 27, respectively). Considering to the zoogeographical origin of the species, there were 55 Atlantic-Mediterranean species, 8 endemic species and 4 cosmopolitan species. The number of endemic species was higher in the BS, the Atlantic-Mediterranean species higher in the AS and SM. Cluster analysis of 17 hauls showed a clear separation according to area (Fig. 2). Samples in the BS separated from in the AS and in the SM at the level of similarity around 18.55%. Samples in the AS separated from the SM at the level of similarity around 51.66%. According to SIMPER results, the average similarity within group AS was 70.90%; Mullus barbatus, Serranus hepatus, Citharus linguatula, Scyliorhinus canicula, Arnoglossus laterna, Lophius budegassa and Serranus cabrilla were responsible species with high contribution (9.15% each) 50% to the similarity of this group. The average similarity within group SM was 77.07%, and within group 50% similarity was attributed to Merlangius merlangus euxinus, S. hepatus, Merluccius merluccius, A. laterna, Raja clavata, Chelidonihthys lucernus, M. barbatus and Gobius niger with relatively high contributions each (from 5.22% to 8.69%). The average similarity within group BS was 61.23%, and Trachinus draco, Scorpaena porcus, M. barbatus, Mezogobius batrachocephalus and Neogobius melanostomus were highly contributing species (from 9.18% to 19.27%) 50% to the similarity of this group. Fish

species richness decreases from AS, SM to BS along the Turkish coast [2]. Similar results obtained in this study. Also, the results supported to identification of biogeographically distinct between three areas. Species composition in the BS was highly dissimilar to the species composition in the AS and in the SM. Some endemic species such as *M. batrachocephalus* and *N. melanostomus*, pontian relic species, occurred only less saline and temperate water in the BS, Atlantic-Mediterrenean species such as *C. linguatula, S.hepatus, A. laterna, S. canicula* and *M. merluccius* were common species in the AS and in the SM at least during the sampling period of this study. High similarity between the AS and SM can be explained by the water characteristics of sampling stations in the SM, in which salinity and temperature were more close to the Mediterranean water considering to the depth range (deeper than 40 m). These results support to the separate management plans for demersal fish species in the three areas in terms of ecosystem [3].

Fig. 2. Dendrogram of similarities for 17 hauls (cluster analysis, group average linkage) sampled during autumn periods in 2006 and 2007.

JELLYFISH IN THE NORTHERN ADRIATIC: A 200 YEAR STORY

Tjaša Kogovšek ¹*, Branko Bogunovic ¹ and Alenka Malej ¹ ¹ Marine Biology Station, National Institute of Biology - kogovsek@mbss.org

Abstract

A 200 year time series of scyphomedusae occurrence in the northern Adriatic was analysed using the wavelet technique to assess the major periodicities. The analysis of the historical time series revealed that four scyphomedusae, *A. aurita*, *C. hysoscella*, *C. tuberculata* and *R. pulmo*, have been present regularly in the northern Adriatic over the last 200 years, with two major periods of jellyfish proliferations. The first period in the years around 1910 was characterised by common significant periodicity of 8 to 12 years. In the second period, from the late 1970's onward, two common periodicities were revealed, those shorter than 8 years and a longer one of 20 - 30 years.

Keywords: Adriatic Sea, Blooms, Cnidaria, Medusae, Time Series

Introduction

In recent years connections between jellyfish blooms and variations in climate have been emphasised ([1], [2]). Very few long-term time series of gelatinous plankton blooms exist due to fragility of these organisms and sampling difficulties. Although large scyphomedusae are generally more rigid than other gelatinous plankton, sampling using conventional oceanographic gears is complicated due to their size [3]. Therefore, most of the data on jellyfish populations are descriptive rather than quantitative, and the problem of choosing a suitable method often arises when analysing time series. Moreover, non-linear, aperiodic and non-stationary processes are very common in nature [4]. This constitutes a limitation when applying most of the analytical techniques for the time series analysis used for detecting periodicity. A powerful tool for analysing such data is wavelet transformation, a time scale and/or time frequency decomposition of the signal useful in analysing the non-stationary, aperiodic and noisy signals that are very often found in ecological time series [5].

Materials and Methods

A data set of the presence/absence of scyphomedusae in the northern Adriatic during the last 200 years was constructed on the basis of 21 papers describing plankton in the northern Adriatic, published over the time span from 1875 till today, in addition to our own (MBS Piran) observations. The constructed time series has been analysed using continuous wavelet analysis [5].

Results

Fig. 1. Wavelet spectra of the four scyphomedusae time series in the northern Adriatic.

Analysis has shown that the five scyphomedusae (Aurelia aurita (Linnaeus, 1758), Chrysaora hysoscella (Linnaeus, 1766), Cotylorhiza tuberculata (Macri, 1778), Pelagia noctiluca (Forskål, 1775), and Rhizostoma pulmo (Macri, 1778)) have been present regularly in the northern Adriatic over the last 200 years. The most frequently reported scyphomedusae in the northern Adriatic over the whole period of study were A. aurita and R. pulmo. In the present decade, notably from 2004 onwards, Aurelia has been present every year in large numbers from the beginning of February to the end of June, while Rhizostoma was the most abundant during 2003 and 2006, after which its numbers decreased significantly. In contrast, Chrysaora and Cotylorhiza were observed regularly during the last decade but never in high numbers, as blooms were rarely noted. The presence of the latter was regularly reported from the northern Adriatic, mostly from August to September. The presence of holoplanktonic P. noctiluca in the northern Adriatic was first recorded in 1790. Between 1976 and 1986 Pelagia formed intensive blooms. The population collapsed after spring of 1986 and only appeared again at the beginning of 2004 after an 18 year absence. During the recent bloom, Pelagia was most abundant in 2006, more precisely from November 2005 to March 2007.

Although the life cycle, population dynamics and the ability to adapt to different environments differ between the species, the wavelet spectra showed a similar pattern for four meroplanktonic scyphomedusae (*A. aurita, C. hysoscella, C. tuberculata* and *R. pulmo*) with two major periods of jellyfish proliferation in the northern Adriatic during the 200 years. The first period began around 1875 and lasted until 1922, while the second has proceed from the late 1970's onward, following nearly 40 years of almost no jellyfish observations. During the first period of jellyfish proliferation the common periodicity of 8 to 12 years was detected. In contrast, the second period has been characterised by a shorter common periodicity of < 8 years and an additional longer term periodicity of 20-40 years. The latter is significant only in the case of *C. tuberculata* and *P. noctiluca* wavelet spectra. The first period of *Pelagia* proliferations is characterised by a significant periodicity of 8 years and the second period with a significant periodicity between 20 to 30 years.

Conclusions

The analysis of the historical time series revealed that five scyphomedusae, *A. aurita, C. hysoscella, C. tuberculata, P. noctiluca* and *R. pulmo*, have been present regularly in the northern Adriatic over the last 200 years, with two major periods of jellyfish proliferations. The first period is characterised by common significant periodicity of 8 to 12 years and the second period with two common periodicities, one shorter than 8 years and a longer one between 20 and 30 years.

REPRODUCTIVE BIOLOGY OF SQUALUS BLAINVILLEI (RISSO, 1826) IN THE EASTERN MEDITERRANEAN SEA

Vasiliki Kousteni^{1*} and Persefoni Megalofonou¹

¹ Department of Biology, Section of Zoology-Marine Biology, University of Athens - bkousten@geol.uoa.gr

Abstract

A total of 491 *Squalus blainvillei* were sampled in the Eastern Mediterranean Sea during the period 2004-2009. The overall sex ratio (females:males) was 1.22:1. Females ranged from 321 to 779 mm and males ranged from 272 to 799 in total length. Total length and weight of the specimens were highly correlated (R^2 = 0.92). Statistically significant differences were found between females and males in mean GSI and HSI values. Total length at 50% maturity was estimated at 565.3 mm for females and at 457.6 mm for males. *Keywords: Eastern Mediterranean, Fishes, Reproduction*

Introduction

Sharks are species particularly vulnerable to the overexploitation because of their k-selected life-history strategy [1]. *Squalus blainvillei* is an ovoviviparous demersal shark distributed in the whole Mediterranean down to about 700 m [2]. Studies on its systematics and biology have been mostly carried out in the Western-Central side [3, 4] while in the Eastern side the knowledge on its population characteristics is still scanty [5]. This study provides preliminary information on the reproductive biology of the longnose spurdog in the Eastern Mediterranean Sea.

Materials and Methods

A total number of 491 *Squalus blainvillei* (269 females, 221 males, 1 hermaphrodite) was obtained from bottom trawl and bottom longline catches from December 2004 to October 2009.

Length and weight measurements were taken and sexual maturity was determined by macroscopic observation of the reproductive organs according to Stehmann [6]. Regression analysis was used to determine length-weight relationship ($Y=aX^b$). Statistically significant differences, between females and males, in length and weight frequency distributions were examined with the Kolmogorov-Smirnov two-sample test. A logistic curve was fitted to the data and the total length at which 50% of individuals are sexually mature was calculated. Gonadosomatic (GSI) and hepatosomatic index (HSI) were determined for each sex. Ovarian fecundity was estimated by the number of ripe oocytes in the ovary of mature females, while uterine fecundity by the number and size of embryos occupying the oviducts.

Results and discussion

Longnose spurdogs ranged from 272 to 799 mm in total length and from 90 to 3079 g in weight (Fig. 2). The overall sex ratio was 1.22:1 (F:M), while among the samples one hermaphrodite was found with internal male reproductive organs and no claspers. Females and males showed statistically significant differences in length and weight frequency distributions (KS test, P>0.05).

Out of the specimens examined, 37% of females and 67% of males were sexually mature. The smallest sexually mature female was 523 mm in total length, while the smallest sexually mature male was 403 mm in total length. Mean total length at 50% maturity was estimated at 565.3 mm for females and at 457.6 mm for males [Figure 1].

Gonadosomatic indices reached higher values in females than in males ranging from 0.07 to 14.66 (2.05 ± 2.71) in females and from 0.04 to 2.51 (1.07 ± 0.57) in males. Hepatosomatic index reached higher values in males ranging from 4.41 to 35.78 (10.44 ± 3.61) than in females ranging from 4.55 to 22.86 (11.81 ± 4.06).

Three oocyte stages (ripe, maturing and immature) were identified macroscopically according to its size and colour. Out of 269 females, 44 were found with embryos ranging from 55 to 177 mm in total length. Embryos' length and yolk sac weight were negatively correlated. Both ovarian and uterine fecundity ranged between 1 and 6.

VARIABLE GROWTH OF BULLET TUNA LARVAE (AUXIS ROCHEI) RELATED TO HYDROGRAPHIC SCENARIOS OFF THE BALEARIC SEA

R. Laiz-Carrión ¹*, A. Pérez-Torres ², J. Quintanilla ¹, A. García ¹ and F. Alemany ²

¹ Instituto Español de Oceanografía. Centro Oceanográfico de Málaga. 29640 Fuengirola, Málaga. Spain. - raul.laz@ma.ieo.es

² Instituto Español de Oceanografía. Centro Oceanográfico de Baleares. 07015 Palma de Mallorca, Islas Baleares, Spain.

Abstract

Biometric differences consequent with variable growth were observed in bullet tuna larvae collected under different hydrographic conditions delimiting water masses of Mediterranean and Atlantic origin. Larger and heavier larvae with higher growth rates were found in the Mediterranean waters together with higher mesozooplankton abundance. *Keywords: Larvae, Growth, Balear Sea*

Introduction

Bullet tuna, *Auxis rochei*, represents one of the most abundant small tuna species commercially exploited in the Mediterranean Sea. The high scombroid growth rates at early life stages have been related to high food requirements and environmental conditions [1]. The aim of this study is to corroborate the linkages between hydrographic conditions and food availability with biometric features in bullet tuna larvae collected under specific hydrographic water masses.

Material and Methods

Specimens of early stages of Auxis rochei were collected in August 2008 off Mallorca Island (Balearic archipelago, Western Mediterranean), during daytime, by means of oblique tows through the upper mixed layer, above the thermocline. Hauls were performed at a speed of two knots, with Bongo 90 net fitted with 500 mm meshes. A Bongo 20 net, equipped with 100 and 200 mm meshes, was placed 1 m above Bongo 90 frame for mesozooplancton sampling. Some tuna larvae from both 500 mm meshes were sorted on board and stored in liquid nitrogen, whereas the rest was preserved in 96% ethanol (replicate 1) and 2% formaldehyde in seawater (replicate 2). Larvae preserved in ethanol were used for daily growth analysis [2]. Once in laboratory, larvae preserved in N2 were measured and weighed for standard length (SL) and dry weight (DW) determination. Zooplankton biomass for the size fractions 100-250 µm and >250 µm was determined drying the samples to a constant weight, and referred to the volume of filtered water (mg/m³). Hydrographic data were collected at each sampling station using a CTD profiler. A principal component analysis (PCA) was carried out to characterize different stations in relation to environmental features (86.6 % representation). To run this PCA, mean temperature (T), salinity (S) and oxygen (O) in first 5 m, were selected after linear correlations between variables were performed.

Results and Discussion

The different stations were grouped in two classes according to the PCA analysis of the hydrographic conditions: group A, characterized by higher T and S values, and group B with lower T and S values. Both groups represent Mediterranean (MW) and Atlantic (AW) waters respectively [3] (Fig. 1).

Fig. 1. Stations sampling distribution according to the PCA analysis in the study area. Mediterranean-MW (white) and Atlantic-AW (black) overlapped to salinity contours.

The SL and DW ANOVA analysis between groups shows significantly larger (p<0.001) and fatter (p=0.002) bullet tuna larvae located in MW (7 stations, 47

larvae, mean SL 7.1 mm and mean DW 0.58 mg) with respect to the AW (7 stations, 49 larvae, mean SL 6.0 mm and mean DW 0.28 mg). These differences are not merely attributable to differences in larval ages distribution; but to higher growth rates (ANCOVA $F_{1, 57}$ =7.16, *p*=0.01) in the larvae inhabiting MW (Fig. 2), which is in agreement with higher Fulton's condition factor in MW larvae (0.137) than in AW ones (0.101) (*p*=0.006).

Fig. 2. Daily growth for bullet tuna larvae in both AW and MW.

These differences are partly due to higher temperatures of MW waters [4]; but could be also a result of higher availability of larger preys, which according to previous studies constitute the major dietary component [5], since size fractioned zooplankton analysis revealed a 7-fold greater biomass (p<0.001) in the fraction >250 µm in MW stations. Moreover, recent studies have shown that the probability of finding bullet tuna larvae increases with higher mesozooplankton biomass (>200 µm) [6].

MARINE BIODIVERSITY AND FISHERY RESOURCES IN SYRO-LEBANESE COASTAL WATERS (LEVANTINE BASIN)

Sami Lakkis ¹* and Waad Sabour ² ¹ Dept. of Biology, Lebanese University, Beirut, Lebanon. - slakkis@ul.edu.lb ² Dept. of Zoology, Faculty of Science, Tishreen University, Lattakia, Syria.

Abstract

A study on fish food and feeding regime was carried out during 2004-2008 in adjacent Syrian and Lebanese coastal water. Stomach and intestine content analysis was conducted on one selected fish herbivorous, carnivorous and omnivorous in order to study the nature and composition of the food as related o fish resources. Herbivorous rabbit fish(*Siganus rivulatus*) feed on available chlorophytes, phaeophytes and rhodophytes algae, whereas demersal carnivorous grouper (*Epinephelus marginatus*) feed on small fishes, cephalopods and crustaceans.Pelagicsardine (*Sardinella aurita*) and anchovy (*Engraulis encrasicolus*) are mostly planktonivorous. Benthic *Solea vulgaris* is a carnivorous regime feeding on benthic invertebrates including meiofauna.. *Keywords: Biodiversity, Fish Behaviour, Fishes, Levantine Basin*

Introduction

Adjacent Lebanese and Syrian seawaters show similar oceanographic characteristics and both of regions present oligotrophic water body inducing low primary productivity and thus poor fish production. In spite of high marine biodiversity and good fish resources, fishing landing remain in deficit. Data on the major flora and fauna are available[1], but the information remain incomplete with regard to the relation between fish resources and marine biodiversity. Based on the knowledge and data available with regard to the composition and abundance of marine flora and fauna of the local coastal, the study of fish food and feeding regime would be easier and reachable. In previous study we attempt to study the diet of some fish species [2]. In this paper an attempt is made to study the diet and feeding regime of some species representing herbivorous, carnivorous and planktonivorous fish and correlated between fishery resources, feeding regime and marine biodiversity.

Methods and Material

Stomach and intestine content analysis was performed on freshly caught fish specimens from different regions of Syrian and Lebanese coastal waters. Hydrological parameters including temperature, salinity, nutrient and chlorophyll.a were taken at the same fishing areas. Information regarding the biodiversity of pelagic, benthic and littoral flora and fauna in the same sampling zone, are available from previous works [3,4,5,6] The selected species subject to food and feeding regime study are: carnivorous *Epinephelus marginatus*, planktonivore *Sardinella aurita*, herbivorous *Siganus rivulatus* and benthic *Solea vulgaris*.

Results and Discussion

The adjacent Lebanese and Syrian coastal waters show similar oceanographic characteristics and mostly the same habitats. Furthermore, certain homogeneity in the biodiversity of flora and fauna is observed and thus a resemblance in fishery resources between the two marine regions. Marine flora and fauna of the Syro-Lebanese coastal waters are highly diversified; most of the Mediterranean groups are found in the area. In addition to those, several species of Indo-Pacific origin, including fishes, were introduced or have migrated from the Red Sea into the Levantine Basin, where many invaders have established permanent populations. The composition of the food in the intestine of Epinephelus marginatus is formed with pieces of small fishes of Scorpaena., Epinephelus, Trigla, Serranu, Mullus, Diplodus, Sparus, Pagellus, Coris julis, Gobius, Blennius, Solea, Venus, Conus, Cardium, Sepia officinalis, Octopus vulgaris, Penaeus, Scyllarus, Palaemonidae, Asterina, Asterina, Polychaetes etc. Herbivorous rabbit fish Siganus rivulatus which is an invading tropical species in the area; it is very abundant in the near coastal water. It feeds all the time without discontinuity, even during the reproduction and spawning periods in spring. The composition of the food in the stomach and intestine of the rabbit fish is formed with pieces of macroalagae from Rhodophytes (Porphyra, Corallina, Galaxaura, Amphiroa rigida, Ceramium, Chlorphytesfrom genera Ulva, Hvpnea. Jania rubens). Enteromorpha, Cladophra, Codium, Phaeophytes (Padina pavonica Sargassum vulgare, Dictyopteris, etc.. Planktonivore fish Sardinella aurita feed mostly on phytoplankton and zooplankton. This pelagic fish is present in our waters only during the spawning periods between May and July. The digestive tube content reveals the presence of debris of diatoms from Chaetoceros, Coscinodiscus, Bacteriastrum, Rhizosolenia, and dinoflagellates such as: Ceratium, Dinophysis, Protoperidinium, Ornithocercus, and pieces of microzooplankton (Codonella, Codonella, Eutintinnus, Globigerina). From

macrozooplankton we distinguish in the digestive tube *Sagitta, Copepods, Cladocera, Polychaeta, Pteropods, Fish larvae*, etc. Benthic flat fish *Solea vulgaris* live on the sandy seafloor; it swim with difficulty and move very slowly above the bottom. The fishing yield of this species is poor may be because of the lack of appropriate fishing gear and the limited fishing ground. The stomach content reveals the presence of benthic invertebrates such as: mollusks, crustaceans, varied meiofauna; we also distinguish benthic algae namely *Caulerpa*, and phanerogams *Zostera* and *Cymodocea*. Fishing activity tends to reduce natural fish stock; in which a big amount is caught according to its abundance and the fishing effort. Other factors might also affect the fish stock such as anthropogenic activity and overfishing which contribute to fishermen, particularly during reproduction and sexual maturity and before spawning; this can lead, to the deterioration and collapse of the stock.

CROISSANCE ET REPRODUCTION DU ROUGET BARBET DE ROCHE (MULLUS SURMULETUS L. 1758) DANS LA BAIE DE M'DIQ (MAROC)

Abdeljaouad Lamrini 1*

¹ Institut Agronomique et Vétérinaire Hassan II, Rabat, 10101, Maroc - a.lamrini@iav.ac.ma

Abstract

Les rougets provenant de la baie sont âgés de 1 à 9 ans (12 - 30 cm). Les paramètres de croissance sont LTinf = 313,4 mm ; K = 0,6 ; t₀ = -0,46 ; Winf = 283 g avec des niveaux plus élevés pour les femelles. Le sex-ratio est en faveur de celles-ci (61,3%), la taille de 1^{re} maturité est atteinte à 167 mm pour les mâles et 178 mm pour les femelles (\approx 2ans). La période de reproduction se situe de mai à juillet. Ces résultats sont plus proches de ceux des autres côtes occidentales méditerranéennes que ceux des côtes de la Méditerranée centrale et orientale.

Keywords: Growth, Reproduction, Western Mediterranean, Fishes, Demersal

Les études relatives à la biologie du rouget barbet de roche (*Mullus surmuletus* L. 1758) en Méditerranée marocaine font défaut surtout dans sa partie occidentale. Ce travail est une contribution à l'étude de sa croissance et de sa reproduction dans la baie de M'diq.

Matériel et Méthodes

292 poissons analysés de février à juillet 2009 ont été échantillonnés (25 individus chaque quinzaine) à partir des prises commerciales des chalutiers fréquentant la baie de M'diq. Après avoir procédé aux mensurations et pesées (tailles et poids des poissons, poids des gonades et du foie), détermination du sexe et stades de maturité, prélèvements (otolithes, fragments de gonades), l'âge a été déterminé par otolimétrie. La clé âge longueur et les croissances, linéaire et pondérale, ont été établies (Modèle de Von Bertalanffy et relations taille poids). Les paramètres de croissance ont été estimés par le logiciel Fishparm. Le sex-ratio et la taille de 1^{re} maturité ont été déterminés. La période de reproduction a été délimitée par examen dans le temps des rapports gonadosomatique (RGS) et hépatosomatique (RHS) ainsi que sur les observations macroscopiques et histologiques des gonades.

Résultats et Discussion

Seules 227 paires d'otolithes (77,74 %) ont permis une détermination des âges compris entre 1 et 9 ans. La clé âge longueur montre que les poissons ont des tailles comprises entre 12 et 30 cm avec une dominance de 15 à 21 cm (2 à 5 ans). La longévité des femelles peut atteindre 9 ans alors que celle des mâles 7 ans. Les équations de croissance linéaire obtenues sont :

Mâles : $Lt = 30,25 [1 - e^{-0,52(t+0,16)}];$

Femelles : Lt = 32,26 $[1 - e^{-0.54(t+0.62)}]$;

Sexes confondus : Lt = $31,34 [1 - e^{-0.60(t+0.46)}]$.

Les relations taille poids ont été établies afin de pouvoir déduire les équations de croissance pondérale à partir des équations ci-dessous :

Mâles : Wt = 4,75.10⁻³Lt^{3,1846} P Wt = 242,80 [1 - e^{-0,52}(t+0,16)]^{3,1846}

What's : Wt = 4,75.10° Lt⁻³ Lt^{3,2506} b Wt = 242,00° [1 - e^{-0.54(t+0.62)}]^{3,2506} Femelles : Wt = 4,16.10°³ Lt^{3,2506} b Wt = 317,05 [1 - e^{-0.54(t+0.62)}]^{3,2506} Sexes confondus : Wt = 4,14.10°³ Lt^{3,2504} b Wt = 283,00 [1 - e^{-0.60(t+0.46)}] 3,2504

Les résultats sont très proches de ceux obtenus en Espagne [1] et en Tunisie [2], alors qu'ils sont assez éloignés de ceux trouvés en Italie [3], ce qui est dû à un environnement différent. Le sex-ratio est en faveur des femelles (61,3%), les mâles montrent une abondance dans les petites tailles à l'inverse des femelles qui abondent dans les grandes tailles, devenant exclusives à partir de 24 cm. Ce résultat est imputable à un taux élevé de masculinité à la naissance, une mortalité plus élevée chez les mâles, une longévité plus grande des femelles ou encore une croissance différentielle entre les deux sexes. La maturité sexuelle a été appréciée par les observations macroscopiques et microscopiques des gonades permettant de distinguer les stades classiques. Elle se produit à 178 mm pour les femelles et 167 mm pour les mâles, ce qui correspond à un âge de 2 ans. Ces résultats sont proches de ceux obtenus en Atlantique Nord-est [4] alors qu'ils sont assez différents de ceux de la Méditerranée et ceux obtenus à Majorque [5]. Le suivi mensuel du RGS, du RHS et des différents stades de maturité sexuelle ainsi que l'étude histologique des gonades ont permis de situer la période de ponte entre mai et juillet ; c'est le cas de la majorité des zones méditerranéennes [6] et atlantiques Nord-est [4], [7], sauf sur les côtes tunisiennes et égyptiennes [8] où l'espèce se reproduit entre avril et mai.

DEMOGRAPHIE, EXPLOITATION ET ETAT DES STOCKS DU ROUGET BARBET DE ROCHE (MULLUS SURMULETUS, L.1758) DANS LA BAIE DE M'DIQ (COTE OCCIDENTALE DU MAROC)

Abdeljaouad Lamrini¹*

¹ Institut Agronomique et Vétérinaire Hassan II, Rabat, 10101, Maroc - a.lamrini@iav.ac.ma

Abstract

La pêche du rouget s'effectue au nord du port de M'diq à 45-65 m sur fonds rocheux et sableux ; elle oscille autour de 40 t/an, soit 4 à 5% des débarquements de cette espèce à l'échelle nationale. Les prises se composent de 3 à 4 cohortes, mais ce sont les juvéniles et les tailles moyennes qui sont les plus exploités. La taille de 1^{re} capture est de 15,2 cm. Les mortalités, totales, naturelles et par pêche, s'élèvent respectivement à 1,25 - 0,75 - 0,5, alors que le taux d'exploitation est de l'ordre de 0,4 ; il s'agirait d'un bon état d'exploitation.

Keywords: Western Mediterranean, Fisheries, Demersal, Stock Assessment, Fishes

Introduction

La situation des stocks du rouget barbet de roche (*Mullus surmuletus* L. 1758) en Méditerranée marocaine est méconnue surtout dans sa partie occidentale. Ce travail contribue à l'étude de sa démographie, son exploitation et l'état de ses stocks dans la baie de M'diq.

Matériel et Méthodes

Pour faire une étude démographique, 2 275 rougets, pêchés de février à juillet 2009, ont été échantillonnés (une à deux caisses chaque quinzaine) à partir des prises commerciales des chalutiers fréquentant la baie de M'diq. Après avoir établi les distributions de fréquence de tailles mensuelles, leur décomposition a été réalisée par la méthode de Bhattacharya [1], ce qui a permis d'apprécier l'importance des différentes cohortes composant le stock et leurs variations au cours de la période d'étude.

L'exploitation a été appréhendée par enquête auprès des principaux patrons de chalutiers fréquentant la baie pour déterminer les zones de pêche et par examen des statistiques de capture entre 2003 et 2008 pour apprécier l'importance des débarquements.

L'état des stocks a été étudié par la méthode de Beverton et Holt [2] en passant par la détermination de la taille à la 1^{re} capture (Lc) et en estimant les différents taux de mortalité (totale : Z, naturelle : M et par pêche : F).

Lc a été déterminée par la méthode de Caddy [3], Z a été calculé par la méthode de Beverton et Holt faisant intervenir Lc et Lm (taille moyenne de l'échantillon) ainsi que K, Linf (paramètres de l'équation de Von Bertalanffy) établis dans un autre article de ce volume [8] ; la relation pour le calcul de M est:

 $Log M = -0,0066 - 0,279 Log Linf + 0,6543 Log K + 0,4634 Log T^{\circ}$ [4]

 T° est la température moyenne annuelle de l'eau où séjourne le stock étudié (19°9 - 21°2 C)

La mortalité par pêche est déduite des deux autres (Z – M). Le taux d'exploitation E définit la proportion du stock prise par pêche [5]. Le stock est équilibré lorsque la prise potentielle est optimisée avec l'égalité entre M et F [6] avec E voisin de 0,5.

Résultats et Discussion

Cinq zones de pêche éloignées au nord du port de M'diq de 3 à 10 miles, sont fréquentées à des profondeurs rocheuses et sableuses de 45 à 65 m (Oued Smir, Restinga, Oued Negro, El canto et Snasel).

Les débarquements annuels fluctuent entre 27 et 47 tonnes environ avec une tendance à la baisse. Ils représentent 4 à 5% des prises à l'échelle nationale (méditerranéenne et atlantique). Au cours de l'année, le maximum est enregistré en automne et le minimum en été.

L'analyse modale des distributions de fréquences de tailles mensuelles permet de distinguer trois à quatre cohortes chaque mois durant la période d'étude. La l^{re} et la 2^e cohorte sont les plus représentées en raison de la fréquentation importante des petits fonds côtiers par les chalutiers ; ce sont les juvéniles et les tailles moyennes qui sont les plus exploités.

Le suivi mensuel des différentes cohortes montre que la 1^{re} (14-18 cm) apparaît chaque mois avec un pourcentage variable (49,6-8,04%), la 2^e (17-22 cm) est représentée par un pourcentage relativement fixe (29-40%) durant la période d'étude, la 3^e (21-26 cm) montre une tendance à la chute d'un mois à l'autre (33,3% en février, 11% en juin), alors que la 4^e cohorte (26-28 cm) n'apparaît qu'à partir de mars avec une faible proportion (5,6-10%).

La taille à la 1^{re} capture correspond à 15,2 cm. Les mortalités, totale, naturelle et par pêche, sont estimées respectivement à 1,25 - 0,75 - 0,5 alors que le taux d'exploitation est évalué à 0,4. La mortalité totale mensuelle est relativement stable durant février, mars et avril (0,96 - 1,03) alors qu'elle augmente durant les mois suivants (1,38 - 1,59) coïncidant avec la période de reproduction durant laquelle les géniteurs sont en état d'épuisement.

La mortalité naturelle (0,75) est située dans la fourchette conventionnelle (0,5 - 1). Le taux d'exploitation laisse présager que le stock du rouget de roche serait bon. Cependant, ces résultats restent approximatifs en l'absence de statistiques fiables sur plusieurs années (effort de pêche, captures, ...) permettant de calculer directement les différents taux.

GENETIC SUBDIVISIONS OF THE RED CORAL (*CORALLIUM RUBRUM*) IN THE MEDITERRANEAN SEA : EVOLUTIONARY HISTORY AND MANAGEMENT IMPLICATIONS

J. B. Ledoux ¹*, D. Aurelle ¹, K. Mokhtar-jamaï ¹, A. Chenuil ¹, J. Garrabou ² and J. P. Féral ¹

Abstract

The genetic structure of the red coral *Corallium rubrum* was analysed in the Western Mediterranean. A clustering analysis identified six genetic groups and evidenced the particular genetic characteristics of Adriatic and North African populations. These data are useful for the management of this harvested species.

Keywords: Genetics, Cnidaria, Western Mediterranean

Introduction:

The management and protection of biodiversity require an analysis of populations structure and connectivity. In the marine environment direct estimation of species dispersal abilities is difficult. Indirect estimates of dispersal can be obtained through genetic data [1]. In the Mediterranean Sea several genetic breaks common to different species have been identified [2] which may define the limits of conservation units [3]. Nevertheless few studies considered samples from Southern Mediterranean (North Africa) whereas a North-South distinction may be observed [4]. The red coral *Corallium rubrum* is an emblematic and harvested species also threatened by climate change [5], [6]. Previous studies indicated genetic differentiation at short distances with several genetic groupings at higher distances [7], [8); up to now no study included North-African samples.

Material and Methods:

We applied seven microsatellites loci [8] to 24 populations representing different regions of the Mediterranean distribution area of this species including Adriatic Sea and North Africa (Morocco and Algeria). A bayesian clustering analysis [9] was used for the identification of different genetic clusters. An Analysis of Molecular Variance (AMOVA) allowed to test genetic differentiation between the obtained clusters.

Discussion:

The clustering analysis are presented in Fig.1 for the retained solutions (K=3 and 6 groups). The clusters correspond to the main geographical subdivisions and are genetically differentiated (p<0.001). Our results confirm the already observed geographical structuring [8] and extend these data with the differenciation of Adriatic samples (a single population analysed before, [7]) and North African samples. Nuclear sequence data suggest a low divergence among these groups [10] and a lack of long term isolation. The North African samples indicate that this area may be a important component of genetic diversity and would deserve more collaborative studies. According to these data the management of this species should take into account these differences at a regional but also a local scale [8].

Abstract

The precious Mediterranean red coral Corallium rubrum is a colonial and aposymbiotic octocorallian characterized by low dynamics and limited dispersal ability. Recently, shallow populations of this species were differentially affected by positive thermal anomalies possibly related to global warming. The question of differential individuals fitness in front of this new environmental disturbance arises. As a first step, we choose to study the relationship between these organisms and their local environment. Populations dwelling in contrasted temperature regimes (i.e.; warm and variable vs. cold and more stable) were reciprocally transplanted. The individuals' fitness was evaluated through the measurement of growth during 6 months including the summer period. These results are discussed in the light of population genetic structure.

Keywords: Genetics, Global Change, Conservation, Mortality

The study of the underlying ecological and/or genetic factors involved in the differential responses of populations to temperature anomalies is a key issue to better understand the impact of the ongoing climate change in the rich Mediterranean communities. This require among other things, the analysis of the degree of adaptation of populations to their local environment (i.e. local adaptation). The different responses observed at the population level during recent mass mortality events (MME) could reflect different levels of thermotolerance [1] that could be linked to different adaptation to local thermal regimes. We conducted reciprocal transplants experiments to test for local adaptation. The Mediterranean red coral Corallium rubrum was used as a model species. Reciprocal transplants of colonies dwelling at 20 m (shallow habitat) and 40m depth (deep habitat) were carried out at two regions (Riou Archipelago (Marseille) and Scandola (Corsica). Contrasted temperature conditions characterize shallow (warm and variable regime) and deep (cold and stable regime) habitats. Colonies were transplanted into experimental plates and labelled with calceine at the beginning of the experiment (spring 2006) for about a 6 month period (Fig 1A).

Fig. 1. A. Transplant plates used for the reciprocal transplant experiment in 2006, Riou Sud 20m. B. Stereomicroscope image showing the calceine labelling in a transplanted red coral colony

Growth rate during the transplant period was used to estimate the relative fitness value (Fig 1B). Only the population from Riou Sud 20 m showed significant decrease in growth rate when transplanted to 40m (from 0.10 mm to 0.04 mm over the 6 month period) (Fig 2).

Fig. 2. Mean maximum growth rates (mm) from the transplanted colonies in different depths (20-40 m) in the two regions studied (Marseilles and Corsica)

All other populations tested did not show significant differences between treatments. Genetic analysis based on 10 microsatellites showed significant structure between populations. Therefore, we conclude that different genotype*environment interactions exist in the studied populations. This result is an important step in the characterization of the local adaptation in the populations of C. rubrum.

Abstract

Seven Lessepsian fish species, *Etrumeusteres, Fistulariacommersoni, Lagocephalussceleratus, Pteragogus pelycus, Siganus luridus, Siganus rivulatus* and *Stefanolepis diaspros*, have been identified in boat-seine catches at depths 11-54 m in the Hellenic Seas from October 2008 to March 2009. The frequency of Lessepsian fish's occurrence in boat-seine hauls tended to decrease from southeastern to northern and western Aegean Sea, while it was generally increasing proportionally to the number of years since each species entry in the Hellenic waters.

Keywords: Aegean Sea, Ionian Sea, Fishes, Lessepsian migration, Coastal Waters

Introduction

Fish species of Indo-Pacific Ocean origin have been reported from the Hellenic Seas since the early 1930's, their findings and expansion being accelerating in recent years [1]. The majority of the 29 up to date Lessepsian fish migrants [2, 3], are neritic species caught down to 68 m [1], usually by artisanal fishing gears. The extensive study of the boat-seine gear and its effects to fish stocks, carried out during the fishing period October 2008 - March 2009, in the framework of the Operational Program of Fisheries 2000-2006 of the Hellenic Ministry of Rural Development and Food, constituted an ideal opportunity to study the frequency of occurrence of Lessepsian fishes in the catches of this selective fishing gear operating in the Hellenic coastal zone.

Materials and Methods

For the analysis of the boat-seine catches, the studied hauls were grouped in the following fishing regions : NE. Ionian, SE Ionian, Corithiakos Gulf, NE Aegean, South Evoikos Gulf, Saronikos Gulf, Argolikos Gulf, Cyclades Islands, Lakonikos Gulf and SE Aegean. The frequency of occurrence of each Lessepsian fish species was calculated as the percentage of the hauls in which it has appeared in relation to the total number of hauls examined by fishing region during the whole study period.

Results and Discussion

Seven Lessepsian fish species have been identified from boat-seine catches. At least one Lessepsian species was present in 115 hauls of the 239 hauls examined and at 8 of the fishing regions studied (Table I).

Tab. 1. Frequency of occurrence (%) of Lessepsian fish species in the boatseine hauls carried out during the fishing period October 2008-March 2009 in the Hellenic coastal zone, by geographic region. The year of species first finding in the Aegean Sea is noted in parenthesis

Fishing Region	L. sceleratus (2005)	F. commersoni (2001)	P. pelycus (1992)	E. teres (1999)	S. luridus (1964)	S .rivulatus (1932)	S. diaspros (1943)
NE. Ionian					18.2	4.6	
NE Aegean		2.8					5.6
S. Evoikos Gulf	17.4						60.9
Saronikos Gulf			14.3		14.3	19.1	52.4
Argolikos Gulf	10.7	10.7	10.7		14.3	3.6	39.3
Cyclades Isl.	9.1	18.2	2.3		40.9		50.0
Lakonikos Gulf		11.8	35.3		29.4	11.8	35.3
SE Aegean		100.0	100.0	33.3	100.0	100.0	

The percentage of hauls, where Lessepsian migrants appeared, was considerably higher (>60%) in the southernmost fishing regions of the Aegean Sea, reaching the 100% of hauls realized around Kos island (SE Aegean). This pattern is obviously related with the pathways generally followed by Indo-Pacific species when enter in the Mediterranean Sea through the Suez Canal, first spreading northward along the Asiatic coasts favored by Asia Minor Current and then westwards involved, as adults or more likely as pelagic early juveniles, in the cyclonic and anticyclonic eddies prevailing at south of Rhodos and Crete islands, as well as in the southern Aegean Sea. As it concerns the frequency of occurrence of individual species, it seems to be increased in proportion to the number of years that have passed since the species' first finding in the Hellenic waters (Table I), with the exception of S. rivulatus that even if it is the older installed species presents relatively low frequency of appearance, probably due to competition with the sympatric S. luridus. S. diaspros was the most often recorded species (at 28% of hauls), followed by S. luridus (at 17% of hauls) while the remainder were found in less than 10%

of hauls. The present study resulted in substantial northward extension of the previously known expansion for *S. diaspros* and *P. pelycus* [3] that is probably favoured by the rise of sea temperature in the Aegean Sea [4]. The new findings of most Lessepsian species, except *L. sceleratus*, widening their spread in the southern Aegean Sea according to previous records in the data base of the Ellenic Network on Aquatic Invasive Species (ELNAIS), should be rather attributed to the lack of previous systematic study of coastal fisheries catches composition. The exceptional multiple records of *L. sceleratus* during the last 3 years is due mainly to the particular interest that was expressed by the social and scientific institutions because offts potential risk for human consumption.

EFFECTS OF CLIMATE-DRIVEN CHANGES ON THE NORTH-CENTRAL ADRIATIC FOOD WEB: INSIGHTS FROM AN END-TO-END APPROACH

Abstract

A biogeochemical model and an Ecopath with Ecosim food web model of the North-Central Adriatic Sea have been integrated for a comprehensive description of ecosystem dynamics. This End-to-End tool has been used to perform scenario analysis for evaluating the effects on high trophic level of potential climatic changes on precipitation and nutrient patterns (changes in timing and volume) in the region.

Keywords: Food Webs, Nutrients, Models, Adriatic Sea

Climatic changes are expected to produce variations that might substantially modify the structure and functioning of marine food webs with important consequences for exploited species. Important factors to be considered include modification of river run-off and water column stratification, which in turn cause modification in nutrient concentration within the euphotic layer with cascading effects on the upper part of the food web. Integration of biogeochemical processes and food web dynamics in an End-to-End approach is a possible way to tackle this issue. In this work, we analyse the potential cascading effects of climate-driven changes on the food web of the North Adriatic Sea ecosystem (Italy, Slovenia and Croatia) by using a hierarchy of linked models. Previous climatic scenario analysis for the North Adriatic region were obtained by comparing highly resolved meteorological outputs of a Regional Climate model (RegCM) for a reference situation (RF, 1961-1990) and two future IPCC scenarios (2071-2100). Results showed local change in the seasonality of precipitation pattern with increase of winter rainy events and a decrease of spring summer precipitation [1],[2]. These changes, observed in both market oriented (A2) and local sustainability policies (B2) scenarios, imply a change in the seasonality of nutrient inputs to the coastal areas whose effects on the food web are studied by using a hierarchy of models. An Ecopath with Ecosim (EwE) model representing the food web of the North-Central Adriatic Sea [3], [4] is forced by a biogeochemical (BGC; [5]) model of the system which, in turn, simulates two future scenarios, one with changes in the seasonality of nutrient inputs (equivalent to A2) and another that also include a general reduction of inputs of nutrient from the rivers due to the implementation of sustainability policies in the land use management (reduction of fertilizers; B2).

The biogeochemical and food web model are integrated through a two steps procedure [6]. In the first step the models are integrated by extending the EwE model for including the main biogeochemical processes thus accounting for all possible interactions among high and low trophic levels. In the second step the nutrient inputs are adjusted in the extended model in order to adjust to the BGC results in terms of nutrient dynamics. The adjustments are necessary for accounting differences in parameterization of the two models, including differences in the time and space scheme used [7]. The effects of climatedriven changes on higher trophic levels are analyzed by comparing the long term evolution of biomass for different trophic groups simulated under the different scenarios, with particular attention to species target of fishing activities (e.g. small pelagic species and demersal predators).

Fig. 1. Schematic representation of the End-to-End model for the North Adriatic Sea used in the climatic scenario analysis. The original food web model comprehend 40 functional groups (black boxes and arrows), that is extended to describe the biogeochemical processes (grey circles and arrows)

Abstract

The 1991-2006 time series of trawl survey data of five demersal species were analysed by means of Min/Max Auto-correlation Factor Analysis (MAFA). The influence of some environmental variables and some fishing effort indices was evaluated as well. The results highlighted the presence of two most important trends in the multiple time series data set. *Keywords: Demersal, Time Series, Trawl Surveys, Tyrrhenian Se*

Introduction

A central challenge in fisheries ecology is to understand why species abundance changes over time [1]. Fishing exploitation is considered one of the main factors determining demersal resources dynamics, although both abiotic and biotic variables influence population abundance. In this context, the time series of experimental trawl survey data are useful to investigate trends and variations of the stocks, their spatial distribution, their relative abundance, etc. The present study aimed to investigate the temporal variations of the populations of five demersal species in the northern Tyrrhenian Sea through the analysis of the time series obtained from trawl surveys. Moreover, the study is focused to investigate the effect of some potential explanatory variables, such as fishing effort indices and environmental factors. The species considered for the study are the horned octopus, Eledone cirrhosa, the European hake, Merluccius merluccius, the red mullet, Mullus barbatus, the Norway lobster, Nephrops norvegicus and the deep-water rose shrimp, Parapenaeus longirostris; these species represent more than 50% of the biomass landed by the trawlers exploiting the fishing grounds in the northern Tyrrhenian Sea.

Materials and Methods

The study was performed in the northern Tyrrhenian Sea, where important traditional trawl fisheries are present. During the investigated period (1991-2006), two experimental trawl surveys per year have been carried out in the framework of national and international projects on the assessment of demersal resources. The time series of mean biomass (kg/km²) were calculated. To investigate the effect of environmental factors, time series of mean monthly values of sea surface temperature (SST, °C), wind speed (W, m/s), Oscillation index and North Atlantic (NAO) were used (http://podaac.jpl.nasa.gov/index.html). Indices of fishing activity and capacity were computed from the Porto Santo Stefano trawl fleet, the main fishing harbour in the area: the total number of days at sea performed by the fleet per month, and the mean gross tonnage (GRT) of the fleet per month. The data were analysed by means of the MAFA (Min/Max Autocorrelation Factor Analysis), a statistical method to extract common trends from multiple time series, and to analyse relatively short data sets [5]. Cross-correlations between the variables and the trends were computed to evaluate the significance of the relationship between the variables and the estimated trends [2].

Results and discussion

The results obtained by means of Min/Max Auto-correlation Factor Analysis (MAFA) highlighted the presence of two main trends (Fig. 1) in the multiple time series data set.

Fig. 1. Common trends extrapolated from the multivariate time series data set by means of $\ensuremath{\mathsf{MAFA}}$

The first trend described an increasing pattern, while the second showed a general rather constant behaviour, even though characterized by a sharp peak

in 2002. As highlighted by the cross-correlations (Tab. 1), the first trend was significantly related to the time series of the deep-water rose shrimp, *Parapenaeus longirostris*. The Norway lobster, *Nephrops norvegicus*, time series was negatively related to this trend, indicating that this species followed an opposite pattern. The European hake, the red mullet and the horned octopus time series were significantly related to the second MAFA trend.

Tab. 1. Cross-correlations between variables and MAFA trends. Response variables: MM = *Merluccius merluccius*, MB = *Mullus barbatus*, EC = *Eledone cirrhosa*, NN = *Nephrops norvegicus*, PL = *Parapenaeus longirostris*. Explanatory variables: Wind = wind speed (m/s), NAO = NAO index, SST = sea surface temperature (°C), Days at sea = number of days at sea per month, GRT = mean gross tonnage. Significance level for correlations \pm 0.35. Significant values are highlighted in bold

		Trend 1	Trend 2
Response variables	MM	0.18	0.43
	MB	0.11	0.75
	EC	-0.02	0.82
	NN	-0.42	+0.30
S .	PL.	0.98	-0.14
Explanatory variables	s MM 0.13 MB 0.11 EC -0.00 NN -0.44 FL 0.98 Des Wind -0.31 NAO 0.16 SST -0.00 Days at sea -0.44	-0.31	-0.23
	NAO	0.16	-0.03
	SST	-0.06	0.07
	Days at sea	-0.41	0.30
	GRT	-0.16	0.70

As concerns the explanatory variables, only the fishing effort indices showed significant correlations with the MAFA trends. The time series of the number of fishing days per month was negatively correlated to the first trend, while the mean GRT time series was related to the second trend. Therefore, the available evidence suggests that fishing effort resulted more important than environmental factors in influencing the trends. The number of fishing days per month time series was negatively related to the first trend. In the investigated period the trawl fleet of Porto Santo Stefano decreased of about the 50% in terms of number of vessels, producing an almost proportional decrease of fishing effort [3]. The reduction of fishing effort was mainly due to the Common fishery policy for the Mediterranean, which promoted the effort reduction through incentives to demolition. The mean size of the trawl vessels of Porto Santo Stefano has increased until 2000s; however, in the last years, it has followed a decreasing pattern, in response to the global crisis which invested fisheries, and to the sharp increase of the diesel oil costs [4].

A MAP OF THE MEDITERRANEANSEA FOR FISHERY PURPOSES USING GOOGLE EARTH

Jordi Lleonart ¹*, Juan Luis Suarez De Vivero ², Susana Requena ³ and Silvia De Juan ¹ ¹ Institut de Ciencies del Mar. CSIC - lleonart@icm.csic.es ² Department of Human Geography. University of Sevilla. Spain ³ RAC/SPA Consultant

Abstract

A chart of the Mediterranean, using Google Earth, is being developed with the objective to help fisheries scientists easily place the different georeferenced features related to fisheries (undersea features, MPAs, jurisdictions, etc.). The map is an open tool and can be improved by users. This tool has been developed in the framework of the activities of UNEP RAC/SPA *Keywords: Fisheries, Mapping*

The UNEP Regional Activity Centre for Specially Protected Areas (RAC/SPA) in compliance with the Mediterranean SPA/BD Protocol, undertook an initiative to promote the establishment of a Specially Protected Areas of Mediterranean Importance (SPAMIs) network, including Mediterranean high seas. In that context, along with the project "Fisheries management/conservation and step-relief areas in the Mediterranean open seas, including deep seas" [1,2], the UNEP RAC/SPA has promoted the development of a geographic tool related to fisheries to help scientists and other potential users working with georeferenced information coming from different sources. Google Earth has been chosen as a user friendly and free software in order to develop such a tool as it will facilitate access to the general public. The map presented has several folders containing the following information:

- Bathymetry. Isobaths of 50, 100, 200, 1000, 2000, 3000, 4000 and 5000 m depth are included. The information has been obtained from GEBCO [3].

- Jurisdictions. It contains information about: internal waters, historical bays, territorial waters, archaeological contiguous area, fishing protection zones, ecological protection zones, exclusive economic zones, high seas, and other particular jurisdictions [4].

- MPAs. Including: UNEP RAC/SPA SPAMIS, GFCM FRAs (Fishing Restricted Areas), MPAs for cetacean conservation, proposals for tuna sanctuaries and any other MPA appeared in MEDPAN and MPAGLOBAL websites. About 280 MPAs are included. In most cases associated to the website that contains its description

- Undersea features. Includes all geomorphological features with a published name. About 35 types of features (the most common, seamounts, canyons, ridges, plains, etc.). The map contains about 450 georeferenced geographical localizations.

- Boundaries, subareas and grids. Contains the different subareas defined by FAO for statistical purposes, and GFCM. It also contains the 10 and 50 km grids promoted by the European Union for environmental purposes.

- Sea surface temperature (SST) and surface primary productivity in terms of chlorophyll-a concentration. Charts of summer and winter averaged temperature and productivity from 2003 to 2008, as well as the main isolines [5]. When possible the georeferenced element is associated to additional information with a link. This map aspires to be an operational tool for marine scientists working in the Mediterranean. It is posted in the public domain and feedback from users, for comments, corrections and additions is expected.

FISH ASSEMBLAGES AROUND FISH AGGREGATION DEVICES IN AEGEAN SEA COAST OF TURKEY

Altan Lök 1* and Aytaç Özgül 1

¹ Ege University, Fisheries Faculty - altanlok@yahoo.com

Abstract

Fish assemblage associated with fish aggregating devices (FADs) in Aegean Sea was carried out between June 2008 and June 2009. Two FADs and two control areas were established to check the aggregation efficiency of the FADs. Small-scale fisheries techniques and underwater visual census have been conducted around of FADs and control sites monthly. A total of 17 families and 24 species of fishes were observed beneath FADs. Pelagic fishes, largely *Trachurus spp., Seriola dumerili, Coryphaena hippurus* and *Xiphias gladius*, dominated the fauna. This study is also show that FAD is provide good opportunity to understand pelagic ecosystem.

Keywords: Aegean Sea, Artificial Reefs, Biodiversity, Fisheries, Pelagic

Introduction

Associations of fishes with flotsam have been widely reported in the literature [1, 2] from subtropical and temperate waters. However, few data are available on the Mediterranean [3, 4]. Despite of the fact that FADs have been used in the other countries for many years, using of FADs for fishing or same aims not reported in coats of Turkey. Any records couldn't be found on use of FADs in pelagic fisheries in coast of the Aegean Sea and Eastern Mediterranean. Therefore, this study has been became the first for Eastern Mediterranean area. This paper focused on the description of composition, abundance and seasonality of fishes associated with FADs in Eastern Mediterranean (Aegean Sea).

Material and Methods

This study was conduct off Gümüldür village which located 40 km south of Izmir. Two steel FADs units were moored in water at 50m and 100m depths respectively. Two zones without FAD, separated one nautical mile from each FADs unit and at the same depth, were taken controls to test for the aggregation behavior of the species. The study was carried out from July 2008 to June 2009. Seasonal variability was studied by sampling each FADs and control cities with a monthly. Samples were collected with small scale fisheries techniques (angling, trolling, gillnet and pelagic loglines) around of FADs and control sites. Underwater visual observations were also conducted to obtain qualitative information on the spatial distribution of fishes.

Results

A total of 17 families and 24 species of fishes were observed beneath FADs. Pelagic fishes, largely *Trachurus spp., Seriola dumerili, Coryphaena hippurus* and *Xiphias gladius*, dominated the fauna. The observed specimens were mainly juveniles, with the exception of a few adults of *Balistes capriscus*, *Centrolopus niger, Lepidopus caudatus* and *Corypheana hippurus*. The recruitment of juvenile middle-sized pelagic fishes to FADs was rapid, with shoals being presented only a few days after FADs deployment.

PRELIMINAR STUDY ON FISHING YIELDS IN THE VICINITY OF TWO NO-TAKES ZONES WITHIN THE MARINE RESERVE OF CABO DE GATA-NIJAR (ALMERIA-SPAIN)

Matias Lozano¹, Jorge Baro^{1*}, Teresa Garcia¹ and Javier Rey¹

¹ Instituto Español de Oceanografía, Centro Oceanográfico de Málaga, Apdo. 285, 29640 Fuengirola, Málaga, Spain -

jorgebaro@ma.ieo.es

Abstract

Marine protected areas (MPAs) are an instrument for improving both fisheries management and marine environmental protection. In order to analyse possible differences in fishing yields we studied the vicinity of two no-take zones (close and further to home harbour) within the MPA located in Cabo de Gata (Almeria, Spain). Species abundance showed a spatial distribution along the coast with two clear separate groups. We suggest that those differences might be due to the effect of fishing pressure. *Keywords: Fisheries, Coastal Management*

Introduction

The Cabo de Gata-Níjar Marine Reserve (CGMR) is situated in the Western Mediterranean (Fig. 1), in the southeast of the Iberian Peninsula. This coastal MPA covers 4,600 ha and represent typical Mediterranean habitats, such as rocky reefs, sandy bottoms and *Posidonia oceanica* seabeds. Local fishing activities are restricted to artisanal fisheries, which are often coastal with boats smaller than 10 m. Within the protected areas and outside the no-take zones (fishing is prohibited), artisanal fishing is undertaken using traditional fishing gears (gill net and trammel net) on diverse target species depending on their abundance and price. Many factors have a significant influence on effort allocation by the fishing fleets, such as distance to the port, distance to the no-take zone and water depth [1]. In general, most of the fishing effort is concentrated near the no-take zones sepecially those closer to home harbour. In Cabo de Gata, the prevailing winds, both east and west, produce losses of between 30-40% of the fishing days during the year, therefore can be considered a factor that could influence the spatial allocation of the fishing effort.

Materials and Methods

In this study we aim to investigate catch abundance within the vicinity of two no-take zones in the CGMR with different accessibility (one close to home harbour (2 nm) and the other further away (8nm)). Experimental fishing surveys in the CGMR were conducted during May 2009 with two artisanal boats operating in the area, with the same gear type used in commercial fishing (Common cuttlefish trammelnets).

Fig. 1. Location of Cabo de Gata-Nijar Marine Reserve (CGMR) on the southest of the Iberian Peninsula. Dots illustrate the experimental fishing sets

Results and Discussion

A total of 48 fishing sets were sampled and sixty species were collected during the study (45 of fish, 6 of mollusc, 5 of crustacean and 5 of equinoderms). To establish the contribution of each species to the mean abundance Bray-Curtis dissimilarity within a group and between groups of samples, similarity percentage analysis (SIMPER) routine was used (PRIMER 6). The MDS analysis revealed differences between both (near and further away) fishing sites. We suggest that those differences might found be due to the effect of fishing on the dominant species *Sepia officinalis*.

Abstract

L'examen de la partie molle de la palourde *Ruditapes decussatus*, prélevée pendant les saisons, estivale et automnale, de l'année 2009 nous a permis de révéler la présence d'une malformation très marquée touchant la morphologie du pied du bivalve. Le suivi spatial de cette perturbation, dans trois stations du littoral tunisien, a montré que le taux, la position et le degré de développement de cette anomalie varient d'une station à l'autre. Nous avons également constaté la présence d'un byssus chez 0,47% de spécimens collecté dans une des trois stations.

Keywords: Bivalves, Pollution, Coastal Waters, Mollusca

Introduction

Ruditapes decussatus est un bivalve d'intérêt économique important. Il se rencontre en Atlantique et en Méditerranée [1]. Cette espèce endogée s'enfouit dans le sédiment grâce à son pied [2]. Lors d'une étude bioécologique, nous avons mis en évidence une malformation très marquée du pied. Cette étude décrit les malformations observées et détermine l'intensité de cette anomalie ainsi que les variations spatiales.

Matériel et Méthodes

Un effectif total de 1 325 spécimens de 19 à 39 mm a été collecté par pêche à pied durant l'été et l'automne 2009 dans trois stations : Radés (nord de la Tunisie), Gargour et le port de pêche de Sfax (Sud Tunisien) (fig1). Au laboratoire, les animaux, de chaque station, ont été comptés puis examinés macroscopiquement et sous loupe binoculaire. Les spécimens prélevés dans chacune des trois stations ont été comptés en vue d'étudier les variations spatiales. Les différents types et degrés de développement de la malformation observée ont été décrits.

Fig. 1. Carte de la Tunisie montrant les sites de prélèvement de la Palourde *Ruditapes decussatus*.

Résultats et discussion

Les observations macroscopiques et microscopiques du pied de Ruditapes decussatus ont révélé la présence d'une malformation qui se manifeste par la différenciation d'une gouttière rectiligne dans le sens antéropostérieur. Cette gouttière, plus ou moins profonde, peut évoluer en longueur et en profondeur donnant deux pieds séparés uniquement du côté ventral. Certains spécimens montrent, en plus, une séparation dorsale. L'animal se trouve donc avec deux pieds complètement indépendants. Certaines palourdes montrent une gouttière et une bifurcation du bout antérieur du pied. Dans ce dernier cas, le stade ultime donne naissance à deux pieds séparés partiellement ou totalement. Le taux de spécimens touchés par cette perturbation (fig.2) est de 100% dans la station du port de pêche de Sfax (effectif examiné = 427). A Gargour, le taux

est de 99,66% (spécimens examinés = 598) contre 46% à Radés (effectif examiné = 300). Nous avons par ailleurs constaté, chez les spécimens du port de Sfax, la présence d'un byssus assez moelleux plus ou moins long (environ 8 mm de long et 1 mm de large) se différenciant du côté postérieur du pied. Le taux de spécimen à byssus est très faible (0.47%). Cette malformation est semblable à celle décrite par Atkins [3] chez la moule Mytilus edulis. Cette anomalie se manifeste par le développement, chez le bivalve, d'un pied surnuméraire à partir du pied principal. Selon le même auteur, le pied de la moule peut également subir soit une atrophie soit une lésion. L'origine de cette anomalie est inconnue [3]. En ce qui concerne notre étude, plusieurs causes peuvent intervenir dans l'apparition de telles anomalies chez Ruditapes decussatus. En effet, les conditions environnementales, la pollution, l'hydrodynamisme, le parasitisme sont des facteurs qui peuvent avoir un impact direct ou indirect sur la morphologie du pied de l'animal. D'après Bartoli [4], le parasitisme intensif chez Venerupis aurea peut modifier le comportement du bivalve en renversant la position normale du bivalve dans le sédiment. Des études, génétique et parasitologique, sont en cours de réalisation en vue de rechercher les causes de cette malformation.

Fig. 2. Variation du taux de la malformation du pied du bivalve en fonction des stations d'étude.

PERIODISM OF CYSTOSEIRA SPINOSA SAUV. (FUCALES) FROND SIZE ON THE MONTENEGRIN COAST

Vesna Macic ¹*

¹ Institute of marine biology - vmacic@ibmk.org

Abstract

Cystoseira spinosa periodism and size structure were studied on three locations of the Montenegrin coast (Adriatic Sea). Samples were taken from Orahovac, Perast and cape Kocište in different seasons between autumn 2005 and spring 2007, at 5m depth. The analysis were made on obtained data for total wet biomass, *C. spinosa* wet biomass, maximum length, length of the main axes and length of ten randomly selected primary branches. For better understanding of *C. spinosa* periodism and monitoring further analysis of deeper populations are needed.

Keywords: Adriatic Sea, Algae, Endemism, Phytobenthos

Introduction

According to published data *Cystoseira* species are very sensitive to antropogenic impacts and there are tendences of their regressions from urban areas. In recent years many scientific efforts has been dedicated to research of the genus Cystoseira as bioindicator species for evaluating environmental state and some antropogenic impacts. In these activities historical data are of great importance, but unfortunately they are very scarse for the Montenegrin coast ([1], [2], [3]). Therefore the aim of this work was to contribute to the better knowledge of endangered, endemic Mediterranean brown algae, *Cystoseira spinosa* Sauv., its periodism and size structure and to provide better base information for further monitoring.

Materials and Methods

The field research was done by seasonal SCUBA diving, on 3 locations: Orahovac, Perast and cape Kocište (Fig. 1), between autumn 2005 and spring 2007 (excluding winter 2006). Sampling was done in 3 replicates scraping off all organisms within quadrates 25cm x 25cm at 5m depth. Following parameters were measured: total wet biomass, *Cystoseira* wet biomass, maximum length, length of the main axes and length of ten randomly selected primary branches. Measured *Cystoseira spinosa* specimens are conserved in 4% formaldehyde solution.

Fig. 1. Locations of the study

Results and Discussion

Seasonal variation of total biomass, with maximum in spring were clearly evident, contrary to biomass of *Cystoseira*. Differences in wet weights of *C. spinosa* between selected locations were significant (F-test and Duncan test, p<0,05) and the highest between Perast ($66.7g/m^2$) and Kocište ($759.9g/m^2$). The biggest variability of maximum length, length of main axes and primary branches were noted in the spring (Fig. 2).

Fig. 2. Values of length for different seasons (Lmax-maximum length; Lax-length of axes and L1gr-length of primary branches)

Some autors ([4], [5]) acknowledge weak seasonal variation of length for main axes and its independes of the phenological state of plants. In this study the lengths of main axes were different significantly (F-test and Duncan test, p<0,05) between locations. Furthermore, as for wet biomass, also for the length of main axes, location Orahovac was with highest variability (6.35-13.2cm) and location Perast with highest values (13.55cm). Conceptacles were apical and present only in the spring.

With scope to improve knowledge of phytobenthos of the Montenegrin coast two new locations for the distribution of *Cystoseira spinosa* are presented (Orahovac and cape Kocište). For this part of the south-east Adriatic Sea presented data of periodism and size structure for this algae are the first one and more or less are similar to data from other parts of Mediterranean Sea. However, because of great polymorphism of *Cystoseira spinosa* further analysis of deeper populations are needed, as well as further monitoring of differences found in this study.

USE OF LAPAROSCOPY FOR THE EVALUATION OF THE REPRODUCTIVE APPARATUS OF EEL (ANGUILLA ANGUILLA)

F. Macri¹, G. Lanteri¹, P. Giorgianni¹, C. De Stefano¹, F. Bucci² and G. Aiudi^{2*}

¹ Dipartimento di Produzione Animale Università degli Studi Messina - g.aiudi@veterinaria.uniba.it

² Dipart Sanità Pubblica Veterinaria Università degli Studi Messina

Abstract

In this paper we evaluate the application of laparoscopy for the assessment of the reproductive status of the European eel, *Anguilla anguilla*, with the final goal of recognizing the mature stage of the gonads. Laparoscopy was carried out on 20 anesthetized eels, using a 1.9 mm rigid cystoscope. Gonads were visualized and histological samples were collected with a forceps and showed presence of gametes at different maturity stages. The application of laparoscopy can be powerful to evaluate sex and to establish the reproductive status of the gonads of eel.

Keywords: Fishes, Reproduction

Introduction

Laparoscopy is a useful diagnostic and therapeutic tool in human and, recently, in veterinary medicine. There are only few reports on laparoscopy application in teleosts [1]. This study is aimed at evaluating in eel the use of laparoscopy to analyze the reproductive tract and to detect the maturation stage of the gonads.

Material and Methods

Laparoscopy was performed on 20 eels (Anguilla anguilla) 60 cm medium length. The study was performed with a rigid cystoscope, a pump for air insufflation and a video device; a forceps was used to collect the bioptic samples. The fish were anesthetized in a tank containing MS 222 0.3 mg/L, and then placed on a grid out of the water; the anesthesia has been maintained conveying water containing MS 222 0.4 mg/L through a small aspiration pump in the oral cavity of the fish, using an i.v. flow regulator; the water has never been recycled. Laparoscopy was carried out placing fish on dorsal decubitus. A pneumocoelom was performed in order to separate the abdominal wall from the viscera. A small paramedian surgical incision, close to the anal pore, allowed the introduction of the Veress needle, linked to the insufflator through an i.v. flow regulator. The laparoscopic surgery door was made with the same procedure about 1 cm cranially from the first incision. After the examination, the coelom was emptied of air and treated with Enrofloxacin 14 mg/Kg; the laparoscopic entry sites were sutured with Vicryl (from 5-0 to 2-0). The fish were then placed again in the tank and the recovery was reached few minutes later. The bioptic samples were processed for paraffin-embedding. Slices were stained with Ematoxylin-Eosin. The follow-up showed a quick recovery and excluded the presence of post-surgery lesions as well as functional alterations within 3 months.

Results

During the laparoscopy the gonads were visualized as paired organs attached to the swimbladder. The histological examination showed presence of gametes at different maturity stages in both sexes. Ovaries were characterized by oocytes at different stage of maturation. Previtellogenic ones were characterized by a reduced size, an evident nucleus and a dense and deeply stained cytoplasm. Vitellogenic oocytes included ova with nucleus still evident and one or more layer of vacuoles filled with lipid yolk, and large ova with vacuoles and stained cytoplasmic material (protein yolk) covering the nucleus. The testes were characterized by Sertoli cells and primordial germ cells.

Discussion

One of the major challenges in fish reproduction is the precise assessment of the gonadal maturity stage before hormone conditioning, necessary for stimulating gamete release in several farmed species [2]. Generally fish not showing sexual dimorphism are sexed through direct observation of gonads, sacrificing the fish, therefore this technique is not reliable for endangered species or expensive fish such as broodstock; radio-immuno assays for determine sex hormone concentration, even if not lethal, is difficult and expensive, and not very sensitive in case of low levels of sex hormones e.g. young fish or onset of reproductive activity [3, 4]. The laparoscopy showed a big potential allowing direct visualization of the gonads and a quick examination. The main problems of this procedure are the cost of the devices, the high expertise and training of the staff and the small size of many teleost fish with consequent potential injuries to coelom organs/cavity.

GASTROSCOPIC, LAPAROSCOPIC AND PATHOLOGICAL FINDINGS IN EXPERIMENTAL ANISAKIASIS IN SEA BASS

F. Macrì¹, M. Manganaro¹, G. Caristina¹, B. Busalacchi²* and F. Marino¹ ¹ C.I.S.S. Dipartimento Sanità Pubblica Veterinaria, Università di Messina

Abstract

In this paper we evaluate and discuss the tissue damage due to Anisakis larvae in experimentally infected sea bass (Dicentrarchus labrax). This is the first endoscopic and laparoscopic study, that has revealed in two fishes hemorrhages and/or nodules on the serosal surface of the intestine. The evidence of tissue change is an unusual occurrence in Anisakis infected teleost fish. Keywords: Parasitism, Teleostei, Pathology

Introduction

Anisakid nematodes are probably the most known fish parasites, also because of their zoonotic potential. The life cycle of these cosmopolite parasites involve marine mammals or fish-eating birds as definitive host and various aquatic invertebrate species, teleosteans and cephalopod molluscans as intermediate and/or paratenic hosts. The tissue damage evoked by these nematode larvae on their teleost host is generally very low. They can be found on the serosa of coelomic organs without any apparent tissue reaction. However its importance as fish-borne zoonosis, few data demonstrate the possibility of experimental induction of the disease from a fish to another using L3 larvae without intermediate host [2,5]. Moreover imaging techniques have been rarely used in teleost fish. This paper is aimed at show the laparoscopic findings obtained during a challenge with Anisakis larvae in one of the most common fish species in Mediterranean aquaculture, as the sea bass, with known susceptibility [1].

Material and Methods

Five fish belonging to the species Dicentrarchus labrax were reared in an aerated tank, 650 l, for 60 days, temperature 25°C, salinity 35‰. Fish were anaesthetized using MS-222. The challenge was performed by endoscopy, using 10 alive Anisakis larvae inserted into the stomach of each fish. Larvae were obtained by the simultaneous necropsy of three teleost fish belonging to the species Lepidopus caudatus. Another challenge with the same protocol was performed 15 days later. At this time, endoscopic exam was carried out. After 60 days, in which fish were daily monitored, an explorative laparoscopy, using a rigid cystoscope, was performed. Fish were carefully examined for Anisakis larvae, after induction of pneumocoelom in a way to show all parietal and visceral coelomic surfaces.

Results

Endoscopic exam, after two weeks, revealed the presence of some larvae at level of gastric mucosa. The laparoscopy performed after two months showed, in two teleosts, hemorrhages and/or nodules on the serosal surface of the intestine. Within each of these changes a single nematode larva was detected. In one case a biopsy was performed from a parasitic nodule. The necropsy was performed a week later and such lesions were sampled for histopathology which confirmed the granulomatous-hemorrhagic nature of the tissue changes. Parasites sampled from L. caudatus and D. labrax were isolated, fixed in 70% alcoholic solution, morphologically identified by light microscope, after diaphanization with lactophenol, as A. pegreffii in both L. caudatus and D. labrax.

Discussion

This paper represents the first endoscopic and laparoscopic study of an experimentally induced parasitic disease [2,3,4,5]. The evidence of tissue change is an unusual finding in Anisakis infected teleost fish. The change here described could be explained because of the high susceptibility of the sea bass towards this parasite, almost never found in wild specimens in Mediterranean, probably in relation to the diet that normally does not include other intermediate hosts. Nevertheless the finding of hemorrhages could also be related to the acute stage of the infection.

DISTRIBUTION OF ANCHOVY EGGS IN BOKAKOTORSKA BAY

Milica Mandic ¹* and Slobodan Regner ¹

¹ Institute for marine biology - mamilica@ac.me

Abstract

Anchovy, *Engraulis encrasicolus* (L.), is a pelagic species, widely spread in Mediterranean as well as in the Adriatic Sea. In this paper distribution of anchovy eggs in Boka Kotorska Bay (Southern Adriatic) is presented. The survey was performed at 18 stations in summer 2006, as a part of the project of ichthyoplankton investigation in Montenegrin waters. *Keywords: Ichthyoplankton, Adriatic Sea*

Introduction

Anchovy (*Engraulis encrasicolus*, L., 1758) is one of the most important small pelagic fish species in Adriatic Sea. Anchovy eggs are pelagic and frequent in plankton from April to September, with peak in June-July. Maximum numbers of eggs occur in the open Adriatic earlier than in the coastal neritic waters [1, 2]. The aim of this paper was to present the distribution of the anchovy eggs in Boka Kotorska Bay during the period of spawning.

Materials and methods

Ichthyoplankton samples were collected in Boka Kotorska Bay in July 2006, by vertical tows of the PairOVET (modified CalVet) plankton net. Diameters of net cylinders were 25 cm each, and total mouth area was 0.098 m^2 , while mesh size was 0.160 mm. Net was towed vertically with the speed of 0.5 m/sec^{-1} . 18 vertical plankton hauls were performed. Maximal depth of sampling was 55 m. At every station data on temperature and salinity, from the surface to the maximal depth attained, were collected by CTD probe. The samples were preserved in 2.5% solution of buffered formaldehyde. Maximal depths of hauls ranged from 12-50 m. Anchovy eggs were removed from the samples, staged and aged using methodology given in [2]. Average temperature from 0 to 20 meters was used to estimate of duration of the egg stage from spawning to hatching [2]. Thus, quantities of anchovy eggs at every station were expressed as number of eggs produced per m² * day⁻¹.

Results and discussion

Diameter of anchovy eggs (longer axis) ranged from 1.15-1.4 mm. Average production of eggs at all positive stations was $61eggs/m^2 * day^{-1}$. The distribution of eggs in the Bay is presented in Figure 1. Maximal production of the eggs was recorded in internal part of the Boka Kotorska Bay (Kotor Bay), while their number gradually decreased towards the entrance of the Bay.

Fig. 1. Distribution of anchovy eggs $(N/m^2 * day^{-1})(L.)$ in Boka Kotorska Bay

Temperature ranged from16.98-23°C, while salinity ranged from 35.01-39‰. These ranges coincide very well with long-term data on temperature and salinity ranges of anchovy spawning in the Adriatic Sea [1, 2]. High spawning intensity in the internal part of the Bay may be explained by the influence of the fresh waters in that shallow area, which cause high organic production. Finally, spatial distribution of eggs found in this survey is in very good accordance with the spatial distribution found in July 1968 [3].

Abstract

Relationship between depth and food availability vs prokaryotes and macrobenthos in deep (1200 to 5000m depth) central-east Mediterranean and Galicia Bank (Atlantic) is explored. Prokaryotic abundance was from 0.1 to 1.1 x108 cells g-1 i.e. 0.2 and 3.1 µgCg-1. The prokaryotic C production in the Atlantic was 7,7 to 104,6 ngCg-1 h-1. Archaea (9-36% Crenarchaeota, 4-15% Euryarchaeota) were on average 31% of total abundance. Positive correlation between prokaryotic abundance and food availability was in the Galicia bank. Mediterranean macrofauna was from 14±16 to 284±44ind/m2 and from 0,03±0,02 to 0,25±0,05g/m2 and was dominated by polychaetes. Its standing stock decreased with depth, prokaryotic abundance and biomass did not. Large organisms were more affected by loss in available energy with depth.

Keywords: Deep Sea Ecology, Biodiversity

Introduction

The deep-sea is the largest ecosystem on Earth and one of the least studied. with a variety of habitats that support one of the highest biodiversities on the planet [1]. Only a very small fraction of the deep sea has been explored to date and this gap in knowledge has been recognised by the Census of Marine Life. However, in parallel with the development of new technologies, industries such as deep-sea fisheries and oil exploitation at entering deep waters, start affecting an ecosystem largely unexplored and highly vulnerable because of the long life and late maturity of many deep-sea species [2]. Additionally, recent studies show that climate change also affects biodiversity and population dynamics in deep-sea ecosystems, although these processes remain largely unknown [3, 4, 5]. In this study we wanted to investigate the importance of depth and food availability for the deep prokaryotic and macrobenthic communities of the central- eastern Mediterranean sea and Atlantic ocean. For this purpose we analysed i) the distribution of prokaryotes' abundance, biomass, community structure, C production, degradation activities of extracellular enzymes; ii) the macrobenthic abundance, biomass and diversity in different deep sea sites of the central-eastern Mediterranean basin; iii) the quality and quantity of sediment organic matter in influencing prokaryotic and macrofaunal communities.

Methods

We compared areas at similar depths with different levels of productivity in the Ionian and Aegean seas (Mediterranean) and in the Galicia Bank (Atlantic). In June and October 2008 a total of 27 deployments of box corer (3 replicates per station) were performed at depths ranging from 1200 to 5000 m. For prokaryotic counts, community structure, prokaryotic activity (extracellular enzymatic activities and carbon production) and organic matter analysis, three sub-core were sectioned (0-1 cm layer) and processed.

Results and Discussion

The distribution of the prokaryotic abundance in the top 1 cm among sites ranged from 0.1 to 1.1 x 10⁸ cells g⁻¹ equivalent to 0.2 and 3.1 µgC g⁻¹, which are values lower than those found in previous studies; but the prokaryotic C production in the Atlantic was high (from 7,7 to 104,6 ngC g⁻¹ h⁻¹) and comparable to those generally found in shallower systems. The percentage of Archaea in the prokaryotic community was on average 31% of total prokaryotic assemblage, unusually higher than values reported for deep sea sediments. Bacteria accounted the remaining portion (69% of total abundance). Archaeal assemblages were dominated by Crenarchaeota (9-36% of total Archaeal abundance) followed by Euryarchaeota (4-15%) and a small percent of unidentified Archaea. Multiple Regression Analysis evidenced a positive correlation between prokaryotic abundance and food availability only in the Galicia bank; the bacterial domain from these areas was strongly related to Biopolymeric C content. Prokaryotes in the deep Mediterranean may be affected by other factors than simply food availability. Macrofaunal abundances and biomass were generally low, from 14±16 to 284±44 ind/m² and from 0,03 \pm 0,02 to 0,25 \pm 0,05 g/m² and dominated by polychaetes in almost all stations but one dominated by crustaceans. Cnidaria and Crustaceans were the second dominant groups but unevenly distributed among stations; a more structured community was in the shallowest station where molluscs and sipunculida, were also found. Most of the polychaetes were deposit-feeders, as often when organic matter is refractory to degradation processes. Species richness (average S=4) and Shannon diversity (average H'=0.6) values were low but individuals were equally distributed among different families (average Eveness = 0.9). Abundance and biomass of macrobenthos decreased with depth (R²=0.91) but increased with the content of phytodetritus into the sediments (R²=0.93 and R²=0.82); biopolymeric compounds did not show valid statistical relationships. A clear depth-related pattern was not found in prokaryotic abundances, and bacterial carbon production. The detrital organic matter of the sediments had a significant correlation with prokaryotes only in the stations in the Galicia Bank. The other factors involved in affecting their distribution, abundances and activities will be further explored. In conclusion, despite the low abundance of microorganisms, the contribution of Archaea was higher than reported until now for marine sediments [6;7]. Also macrofauna abundance and biomass were characterized by very low values and showed a negative correlation with depth, as previously reported [8;9]. Prokaryotic abundance and biomass show no decline with depth and large organisms are very likely affected by the reduction in available energy with depth more than others.

This work was funded by ESF as part of the BIOFUN (EURODEEP project).

Abstract

The age and growth data of *Squalus blainvillei*, in the Gulf of Gabès, derived from spines reading, were used to estimate the von Bertalanffy parameters: $L^{\infty} = 105.7$ cm, K= 0.11, t0 =-1.12 for females and: $L^{\infty} = 91.1$ cm, K= 0.14, t0 =-1.42 for males. Ages at maturity for females and males were 7.44 and 4.79 years respectively. The maximum age was 19 years. *Keywords: Growth, Elasmobranchii, Gulf Of Gabes*

Introduction

Longnose spurdog *Squalus blainvillei* occurred throughout the Mediterranean Sea up to 700 m depth [1]. Data on its age and growth were scarce in the Mediterranean Sea except those of the Sicilian Channel [2]. Life history parameters, mainly age and growth, are essential for adequate management of shark catches. Thus the aim of this work is to estimate age and growth of *S. blainvillei* using spines.

Materials and methods

115 specimens of *S. blainvillei* fished in the Gulf of Gabès were sampled from May 2004 to July 2005. The second dorsal fin spines (DFS) were removed and prepared [3]. Growth bands were counted in each spine section throughout a specific line transept within the internal dentine layer and using a Microscope and Olympus S2X9 stereomicroscope at x 20 magnification; a band was defined as a pair of dark (opaque) and light (translucent) concentric rings [3]. The TL-atage data were fitted to the von Bertalanffy growth model (VBGM).

Results and discussion

The total number of bands counted increased with length for both males and females. Estimated parameters of the von Bertalanffy equation were shown in tab 1.

Location	Sicilian C (Cannizz 199	Channel aro <i>et al.</i> 95)	Gulfof Gabès (Present study) Internal dorsal spine band count	
Method	ventebralb	and count		
Sex	Ŷ	8	ę	8
L.º: theoretical asymptotic length (cm)	117.9	96.0	105.7	91.1
K: growth rate coefficient(year -1)	0.10	0.13	0.11	0.14
To: theoretical age at zero length (years)	-1.38	-1.39	-1.12	-1.42
A. mat : age at maturity (years)	5.1	3.3	7.44	4.79
A.max: oldestfish (years)	8	8	19	15

Tab. 1. Growth parameters and age of *S. blainvillei*

Until 8 to 10 years, males grew more quickly than females. After that, females continued to grow faster (Fig. 1). The age at maturity was estimated respectively for females and males at 7.44 and 4.79 years. As shown in table 1, *S.blainvillei* reached a maximum age more important in the Gulf of Gabès than in the Sicilian Channel. These differences may be related to the structure used (spines or vertebrae), the variability between readers, the stock state and fishing pressure and to species confusion, it seems in fact that both *S. blainvillei* and *S. megalops* occurs in the same area.

Fig. 1. Von Bertalanffy growth curve in length of *S. blainvillei* from the Gulf of Gabès

Abstract

Fourteen specimens of *Ophiocomina nigra* were collected in a restricted area of the Sicilian Channel under the influence of Atlantic Ionian Stream, between 64 and 97 m depth. The species was associated with the sea urchin *Stilocidaris affinis* (Philippi, 1845), a species "characteristic" of the Coastal Detriticus biocenosis. The Sicilian Channel represents the eastern border of the species occurrence in the Mediterranean.

Keywords: Echinodermata, Biogeography, Sicilian Channel

Ophiocomina nigra (Abildgaard, in O.F.Muller, 1789) is a brittle star living in the eastern Atlantic from the Azores to northern Norway and rarely in the western Mediterranean [1]. A first synthesis of Mediterranean distribution was given in [2], the species occurring in waters off Sicily, Algeria, Tunisia, Baleares, France and Catalonia. Further records were reported along the southern Spanish coasts [3]. More recently, the species was confirmed in Sicily (South Tyrrhenian Sea) [4] and off the Maltese Islands [5, 6]. Our specimens were collected within the European Data Collection Framework (Reg. CE 199/2008) during the trawl surveys (MEDITS and GRUND) and the sampling of the commercial trawling discard (DISCARD). The main information on the records is reported in Table 1.

Tab. 1. Main information on the new findings of *O. nigra* in the Strait of Sicily

Survey	Date	Appr. Lat.	Appr. Lon.	Depth (m)	N individuals
MEDITS 2008	13/05/2008	37°23.2'	12°11.4'	64-67	1
GRUND 2008	09/11/2008	37°29.6'	12°00.4'	97-96	1
GRUND 2008	10/11/2008	37°11.9'	12°12.5'	66-69	1
GRUND 2008	10/11/2008	37°12.9'	12°07.9'	76-80	1
MEDITS 2009	22/05/2009	37°11.3'	12°12.6'	67-72	9
DISCARD 2009	30/01/2009	37°12.0'	12°12.0'	10-150	1

The reported findings occurred in a limited area between 64 and 96 m on the external border of the Adventure Bank in front of Pantelleria Island (western side of the Sicilian Channel). The species was associated with the sea urchin *Stilocidaris affinis* (Philippi, 1845), a species "characteristic" of the Coastal Detriticus biocenosis (CD). The *O. nigra* distribution in the Mediterranean suggests a strong link with the Atlantic water (AW) [2], the Sicilian Channel representing the eastern border of the species occurrence in the Mediterranean.

FEEDING HABITS AND TROPHIC STATUS OF MEDITERRANEAN MORAY EEL, *MURAENA HELENA* L. 1758 IN THE ADRIATIC SEA – PRELIMINARY APPROACH

S. Matic-Skoko^{1*}, P. Tutman¹, E. Marcelja², D. Skaramuca², D. Đikic³, D. Lisicic³ and B. Skaramuca²

Abstract

The feeding habits of *Muraena helena* from Adriatic Sea were studied using frequency of occurrence, numeric and gravimetric percentage, an index of relative importance (IRI), main food index (MFI) and coefficient of nutritiveness (Q). *M. helena* is a carnivore, mainly piscivore with a trophic level of 4 and up. Diet composition including 14 different prey taxa was evidently homogenous among *M. helena* size groups. Principal prey items by decreasing importance were Pisces and Decapoda. The study will be completed by analysing dietary overlap among size groups and seasons. *Keywords: Adriatic Sea, Fishes, Diet*

Species from Muraenidae family are relatively big group of fishes famous by their lurking in holes, and writhing snakelike through crevices, under rocks or corals and by ability to swallow very huge prey [1]. *M. helena* is common in eastern Atlantic and Mediterranean. Two moray species are found in Adriatic Sea: very rare *Gymnothorax unicolor* and more common *M. helena*, both with minor commercial importance.

While other morays are carnivores that feed on fish, crabs and octopus with a significant role in population dynamics of many demersal fish [2], very little is known about the biology of *M. helena* and of its ecological role in Adriatic coastal ichthyocommunities.

A total of 267 individuals of *M.helena* were caught in the Southern Adriatic $(42^{\circ}38' 51,72" N; 18^{\circ} 02' 43,57"E)$ by bottom long-line. Prior to alimentary tract removal, fish were weighed and measured. The tracts were individually stored in 4% formaldehyde. The alimentary tracts were opened and prey items were separated using a binocular microscope (magnification 10-60x). The number of empty tracts was recorded. Prey items were counted, weighted and identified to the lowest possible level. The weight of items was obtained by wet weight method. Whenever fragments were found, the number of individuals from which fragments could have originated.

Three indices were used to describe the diet, these were: the frequency of occurrence (%F), percent numbers (%N) and weight (%W) [3]. The index of relative importance IRI = (% N + % W) * %F was calculated for each prey category as proposed by [4]. For diet comparisons, the %IRI for each food category was applied after grouping prev taxa into categories based on their taxonomy and ecology. Main food Index (MFI) by [5] and coefficient of nutritiveness (Q) by [3] were also computed. Three size groups were determined: 25 - 50 cm; 50 - 75 cm; 75 - 100 cm. In ecology, the trophic level is the position that an organism occupies in a food chain - what it eats, and what eats it. Each link in this chain of consumption is termed a trophic level. Because only a fraction of the energy used by a level is converted to biomass, less energy is available at higher levels. Primary producers often have trophic level 1. There is no in-principle limit to the number of levels in a trophic system, but as only a fraction of the energy of each level can be processed by the next (10%), trophic systems with more than five levels of consumption are exceptional.

The stomach contents of M. helena (total length 27.5 - 100.0 cm; total weight 116.1 - 2280.0 g), were examined of which all were full. Recognizable preys of 14 different taxa were identified and grouped in 6 classes and values of IRI, MFI and Q for them are presented in Table 1. Diet was evidently homogenous among M. helena size groups. The diet of M. helena consisted of a wide variety of macrobenthos. Pisces, occurring in 2/3 of all stomachs dominated in the diet. Crustacea and Mollusca followed this group in frequency of occurrence and weight. Decapoda represented 21.1% of occurrence in all stomachs. The principal prey found were Pisces (IRI=9755.8) with dominant species Phycis phycis (IRI=714.1) that was found in 11.54% of stomachs and Crustacea (IRI=913.0) including more important species as Pilimnus hirtellus (IRI=44.7) and Galathea strigosa (IRI=20.2). Besides Algae, other groups were represented with approximately 2% in total stomachs contents. It is evident that Pisces are most frequent as prey in numbers and weight, they have highest index of relative importance, and besides Crustacea they represented main type of food and have the highest nutritive value, while Algae, Gastropoda, Bivalvia and Remains were secondary or accidental food. Of total analyzed stomachs, 50% were those of which the content was not possible to identify, so we classified it as digested fish material remains. Due such results, M. helena have a trophic level 4.2 ± 0.61 (SE) by main prey types in nutrition, which were

fishes and crabs with trophic level 2.8 and up.

Tab. 1. Diet composition of *Muraena helena*, Adriatic Sea (F is frequency of occurrence; N is numerical composition; W is gravimetric composition; IRI is index of relative importance, MFI is main food index and Q is index of nutritiveness)

Food items	%F	%N	%W	IRI	MEI	Q
ALGAE	4	3.85	0.14	15.96	0.56	0.55
GASTROPODA	2	1.92	1.92	7.68	3.76	3.69
BIVALVIA	2	1.92	0.96	5.77	1.88	1.85
POLYCHAETA	2	1.92	10.36	24.58	20.33	19.93
CRUSTACEA	22	21.15	20.35	912.99	438.99	430.39
PISCES	72	69.23	66.27	9755.82	4679.46	4587.70

Only [6] reported results of *M. helena* feeding habits (zoobentos, nekton, benthic crabs, crustacean, squids and octopus) and its findings are in agree with our results in all except by non presence of cephalopods. But, at this preliminary degree, all our samples are not analyzed till this moment (only two seasons are processed and diet may strongly vary seasonally). Moreover, high percentage of unidentified prey was present and will be carefully examined once again in terms of finding structures which may belong to other animal components.

The index of relative importance (IRI) is a frequently used to estimate diet composition, but it has disadvantages due impact to its key components. Percent frequency of occurrence (%F) does not account number and weight of the prey item. Numeric percentage (%N) does not account weight and frequency of occurrence. Consequently, %N is highly influenced by very small, but numerous preys while very rare and large prey can underline % W. Also, the results in terms of relative importance of different prey groups should be treated with caution. Some prey items that are small, soft and rapidly digested may be underestimated, while large prey with durable hard parts may be given undue importance.

Piscivorius, agressive species as *M.helena* are less influenced by abundances of specific prey taxa then are for example more specialized feeders [1] [2]. The ecological importance of this species within the mediterranean coastal communities appears to be significant and further studies are needed to assess it. Those findings will lead to the implementation of multispecies approaches to the management of Mediterranean artisanal fisheries.

STATE AND PERSPECTIVE OF SCORPAENA SCROFA AND MULLUS SURMULETUS – TWO HIGHLY VALUED SPECIES OF EASTERN ADRIATC ARTISANAL FISHERIES

Sanja Matic-skoko¹*, Nika Staglicic¹ and Armin Pallaoro¹ ¹ Institute of Oceanography and Fisheries - sanja@izor.hr

Abstract

The state and perspective of two main target species of Croatian artisanal fisheries: largescaled scorpionfish, *Scorpaena scrofa* and striped red mullet *Mullus surmuletus* were investigated by detailed analysis of experimental catches. Basic demographic characteristics of those species and recommendations for sustainable use of coastal resources are presented. *Keywords: Adriatic Sea, Fisheries, Coastal Management*

Introduction

Croatian artisanal fisheries takes place in a relatively small area which corresponds to about 6% of the Croatian Adriatic total fishing grounds. Nevertheless, it generates a substantial yield taking second place in the overall catch statistics, indicating that coastal area is subjected to high level of exploitation. As a biologically diverse and lush area Vis aquatorium has historically been one of the most important eastern Adriatic fishing grounds, especially for highly valued species such as largescaled scorpionfish, *Scorpaena scrofa* and striped red mullet, *Mullus surmuletus*. Therefore, it was chosen as a pilot area where we assessed in detail the status of the two aforementioned fish species.

Material and methods

Largescaled scorpionfish, *S. scrofa* and striped red mullet, *M. surmuletus* were caught by employing 'poponica' - trammel bottom sets with standard construction characteristics.

Results

S. scrofa specimens ranged between 14 - 45.1 cm total length (average 24 cm) and 30-1347 g weight (average 273.33). Scale reading of caught specimens gave the age range of 3-8 years. Assessing the destructiveness of 'poponica' nets for *S. scrofa* population by taking into account minimal landing size of this species (25 cm) ordained by [3] it can be seen that the overall catch is dominated by undersized specimens (62.5%) (Fig.1). Situation is even more concerning if biologically justified size at first sexual maturity is applied (TL 30 cm). The proportion of immature specimens is in that case as high as 90%. All of the above-mentioned indicates a rather alarming status of *S.scrofa* populations.

Fig. 1. Length frequency distribution of *Scorpaena scrofa* catch from trammel nets, Adriatic Sea (MLS – minimal landing size; rMLS – recommended minimal landing size)

In wider Vis aquatorium area a high number of *M. surmuletus* specimens were caught in trammel nets due to the fact that most of fishing operations have taken place during the warm summer-autumn period when this species comes closer to shore for feeding and is therefore more easily caught. Total length, weight and age ranges of caught specimens are 17-30.9 cm (average 24.12 cm), 33-337 g (average 159.2 g) and 3-6 years, respectively. Taking into account minimal landing size of this species (11 cm) ordained by [3] no undersized specimens were present in the overall catch. Even when demersal long line destructiveness is assessed considering biologically justified size at first sexual maturity (18 cm), then catches contained a rather low, satisfying 1.2% of immature specimens.

Discussion

Negative impacts related solely to fishing activities of those target species are as follows: decline in total CPUE (average CPUE with unit effort being one 32 m long trammel net is 0.66-3.31 kg/net), increase in the CPUE of Scorpaenidae family (the incline is, however, mostly due to *S. porcus* and not to commercially more valuable *S. scrofa*); decrease in average catch length and weight of targeted fish and increased proportion of immature specimens.

Nevertheless, the situation is quite favourable in the project area when compared to any other in the Adriatic. However, it is not without concern. Namely, looking at biometry characteristics of commercially important species S. scrofa and M. surmuletus, it is evident that large specimens are only rarely caught. Average landing sizes are more than twice smaller than those maximally attainable.

Changes in quantitative and qualitative catch structure of coastal fish populations can be due to various reasons. It is generally acknowledged they are mainly due to intensive fishing. However, different species vulnerability to fishing activities, density dependent effects as a result of complex ecological relationships in coastal communities, predation, growing marine pollution and climate change all play a part [4].

Regarding the fishing gear used for catching fore mentioned target species, it can, first of all, be said that trammel net 'poponica' is highly nonselective and its use coincides with reproduction period of most species. Other used gillnets are selective and generally catch adult specimens if are not misused. Recommendation therefore, is a more responsible conduct encouraged by a more efficient surveillance. Temporal restriction should be considered in order to allow undisturbed reproduction of targeted species. It is necessary to increase minimal landing size of 11 cm for *M. surmuletus* because in [3] this value is given for both Mullidae species. In order to insure sustainable small-scale coastal fisheries, all of the aforementioned issues need to be taken into consideration. Most importantly continuous monitoring and effective implementation of existent regulation measures should be established.

Abstract

In this work, the *mt* DNA marker has proven its usefulness as informative source of genetic variation by the identification of four population units of *Pomatoschistus marmoratus* and by delineating their boundaries. *Keywords: Genetics, Eastern Mediterranean, Western Mediterranean, Fishes*

Introduction

The genetic population structure of marine species is shaped in space and time by the combined impacts of their historical events and the complex interactions of biology, geography, and climatic shifts [1]. Hence, the identification of these ecological and evolutionary factors that control local differentiation of populations is crucial in order to understand fine-scale micro-evolutionary processes [2] and to examine the spatial and temporal scales at which populations are genetically structured. Previous studies have suggested significant population structuring in the Mediterranean Sea (MS) in relation to some of the factors listed above and which trigger intraspecific fragmentation. Some of these numerous phylogeographic studies have a great focus on Gobiid species well distributed and diversified in the MS. Among these numerous species, the marbled goby Pomatoschistus marmoratus (Risso, 1810), which is a strictly inhabiting lagoons species and a poor dispersers one. In this study, a thorough analysis of the genetic variation of P. marmoratus at different geographic scales and across much of its distribution area, is presented and discussed. Its phylogeography was inferred using mtDNA 16S ribosomal RNA gene (16S-rRNA) and Cytocrome Oxidase I gene (COI) sequences and, a robust statistical framework of hypothesis for characterizing the present and past population genetic of this goby. Using this organism as a model, we test how physical and evolutionary factors lead to the structuring of marine populations in MS.

Materials and Methods

A total of 56 marbled gobies were sampled from eight Mediterranean localities (Three sites from western Mediterranean: Thau lagoon, and Vaccarès lagoon, in Southern France, Bizerta lagoon, in Northern Tunisia; five sites from eastern Mediterranean, subdivided in the following areas: two samples from Lybico - Tunisian Gulf, Lella el Hadria lagoon, and El Biban lagoon, in Southern Tunisia, two samples from Adriatic Sea, Venice lagoon, in Northern Italy and Soline Bay, in Croatia, and one sample from Aegean Sea, Vassova lagoon, in Greece). A fragment of the mitochondrial 16S-rRNA gene (501 bp in length) was amplified with the universal primers H16 and L16. A fragment of the mtDNA COI gene (647 bp in length) was amplified using the universal primers FishF1 and FishF2. Sequencing results were manually edited with BioEdit program version (7.0.5.3) and aligned using the CLUSTAL-W program. Phylogeographical and molecular evolutionary analyses were performed for each separate gene and considering all data together. Phlogenetic analyses were conducted using PAUP 4.0b10, DNAsp v.4.50 and ARLEQUIN v.3.11. Levels of mtDNA diversity and population genetic statistics were investigated by comparing population estimates of mitochondrial haplotype diversity (Hd), nucleotide diversity (π), number of segregating sites (SS) and gene flow (F_{ST} and N_em). To examine hierarchical population structure as well as the geographical pattern of population subdivision, we used analysis of molecular variance (AMOVA). In addition, we carried out SAMOVA (Spatial Analysis of MOlecular VAriance) using the program SAMOVA.1.0. Besides, an unrooted network of mtDNA haplotypes was constructed using the program TCS 1.13 with 95% parsimoniously plausible branch connections between haplotypes. This statistical parsimony network (SPN) method was used because analyses based on networks are thought to be more accurate at representing historical processes.

Results and discussion

Pomatoschistus marmoratus shows a remarkable degree of genetic population subdivision and phylogeographic complexity within the MS. Sequences show a tendency to gather by sampling locality providing four clusters matching the geographical positions. These phylogroups appeared as monophyletic with high bootstrap support values equal to 100%. According to the geographic locations of the specimens in each major clade, our mitochondrial DNA analysis of *P. marmoratus* in the Mediterranean revealed a west–east phylogeographic split involving four highly divergent phylogroups with no

geographical overlap. Each of these lineages roughly corresponds to a different Mediterranean sub-basin. We designated the four clades as Western Mediterranean Sea, Lybico Tunisian Gulf, Adriatic Sea and Aegean Sea. These four clades are disconnected also in the SPN and constitute the most probable and only statistically significant grouping in the Samova analysis. Pairwise FST values were generally high and well significant within the four clades and the Nem was very low and does not exceed 0.06 migrant per generation suggesting that the gene flow between the four clades is almost absent. The networks of the LTG and AEG clades showed evidence of star-like phylogenies, suggestive of past demographic expansions; however, the WMED and ADR networks suggest an equilibrium status. Looking at the biology and life history of the studied fish, the past geomophological processes and the hydrographic patterns within the MS we can understand the occurrence of this split within the different analysed populations and the lower genetic variability encountered within the different phylogroups. This pattern is consistent with the potential effects on dispersion of the Siculo Tunisian Strait and the Hydrographic isolation of the Adriatic and Aegean Seas where selective forces related to physical, chemical and/or ecological conditions present in each basin could account for the phylogeographical break. The strong currents that limit the mixing of the different bodies' water may interact with the local features and the particular bottom topography of the zone and could have allowed progressive intraspecific genetic differentiation

LENGTH-WEIGHT RELATIONSHIPS OF THE ALIEN JINGA SHRIMP, METAPENAEUS AFFINIS (H. MILNE EDWARDS, 1837) (DECAPODA, PENAEIDAE) IN THE MEDITERRANEAN SEA

Gulnur Metin¹*, Ilker Aydin¹ and Bella s. Galil² ¹ Ege University Faculty of Fisheries - gulnur.metin@ege.edu.tr ² National Institute of Oceanography, 8030, Haifa 31080, Israel

Abstract

Seasonal length-weight relationships (LWR) of the recently introduced Jinga Shrimp, Metapenaeus affinis, population in the Izmir Bay are presented. A total of 1795 specimens were collected, and LWR for females, males and combined sexes, were calculated as $W=0,0046L^{3,19}$, $W=0,0076L^{2,96}$ and $W=0,0041L^{3,23}$ respectively. Whereas females showed positive allometry, males showed negative allometry.

Keywords: Alien species, Crustacea, Aegean Sea

Introduction

Metapenaeus affinis occurs in the Indo-West Pacific Ocean, from the Persian Gulf and the Arabian Sea, to Indonesia, China, Philippines and New Guinea [1]. The species is commercially of major importance in the Persian Gulf, where it is commonly captured on shallow muddy bottoms. It is raised commercially in the Philippines. It was first noted in the Mediterranean in April 2008, when 64 specimens were caught by trammel net set on muddy bottom, at depth of 8-12 m, at the inner part of Izmir Bay, on the Aegean coast of Turkey [2]. We monitored this population ever since.

Material and Method

A total of 1795 specimens were collected at the inner part of the bay by shrimp trammel net at monthly intervals between November 2008 - October 2009. Sexually mature male and female specimens were collected between May and October. LWR measurements of the newly established population were taken and compared to data from the species native range, and to serve as baseline for possible future studies of possible adaptation to the local environment. The relationship between length and weight was established as $W=aL^b$, where W is total body weight (g), L is total length (cm), and a and b are coefficients [3]. The parameters a and b of length-weight relationships were estimated by linear regression analysis on log transformed data. The association degree between variables was calculated by the determination coefficient (R²). The growth type was identified by Student's t-test.

Fig. 1. Sampling area, where specimens were collected

Results and Discussion

Total length varied between 8-17,5 (±1,34) cm and weights were 3,2-38,9 (±4,87) gr. The smallest individual was a male collected in May, the largest a female collected in September. The maximum length for males was 14,6 $(\pm 1,12)$ cm as compared with 22.2 cm in its native range [4]. The population shows a normal distribution with sex ratio 1:1.2. Generally females are larger and heavier than males. According to calculations, growth for female and combined sex individuals showed positive allometry, but males showed negative allometry. In addition the slope (b) values revealed differences between the seasons (p<0,05). There are few LWR data for jinga shrimp. One study estimated $W=0.7079C^{2.770}$ whereas another $W=.0000495L^{2.7867}$ [4, 5]. The introduction of M. affinis, and the establishment of a population large enough to be commercially exploited, is a boon for Izmir Bay's artisanal fishermen, who turned from beach seining to trammel netting for prawns. During the summer of 2009, 10-12 fishing vessels were profitably engaged in this fishery, with wholesale price 4.5 euro per kg, and retail at 6.5-7 euro. The population dwindled in August, due possibly to intense illegal fishing.

AGE AND GROWTH OF FATTENING BLUEFIN TUNA (*THUNNUS THYNNUS* L., 1758) IN THE EASTERN MEDITERRANEAN SEA

Nicky Milatou^{1*} and Persefoni Megalofonou¹

¹ Department of Zoology and Marine Biology, Faculty of Biology, University of Athens, Greece - nmoceanology@msn.com

Abstract

A total of 188 specimens of bluefin tuna (*Thunnus thynnus* L., 1758) were sampled from the Greek Bluefin Tuna farm, in the Ionian Sea, between December 2007 and January 2008. The samples ranged from 127 to 272 cm in fork length and from 43 to 475 kg in round weight. Their age was estimated from 5 to 16 years, using caudal vertebrae and the length-weight relationship revealed a positive allometric growth.

Keywords: Eastern Mediterranean, Aquaculture, Growth, Pelagic, Teleostei

Introduction

Bluefin tuna (*Thunnus thynnus* L., 1758) is a large pelagic fish with a highly migratory behavior and trans-oceanic movement. It is found in the Atlantic Ocean including the Mediterranean Sea and sustains important recreational and commercial fisheries as well as the aquaculture industry [1, 2]. The aim of this study is to estimate the age of fattening bluefin tuna using caudal vertebrae and to determine the length-weight relationship.

Materials and Methods

Fork length (FL) and round weight (RW) measurements were taken from 188 bluefin tuna specimens sampled from the Greek Bluefin Tuna farm, in the Ionian Sea, from December 2007 to January 2008. Length measurements were taken to the nearest centimeter (cm) and weight to the nearest gram (g) and the length- weight relationship was calculated using the equation RW=a*FL^b.

A total of 99 caudal vertebrae were used to estimate age by counting the annual growth zones observed on the inner surface of the cones of the whole vertebrae. One ridge and one groove were interpreted as one annulus. Mean lengths at age and the precision of the ageing method were calculated.

Results and Discussion

Fork length and round weight data ranged from 127 to 272 cm and 43 to 475 kg, respectively. The more frequent length classes were between 220 and 240 cm and the more frequent weight classes were between 240 and 270 kg. The slope of the length-weight relationship was bigger than 3 indicating positive allometric growth (Fig. 1). However, the length-weight relationships for the wild individuals present mostly negative allometric growth [2].

Several studies have estimated the age and growth of wild bluefin tuna using calcified structures, but no one has estimated the age of fattening bluefin tuna. The range of the estimated ages was from 5 to 16 years with mean fork lengths 139 cm and 267 cm, respectively (Fig. 2). The age group 10 was dominant. From the samplings we had no young specimens, because at the aquaculture there are only older, from 5 years and over, specimens. A comparison of our results with similar studies revealed that the fattening bluefin tuna present higher mean lengths at age values than these of the wild bluefin tuna [3].

The Average Percent Error (APE), the Coefficient of Variation (CV) and the Index D were 2.21%, 2.89% and 1.67%, respectively. The values of precision estimated keep up with the values of the existing bibliography [3]. The present study revealed the difficulty in distinguishing between the closely spaced increments on the centrum margin of the vertebra that becomes severe at the age of 8 years and onwards. The same difficulty has also been noticed in previous studies [3]. This probably constitutes the major disadvantage of the vertebra method and it is likely to underestimate the age of older fish.

PRODUCTION AND COMPOSITION OF SMALL-SCALE FISHERIES LANDINGS IN THE EASTERN AEGEAN SEA

Anastasia Miliou¹*, Stefan Kolle¹, Joanne Clarke¹ and Monica Demetriou¹

¹ Archipelagos, Institute of Marine & Environmental Research of the Aegean Sea - a.miliou@archipelago.gr

Abstract

The biomass and species composition of the landings from 7 coastal small scale fisheries vessels were compared over a 5 month period in SW Samos, eastern Aegean Sea. The quantitative composition of the landings was assessed for the different metiers: trammel net, small gillnet, long line, boat seine and a locally practiced metier, "kalami". The total landing weight of this fleet between June and October was 14.3 tons, dominated by the catches of the small gill net metier (52.7%). *Keywords: Aegean Sea, Eastern Mediterranean, Fisheries, Coastal Management*

Introduction

Monitoring of small-scale fisheries can be problematic, due to their wide distribution across the 18,000 km coastline of Greece. Little quantitative information is available on various aspects of Greek small-scale fisheries, and a large part of the catch reaches the local market unreported, especially in non-central regions. However small scale fisheries contribute significantly in terms of weight and value to the total Greek fisheries and are of primary socio-economical importance [1,2]. The species composition of small-scale fisheries have only been studied in a few regions of the Greek seas [1,3,4,5,6,], and have illustrated variation in dominant species caught in the different regions and with different metiers. In this work the quantitative composition of the landings of a small scale fishing fleet in Ormos port, Marathokampos Bay, SW Samos has been examined.

Materials and Methods

The fleet of Ormos port is composed from 7 active small-scale fisheries vessels. This fleet utilizes several metiers, according to the season and the yield of the landings and comprises mainly of trammel nets (mesh size 22-36mm), gill nets (8-9mm), long lines (hook N° 9-14) and boat seines. One boat practiced an unusual local metier named "kalami" (September, October), comprising of an adapted fishing rod targeting *Dentex gibbosus* at 50-150 m depth. The landings of this fleet were recorded on a daily basis from June to October 2009. Recording took place on the port immediately after the arrival of the vessels. The number of individuals and the weight per species were recorded. Information about the used gear, the mesh size or the size of the hooks, the length of the nets or the number of the hooks were collected.

Results and Discussion

The total fishing effort of the fleet during the 5 months of the survey period was 544 days at sea; 56.3% of the time was with trammel nets, 16.5% with 8-9mm gillnets, 14.5% with longline, 7.2% with boat seine and 5.5% with "kalami. The total landings of the trammel net 30-36mm metier were 2039 Kg. The main target species in this metier is S. scrofa (20%), P. elephas (13%), P. pagrus (8%) and Dentex dentex (6%). Other fish species accounted for the remainder of 53% of the landed biomass in this metier (Fig.1, A). The 22-24 mm trammel net had total landing weight of 922 Kg, with main target species being M. surmuletus, comprising 25.7% of the total landing. The seasonal landings of Scomber japonicus and Coryphaena hippurus accounted for another 35.9%, whereas other fish species accounted for 38.4% (fig.1, B). The total landing weight in the longlines metier was 1033 Kg, with the main species being P. pagrus (32%), Spondyliosoma cantharus (26%), Diplodus vulgaris (15%) and D. dentex (4%) (Fig.1, C). The landings of the boat seine comprised mostly of juvenile fish of various species. The species composition was mainly juvenile B. boops, A. boyeri and Sardina pilchardus, which together accounted for 41.7% of the landed weight (Fig.1, D). The landings from the 'kalami' metier were 474Kg, targeting solely D. gibbosus. Further research needs to be carried out to improve the understanding of this locally practiced, high yielding technique. The 8-9 mm gillnet metier accounted for the majority of the total landings (52.7%), by number as well as by weight. This has been reported to be exceptionally high this year yielding a total landing of 7.54 tons from 90 fishing days. The catch was dominated by B. boops (84%) and A. boyeri (10.2%). Other species such as Sarpa salpa and S. pilchardus were also present but accounted for <1% of the total landings weight.

The 30-36mm trammel nets target *Scorpaena sp.* and *P. elephas*, but this type of net also caught *P. pagrus*, *Phycis sp.* and *D. dentex*. These are target species of the longline métier, indicating some degree of gear competition. Landings of the 22-24mm trammel net métier show some similarity to the landings reported from the South Euboikos Gulf [4] and the region of Kastellorizo [5] in respect to the common main target species of *M.surmuletus* and *P. arcane*. However,

much fewer *M.babartus*, *Spicara maena* and *B.boops* were caught in this métier in Marathokampos Bay. In conclusion, for a greater understanding of the catch composition of small scale fisheries in the Greek seas, further long term research is necessary, covering a wider region and over different seasons. This knowledge is a prerequisite for the development of sustainable fisheries management for multispecies and multi-geared Greek small-scale fisheries.

Fig. 1. Catch composition in small scale fisheries metiers in Marathokampos Bay: A) Trammel net, 30-36 mm (06-09/2009), B) Trammel net, 22-24 mm (07-10/2009), C) Long Lines, hook No 9– 14 (08-10/2009) and D) Boat seine (10/2009)

Abstract

The sardine and anchovies' larvae and juveniles age interpretation criterials are defined based on otolith microstructure analysis. Included in SARDONE project, this comparative study was developed in order to understand the life history and recruitment of these key species in the pelagic ecosystem.

Keywords: Fishes, Growth

Introduction

Small pelagic fishes, such as Sardina pilchardus and Engraulis encrasicolus, are relevant constituents of the Mediterranean pelagic ecosystem. Their populations show evidence of important long-term natural fluctuations in their abundance, related, among other factors, to large-scale climate variability raising important scientific and economic concerns. It is commonly assumed that recruitment variability is largely determined by survival during the larval and juvenile stages. An important tool to decipher the initial life phases relies on them being encoded into otoliths both in the daily growth increments numbers, providing information about the age in days, and in the increment width, which is a proxy of fish growth. However, small pelagic otoliths have complex structures with numerous sub-daily units, that difficult the increment interpretation [1]. Therefore, and as part of SARDONE project (FP6-44294), it was necessary to establish a common age protocol before comparing three Mediterranean area's temporal and spatial patterns in small pelagic larvae and juveniles age and growth. This task was achieved by a step by step process based on the following: a) Interchange of otoliths images for joint otolith interpretation. b) An age interpretation Workshop, which was held in AZTI in 2008 knowledge gaps and which also lead to the establishment of a common protocol. c) A second round interchange of images. d) The 2nd Year meeting was held in the ICM in March 2009. In this meeting it was noted that the ageing was not performed in the same way by all the participants. The main discrepancies were found on the calibration of the images, the identification of the growth patterns and the otolith edge interpretation. e) A second otolith daily increments interpretation workshop, using real otoliths, was considered necessary. It was organized at IMEDEA on May 2009. Based on this iterative method a common criteria was established and applied. AGEING PROTOCOL In order to differentiate daily from sub-daily rings, the methodology suggests bringing the preparation into a focus where all growth structures can be clearly read and then slightly varying the focus, so that the sub-daily increments should disappear. This method could not be applied to the juveniles of small pelagics due to the presence of multiple wide rhythmic growth patterns in the central zone of otoliths (whiter and darker bands) and groups of multiple increments. The method, named Group Band Reading (GBR), consists on counting as one every repetitive cyclic set of growth bands or apparently groups of microincrements (usually 2 but occasionally more), assuming that they are sub-daily marks in postrostral zones corresponding to the early juvenile period [1]. The otolith nucleus should be read at 1000 magnification, whilst the rest of the otolith at x100 for anchovy and X200 for sardine. When necessary to assess the growth pattern higher magnification may be used. The grouping of sub increments forming growth bands (GB) is common in all individuals and starts very early in the life history of the fish. The width of the GB is conservative, not sudden changes occurs. In some cases the sub increments are very clear and difficult the identification of the GB. However, once the GB is initiated, this pattern continues. Therefore the group banding interpretation has to be maintained.

Anchovy:The first increment corresponds to the hatch check with a radius between 3.5 and 5 μ m [2], the following increments have a width around 1 μ m. The GB starts very early in life, with double bands, once formed this pattern has to be kept in all the otolith.

Fig. 1. Anchovy otolith showing the group band pattern age interpretation

Sardine:The hatching check appears at 5-7 μ m, the following increments have a width around 1 μ m. The GB appears at 40-80 increments after the hatching check, once formed this pattern has to be kept in all the otolith.

CHANGES ON BIOMASS ESTIMATION AND SPATIAL DISTRIBUTION OF ANCHOVY (ENGRAULIS ENCRAUSICOLUS) IN THE CATALAN PLATFORM

Alicia Mosteiro Cabanelas ¹*

¹ Tecnologías y Servicios Agrarios S.A. - alicia.mosteiro@gmail.com

Abstract

This document provides an insight on the changes detected in the Catalan platform to the anchovy population. Data were collected through two acoustic surveys in 2007 and 2008, providing biomass estimation and spatial distribution as well as some biological information. A significant recovery of the anchovy local population was detected. The length mode has increased from 5.5 cm in 2007 until 9 cm in 2008.

Keywords: Acoustics, Biomass, Ebro Delta, Pelagic

Introduction

An acoustic survey for the follow up of the small pelagic populations in the Catalan platform is carried out annually during December. Up to 10 small pelagic species are assessed during these surveys. The data collected is used as support for management of these species. The situation of anchovy (*Engraulis encrausicolus*) resources in the area was of major concern.

Material and Methods

Acoustic data collection takes place during day hours in December from a vessel platform with a scientific echosounder EK60 mounted on the keel equipped with 3 frequencies (38, 120 and 200 kHz). A pelagic trawl net Gloria352M with 20 m horizontal opening and 10 m vertical opening is used to collect the groundtruth data (biological samples) necessary to identify the schools and determine biological characteristics of the species collected. Transects perpendicular to the coast line are separated 6.5 nm from each other from the Spanish-French border until south of Ebro river delta. Data collection speed is 10 knots and trawling speed is 4 knots. The coefficient for TS calculation was - 72.6 for anchovy.

Results and Discussion

Anchovy population has been decreasing in the last years reaching very low levels in 2007. Several management measures like close seasons and minimum landing size have been put in place in order to protect this pelagic stock but they showed no positive results until 2008 when a recovery was detected. The 2007 biomass estimation indicated a stock of 350 tons in the 2000 mn² study area with a distribution mainly located in the north of Ebro river delta in front of Tarragona. The individuals collected were very scarce (n=148) and showed a mode in length of 5.5 cm being all immature individuals (size of first maturity is 10 cm).

The length-weight relationship for these samples was as follows: $W=0.0018*L^{3.6131}$; where $R^2=0.7328$

However, the 2008 biomass estimation showed a recovering situation of the anchovy stock with 8,575.8 tons, twenty times the estimated biomass in 2007. Its spatial distribution was wider indicating that the majority of the population was located in the Gulf of Rosas and the Ebro river estuary (Fig. 1). No samples were found in the rest of the area (approximately 2,000 nm²).

Fig. 1. Spatial distribution and relative abundance of anchovy

Samples were composed by anchovy in 65.7% of weight. The samples collected were more abundant (n=3,264) showing a 9 cm mode in length overall, being 14 cm in the Ebro estuary area, indicating that mature individuals were present in the area in 2008.

Fig. 2. Anchovy length-frequency for 2008 Gulf of Roses samples

The length-weight relationship for 2008 samples was as follows: $W{=}0.0064{*}L^{2.93} \text{ ; where } R^2{=}0.8988$

The coefficient of determination indicates a positive correlation between length and weight of the specimens. The number of specimens measured and weighed was much larger than in 2007 assuring the representativeness of the samples (Fig. 2).

Conclusions

The anchovy population in the Catalan coast has shown an important recovery from 2007 figures. Mature individuals were found mainly in the Ebro river delta area. The Gulf of Roses has notably increased its anchovy stock.

SPATIAL CONGRUENCE BETWEEN FISH BIODIVERSITY HOTSPOTS, HUMAN IMPACT AND THE NETWORK OF MARINE PROTECTED AREAS AT THE MEDITERRANEAN SCALE

David Mouillot ¹*

¹ Université Montpellier 2 UMR 5119 - david.mouillot@univ-montp2.fr

Abstract

The biodiversity of the Mediterranean Sea is exceptional relative to its water volume. This hotspot of biodiversity and endemism is facing ever increasing human-induced threats and marine protected areas (MPAs) have been extensively established. Rather surprisingly, no attention has been paid to how well the actual network of MPAs spatially matches with the hotspots of biodiversity and how much these hotspots are spatially congruent with human pressures. Here we used spatially explicit data to provide a first global assessment of these congruencies. We show that the global network of Mediterranean MPAs is spatially congruent with fish richness and fish endemic richness hotspots while the highest human pressures spatially matches with hotspots of fish endemic richness.

Keywords: Biodiversity, Conservation, Fishes, Marine Parks

We used the database compiled by Ben Rais Lasram (2009) which includes the geographical distribution areas of all known fish species in the Mediterranean Sea, i.e. 619 species among which 81 are endemic and 120 are exotic. These distributions areas were compiled from the FNAM atlas (Fishes of the Northern Atlantic and Mediterranean) (Whitehead et al. 1986) and digitized using a Geographical Information System software (ArcView3.3 by ESRI). These areas correspond to those of adult stages since they are based on observations and samples and may ignore spawning areas and larvae migration paths.

The digitized polygons were overlaid to a regular grid with a total of 27078 cells covering the whole Mediterranean basin $(0.1^{\circ} \text{ latitude x } 0.1^{\circ} \text{ longitude})$. For each cell, species richness was estimated as the sum of the species co-occurring. We excluded exotic species because they are not included in conservation strategies. Migratory, large pelagic species as well as those occurring beyond the continental shelf were also excluded from the analysis because coastal reserves do not provide any benefit for them. Indeed, Mediterranean reserves are often small (e.g. 0.003 km2 for Temuli/Sagone marine cave), and pelagic and migratory species undergo high fishing pressure out of the reserve limits. Species exhibiting a distribution area fraction up to 40% on the continental shelf were considered as coastal and thus included in the analysis. Thus, the final database includes the distribution areas of 345 species.

Even if Marine Protected Areas (MPAs) are not only devoted to fish diversity, since they care much about habitat diversity, recent studies point out their positive effects on fish density and biomass even outside reserve boundaries. Reserves locations were digitized using the Geographical Information System software and compiled from the MedPan data as well as from maps, polygons and GPS coordinates provided by persons in charge of the Mediterranean reserves. Digitizing was carried assuming that even if a small part of a cell belongs to a reserve, the whole species occurring in that cell potentially benefit from the reserve effect. Since the 100 Mediterranean reserves (the Pelagos sanctuary being excluded) are strictly coastal, we only considered the continental shelf because deep-sea ecosystem conservation would require particular strategies. We thus extracted a set of 8186 cells corresponding to the limit of 200m water depth from the 27078 cells constituting the whole Mediterranean Sea dataset.

Each of the 8186 grid cells contained the following information: (i) MPA network with reserve presence (coded 1) or absence (coded 0) (Res), (ii) fish species richness excluding migratory and large pelagic fish and species usually inhabiting beyond the continental shelf (Rich), (iii) endemic fish species richness (End); and (iv) the human-induced pressure values (Press). So, the database consisted of a 8186 rows (grid cells) x four columns (three variables and the reserve network) matrix.

We implemented two different methods that are commonly used to assess spatial congruence: correlations and overlap between hotspots. First, we calculated coefficient of correlations between all pairs of variables. Significance levels were calculated using Dutilleul's degrees of freedom (a correction for spatial autocorrelation), as implemented in the program 'Modttest'. This correction was necessary because spatial autocorrelation in both of the variables under consideration can greatly inflate Type-I statistical error rates. Second, we tested for congruence between the three variables and the reserve network by measuring the extent of spatial overlap between hotspots. To this aim we needed to identify hotspots for human impact and for biodiversity (fish richness and fish endemic richness). Since MPAs are present in 390 cells which roughly represents 5% of the total number of cells on the continental shelf we defined hotspots as the 5% of grid cells with the highest values with respect to species richness, endemism or threat, respectively. When two or several cells had the same number of species they were all included in hotspots. Thus the 5% highest values of each variable were replaced by 1 and other values by 0. So, the new data matrix consisted of 1 and 0 and showed 519, 412, 410 and 390 cell grids with 1 for *Rich, End, Press* and *Res*, respectively. Then we computed the proportional overlap, as a measure of area shared between two entities expressed as a percentage of the one with the smallest area (number of cells). To this aim, all pairs of columns were considered successively (6 unique combinations) and the observed number of overlaps O_o (i.e. the number of cells for which we had a couple of 1: congruence of hotspots) was counted.

The fish richness pattern exhibits a decreasing gradient from west to east, the Alboran Sea being a hotspot of richness. The endemic species gradient is more pronounced latitudinally, i.e. from north to south: the northern side exhibits a greater richness and the Adriatic appears as a hotspot of endemism with a maximum of 45 species per cell. We observe that fish richness and fish endemic richness hotspots are not congruent at all (0 observed overlap) and significantly less than expected by chance (26.1 cells with overlap). Fish richness and fish endemic richness hotspots are significantly more congruent than expected by chance with the MPA network. Fish richness hotspots are significantly less congruent with human pressure hotspots. Finally the MPA network is spatially independent from the hotspots of human pressure. Nevertheless MPAs are not the only tool to sustain fish biodiversity and conservation in the Mediterranean may also deal with fishery management and habitat protection.

THE MID DOMAIN EFFECT IN THE MEDITERRANEAN SEA: DO GEOMETRIC CONSTRAINTS SHAPE FISH DIVERSITY PATTERNS?

David Mouillot ¹* and Frida Ben Rais Lasram ¹ ¹ Université Montpellier 2 UMR 5119 - david.mouillot@univ-montp2.fr

Abstract

We challenged the hypothesis that fish richness gradients are simply artefacts of the bounded nature of the Mediterranean Sea (Mid Domain Effect theory). To this aim, we built a new database on the distribution of the 619 Mediterranean fishes and we implemented one dimensional as well as two dimensional MDE null models to predict fish diversity patterns. Our results revealed that a strong MDE is displayed in 1D and that in 2D, the MDE accounted for a non negligible proportion of species richness variation but is not sufficient to explain the diversity pattern in the Mediterranean Sea. *Keywords: Biodiversity, Fishes*

Introduction

The foundations underlying fish diversity patterns in the Mediterranean Sea have been overlooked despite the conservation importance of this biodiversity hotspot. One of the most intriguing theories that have been proposed to explain the spatial distribution of species richness is the Mid Domain Effect (MDE). This theory posits that geometric constraints on species range distributions may create patterns in richness without any environmental gradient. The Mediterranean is an "archetypal situation" where we would expect a MDE, so we tested the predictions of the MDE for fish richness spatial patterns in one (longitude and latitude) and two dimensions.

Material and Methods

We created a database on the geographical distribution areas of all known fish species in the Mediterranean Sea using a Geographical Information System software (ArcView3.3). Data on exotic species were compiled by updating the list of the CIESM Atlas [1] and the list of Quignard and Tomasini [2]. For all other species, data were compiled from the primary literature and particularly from the FNAM atlas [3]. The database was used to map the geographical distribution of fish diversity by overlaying range maps of the 619 species to a 0.1° bin grid for one-dimensional analysis and to a 0.1° cell grid for twodimensional analysis. Species were also classified according to their range extent into small, intermediate and large ranges [4]. Empirical patterns of species richness in one dimension (longitudinal then latitudinal gradient) were compared to the predictions using two null models: the Colwell's model [5] and the Willig & Lyon's model [6]. We also explored the Mediterranean fish species distribution patterns using the null model of Willig & Lyon extended by Bokma et al. [7] in two dimensions. The relative predictive power of the MDE was assessed by a coefficient of determination (R²) of the regression between the empirical values of species richness and the predicted values of the models.

Results and Discussion

Longitudinally, fish richness patterns are highly asymmetric for the entire species pool and for the "without exotics" pool, and thus differ markedly from mid-domain predictions. At the opposite, the longitudinal gradient of endemic fish richness appears much closer to MDE predictions ($R^{\tilde{2}}$ =0.69, p < 0.001): endemic species richness (especially large ranged species) exhibits a pronounced mid longitude peak consistent with predictions of a simple 1D MDE model between 13.45° and 15.55° of longitude, which corresponds to the middle of the Mediterranean longitude. Latitudinally, agreement between observed and predicted fish richness gradients was weak for the endemic pool while the agreement was very strong for both the entire species and the "without exotics" pools. When all species were considered together, the explanatory power of MDE on latitudinal fish species richness is strongly significant ($\hat{R^2}$ =0.63, p < 0.001). The highest species richness occurs at about 37.85° to 38.15° of latitude, which corresponds to the middle of the Mediterranean latitude. In two dimensions, R^2 were low except for the large range species. Indeed, the MDE explained 38% (p= 0.001) of variation in fish richness for both the entire and "without exotics" pools and 26% (p < 0.001) of variations in fish richness for the endemic pool when considering large range species. For large range species, the highest richness values were found around Sicily, northern Tunisia and Sardinia which is consistent with predictions of the 2D MDE model. Conclusion The Mediterranean Sea can be defined as an archetypical domain where we expect a MDE because this biome is a big domain, is an enclosed area with well defined boundaries, has a high rate of endemic species and has a non negligible proportion of large range species. While a strong MDE is displayed in 1D (both latitudinally and longitudinally), our data on fish species are less consistent with the 2D patterns predicted by

the null model: in2D, the MDE accounted for a non negligible proportion of species richness variation but is not sufficient to explain the diversity pattern in the Mediterranean Sea, which corroborates other bi-dimensional studies testing the MDE [8]: other processes such as biological and environmental factors should be considered. However our results suggest that geometric constraints on the locations of large range coastal fish species imply a marked mid-domain peak in species richness, even in the absence of any environmental gradient.

SEISMIC EXPLORATION INSIDE THE INTERNATIONAL SANCTUARY FOR THE PROTECTION OF MARINE MAMMALS: RESULTS OF THE MARINE MAMMAL OBSERVERS MONITORING

Aurelie Moulins ¹*, Massimiliano Rosso ¹ and Mehdi Aïssi ² ¹ CIMA Foundation - aurelie.moulins@cimafoundation.org ² Dipartimento di Biologia, Università degli Studi di Genova

Abstract

Since 2002, the Pelagos Sanctuary have entered into force, delimiting a large marine area (100,000 km²) where cetaceans populations are protected. Being in its first stage, Pelagos aims to estimate the human impacts on long-term cetacean conservation. The study presents the results of the April 2008 seismic operations and proposes some recommendations. Keywords: Seismics, Cetacea, Ligurian Sea

Introduction

Marine anthropogenic noise increases decade by decade with the current uses of sonars and seismic devices. However, effects on the marine ecosystems are not mostly unknown. On cetaceans, the assumed effects are manly distinguished into three categories: (i) effects on the physiology of the animals; (ii) effects on the behaviour of the animal; (iii) indirect effects on prey [1]. All species of the Pelagos Sanctuary can be affected and specifically some had already been involved in mass strandings as Cuvier's beaked whales (Ziphius cavirostris), long-finned pilot whales (Globicephala melas) or sperm whales (Physeter catodon).

Material and methods

The seismic campaign was realized in April 2008 (20-27). The aim was to characterize the seismic activity in the Ligurian basin using ocean-bottom seismometers (OBS) as recorders of air gun shots realized in the study area. The 21 OBS deployed were then left for six months in the area to monitor the seismic activity. Five Marine Mammal Observers (MMO) participated to the campaign in order to detect visually cetaceans. Visual detection was realized using naked-eyes and binoculars. The 360° around the boat were dived into 4 sectors of 90°, each sector was watched by one MMO. The 5th MMO was in charged of the data recording and of communications with the cruise staff for eventual interruptions of the air gun shots. All MMO were positioned at 10 meters above the sea surface and their positions were shifted each 30 min to avoid tiredness. Observation period initiated at 8:30AM and finished at 6:30PM with a 1-hour lunch break for each of the MMO organized into two shifts. Observation was interrupted with bad weather conditions (wind stronger than 15 knots or low visibility). The procedure applied for the campaign was: (1) to start visual detection 30 minutes before any emission of sound; (2) to realize a RAM-UP period of 20 minutes with half of the air guns; (3) then to proceed with all air guns. In the case of cetacean detection inside the 3200 meters around the vessel, sound emissions were automatically interrupted. Once the animal(s) got out of the 3200 meter area, the RAM-UP procedure re-start for 20 minutes then the air guns shots were set as normal capacity.

Results and Discussion

The before exposure period was monitored only during the morning before (4 hours and a half) then the weather got bad (with wind stronger than 15 knots). Three sightings occurred on the continental slope (where water depth is between 1000 and 2000 m): 3 groups of striped dolphins. The last group was the larger group with about 40 dolphins. No other species has been observed during the morning. On April, the 21st, after 30 minutes of no cetacean detection, the RAM-UP period started at 9:17AM, then "full" air gun shots started at 9:37AM and emission went on until the 27th in the early morning. During the 6 days of sound emission, the vessel covered 1308 km: 563 km during the night (43 %). Considering the working period of the 5 MMO (limited to 8:30AM-6:30PM), 56 % of the sound emission period were not monitored including the 175 km realized during the early morning or during the late evening. On the total period of sound emission, 27 % were realized with bad weather conditions (that did not allow cetacean detection); however, a part of those occurred during the night period. On 7 occasions, cetacean were detected. In all cases, they were striped dolphins. Only in two cases, dolphins were inside the 2000 meter area, therefore sound emission have been interrupted until the animals got away. Both times, no direct modification of the behaviour have been registered before and after the interruption (looking at group head or breaching behaviour). Nevertheless, the direct influence of sounds is hard to determine. The afterexposure period was monitored for 7.5 hours on the track to the home port. Eight sightings occurred inside the study area (where air gun shots have been performed before). The sighted species were: fin whales (3 times), sperm whale (1) and striped dolphins (4). No unusual behaviour have been sighted.

Data from the French stranding network registered before, during and after the seismic exploration did not indicate particular increase of strandings (personal communication from F. Dhermain).

In conclusion, the seismic campaign was realized during April, month of spring period in which the Ligurian sea gets usually rich in biodiversity. Considering the high presence of cetaceans in the Pelagos area especially at this moment of the year, MMO were necessary. Results of this campaign could be use for further recommendations: (1) to ensure success of visual detection (and avoid of tiredness) during the 14 hours of daytime period, it is necessary to organize shifts with sufficient number of MMO; (2) pre-exposure and post-exposure periods (being fundamental to determine the effects of sound emissions) should be extend to more than one day (to maximize the potential of monitoring); (3) the RAM-UP period seems to allow cetaceans to get out of the risky area without having physiological damages; (4) the choice of emission survey period should depend on the seasonal use of cetaceans, especially in the Pelagos Sanctuary; (5) the survey organization should take into account of the use of the study area by the species; for instance covering areas with higher risk during the davtime.

Fig. 1. Sound emission track during the MMO monitoring (light grey), during the daytime without MMO (dark grey) and during the night (black); dots: positions of striped dolphin sightings; depths: 500m, 1000m, 1500m, 2000m and 2500m.

Acnowledgements : We thanks Geoazur for the logistic support and all the GROSMARIN team on board.

EGG PRODUCTION, FEEDING AND METABOLISM OF CLAUSOCALANUS FURCATUS IN A MEDITERRANEAN COASTAL AREA (SARONIKOS GULF, AEGEAN SEA, GREECE)

A. Moutsopoulos^{1*}, E. Christou¹, S. Zervoudaki¹, C. Frangoulis¹, A. Pavlidou¹, I. Siokou¹ and T. Zoulias¹ ¹ Hellenic Centre for Marine Research - thanmoutsop@ath.hcmr.gr

Abstract

Egg production, feeding and metabolism experiments of the calanoid copepod Clausocalanus furcatus were studied from July until October 2009 in an eastern Mediterranean coastal area. Egg production rate ranged from 8,28 to 20,65 eggs/fem/day. Ingestion rate ranged from 0,0013 to 0,0208 µg chl-a/fem/day. The range of respiration rate was 0,0614 - 0,0958 µl O2/ind/hour, while those of phosphate-P and ammonium-N excretion rates were 0,0001 - 0,0002 µg P/ind/hour and 0,0010 - 0,0034 µg N/ind/hour respectively. Egg production was not related with $chl-\alpha$ whereas ingestion was in agreement with egg production. In general ingestion followed chl- α variability.

Keywords: Aegean Sea, Copepoda, Eastern Mediterranean, Zooplankton

Introduction

Clausocalanus furcatus is a widespread species inhabiting epipelagic waters in subtropical and tropical areas [4]. In Mediterranean it attains high numbers during warm season [8]. Most studies concerning this copepod deal with spatial and temporal distribution whereas little is known about its biology ([1], [2], [3], [5], [6], [7], [9], [10]). The present study provides data on feeding activity, egg production and metabolism of this copepod in a coastal area of the eastern Mediterranean during summer and autumn 2009.

Materials & Methods

Adult females were incubated in seawater collected from the sampling area. A total of 20 experiments (9 for egg production, 7 for feeding and 4 for metabolism) were performed biweekly from July 2009 until October 2009. Experimental bottles were incubated in a temperature-control room at in situ temperature with photoperiod (egg production, feeding) or in the dark (metabolism) for 24 hours.

Results & Discussion

Temperature ranged from 26,5 °C to 22,7 °C showing a constant decline during the study period. Chl-a (from the initial bottles of the feeding experiments) ranged from 0,071 to 0,336 µg chl-a/lt. Egg production rate (EPR) ranged from 8,28 to 20,65 eggs/fem/day and Ingestion rate (IR) ranged from 0,0013 to 0,0208 µg chl-a/ind/day (Fig. 1). Ranges of metabolic rates were 0,0614-0,0958 µl O2/ind/hour for respiration, 0,0001 - 0,0002 µg P/ind/hour for phosphate-P excretion and 0,0010 - 0,0034 µg N/ind/hour for ammonia-N excretion (Fig 2). Egg production was not related with $chl-\alpha$ whereas it was in agreement with ingestion. Ingestion appears to follow the pattern of chl-a. Concerning metabolism, the maximum of respiration and the minimum of excretion (for both phosphate and ammonium) are all recorded at the end of the study period.

Fig. 1. Egg production rate, initial $chl-\alpha$ and ingestion rate

Fig. 2. Respiration rate, Phosphate-P and Ammonium-N excretion rate

RELATIONSHIPS BETWEEN OCTOPUS VULGARIS LANDINGS AND ENVIRONMENTAL FACTORS IN THE NORTHERN ALBORAN SEA: AN ATTEMPT TO DEVELOP A PREDICTIVE MODEL

F. Moya ^{1*}, M. Vargas-Yáñez ¹, M. González ¹, M. García-Martínez ¹, P. Zunino ¹ and J. Rey ¹

¹ Instituto Español de Oceanografía. Centro Oceanográfico de Málaga - francina.moya@ma.ieo.es

Abstract

The stock abundance of short life-cycle species is very sensitive to the strength of annual recruitment, and the latter is influenced by environmental factors [1]. One of the aims of the present work is to accurately delimit the spawning period of *O. vulgaris* in the northern Alboran Sea, using maturity data, and the fishing season (from landing data). Finally we develop a predictive model which relates landings during the fishing season to environmental variables some months on advance. We show that environmental monitoring programs provide information that is extremely valuable to understand the factors that affect the abundance variability of this species, as well as for predicting and managing this resource.

Keywords: Alboran Sea, Cephalopods, Models, Monitoring, Time Series

Introduction

Numerous environmental variables influence recruitment strength and stock abundances of fish species [1], [2]. This fact is more important in short lifecycle species because the stock abundance is very sensitive to the strength of annual recruitment. *O.vulgaris* is especially susceptible because annual recruitment is responsible for the entire stock biomass. In this work we have obtained environmental variables-abundance relationships in order to develop a predictive model for the northern Alboran Sea (fig. 1).

Maturity data have been used to delimit the spawning season, helping to choose the months when environmental variables should be used as predictors of the fishing season landings. Finally, the environmental factors-landings relationships found are used for developing a predictive model.

Fig. 1. Alboran Sea

Material and Methods

Monthly octopus landings from 1987 to 2008 in the northern Alboran Sea were used. Monthly environmental data were collected for the same period from ICOADS, NOAA, the Mediterranen Group on Climate Change from Instituto Español de Oceanografía (www.ma.ieo.es/gcc), from the project RADMED ("Series Temporales de datos Oceanográficos") funded by IEO, and also from the NCEP. Octopus landings and environmental variables time series were de-trended. Resultant time series were tested for normality and Pearson correlation coefficients between landing anomalies and environmental variables were calculated. Selected variables were used in a stepwise linear regression in order to select a set of candidate models. Akaike Information Criterion AICc and Cross Validation tests were used to select the best model.

Results and Discussion

The best predictive model was a linear combination of the mean Alboran Sea SST and the local temperature in Fuengirola beach. Our results show that an increase of octopus landings is related with negative temperature anomalies. Using the model, we have predicted octopus landings one year ahead (fig. 2) using natural years for defining the predictors and the landings. In the future, octopus maturity data will allow us to define accurately the spawning season and then select the months in which environmental factors will be considered. In this way, we would construct a model that would be more adjusted to the reality. This work has demonstrated that environmental an extremely valuable tool for the management of this resource.

PRELIMINARY DATA ON THE TROPHIC INTERACTIONS BETWEEN SCYLIORHINUS CANICULA (SCYLIORHINIDAE) AND RAJA CLAVATA (RAJIDAE) IN THE CENTRAL-WESTERN MEDITERRANEAN

Antonello Mulas¹, Andrea Bellodi¹, Antonio angelo Pendugiu¹ and Serenella Cabiddu¹*

¹ Department of Animal Biology and Ecology, University of Cagliari, Italy - cabiddus@unica.it

Abstract

Preliminary data on the diet and trophic competition between *Scyliorhinus canicula* and *Raja clavata*, caught in the seas surrounding Sardinia (central-western Mediterranean), during trawl surveys carried out from 2005 to 2008 are given. The low values of Levin and Shannon-Weaver indexes showed that these two species are specialized predators. The ontogenetic analysis of the diet showed different predatory patterns.

Keywords: Diet, Western Mediterranean, Biodiversity, Competition

Introduction

The Scyliorhinidae Scyliorhinus canicula L., 1758 and the Rajidae Raja clavata L., 1758 are certainly included among the most common selachian species caught by trawl in the italian seas [1]. Despite this relative abundance, not much is known about the trophic interactions between these two species occupying the same depth ranges. The aim of this work is to add further data on this item through the analysis of the levels of trophic competition between the two selachians.

Materials and Methods

A total of 541 specimens (299 of *R. cavata* and 242 of *S. canicula* respectively) were caught at depths between 40 and 660 m, during trawl surveys carried out from 2005 to 2008 in the seas surrounding Sardinia (central-western Mediterranean). In order to examine the diet of each species, %Cn, %F, %W and %I.R.I. were calculated. The diet breadth was studied through the indexes of Levin (Bi) [2] and Shannon–Weaver (H') [3]; Morisita's simplified index (C) [2] and multidimensional scaling (MDS) [4] were also used in order to determine the intra and interspecific competition. The prey categories responsible for the groupings derived from the MDS were identified by SIMPER test [5]. The ontogenetic variation of the diet was also performed on three size classes (small, medium and large).

Results and Discussion

Despite the high variety of preys, the low values of Bi and H' (Bi = 0.46 and H' = 2.27 for S. canicula, and Bi = 0.44 and H' = 2.20, for R. clavata), showed a stenophagous alimentary behaviour. In S. canicula 44 prey categories, assembled in 7 main groups (Crustacea, Osteichthyes, Cephalopoda, Polychaeta, Cnidaria, Tunicata, Echinodermata) were found. Crustacea (%Cn = 67, %I.R.I. = 77.9), and particularly Decapoda (%Cn = 34, % I.R.I. = 70), Mysidacea (%Cn = 26, %I.R.I. = 13) and Euphausiacea (%Cn = 28, %I.R.I. = 14) dominated the diet, while Osteichthyes and Cephalopoda were the most important secondary preys. A total of 95 prey categories were identified in the stomachs of R. clavata, grouped into 10 main groups (Crustacea, Osteichthyes, Chondrichthyes, Cephalopoda, Gastropoda, Foraminifera, Polychaeta, Cnidaria, Tunicata, Echinodermata). Crustacea (% Cn = 77, %I.R.I. = 69), and particularly Decapoda (%Cn = 28, %I.R.I. = 73) and Mysidacea (%Cn = 32, %I.R.I. = 16), represented the most predated items. Osteichthyes were secondary preys. In both species the diet is influenced by size. Diet of juvenile R. clavata was centred on small Crustacea (mainly Mysidacea, Decapoda and Amphipoda), substituted by Osteichthyes (principally Glossanodon leioglossus) and larger Decapoda (Solenocera membranacea) in the medium and large size classes. In S. canicula, the stenophagy decreased during the ontogenetic development. Smaller individuals feed mainly on Euphausiacea, while Decapoda increased in importance during the growth. Morisita's index showed relatively high levels of intraspecific competition in all the S. canicula size groups (C= 0.78, 0.61 and 0.86 among SC1-SC2 SC1-SC3 and SC2-SC3 respectively) and only among medium and large specimens in R. clavata (C= 0.89); interspecific competition was relevant only among juveniles R. clavata and the first two S. canicula groups (C values near 0.70), due to the consumption of Crustacea, and among medium R. clavata and large S. canicula (C = 0.75), due to Crustacea and Osteichthyes. These results were confirmed by the MDS analysis, with the only exception of small S. canicula which formed an isolated group, due to the high presence of Euphausiacea in their diet (SIMPER test). Despite of the same depth range occupied, the two species showed different alimentary patterns. Considering their K type life strategies, these particular predatory behavior should probably be adopted in order to minimize trophic competition, facilitating the species' survival. Further studies will be useful to clarify these statements.

INVESTIGATION ON THE FEEDING HABITS OF EUROPEAN HAKE *MERLUCCIUS MERLUCCIUS* (LINNAEUS, 1758) IN THE NORTH MARMARA SEA

Elif Murat Dalkara 1* and Ahsen Yuksek 1

¹ Istanbul University, Institute of Marine Sciences and Management - elfmurat@yahoo.com

Abstract

This study was performed between April 2008 and August 2009 to determine the feeding habits of European hake (*Merluccius merluccius*). The specimens were collected from the range of 20-90 meters depth by trawl net from the North Marmara Sea. During the research period, a total of 343 specimens were examined and the main diet of European Hake, based on prey index of relative importance, comprised Teleostei (91,2%), Crustacea (5,1%) and Echinoidea (3,6%).

Keywords: Fishes, Diet, Marmara Sea, Fish Behaviour

Introduction

European hake (*Merluccius merluccius*) is an important predator of Marmara communities. Hake's ecological and economic importance are related to many aspects of its biology [1]. Dietary studies are crucial for their contribution to a better understanding of the trophic levels and food webs [2]. The purpose of this study was to examine to feeding habits of European hake caught in north of the Marmara Sea with based on the seasonal analysis of its stomach contents.

Materials and Methods

Specimens were collected from April 2008 to August 2009 from the range of 20-90m depth in all seasons from the Sea of Marmara by using a bottom trawl (Fig. 1). A total of 343 hakes were dissected on board immediately after capture. Stomachs preserved in 4% formalin for further analysis. Prey items were identified and sorted into taxonomic groups at the level of species in the laboratory. Remains of the preys that contained otoliths of various fishes were identified by the help of published guides. Each prey was weighted to the nearest 0,01g. After analysis, percentage frequency of occurrence (F%), percentage by numbers (N%), percentage by weight (W%), the index of relative importance (IRI) and percent of IRI (IRI%) were calculated [3, 4].

Fig. 1. Location of sampling areas in the Marmara Sea

Results and Discussion

During the research period, a total 343 *M. merluccius* were examined. 134 stomachs of specimens were determined to be empty and 209 stomachs of them were determined to be full. As families or species 20 different prey groups were identified from the stomach contents, Teleostei represented 91,2% the index of relative importance (IRI%), Crustacea 5,2% and Echinoidea 3,6%. During all seasons except summer, the main food group (diet) of hake, based on weight was Teleostei, (Table 1). Crustacea, especially shrimps, were the most represented prey group in summer with 55,8% of IRI. The most important Teleostei species was *Trachurus mediterraneus* in the diet. Echinoidea seemed to be an important prey group in the diet of juveniles, this situation can be related to the way of foraging of juveniles.

FEEDING HABITS OF CEPOLA MACROPHTHALMA (PISCES: CEPOLIDAE) IN IZMIR BAY, AEGEAN SEA

Tuncay Murat sever ¹, Bahar Bayhan ^{1*} and Semih Leblebici ¹

¹ Ege University, Faculty of Fisheries, Department of Hydrobiology, 35100 Bornova-Izmir, Turkey - bahar.bayhan@ege.edu.tr

Abstract

Stomach contents of 180 *Cepola macrophthalma* (Linnaeus, 1758) specimens collected from Izmir Bay, Aegean Sea (Turkey) have been analyzed. A total of 17 different species of prey was found belonging to nine major systematic groups, i.e. Polychaeta, Crustacea, Mollusca, Chaetognatha, Thaliacea, Appendicularia, Medusae, Siphonophora and Teleostei. Crustaceans (especially copepoda and decapoda) were the most important prey in terms of IRI% in overall diet composition. However, fish larger than 19.9 cm feeding on teleost larvae.

Keywords: Diet, Fishes, Aegean Sea

Introduction

The red bandfish is a demersal species inhabiting soft and muddy bottoms at depths ranging mainly from 15 to 200 m. It occurs in both temperate and subtropical waters and is known to be distributed in the eastern Atlantic from the British Isles to the north of Senegal [1, 2]. It is also common throughout the Mediterranean, as well as in Turkish seas, but not in the Black Sea [1, 3]. The red bandfish has economical importance in Spain and Italy [2, 4], but has no commercial value in Turkey [5]. Biological aspects of the red bandfish have been studied by several authors [2, 4, 6, 7, 8], especially in its westwards distribution in the Mediterranean. However, published data on its diet composition in Turkish seas is not currently available, except the data on its age and growth parameters [5].

The purpose of the present study is to improve knowledge on the feeding habits of red bandfish on the Izmir Bay (Aegean Sea coast of Turkey).

Material and Methods

Specimens were collected by trawl in the Izmir Bay, Turkish Aegean Sea from May 2005 to June 2006. A total of 180 *C. macrophthalma* stomach contents was examined for 45 number every season. Quantitative description of the diet was given as [9]. Besides, IRI% was estimated in order to determine ratios of food groups in the stomach to overall food groups.

Results and Discussion

The overall diet composition revealed that the chub mackerel fed mainly on copepods during all seasons (Table 1). Only in summer decapods were the second main important prey. However, fish larger than 19.9 cm feeding on teleost larvae (Fig. 1). An examination of the previous literature has shown that, *C. macrophthalma* is an planktivorous fish species with diet varying according to specimen size, locality, season etc. [6, 7].

THE SPATIAL ZOOPLANKTON DISTRIBUTION IN THE NORTH – WESTERN BLACK SEA REGION: SPRING AND AUTUMN, 2008

Mihaela Muresan¹* and Teodora Maria Onciu²

¹ National Institute of Marine Geology and Geoecology - GeoEcoMar, Constanta Branch - mmuresan@geoecomar.ro

² Ovidius University Constanta

Abstract

The seasonal distribution of zooplankton community in the NW part of Black Sea have been assessed regarding on the variability of numerical abundance and biomasses as well as the vertical patterns of distribution in the water column. The results are based on 66 quantitative samples collected within SESAME international projects carried out in 2008. 28 taxa belonging to 13 systematic groups have been found. The greatest number of species had Crustacea Class while *Noctiluca scintillans* was remarked for its density. *Keywords: Zooplankton , Vertical Profile, Black Sea*

Introduction

Climate change affects in many ways the response of marine ecosystem biota. Temperate marine environments may be particularly vulnerable to these changes because the recruitment success of higher trophic levels is highly dependent on synchronization with pulsed planktonic production [1]. SESAME aims was to assess and predict changes in the Mediterranean and Black Sea ecosystems as well as changes in the ability of these ecosystems to provide goods and services.

Materials and methods

During April and September 2008, have been collected 66 quantitative samples of zooplankton in 9 stations in the NW part of Black Sea (between 44^046 ' N and 42^029 ' N latitude and $28^{\circ}64'E$ and $30^{\circ}59'E$ longitude). The sampling was performed using a Hensen zooplankton net with mouth area 0.384 m², and mesh size 125µm. The vertical profile included 6 or fewer intervals of depths (0-10, 10-25, 25-50, 50-100, 100-150, 150-200 m) between isobaths of 15 m inshore to 2000 m outshore. Sampling volume was estimated by multiplying the mouth area with the wire length.

Results and Discussion

There where identified 24 taxa: 1 Dinophyceae, 2 Rotifera, 3 Ctenophora, 4 Branchiopoda (Cladocera), 8 Crustacea (Cirripedia –1, Calanida – 6, Cyclopida – 1), Chaetognata – 1, Tunicata – 1 and meroplanktonic larvae (Polychaeta, Gastropoda, Bivalvia, Decapoda). Their populations have registered an average density of 703.15 ind.m⁻³ and an average biomass of 52.34 mg.m⁻³ The numerical structure of zooplankton communities was composed by 63% Crustacea (34% Calanida, 27% Cladocera), 18% Dinophyceae, 12% Rotifera, 2% Tunicata.

Fig. 1. Average density of zooplanktonic populations' distribution in the water column in the area investigated

The analysis of taxonomic groups evidenced the numerical dominance of copepods and cladocerans. Of these, 8 species were most abundant, comprising almost 86% of the total average density. These are *Noctiluca scintillans*, *Penilia avirostris*, *Pleopis polyphaemoides*, *Acartia clausi*, *Pseudocalanus elongatus*, *Paracalanus parvus*, *Calanus helgolandicus* and

Synchaeta littoralis. In both seasons was evincesed a greater diversity in September (22 taxa) than in April (14 taxa). Opposite, the numerical abundances were greater in spring (752.96 indv.m⁻³) than in autumn (667,6 indv.m⁻³), due to Danube debits which positively influenced the abundance of planktonic populations through nutrients aport for phytoplankton and rotifers proliferation. Distribution in the water column down to 200m deep in both seasons evidenced that the diversity and also numerical abundance (2,350 ind.m⁻³) were highest in the surface layer (50-0m) in April (Fig. 1). *N.scintillans, S.littoralis, P.avirostris, P.polyphaemoides* and *A.clausi* were the main species that formed the littoral nucleus. These species has a great adaptation potential and quickly response related to climate factor variability, their proliferation being enhanced by the blooming events and warming tendency. In September the highest densities recorded (1,867 ind.m⁻³) were distributed in the first 25m depths.

In the ecological conditions of April 2008, vertically distribution of zooplankton had maximum biomasses in 100-50 m layer while that in September at 50-0 m depth. This suggests that in September was still a suitable temperature for populations of zooplankton, which mainly develop in summer season. *N. scintillans, C.helgolandicus, Pleurobrachia rhodopis*, were the dominant species after biomass (Fig.2).

Abstract

This paper presents a comparison between reproduction cycle of sardine *Sardina pilchardus* and gilt sardine *Sardinella aurita* in the Adriatic Sea. Based on the greatest values of gonadosomatic index, sardine spawned from October to May, while gilt sardine reproduction started in June and lasted until September. The average cubic condition coefficient for sardine was $K=0.7702 \pm 0.05$ and for gilt sardine $K=0.7382 \pm 0.05$.

Keywords: Adriatic Sea, Reproduction, Fishes

Introduction

The aim of this study was to identify the differences between *Sardina pilchardus* and gilt sardine *Sardinella aurita* length, gonad and body weight, gonadosomatic index and condition factor in the Middle eastern Adriatic Sea. In the Adriatic Sea, sardine is one of the most abundant species, while gilt sardine is invasive and under-represented [1, 2].

Both fish specimens take the same ecological niche and are caught together by purse seines. They spawn at a completely different time of year and their condition values differ through the whole analyzed period.

Material and methods

All of the fishes were obtained from the catches of inshore (Virsko more) and offshore waters (Dugi Otok) in the Middle eastern Adriatic Sea, from March 2004 to January 2009. A total of 1,219 sardine and 2,033 gilt sardine specimens were measured to the nearest mm and weighed to the nearest g. The monthly gonadosomatic index (*GSI*) was calculated by the monthly gonad weight (*Wg*) as a proportion of the total body weight (*W*): *GSI* = 100 *Wg* / *W*. The cubic condition factor (*K*) was calculated using Fluton's coefficient $K = 100W L^{-3}$. To avoid the bias caused by fish size (*L*) in the condition analysis, only sardines between 14.0 and 18.0 cm, and gilt sardines from 18.0 to 28.0 cm *LT* were used to compare condition changes.

Results

Sardine and gilt sardine total lengths and body weights ranged from 13.0 to 19.0 cm (mean=16.0 \pm 0.9 cm) and from 16.7 and 51.5 g (mean=31.5 \pm 5.3 g), then from 10.0 to 32.5 cm (mean=22.0 \pm 3.7cm) and from 6.43 to 298.32 g (mean=85.77 \pm 37.5 g), respectively. Sardine *GSI* showed greatest value in July (3.38%) and lowest in February (0.37%). Gilt sardine *GSI* ranged from 0.41%-July to 4.32%-December (Fig. 1).

Fig. 1. GSI of sardine (*) and gilt sardine (•), Middle eastern Adriatic Sea, 2004-2009

The average cubic condition coefficient (*K*) of sardine varied from 0,6939 (January) to 0.8282 (September) (mean K=0.770 ± 0.05), and of gilt sardine from 0.6515 (February) to 0.8025 (January) (mean K=0.738 ± 0.05) (Table 1).

SD	0.045	0.045

Discussion

According to this study there were differences between sardine and gilt sardine spawning season and its duration. Sardine spawns during the winter months (from October to May), whereas gilt sardine spawns in summer (from June to September) [3]. Gilt sardine spawning period lasts longer in warmer waters compared to the ones with a lower average temperature [1, 4, 5].

In general, sardine showed greater values of cubic condition factor during summer months than during the winter (spawning) period. Condition of gilt sardine was also better after spawning (October-November); its greatest value was noticed in January (K=0.803).

³ Système d'Information pour la Promotion de l'Aquaculture en Méditerranée

Abstract

Le golfe de Gabès est un pôle important de la pêche maritime tunisienne puisqu'il représente environ 40 % en poids et 50 % en valeur de la totalité des apports. Une exploitation de la crevette (*Penaeus kerathurus*) s'est développée, notamment, depuis les années 1980 entraînant des changements quantitatifs et qualitatifs profonds du profil des pêches. En vue d'analyser ces changements, des données sur les captures de cette région ont été recueillies depuis le début du développement de l'exploitation de la crevette (1980) jusqu'aux années 2000.

Keywords: Fisheries, Gulf Of Gabes

Les données utilisées dans cette étude proviennent :

- des statistiques de pêche collectées auprès des services de la Direction Générale de la Pêche et de l'Aquaculture (DGPA) [1].

- des campagnes de chalutages expérimentaux réalisées par l'Institut National des Sciences et Technologies de la Mer (INSTM) [2], [3], [4], et [5].

Les résultats obtenus dans la région de Gabès montrent que, durant la période étudiée, les profils des débarquements de cette région ont subi de réelles modifications quantitatives et qualitatives dont les plus importantes sont :

- un appauvrissement de la diversité biologique des débarquements de la pêche benthique (fig.1) alors que cet appauvrissement est moins ressenti pour les pêcheries pélagiques (fig.2). La régression de la biodiversité est traduite par la baisse du nombre d'espèces pêchées. Ainsi, certaines espèces comme le mérou, le merlu, les rascasses et certains sparidés ne figurent plus dans les prises ou sont en nombre insignifiant.

- une abondance beaucoup plus importante des espèces à faible longévité comme les crevettes et les céphalopodes au dépend des espèces à grande longévité (poissons benthiques, merlu, mérou, pageot,...).

 la régression de la part relative de la pêche côtière dans les débarquements du Golfe alors que celle du chalutage s'est substantiellement développée. Notons que ce dernier est beaucoup moins sélectif du point de vue inter-espèces et intraespèce.

- les tailles moyennes de nombreuses espèces benthiques ont sensiblement diminuées dans les captures et par conséquent la biomasse du stock des géniteurs pourrait être affectée.

Ces résultats constituent des indicateurs importants pour le diagnostic de l'évolution des pêcheries du golfe de Gabès; ils mettent en exergue la fragilité actuelle de l'écosystème de cette région. En outre, ils fournissent des éléments précieux pour améliorer la gestion des pêcheries de cette région et préserver leur durabilité.

TROPHIC RELATIONS OF WILD FISH ASSOCIATED TO AN OPEN-WATER FISH FARM IN THE SOUTHWESTERN MEDITERRANEAN

F. Navarrete-Mier^{1*}, C. Sanz-Lázaro¹, M. Belando¹, D. Celdrán¹, P. Sánchez Morillo-Velarde¹ and A. Marín¹ ¹ Departamento De Fisiología Animal, Facultad De Biología, Universidad De Murcia, 30100 Murcia, Spain kfrancisco.navarrete@um.es

Abstract

The aim of this work was to determinate the trophic relationships of wild fishes associated to an open sea fish farm. We take samples of cultured and wild fishes in an ecological gradient to analyze his contents of stable isotopes of carbon and nitrogen. This study showed how the influence of the uneated feed of net-cages change the normal trophic behaviour of associated wild fishes. *Keywords: Aquaculture, Food Webs, Fishes*

Introduction

The fish farms in open sea attract an unusual ichthyc biomass [1]. The reason of this attraction is not clearly identified, nevertheless is possible that the high protein food lost through the cages could have an elevated attractable effect on the wild fishes. The presence of a high number of fish-farms in the Mediterranean Sea, make indispensable more studies related to this system and the trophic structures in wild fish associates [2].

In studies of marine ecology, stable isotopes analyses have emerged as reliable tools for elucidating trophic structure and inferring pathways of energy flow in food webs. $\delta^{13}C$ allows differentiates the carbon source, while $\delta^{15}N$ permit us assess the relative trophic position of an organism. Thus nitrogen and carbon stable isotopes can provide us the time-integrating fish's trophic interactions [3].

The objectives of this study were to determinate if the fish consume the products of the net-cages and to trace its influence related to the distance of the culture. It was measured by the content of stable isotopes in pelagic fish associated to the fish farm, which also allows us an approaching to explain at specific and community level how the net cages influences on the trophic relationships of wild fish.

Materials and methods

This study was carried out in the surroundings of a marine fish farm located in Águilas, SE Spain, (western Mediterranean; 37º 24' 56.2" N, 1º 32' 4.0" W), which produces gilthead sea bream (Sparus aurata) and European sea bass (Dicentrarchus labrax). We defined four stations for analyses: (I) Inside the cages, (O) Outside the cages (ca, 90 m around the net-cages), (F) Fraile Island (750 m to the west to the net-cages), and (C) Cape Cope (2500 m to the east from the net-cages) as control station. At each station, the diversity and abundance of the fish community were valuated by visual techniques. Also we take samples of white muscle of each species of fish and freeze-dried it for stable isotopes analyses. The carbon and nitrogen isotope ratios of the samples were measured with an elemental spectrometer of isotopic relationships Delta^{plus} (ThermoFinnigan). All the isotopic data were reported in the conventional δ notation. δ 13C values were reported as the deviation relative to the Vienna Pee Dee Belemnite Limestone Standart (v-PDB), while $\delta 15N$ standards were calibrated and results were reported relative to atmospheric nitrogen.

Results and discussion

The higher wild fish abundance was found closed to the fish farm, demonstrating the attraction effect of the open water aquaculture. The community structure of wild fish also changed depending of distance from fish farm. The isotopic analyses of δ^{13} C and δ^{15} N showed a tendency to major accumulation of carbon isotopic in fishes of stations away from the net cages. The spatial pattern of δ^{15} N did not exhibit clear differences between stations (Figure 1). The changes in the isotopic concentrations were accompanied by a notorious compression of the trophic niche of fish communities closer to the artificial feed source (Figure 2).

Fig. 1. Bi-plot of $\delta^{13}C$ and $\delta^{15}N$ accumulation (mean \pm SE n=4), for European sea bass (*Dicentrarchus labrax*) and fish feed

Fig. 2. Dispersion of fish community content of carbon and nitrogen stable isotopes in each station. These results are representative of 89 fish and 19 species

This adaptative behaviour of wild fishes to an artificial source of food would imply ecological consequences that should be deeply analyzed.

Abstract

In the present work we described the marine food web structure of the Ebro Delta marine area by applying; (1) an ecological model and (2) stable isotope analyses. Stable isotope analyses provide information of the predator-prey relationships and the foraging areas of each species in the food-web. The ecological model also delineated the food web structure of each species by estimating their trophic level. We showed some discrepancies and similarities between both approaches. In conclusion, both methodologies were insightful to describe the food-web traits of the Southern Catalan Sea and enabled us to complement our understanding of the area and to validate our results.

Keywords: Food Webs, Ebro Delta, Carbon, Models, Predation

Introduction

Due to the importance of predator–prey relationships and their dynamics on the evolution and structure of marine communities, ecologists have focused their research into different aspects of food webs to determine the influence of the community structure on it stability, complexity, connectivity and equilibrium. In the present communication, by using two complementary approaches, ecological modelling (with EWE: Ecopath with Ecosim) and stable isotope analyses (SIA: $\partial^{15}N$ and $\partial^{13}C$ values), we described the food web structure of the Southern Catalan Sea (NW Mediterranean). We compare results from both tools regarding abundant marine species in the area.

Material and methods

The study was conducted in the continental shelf of the Ebro Delta (ED) marine area (NW Mediterranean). To establish the predator-prey relationships among the different marine species we analyzed both $\partial^{15}N$ and $\partial^{13}C$ values from different marine species of the ED; 16 fish and 1 seabird species (the Audouin's gull) sampled in the ED during 2003. We used published SIA values of 3 predators species;the bottlenose dolphin [1], the loggerhead sea turtle [2] and the Balearic shearwater [3]. EwE was used to model this area and described the structure and functional traits of the food web [4], calculating the trophic level of each species.

Results and Discussion

By using SIA method we depicted the predator-prey relationships among the different species of the food web in the ED. As expected, $\partial^{15}N$ values indicated that bottlenose dolphin, Audouin's gull and the group composed by other seabirds were located at the top of the food web, while sardine, benthopelagic fish and the other demersal and pelagic fish and cephalopods were located at the base of the food-web or at intermediate positions (Fig. 1). Moreover, $\partial^{13}C$ values helped to determine the foraging areas of each species, in relation to their pelagic or benthic localisation; the low $\partial^{13}C$ values of Audouin's gull and anchovies indicated that these species fed on pelagic waters, whereas the high $\partial^{13}C$ values showed in the loggerhead sea turtle and the benthopelagic cephalopods indicated that these species fed on benthic waters (Fig. 1).

The EwE approach showed some discrepancies and similarities with the stable isotope approach. For several groups, the TL values estimated in the EwE were similar to the estimated by SIA method (i.e. the loggerhead sea turtle or the bottlenose dolphin). However, the EwE showed lower TLi for the seabirds suggesting that seabird species were located at the base of the food web. This is a artefact in the EwE due to consideration of the discards, the main food for the studied seabirds, with very low trophic level value (TL=1) because we did not did not considered demersal and pelagic fish in the discards. Thus, the real trophic position of seabirds in the area may be around TL=4.

In conclusion, both methodologies were insightful to describe the food-web traits of the ED and enabled us to complement our understanding of the area and to validate our results.

SPAWING INDUCTION, FERTILIZATION AND LARVAL DEVELOPMENT OF *HEDISTE DIVERSICOLOR* (NEREIDIDAE, POLYCHAETA) UNDER DIFFERENT EXPERIMENTAL CONDITIONS

N. Nesto ¹*, A. Libertini ¹, D. Prevedelli ², R. Simonini ² and C. Tola masala ³ ¹ Institute of Marine Science, National Research Council - nicoletta.nesto@ve.ismar.cnr.it ² Department of Animal Biology, University of Modena and Reggio Emilia ³ International Marine Centre, Torregrande, Oristano

Abstract

A suite of experiments with the polychaete *Hediste diversicolor* were performed to assess the induction of gamete spawning by endogenous substances, to evaluate the percentage of fertilised and hatching eggs in two different conditions ("natural" and *in vitro* fertilization), and to measure the density effects on larval growth and survival. The results showed that mature females were induced to spawn by adding mature male tissue homogenate in the medium. The percentages of fertilised and hatching eggs were higher in the *in vitro* fertilisation and larval/juvenile survival was affected by density.

Keywords: Polychaeta, Larvae, Reproduction

Introduction

The ragworm *Hediste diversicolor* is a polychaete belonging to the Nereididae family which is used and appreciated as commercial bait for fishing [1]. This gonochoric species has a holobenthonic life-cycle and can be easily reproduced in laboratory conditions [2]. A series of laboratory experiments were performed to standardize a number of biological parameters to be included in rearing technical procedures.

Materials and Methods

The influence of endogenous substances on gamete spawning was evaluated in sw aquaria at 16 psu and 16°C, where individual mature females and males were separately exposed to homogenates made up with whole mature organisms, male and female respectively, up to one week.

To evaluate the influence of different fertilisation conditions ("natural" and *in vitro*) on the percentage of fertilised and hatching eggs two types of experiments were performed. In the first one pools of mature female and male organisms were introduced in aquaria with glass tubes on the bottom reproducing the natural burrows within which the whole organism life-span occurs. In the second type of experiments, naturally spawned eggs were fertilisation occurred in a becker containing 0.5L of filtered (0.2 μ m) sw at 16 psu and 16°C. For both experiments, 6 replicates of 100 eggs were collected and the larval development was followed until nectochaete hatching.

To test the influence of density on the development and survival of nectochaetes the following experiment was performed. The sw aquaria (16 psu and 16°C) were provided with biological filters and 2 cm of fine sand sediments. Groups of ten-days nectochaetes were established in order to obtain two experimental densities: 5200 ind/m^2 (3 replicates) and 10400 ind/m² (2 replicates). Organisms were fed *ad libitum* using commercial fish feed (classic C22, Hendrix) three times a week for 8 weeks. Survival and growth rate were checked at the end of the experiment.

Results and Discussion

The results of the spawning experiments showed that the percentage of spawned animals, determined at the end of the experimental period, was significantly higher than in the controls only for females (57% vs 14%), indicating preliminarily that mature females were susceptible to spawning induction by a likely mixture of not determined endogenous compounds.

The results of the fertilisation experiments showed that the percentages of fertilised (64-91%) and hatching eggs (46-88%) obtained from the "natural" fertilisation experiment were always lower than the ones from the *in vitro* fertilisation, when the values ranged from 94-100% (fertilised eggs) and 94-99% (hatching eggs). This may be tentatively explained by a safer microbiological condition of the medium in the second experiment, as suggested by the observed minor number of swimming protozoa.

The growth rates of nectochaete maintained at two densities showed similar values, and juveniles reached a mean fresh weight of 30 mg in 8 weeks. On the contrary, density affected the mortality rates of nectochaetes and juveniles, survival resulting in the ranges of 57-81% and 53-57 % at low and high density, respectively.

MONITORING OF ZOOPLANKTON IN THE COASTAL AREA OF THE NE BLACK SEA IN 2005-2009.

Anastasia Nikishina ¹*, Elena Arashkevich ¹ and Nora Louppova ²

¹ Shirshov Institute of Oceanology, Russian Academy of Sciences - anastasia.nikishina@gmail.com

² Shirshov Institute of Oceanology RAS, Southern Branch

Abstract

The monitoring of the zooplankton community was conducted from June 2005 to October 2009 in the North-East Black Sea coastal area. Samples were taken along the cross-shelf transect at three stations. In the present work we studied the intensity of the cross-shelf exchange of the zooplankton in different seasons, seasonal changes in the zooplankton community and made a comparison of the present and past state of the zooplankton in this region.

Keywords: Zooplankton, Black Sea, Coastal Systems

Introduction

It is known, that shelf pelagic ecosystems are very productive, in different basins they provide up to 80% of the total production. In the Black Sea, where the most of the water column is contaminated by hydrogen sulfide, the productive abilities of the basin are limited. So the processes that take place on the shelf and continental slope play the key role for the whole basin. The Caucasian sector of the Black Sea has a narrow shelf with width of 3-5 miles and a steep slope. Due to the bottom topography, the hydrodynamic processes (generation of eddies, cross and along shelf water exchange) are very active in this region [4, 1]. That's why the distribution of the zooplankton is very heterogeneous and the species composition changes very quickly in the coastal area. Pelagic system of the Black Sea has changed dramatically during the last decades. The invasion of ctenophore Mnemiopsis leidyi in the middle of eighties caused significant decrease in zooplankton biomass and led to the changes in species composition of zooplankton. The invasion of ctenophore Beroe ovata feeding on Mnemiopsis led to the enhancement of zooplankton community in the end of nineties. The detailed monitoring of the coastal ecosystem has not been conducted since 1994. This work was aimed to reveal the cross shelf exchange of zooplankton in the different seasons; to study the seasonal changes in zooplankton community in the different regions of the coastal zone (inner shelf, middle shelf and continental slope); to make an assessment of the current state of zooplankton community.

Methods

Zooplankton sampling along with CTD probes were done monthly from June 2005 to October 2009. Zooplankton was collected with a Juday net (mouth area 0.1 m^2 , mesh $180 \,\mu\text{m}$) at three stations located over the inner shelf, middle shelf and continental slope along the transect off Geledzhik. Zooplankton were identified to species level and counted under the dissecting microscope.

Results

Zooplankton composition differed significantly over the shelf and the continental slope. Bathypelagic species were mostly found over the slope while the surface dwelling species were distributed evenly along the transect. Seasonal changes in species composition were more pronounced over the shelf than over the slope because of decline/disappearance of these species in winter. The seasonal dynamics of zooplankton biomass differed from year to year. On average, two biomass maxima were observed during a year and the autumn maximum was higher than the spring one (fig. 1).

Fig. 1. The seasonal dynamics of the zooplankton biomass in different years

High values of zooplankton biomass in 2005 and 2006 as compared with the average biomass for the last 50 years indicates the recovery of plankton

community after its collapse in the 90-s. There were some differences in species composition and seasonal dynamics of zooplankton between these periods. In 1991-1994, cladoceras shrank and chaetognaths virtually vanished from zooplankton. The share of these species in the total biomass was higher in 2005-2008 than in 1970's. Populations of Oikopleura and meroplankton have also decreased since 1970's, these populations haven't recovered yet. In 1970's maxima of plankton biomass were observed in April and August-September [3]. In 1991-1994's maximum of plankton biomass was observed in March, another small peak was observed in October [2]. In 2005-2009 plankton biomass was the highest in September-November (fig.2).

Fig. 2. The seasonal dynamics of the zooplankton biomass in different periods

Conclusions

In the study period, the cross-shelf exchange was very intensive, since the distribution of zooplankton was even in the upper mixed layer. The hydrophysical conditions played the important role in zooplankton distribution along the transect. The considerable interannual changes in seasonal dynamics of zooplankton community in 2005-2009 were evidence of the life cycle plasticity and seasonal shift in reproduction of dominant species. At present, zooplankton abundance and biodiversity have recovered after the collapse of 1991-1994, and reached the values observed in 1970-es before the alien ctenophore invasion.

Abstract

Posidonia oceanica (L.) Delile is the most widespread seagrass in the Mediterranean Sea. It plays an important role in ecosystems of shallow coastal waters in several ways. Experimental evaluations about the impact of anchors of sea vessels have previously shown that each anchoring can on average damage up to six shoots of *Posidonia oceanica*, removing small amount of biomass and, at the same time, interrupting continuity among shoots [1]. When the density of *P.oceanica* meadows is decreased and their state of being well is damaged, the stability of the environment is ruined and loss of habitat occurs. The aim of the study was to determine the effects of boat anchoring on *P. oceanica* seagrass beds on Gokova SPA between 2005-2006.

Keywords: Posidonia, Eastern Mediterranean

Introduction

The endemic seagrass species of Mediterranean basin *Posidonia oceanica* (L.) Delile covers about 2% of the seafloor of Mediterranean Sea [2]. It plays an important role in ecosystems of shallow coastal waters in several ways by providing habitat for a highly diverse fauna and flora; significantly reducing coastal erosion and offering a nursery area for many fish and invertebrate species [3]. Current main threats to the *P. oceanica* habitat are related to: water and sediment enrichment (eutrophication), the disruption of the sedimentation/erosion balance along the coast and direct destruction by human modifications of the coastline, degradation by boat trawling and anchoring [4]. Major damage to seagrasses seems to be caused by dragging anchors and scraping anchor chains along the bottom, as boats swing back and forth [5]. *Posidonia oceanica*, removing small amount of biomass and, at the same time, interrupting continuity among shoots [1]. The aim of the study was to determine the damage caused to *P. oceanica* habitat coverage by anchoring.

Materials and Methods

This study is based on the project "Coastal and Marine Biological Diversity Assessment of Gokova Specially Protected Area". The study was carried in 3 sampling periods between 2005 and 2006 (June-July 2005, April-May 2006 and June-July 2006). 309 scuba dives and 128 skin dives were performed on 220 km coastline of bay during total 75 days. Estimation of *P. oceanica* coverage and anchor damage was done by visual census method. For indicating the dimention of damage, Geographic Information system ArcGIS, was used for mapping and demonstration of sampling and remark data.

Results

It was determined that P. oceanica meadows has especially turned the severe marine environment into a more stable environment and ensured it to be used as a habitat for almost all species in the Gokova SPA. When the distribution of P. oceanica is decreased and their state of being well is damaged due to the various reasons, the stability of the environment is ruined and the loss of habitat occurs; because of those significant changes occurred in a very short period, biotopes and habitats begin to collapse rapidly. All those events result in the grave changes in the biota. In the study carried out in the Gökova SPA it was observed that most of the bottom was covered by *P. oceanica*. The average percent coverage was calculated as %61 approximately 6.9 km² in the studied area. It was significant that P. oceanica coverage decrease when area damaged with boat anchor. The areas most frequently used for the anchorages were determined as the west part of Akyaka (Gokova Bay), Çam Harbor, Sedir Island, Ingiliz Harbor, Tuzla Inlet, Hirsiz Inlet, Yediadalar and Çatalca Inlet. At the same time in those locations P. oceanica was widely distributed especially in Sedir Island, Catalca and Hirsiz inlets and Yediadalar. That the sea grasses widely distributed in the vicinity of Sedir Island were extensively exposed to the impact of the daily tour boats should be observed carefully [Fig.1]. The percent coverage was usually higher in the south part of Gökova Bay where there is no or few anchor damage. In addition no distribution of P. oceanica was observed in Ingiliz Harbour, Akyaka (Gökova) Bay and Çamli Bay. This situation was created by both natural and human impacts. P. oceanica was under a lot of stress due to the touristic activities in the densely populated locations such as Akyaka, Akbük and the damage caused by the private yachts, the daily tour boats and the Blue Cruise boats during the summer as well. Especially Akyaka Bay has the muddy bottom and a lot of

freshwater inputs. The value of transparency is lower. The settlement is extensive; in addition there are a harbor and a shipyard. Especially Ingiliz Harbor, Çam Harbor and Karacasögüt were preferred as the anchorages because of their being sheltered places; apart from the extensive sedimentation due to their semi-closed nature, the anchoring and the other activities also caused damages to *P. oceanica* in those areas.

Fig. 1. Posidonia oceanica coverage and determined anchor damage along the coasts of Gokova SPA

Discussion

The anchoring should be controlled in the locations with the sea grass meadows given in Figure 1. With the aim of the control, the buoys should be fastened to the bottoms in the west part of Akbük Inlet, Ayin Inlet, Löngöz Inlet, Yediadalar Inlet, Amazon Camping and Çati Inlet.

AUTUMN OVERLAPPING OF SARDINA PILCHARDUS AND MERLUCCIUS MERLUCCIUS EARLY STAGES IN THE NW MEDITERRANEAN: DISTRIBUTION AND DIET

M. pilar Olivar¹*, Elvira Morote¹ and Mikhail Emelianov¹ ¹ Institut de Ciències del Mar, CSIC - polivar@icm.csic.es

Abstract

This study analyses the distribution and diet overlap of the early stages of sardine and hake off the Catalan coast during the autumn spawning period. Data on horizontal and vertical distributions of eggs and larvae, the larval size structure in the overlapping zones and the diet composition are examined. Information derived from the study of larval diet was used to discuss the consequences of the overlapping distributions.

Keywords: Ichthyoplankton, Diet, Western Mediterranean

In this study we analyse whether there is overlap in horizontal and vertical distribution of eggs and larvae of sardine and hake, as well as on their larval feeding preferences. Samples were collected in November 2005 off the Catalan coast, by means oblique Bongo (300 µm) hauls in a grid of stations from coastal to slope regions. Stratified samples differentiating water column at 10 m intervals, from surface to 150 m, were also obtained by means oblique hauls using a Longurst Hardy Plankton Recorder (LHPR) (280 µm) performed in a transect carried out following the 200 m isobath. Sardine larvae were the most common and abundant species during the cruise, 97% of occurrence; while hake larvae occur in 67% of the stations. Although the sampling was performed during the spawning period for both species (1, 2), the abundance of sardine eggs and larvae was an order of magnitude higher than that observed for hake. Horizontal egg and larval distributions of both species showed a conspicuous overlap in the shelf-break region. Sardine eggs and larvae were found along all the study region, with higher abundance of earlier stages (eggs and <5 mm larvae) on the shelf region. Hake larval distribution was restricted to the shelf break, while eggs showed a slightly widespread pattern, but with higher abundance also at the shelf-break.

The vertical structure of the water column shows the initiation of the autumn mixing processes, with slight stratification (Fig. 1), under this situation, an important overlap in vertical distributions of eggs and larvae of sardine and hake was evident, both species appearing along the 150 m of the water column, although sardine showed higher concentrations in the first 100 m.

Fig. 1. Vertical distribution of temperature along the 200 m isobath transect, with overlaying sardine and hake larval abundance (log scale). Highest sardine symbol denote 5416 larvae/1000 m^3 , and highest hake symbol denotes 108 larvae/1000 m^3

The comparison of the diet composition of the larvae of the two species along their development (sardine larvae from 5.5 to15.8 mm SL and hake from 2.5 to10 mm) showed that there is no overlap in the prey items the feed on (Horn index=0.37). While preflexion sardine larvae (<10 mm) mainly fed copepod nauplii and small preys as tintinnids, small hake larvae (<4 mm) have a diet already based on adult copepods. Larger sardine larvae (from 10-16 mm) showed a shift in their diet to the postnaupliar stages of calanoid copepods like *Clausocalanus* sp. Hake larvae from 3-10 mm continue with a diet based on adult copepods, being *Clausocalanus* sp., by far, the dominant prey, followed

by Paracalanus sp.

Trophic ecology of hake larvae are influenced by its big mouth and large loopedguts, which allows them to eat and digest a relatively high number of big preys. The feeding incidence in these larvae was significantly higher than in sardine (90>30%). Although there is an important overlap in the distribution of the larvae of both species and sardine larvae are more abundant than hake, we think that there is no competition among larvae of both species because there is no overlapping between their diets (Fig.2, Costello's graphic).

Fig. 2. Diet composition according to Costello's graphic method for *Merluccius merluccius* and *Sardina pilchardus* larvae. N%: Percentage of abundance and F%: Percentage of occurrence of each prey item in the larvae

THE QUALITATIVE AND QUANTITATIVE STRUCTURE OF ZOOPLANKTON IN THE SHALLOW WATERS OF THE BLACK SEA: COMPARISON OF DATA FROM 1973 AND 2007

Teodora Maria Onciu¹* and Ciprian Samoila¹ ¹ Ovidius University Constanta - tmonciu@univ-ovidius.ro

Abstract

The paper presents the species diversity and the quantitative structure of the shallow waters zooplankton, which were collected from standard horizons in 10 stations at the Romanian littoral of the Black Sea in summer 2007 and compared to data from 10 samples collected from surface waters (0 m) at Portita in 1973. In 2007, there were 22 holoplanktonic species and 4 benthic larvae identified: 53.85% of all species were marine and the rest were limnic organisms brought by the Danube. In 1973, there were recorded species such as *Anomalocera patersoni*, *Centropages kroyeri* var. *pontica*, which have become extinct or very rare nowadays. *Keywords: Black Sea*, *Zooplankton*, *Biodiversity*, *Density*, *Biomass*

The chronic blooming of phytoplankton due to eutrophication led to an increase in the concentration of particulate organic matter (POM) in the water column and sediments, and implicitly to a phenomena of oxygen depletion or hypoxia [1], [2]. A number of 22 quantitative samples of zooplankton were studied; the samples were collected in late summer 2007 (29.08.-01.09.2007) from standard horizons in 10 stations located in four areas at the Romanian littoral: near the mouths of Danube river at Sf. Gheorghe (Φ =44°52', Λ =29°38'; Φ =44°51', Λ =29°04'; Φ =44°50', Λ =29°47'), then southward at Portia (Φ =44°38', Λ =29°04'; Φ =44°36', Λ =29°08'; Φ =44°18', Λ =29°14'), Midia (Φ =44°21', Λ =28°47'; Φ =44°19', Λ =28°47') and Tuzla (Φ =44°00', Λ =28°57'). The sampling was performed with a vertical-tow net made of silk tissue with a 90µm mesh. In 1973, there were 10 samples collected from the surface (0m), by filtering 1001 of water through the same type of net. The quantitative data relate to 1m³ (D_{density}= number of individuals for one cubic metre of water - ind·m⁻³, B_{biomass}=mg·m⁻³).

In the late summer of 2007, the zooplankton quantity varied from 41 ind m^{-3} and 1.30 mg m⁻³ (Midia area, station 8, horizon 25-10 m) to 12505 ind m^{-3} and 82.49 mg m^{-3} (Portita area, station 4, horizon 15-10 m); a maximum quantity was based on the weight of Bivalvia larvae (53%), as well as the fresh water rotifers (24%). The number of eudominant species (F -75,1-100%) is large (*N. scintilans*, larvae of Polychaeta, Bivalvia and *Balanus*), with only one copepod, *Acartia clausi*, found among them (table 1).

In 2007, a number of 8 species of rotifers were identified (representing 31% of total found species), where only one is a marine species (*Synchaeta littoralis*), and the rest are limnic, also tolerating lower concentrations of oxygen (*Rotaria citrina, Brachionus* sp., *Eosphora ehrenbergi, Polyarthra vulgaris*). The crustaceans were represented by 4 species of Cladocera and 5 species of Copepoda, most of them eurihaline and euryoxyc species that usually live in fresh waters (like the cladocers *Bosmina longirostris* and *Chydorus sphaericus*,

and copepods such as Calanipeda aquae-dulcis, Eurytemora affinis and Cyclops vicinus).

By comparing the data from 2007 and before 1970 when the eutrophication began [1], we observed that the biomass of the zooplankton was 3.7 times lower due to a decrease in numbers of the copepods. The density is higher as the light-weighted *Noctiluca* and rotifers numbers increase. The value of average density in 2007 was four times lower than in 1973, when the copepods held the major weight among eudominant species (*Acartia clausi* – registered a density of 6617 ind•m⁻³, and a biomass of 17.38 mg•m⁻³ in July, followed by *Oithona nana, Centropages kroyeri* var. *ponticus* and *Paracalanus parvus*) (table 2). In 1973, only one fresh water species (*Calanipeda aquae-dulcis*) was found. In summer months, there were records of thermophilic copepods such as *Centropages kroyeri* var. *ponticus, Anomalocera patersoni* and *Oithona nana,* which were

not to be found again in 2007.

Tab. 2. The qualitative and quantitative structure of the zooplankton in the Black Sea shallow waters on Portita transect in 1973 (D_{eco} =ecological average. D%=dominance. F%=frequency. W= ecological significance index. R=rank)

Oithona similis	0	0	0	0	0	4	0	20	0	15
Oikopleura dioica	8	0.1	50	0	10	44	0.5	100	0.5	8
Sagitta setosa	4	0	75	0	11	9	0.1	100	0.1	12

We may conclude that the modification of environmental variables in the water column led to a decrease in the species diversity of zooplankton, an increase in the weight of euryoxyc limnic species, both small and light sizes. It must be outlined the fact that the high density of bivalves larvae recorded in 2007 in the North sector (1337 ind•m⁻³) indicates the revitalisation of endopsamic mollusc populations in the area.

CONSIDERATIONS REGARDING THE FREE-LIVING MARINE NEMATODA IN THE NORTHERN AREA OF THE ROMANIAN BLACK SEA COAST

Teodora maria Onciu ¹*, Ciprian Samoila ¹ and Mihaela Muresan ¹ ¹ Ovidius University Constanta - tmonciu@univ-ovidius.ro

Abstract

From seven quantitative samples performed in the northern area of the Romanian coast of the Black Sea, 38 species of free-living Nematoda were determined. Thus, the species richness of observed Nematoda at the Romanian Black Sea coast increased of eight species (*Enoploides brevis, E. hirsutus, Chromadorella pontica, Paramonhystera elliptica, Theristus littoralis, Terschellingia pontica, Sphaerolaimus gracilis, Sphaerocephalum crassicauda*). *Keywords: Zoobenthos, Black Sea, Biodiversity*

Introduction

The scientific literature concerning Nematoda at the Romanian Black Sea coast are quite poor and each paper presents some species that were not described before in the studied area [1-6].

Material and Methods

The present paper is based on a research study where Nematoda species were identified from seven quantitative samples. In the period May-July 2003, the samples were obtained by collecting 100 cm^2 of sediment at different depths (3m, 5m, 15m, and 20m) in the northern part of the Romanian Black Sea Coast, between Sf. Gheorghe (near the mouths of the Danube) and Mamaia, on sedimentary (mud and fine sand) sea bottom.

The density data is expressed as number of individuals per 1 square meter (D= ind·m⁻²). A total of 38 species of free-living Nematoda were determined (table 1).

Results and Discussion

The determined species belong to four orders (Enoplida, Chromadorida, Monhysterida and Areolaimida), respectively 11 families (Enoplidae, Oncholaimidae Comesomatidae. Cyatholaimidae, Choanolaimidae. Chromadoridae, Monhysteridae, Linhomoeidae, Sphaerolaimidae, Axonolaimidae and Tripyloididae). Among them, the families Oncholaimidae and Monhysteridae include seven species each, followed by Linhomoeidae with five species and Enoplidae and Axonolaimidae with four species each. Eight of the total number of observed species (Enoploides brevis, E. hirsutus, Chromadorella pontica, Paramonhystera elliptica, Theristus littoralis, Terschellingia pontica, Sphaerolaimus gracilis, Sphaerocephalum crassicauda) proved to be new records at the Romanian coast of the Black Sea. The species diversity of Nematoda living on muddy substrata (Sf. Gheorghe area)(28 species) and their density (between 800 ind-m-2 and 77 200 ind-m-2) are remarkable. Ten species (35,7 %) have densities which reach over 10 000 ind·m⁻². In the area of Mamaia resort, there were found only 24 species on fine sand bottom. Their density varies between 400 ind-m-2 and 119 900 ind-m-2, the density of six species (25,0 %) reaching values greater than 10 000 ind·m⁻². The densities of *Theristus littoralis* (38 400 ind·m⁻²) and of *Th. maeoticus* (119 900 ind·m⁻²) were particularly high. Sixteen species are ubiquitous (Enoplus quadridentatus, E. littoralis, Viscosia cobbi, V. minor, Oncholaimus dujardini, O. campylocercoides, Sabatieria clavicauda, Halichoanolaimus clavicauda, Chromadora nudicapitata, Theristus maeoticus, Th. longicaudatus, Th. littoralis, Th. latissimus, Sphaerolaimus dispar, Bathylaimus assimilis, B.cobbi) and are present in each zone sampled. In terms of values of density, the representative species of free living Nematoda for the sedimentary zone in the North area of the Romanian Black Sea coast are Sabatieira clavicauda and Theristus maeoticus. In terms of values of density, the representative species of free living Nematoda for the sedimentary zone in the North area of the Romanian Black Sea coast are Theristus maeoticus (dominance = 20,41%, index of ecological significance = 34,15) followed by Sabatieria clavicauda (dominance = 13,05%, index of ecological significance = 19,31) and Metaparoncholaimus campylocercoides (dominance = 8,22%, index of ecological significance = 28.66)

In conclusion, the list of free-living marine Nematoda at the Romanian coast of the Black Sea has reached a number of 91 species, now including the new eight species recorded in the Northern area in 2003.

DISTRIBUTION AND ABUNDANCE OF SARDINE AND ANCHOVY LARVAE IN THE EASTERN MEDITERRANEAN SEA

Isik K. Oray ¹*, Ibrahim Tamer Emecan ² and Didem Göktürk ³ ¹ Cyprus Marine Science Foundation - isikoray@yahoo.com ² Istanbul University, Vocational School of Technical Sciences, Underwater Technology ³ Istanbul University, Faculty of Fisheries

Abstract

The distribution, abundance and size structure of sardine and anchovy larvae were collected in the northern Levantine Sea (eastern Mediterranean) in an ichthyoplankton survey between 5-18 June 2004. Sardine and anchovy larvae showed a wide distribution off the Turkish continental shelf. Especially Mersin Bay was an important spawning area in the northern Levantine Sea. *Keywords: Ichthyoplankton, Fishes, Pelagic, Larvae, Eastern Mediterranean*

Introduction

Anchovy, *Engraulis encrasicolus* (Linnaeus, 1758), one of the most import pelagic species of the Turkish fishery taking the first place with 385000 tons/year, and sardines, *Sardina pilchardus* (Walbaum, 1792), with 21000 tons/year ranges third after the Atlantic horse mackerel [1]. Anchovy are caught mostly in the Black Sea. The sardine catch is concentrated mainly in the Aegean Sea. 13.7% of the total sardine and 0.04% of anchovy catch comes from the northern Levantine Sea. Research has been carried on the distribution of the eggs and larvae of anchovy and sardine in the Marmara, Aegean and Black Seas ([2], [3]) but no investigations was done on these important pelagic species in the eastern Mediterranean Sea. The aim of this paper is to give the results of larval research on the distribution and abundance of the sardine and anchovy larvae in the northern Levantine Sea.

Material and Methods

The ichthyoplankton samples were collected in the TUNALEV survey on board of the Turkish trawler 'Emicaoglu' from 05-18 June 2004 in the northern Levantine Sea (Fig. 1).

Fig. 1. A) Map of the study area, B) Distribution and abundance of sardine larvae (larvae/1000 m^3), C) Distribution and abundance of anchovy larvae (larvae/1000 m^3)

A total of 104 sub-surface plankton horizontal tows with a Bongo 90 cm of quadrangular mouth opening with a 1 mm mesh for horizontal surface tows

and a Bongo net of 60 cm inlet diameter equipped with $250 \,\mu\text{m}$ mesh for oblique tows were made. The distance between each station was chosen as 10-15 nautical miles. All tows were fixed at 10 minutes duration. The collected ichthyoplankton material was then preserved in 5% neutralized formalin.

Results and Discussion

During the ichthyoplankton survey, the sea water temperature was measured as $21.8-29.3^{\circ}$ C, where by the salt content varied between $34.9-38.8_{\odot}$, the water depth being 63-2448 m. In this larval survey, 1779 larvae of *Sardina pilchardus* and 744 *Engraulis encrasicolus* were collected. Fig. 1B-C shows the distribution of sardine and anchovy larvae. High abundance of these fish larvae was observed in the Cilician Basin, between Turkey and northern Cyprus and in Mersin Bay. The larvae of these fish species were observed in very small numbers in Antalya Bay.

During the larval survey; ichthyoplankton was sampled in 104 stations. The sardine larvae were collected in 39 stations where by the 10-14 mm SL larvae comprised 65% of the sardine individuals. The length of the sardine larvae was 4.0 - 22.0 mm SL, the medium length being 12.4 ± 0.06 (SE) mm. The anchovy larvae were found in 58 stations. The 10-14 mm SL individuals comprised 55.5% of the anchovy larvae. The length of the anchovy larvae was 4.0 - 22.0 mm SL, the medium length being 12.2 ± 0.12 (SE) mm. The anchovy larvae were distributed in a wide area. The water depth of the sampled stations, where sardines were collected was 80-1170 m. The anchovy larvae were observed at sampling stations in water depths of 60-2000 m. The sardine and anchovy larvae were abundant in shelf. The number of the larvae decreased in off shore areas. According to Murua and Saborido-Rey [4], the presence of larvae in our research deeper than 1000 m could possibly be related to advection by sea currents in the study area.

In the previous papers, the distribution and abundance of the tunas (large pelagic species) in Mersin Bay, *Thunnus thynnus, Thunnus alalunga, Auxis rochei, Euthynnus alletteratus, Scomber scombrus, Scomber japonicus, Katsuwonus pelamis* have been reported [5]. The results of this survey confirm that Mersin Bay is an also spawning ground of small pelagic fish; namely of sardine and anchovy.

This important spawning ground should stay under protection. Excessive fishing should not be exercised. Pollution and introduction of energy sources leading to ecological changes in Mersin Bay should be avoided. Renewable energy such as solar, and wind energy should be preferred.

ASSESSMENT OF THE ECOLOGICAL STATUS OF SLOVENIAN COASTAL WATERS WITH MACROBENTHIC BIOLOGICAL ELEMENTS

Martina Orlando-bonaca¹*, Borut Mavric¹ and Lovrenc Lipej¹ ¹ Marine Biology Station, National Institute of Biology - orlando@mbss.org

Abstract

Benthic macrophytes on hard bottom and soft-botom invertebrates are two important biological elements for the assessment of the ecological status (ES) in coastal waters, according to the European Water Framework Directive (WFD, 2000/60/EC). The aim of the study is to verify whether the monitoring results reconfirm the preliminary evaluation of the ES according to these biological elements. The ES was reconfirmed as *Good*.

Keywords: Monitoring, Coastal Waters, Biodiversity, Bio-Indicators, Adriatic Sea

Introduction

The results of a preliminary assessment of benthic macroalgae in Slovenian coastal waters [1], according to the WFD, led to a selection of 7 sampling sites on hard bottom for the surveillance monitoring programme. In the same way, a preliminary assessment of benthic invertebrates led to a selection of 6 sampling sites on soft bottom. The aim of the study was to verify whether the results of the first two years of monitoring programme confirm the preliminary assessment of benthic elements or indicate different conditions/situation of these organisms in Slovenian coastal waters.

Material and Methods

The Slovenian coastal sea covers the southern part of the Gulf of Trieste. Its coastline is approximately 46.7 km long. It is a shallow semi-enclosed gulf with a maximum depth of ca. 33 m in waters off Piran. During 2007 and 2008, benthic macroalgae were sampled in three water bodies (WB): SI5VT3, SI5VT4 and SI5VT5, while benthic invertebrates were sampled only in two WB: SI5VT3 and SI5VT5. SI5VT4 was characterised as "rocky shallow moderately exposed", while the other two (SI5VT3, SI5VT5) as "sedimentary shallow moderately exposed". All sites were sampled twice: in spring and in late summer. Macroalgae were sampled and their status assessed according to the national methodology (3] using *M-AMBI*(Multivariat Azti Marine Biotic Index) [4, 5].

Results and Discussion

During the 2007-2008 period, 5 sampling sites for macroalgae were evaluated as High, one as Good and one as Poor ES. After the application of the spatial scale weighted EEI, the WBs ES was evaluated as High in SI5VT4 and as Good in SI5VT5, which reconfirm those from the preliminary study [1]. The macroalgae monitoring revealed seasonal differences in species composition and coverage. At almost all sites, the ES was higher in summer then in spring. The ES evaluation of benthic invertebrates in 2007 and 2008 classified both SI5VT3 and SI5VT5 as Good ES, which is in accordance with the preliminary ES evaluation. In both years the situation was better in late summer. There are slight discrepancies in the Ecological Quality Ratios (EQRs) for SI5VT3. The overall EQR value for both monitoring years lies on the border between Good and Moderate class (0.62), while in the preliminary study, the EQR value lies in the middle of the EQR range for Good class (0.70). The results of the assessment from 2006 to 2008 show a Good ES of Slovenian coastal waters. Further samplings and studies need to be carried out in order to rise confidence of the obtained results and applied methods.

MEDUSIVOROUS FISHES OF THE LIGURIAN SEA 1. CHUB MACKERELS AND OTHER PELAGIC FISH SPECIES SOMETIMES "HAVE THE MEDUSA" PELAGIA NOCTILUCA

Lidia Orsi Relini^{1*}, Fulvio Garibaldi¹, Luca Lanteri¹ and Marco Relini¹ ¹ Centro di Biologia Marina del Mar Ligure, University of Genoa - largepel@unige.it

Abstract

During blooms of *Pelagia noctiluca* periodically occurring in the Ligurian Sea (North Western Mediterranean), a natural mark, formed by the jellyfish pigments, characterizes fish eating this species. *Keywords: Western Mediterranean, Medusae, Pigments, Fishes*

CIESM is promoting observations about gelatinous zooplankton blooms, in particular those of jellyfish, which may be related to basic transformations of ecosystems, both of climatic and anthropogenic nature (1, 2). Such renewed attention to medusozoans has the consequence that parallel studies should be carried out about the consume of jellyfish by many marine organisms (3), particularly the most abundant fishes (4, 5); in fact if fishing or other anthropic activities are mentioned among possible causes of jellyfish blooms (2), it is necessary to know the trophic relationship among the concerned organisms.

Worldwide studies about medusivorous fish (3, 4, 5) allow us to list the following species which are also part of Mediterranean ichthyofauna, with indication in parenthesis, of the area in which the jellyfish consume was observed: *Squalus acanthias* (North Sea), *Etmopterus spinax* (North Atlantic), *Centroscymnus coelolepis* (North Atlantic), *Alepocephalus rostratus* (South Atlantic, Mediterranean sea), *Scomberesox saurus* (North Atlantic), *Boops boops* (Gulf of Tunis), *Trachurus trachurus* (North Sea), *Coryphaena hippurus* (Mediterranean Sea),

Sparus aurata (New Zealand waters), Scomber colias (Japanese waters), Scomber scombrus (Baltic Sea, North Sea, Western North Atlantic), Luvarus imperialis (Eastern North Atlantic), Centrolophus niger (Mediterranean Sea), Hyperoglyphe perciformis (Gulf of Maine), Schedophilus medusophagus (Mediterranean Sea, North Atlantic), Stromateus fiatola (Mediterranean Sea), Mola mola (North Atlantic), Japanese waters, Gulf of Maine, North Pacific), Ranzania laevis (North Atlantic). Only in few cases the consume of jellyfish have been observed in the Mediterranean; in particular the observations regarding Mediterranean stromateoid fishes occurred in Italian waters more than one century ago, thanks to Anastasio Cocco and Salvatore Lo Bianco.

All the listed fish species are present in the Ligurian Sea, an area of recognized richness of pelagic life (6), including offshore and coastal protected areas, such as the Cetacean Sanctuary and Portofino MPA, both SPAMI under the Barcelona convention. During recent blooms of Pelagia noctiluca we have ascertained its consume by four species of fish, three of them already known as medusivorous, i.e. S. colias, T. trachurus and S. medusophagus (7) and one, Oblada melanura, representing a new entry in the group. With regard to prey, P. noctiluca is well known in our study area. On the basis of impact on anthropic activities, organized research (frequently on international basis), assembled knowledge (but not all life cycle is exhaustively known), P. noctiluca can be placed in the top six jellyfish species of the world (8). Fluctuations of abundance of P. noctiluca in the Ligurian Sea have been studied assembling 200 years of Mediterranean records (9). A twelve years periodicity was found, each period being formed by groups of years with and without blooms of this species. Using a forecasting model, climatic variables, notably temperature, rainfall and atmospheric pressure appeared to predict years with Pelagia.

P. noctiluca has an olopelagic life history: a large egg (0.3 mm) gives rise to larval forms (*ephyrulae*) which in three months become young *medusae* (8). The nice pink-lilac colour of *P. noctiluca* is due to four different pigments, a brown, a magenta and two blue substances, distributed with sexual dichromism in mature individuals (8). When fish eat large quantities of *P. noctiluca*, pigments and/or their indigested residues reach a great concentration in the gut colouring the entire intestinal tract, to the anus (7).

During the most recent blooms (from 2006 onward), *Scomber colias, Trachurus trachurus, Oblada melanura* arrived to the market with the mark of *P. noctiluca*, that is presenting the anal rim surrounded by a violet blot (fig. 1). This fact brought to a popular level the knowledge of jellyfish consume: asked for the reason of such colour, fishermen and retailers simply answer that the fish "has the medusa".

In conclusion: 1) consume of jellyfish is not easily studied, given the fragility of tissues and the necessity to look for specific structures such as nematocysts at the microscope. In the case of *Pelagia* probably a relevant part of predation occurs on larvae and goes unnoticed. But when the stage of medusa is reached and aggregations are forming, studies on consumers are made easier by the natural mark; 2) chub and horse mackerels are able to use large quantities of *P*.

noctiluca, because of their massive presence. In fact these species are in a growing phase since at least ten years (10); 3) in healthy pelagic ecosystems (the Ligurian Sea has a very important presence of top predators and a reduced fishery pressure), global warming is probably enhancing the presence of some jellyfish species and of their consumers as well, maybe building new balances.

MEDUSIVOROUS FISHES OF THE LIGURIAN SEA 3. THE YOUNG GIANT, MOLA MOLA AT THE CAMOGLI TUNA TRAP

Lidia Orsi Relini¹*, Giovanni Palandri¹ and Marco Relini¹

¹ Centro di Biologia Marina del Mar Ligure, University of Genoa - largepel@unige.it

Abstract

The fishery of *Mola mola* occurred in the Ligurian Sea from ancient times to the end of the '90s when the use of *M. mola* as food was banned by the European Community. *M. Mola* was fished at the small artisanal tuna trap of Camogli, a very ancient gear at present located in the Portofino MPA. We used literature data (commercial product in the periods: 1950-1974, 1996-2000) and original unpublished data size structures per month (1993-1995; fillets/fish ratio) to estimate numbers of fish caught during the past exploitation. These were very young fish whose utilization can be traced at least one century ago. The Camogli tuna trap has allowed the monitoring, albeit in relatively short time periods, of the abundance of seven species of regular (*M. mola*) or potential medusivorous fish.

Keywords: Western Mediterranean, Fisheries, Coastal Waters

Among medusivorous fish (1), the sunfish Mola mola (Linnaeus, 1758) is classified in the group of species which feed only on jellyfish or use a prevailing quantity of this prey; the latter category seems the most appropriate for M. mola. The use of gelatinous macroplankton allows fast growth and the attainment of the most relevant size among living bony fish; a parallel case can be found in the marine turtles, with Dermochelys coriacea. In the last ten years, these characteristics have promoted a renewed interest to M. mola and the development of new research lines, especially based on archival tags and satellite tracking: the reason is that "data on what environmental factors influence the abundance and distribution of *M. mola* can also offer additional insight into what may be influencing the availability and blooms of gelatinous prey species" (2). However M. mola remains a poorly known species, particularly in the Mediterranean, Reproduction, in terms of times and locations, remains a major gap of its life history (3) and also distribution is scarcely understood. At the best of authors knowledge, M. mola results really abundant in few Mediterranean areas: one is located in the Ligurian Sea, at Camogli (western side of Portofino promontory), where fishermen still use an ancient two-chambered artisanal tuna trap (six men crew for hauls). This gear was common about four centuries ago along the Ligurian coast, from Marseille (4) to La Spezia. The trap is active from April to September, with three hauls per day. Until 2000 (5), commercial landings per fishery season resulted about 50 tons, and included more than 40 fish species, with a Mola product of about 2 tons, but at present, due to E.C. regulations, this fish cannot be used as food and is released alive. Parona (6), during a local visit in June 1912, recorded more than 500 individuals of *Mola* in the trap and reported that although this fish was part of the commercial product, sometimes its abundance reached numbers considered by fishermen unfavourable for the fishing of bluefin. Total catches of the tuna trap were studied in the '70s (7), thanks to the daily registration of the commercial products carried out from 1950 onward by the same fishermen who were experimenting different kinds of net in the trap chambers. Two form of CPUE (a proxy of fish abundance) were derived: total landings per fishery season and average daily landing of the top ten species in a time series of 25 years, from 1950 to 1974: the species were Auxis rochei, Boops boops, Sarpa salpa, M. mola, Oblada melanura, Sarda sarda, Scomber japonicus, Scomber scombrus, Scomberesox saurus, Trachurus trachurus (7). M. mola was registered with quantities varying between 0.86 and 5.84 tons per fishery season (164-182 days of fishing). In the study of the fishery trends of the top species M. mola resulted one of the most regular (7), uninfluenced by materials used in the gear construction. In the period 1993-1995, thanks to an E.C. funding regarding large pelagic fish, we studied the size structure of the fished stocks by different gears, including the Camogli tuna trap. Observations regarding M. mola (an example of 1/f distribution is given in fig. 1), that was not a target species, remained unpublished. At present large numbers of fish are observed as at the time of Parona (6), but in absence of fishing, it is impossible to quantify their presence (8). Moreover the quantities registered from 1950 to 2000, don't regard directly the fish, but its commercial form, the fillets. Which is the ratio fish-fillets? From the structure of the fished stock we have obtained the average fish, 45.4 cm total length and about 5 kg weight (9), supposed in the first year of life. This represents the modal size in June that is the core of the fishing season. In this month we have observed the preparation of fillets: an average of 0.82 kg of product per specimen (N=80; range 36-75 TL) that is the 16.4% of the fished biomass. Such data allow to transform the above indicated total catches in number of fish: in the 25 years series the range was about 1000-7100 fishes with an average of 3626 per fishery season and at the end of the '90s the average catch was consisting of about 2436 fishes. We cannot say if this number represent a decrease in respect of the past series because in the years 1950-1960 seven annual catches resulted under this level (7): the indicated time period is not suspected in regard of the other gears which can capture the sunfish i.e. driftnets, which were developed in the '80s. Taking into account the list of Mediterranean medusivorous fish (10), we can observe that the Camogli tuna trap till recent times was permitting the monitoring of seven species of regular and potential medusivorous fish: at present the monitoring of *M. mola* is cancelled as well as an ancient know how regarding the fish and the possibility to offer the sun (in english) or the moon (in italian pesce luna) on the table at Portofino. Given the present relevance of this species for research at ocean scale (2) we suggest to open a debate on this subject.

Fig. 1. Length/frequency distribution of *M. mola*, caught by the Camogli tuna trap (sum of hauls carried out in May-July 1993).

SETTING UP AN EGG-DENSITY MODEL FOR EUROPEAN ANCHOVY, ENGRAULIS ENCRASICOLUS

Andrés Ospina-álvarez¹ and Isabel Palomera^{1*}

¹ Institut de Ciències del Mar (ICM-CSIC) - isabel@icm.csic.es

Abstract

The vertical distribution of pelagic fish eggs is an important issue in modeling and fisheries science. Knowledge on the influence of egg-density is a key aspect in IBM's where satisfactory equations to simulate realistic spatial variation are required. The egg-density of European anchovy is poorly known and only some studies on Atlantic provide information about it. An equation was fitted to describe changes in egg-density across development time. We found that the egg-density of anchovy in the Mediterranean is higher than in Atlantic waters. A functional model suitable for Mediterranean and Atlantic waters was established. Keywords: Fishes, Density, Ichthyoplankton, Models, Spawning

Introduction

Small pelagic fish populations have a reproductive strategy resulting from past natural selection pressure, which make them adapted to the constant structural instability where they persist [1]. One adaptation is the buoyancy of eggs due to density changes through development [2]. This is an important issue in fisheries and modeling science, because they affect the vertical distribution of eggs, and therefore the transport [3]. The Individual Based Models IBMs that study the transport of fish eggs from spawning to nursery grounds is a novel approach that might be useful to further understand the recruitment variability [4]. In the southern Benguela ecosystem, simulations on the effects of physical and biological variables on the transport of anchovy (Engraulis capensis) eggs including a buoyancy model scheme maximize the average particle transport success [3, 5]. Modeling studies that include a fixed value for egg density overestimate the effects of the egg-buoyancy in the transport. However, the density of pelagic fish eggs is not constant and the egg-density changes during development [6, 7]. We fit an equation to describe the egg-density of European anchovy through development. A better knowledge of egg-density could improve the present models of

transport on IBM's. Materials & Methods

Ichthyoplankton samples from the Gulf of Lions were collected in May-June 2008 survey. The samples were immediately taken to the laboratory onboard. We identified anchovy eggs and their stages; only early stages (I-II) were selected for the experiment. Egg-density measurements were carried out in a Density Gradient Column (DGC) [6]. The eggs were introduced in DGC and their height was measured at intervals until hatch. The height of eggs in DGC is an indication of their density. The DGC was kept at 18.5°C. The total duration of incubation of anchovy eggs varies with temperature; some eggstages being more or less durable than others. By merging equations (Fig.1) we obtained a polynomial equation (eq.3) to calculate egg-density considering the time from fertilization, the effect of temperature and the spawning and hatching densities. With the resulting equation we built a model (Fig.1c) by comparing the egg-density in the Bay of Biscay [7] and in the Gulf of Lion. Additionally, we include the egg-density model in ICHTHYOP [8] analyzing the

effect of buoyancy in the egg transport.

Results

We found that the egg-density of anchovy in the Mediterranean is higher than in Atlantic waters. However, the curve shape describing the egg-density trough development is the same (Fig. 1c). The main factors influencing the eggdensity changes in the model are the seawater densities at spawning and hatching points. The incubation time is determined by the seawater temperature [9]. We found differences in simulated trajectories patterns of anchovy eggs when: 1) egg-density was not considered, 2) a fixed egg-density was included and 3) with a variable egg-density equation.

Discussion

Knowledge on reproductive habitats is a key aspect for management of small pelagic fishes. The IBM's focuses in transport are an important tool for these aspects. However, satisfactory biological equations to simulate realistic spatial variation are required. The egg-density and subsequently buoyancy are poorly known. Some models include the assignation of a fixed value to egg-density and its movements according to Stoke's law. However, we found differences when variable egg-density is considered. In Mediterranean waters the incubation of anchovy eggs during peak spawning is approximately 48 hours, in other words during the first 48 hours of transport the egg-density is influencing the horizontal and vertical trajectories, routes and hatching zones. Additionally, during this time anchovy eggs experience different temperatures, salinities and densities. It is then essential to include an egg-density equation into transport

models to improve the current IBM models.

Abstract

During the last decades, 4 alien isopods have been reported from harbours and nearby lagoons in Tunisia. The intensification of shipping activities and the significant increase in the average water temperature has been enhanced the introduction and the establishment of non indigenous species. Since its occurrence *Sphaeroma walkeri* was studied. A brief description and some ecological main features are given and discussed.

Keywords: Infralittoral, Lagoons

Surveys conducted among benthic communities in Tunis Southern lagoon and nearby ports during last decades allowed us to observe 4 alien isopods, Paracerceis sculpta [1], Paradella dianae [2], Sphaeroma walkeri [3] and Sphaeroma venustissimum [4]. Among this invasive fauna, Sphaeroma walkeri is the most acclimated isopod with Paracerceis sculpta in the Tunisian brackish waters. According to Zibrowius [5] it is one of the most widely shiptransported alien species in the world, and was first recorded in the Mediterranean during the earlier part of the last century. Sphaeroma walkeri is a thermophilic isopod native of the Indian Ocean. It is commonly found in intertidal fouling communities and has been widely reported from ports in warm and warm-temperate waters worldwide [6]. Sphaeroma walkeri was regularly sampled from 2003 until 2009 in the Tunis Southern lagoon and the specimens have been identified following the description and illustrations given by Jacobs [7]. Sphaeroma walkeri is an isopod that grows up to 10mm in length (Figure 1). Adult females are smaller than adult males. Maximum length observed in our samples is 16mm. The surface of pereionites is smooth but pereonites 3 & 4 each bear 2 irregular rows of low tubercles. Pereonites 5 &6 and the pleon each bear one row of prominent round tubercles, with the posterior edge of the pleon having a second row of small round tubercles. The pleotelson is long and tapers to a rounded point that is slightly upturned with 4 rows of 3-6 tubercles running lengthways on the surface. The uropods are flattened and attached on the side of the pleotelson towards the front. The endopod is rigidly fused while the exopod is movable and greater than or equal to the length of endopod. S. Walkeri was permanently collected in Tunis Southern Lagoon, a euryhalin ecosystem, among sponges and ascidians in very shallow waters less than 3 metres depth. This isopod was the most abundant alien species found in Tunis Southern lagoon during hot season from April to August. Salinity, temperature and suspended solids were observed to influence the occurrence of this species. This specie is commonly associated with one or both of the isopods Dynamenella dianae and Paracerceis sculpta. The evolution of densities of Sphaeroma walkeri according seasons is summarized in table1. This isopod is found in high densities. The average value observed was 15 specimens /m². The highest values have been observed during the hottest season. Among fouling communities, S. Walkeri prefers sponges than ascidians. The specie reproduces in sponges. All stages, adult from the two sexes, ovigerous and non-ovigerous females and sub-adult males, are observed in sponges.

Fig. 1. Male of Sphaeroma walkeri Stebbing, 1905 collected from the Tunis Southern lagoon

Tab. 1. Seasonal evolution of densities of S. walkeri in Tunis Southern Lagoon

Seasons	Autumn	winter	spring	summer
Densities of S. Walkeri associated to sponges	12 ind/m ²	7 ind/m ²	18 ind/m ²	23 ind/m ²
Densities of S. Walkeri associated to ascidians	3 ind/m ²	2 ind/m ²	7 ind/m ²	9 ind/m ²

S. walkeri is one of the most abundant alien isopods observed in Tunisian shallow waters. According its establishment and acclimatisation in lagoons near ports, this thermophilic non indigenous species was probably introduced by vessels traffic.

THE BIOMASS AND SOME BIOLOGICAL ASPECTS OF THE MEDITERRANEAN SLIMEHEAD HOPLOSTETHUS M. MEDITERRANEUS, FROM SAROS BAY (NE AEGEAN SEA, TURKEY)

Melike idil Öz¹* and Ali Ismen¹

¹ Çanakkale Onsekiz Mart University, Faculty of Fisheries - idiloz@gmail.com

Abstract

The CPUE, biomass indices and some aspects of the biology of *Hoplostethus mediterraneus mediterraneus* from Saros Bay (NE Aegean Sea) are determined. Specimens were caught by commercial trawl from the depth interval 200-500 m, in the period of January 2005-September 2008. Lenght-weight relationship is found W=0,0101*L^{3,1041} for both sexes. Total lenght and total weight ranged from 4,0 to 24,6 cm and from 0,83 to 209,7 g respectively.

Keywords: Biomass, Aegean Sea, Trawl Surveys

With the arisen awareness of the 'ecosystem-based fisheries management', discarded species are no longer considered as less important constituents of the integrated ecosystem. However information is still scarce regarding many non-commercial species' distribution, population status and biology. The Mediterranean slimehead is a good example for this situation. *Hoplostethus mediterraneus mediterraneus* Cuvier, 1829 (Beryciformes: Trachichthyidae), having no commercial value in the Mediterranean Sea fisheries, is a cosmopolitan, benthopelagic, marine species living at a depth range of 100 - 1175 m [1]. This species has received relatively little scientific attention and many basic aspects of its biology are as yet unknown. [2].

Methods

Samples were collected by a commercial bottom trawl net with a cod end stretched mesh size of 22 mm, at monthly sampling intervals from January 2005 to September 2008. *H. mediterraneus mediterraneus* specimens were caught from the depth range of 200-500 m, tow duration was restricted to 30 min and the vessel speed was kept constant at 2,7 knots during hauling. CPUE was calculated for 1 hour, biomass was estimated using the swept area method. Total length, weight and if possible sex and maturation stage were recorded for each specimen, also some of the gonads, stomachs and otoliths were dissected and sampled in order to evaluate for further studies. Length weight relationship were calculated and expressed $W=aL^b$.

Results and Discussion

The CPUE and biomass indices show that *H. mediterraneus mediterraneus* is widely distributed in Saros Bay.

According to Table 1, especially in October and November the values are much higher than the other months of the years. On the contrary, June'05 is an exception, but the other summer months and May values are low and September values are zero for all the four years. For these 5 months we may assert that fish inhabit deeper levels that our gear was unable to reach. This behavior can be estimated as the effects of changes in the water temperature or as a spawning behavior. Yet the spawning period is given in [3] as May-September which reflects the absence of *H. mediterraneus mediterraneus* in our study.

Overall, 305 sexed individuals, 171 were female (56%), 73 were male (24%)

and 61 were juveniles (20%). Juveniles were mostly captured at depths between 300-440 m, in May'06, July'06 and '08. The most frequent size class for both sexes is 15 cm, for females 17 cm and for males 15 cm.

The parameters of the length-weight relationship of our study and previous studies on the same species from different localities are given in Table 2.

Abstract

This paper presents the abundance and biomass of the 18 exotic fish species caught during the bottom trawl survey carried out in the Gulf of Antalya in the summer period of 2009. Among 76 teleost species identified, exotics constituted 9.74% of the average abundance and 7.93% of the average biomass of the teleosteans. *Keywords: Trawl Surveys, Demersal, Teleostei, Biomass, Levantine Basin*

Introduction

The Gulf of Antalya locates in the Norteastern Levantine Basin and is highly susceptible to invasions by aliens due to the proximity to the Suez Canal. 120 established and casual alien fish were reported from the Mediterranean Sea [1] and 50 of them were recorded from the Levantine coast of Turkey [1,2]. Except for the species records, the studies concerning the biomass and abundance of the exotic fish community in the Northeastern Levant Sea are limited to [3,4]. This paper presents the first detailed information on the exotic fish community of the Gulf of Antalya.

Material and Methods

This research was carried out in August 2009, in the Gulf of Antalya, between the depths of 25-200 m, using a commercial bottom trawler. The cod-end mesh size 22 mm (knot to knot). The samples were collected day time with 2.5 n.m./h average trawling speed. The geographical coordinates of 30 trawling stations vary between N36° 52' 48.5 - 36° 23' 00.0'' - E31° 32 32.2' - E30° 31' 11.3''. The total catch from each haul was identified to species, counted, weighed and standardized to unit trawling hour. The stock amount is calculated according to the swept area method [5].

Results

A total of 30 hauls were carried out at the depths of 25, 50, 75, 100, 150, 200 m. The overall average abundance of the 18 exotic species was 4942 ± 1371 ind./nm² (±se) and average biomass was $229,67\pm49,58$ kg/nm² (±se) (Tab.1).

Tab. 1. The number of hauls, average biomass (kg/nm² \pm se), abundance (ind./nm² \pm se) and number of exotic species and percentages of exotics in among teleosteans at six depth levels in the Gulf of Antalya.

Depth	Number	Average Bion	nass	Average Abu	idance	Number of
(m)	of hauls	kg/nm ² ±se	(%)	ind./nm ² ±se	Species (%)	
25	6	348.30 ±151.88	(14.47)	15342 ± 4560	(17.42)	15 (29.41)
50	6	409.11 ±112.36	(17.81)	5291 ± 1546	(9.81)	12 (22.22)

100	6	170.3 ±112.19	(6.21)	1691 ± 1122	(2.81)	3 (9.38)
150	4	96.51 ±49.52	(3.52)	1036 ± 665	(1.49)	7 (19.44)
200	2	0.69 ± 0.69	(0.08)	40 ± 40	(0.14)	1 (4.76)
Total	30	229.67 ± 49.58	(9.74)	4942 ± 1371	(7.93)	18 (23.68)

The highest biomass of the exotic species was recorded at the depth of 50 m and the abundance decreased with depth. The most frequent species was Saurida undosquamis (Linnaeus, 1758) (83,3%), Upeneus moluccensis (Bleeker, 1855) (83,3%), Lagocephalus suezensis Clark & Gohar, 1953 (36,7%), Lagocephalus sceleratus (Gmelin, 1789) (36,7%), and Equulites klunzingeri (Steindachner, 1898) (30%). In the total average of 30 hauls, S. undosquamis (Linnaeus, 1758), L. suezensis Clark & Gohar, 1953, U. moluccensis (Bleeker, 1855), L. sceleratus (Gmelin, 1789), and E. klunzingeri (Steindachner, 1898) are the species that have the highest biomass. E. klunzingeri (Steindachner, 1898), U. moluccensis (Bleeker, 1855). S. undosquamis (Linnaeus, 1758), L. suezensis Clark & Gohar, 1953, and Upeneus pori Ben-Tuvia & Golani, 1989have the highest abundance, respectively. The average biomass (kg/nm² (±se)), and abundance (ind./nm² (±se)) of 18 exotic species at six depth levels are given in Table 2.

Discussion This paper presents the first detailed information on the exotic fish community of the Gulf of Antalya. This research was conducted in the "pre-fishing" season both in the fishing-prohibited and open areas. For the "pre-fishing" season, [3] reported that the Red Sea teleosteans constituted 51.91% of the average percentage of the teleosteans and decreased to 34.85% in the post fishing season in Gulfs of Iskenderun and Mersin. The keystone species responsible for this fluctuation was shown as E. klunzingeri (Steindachner, 1898) which was also found as the most abundant species in this study. Invading species have been found to comprise 62% of the demersal fish biomass in the Gulf of Iskenderun and 34% in Mersin Bay, Turkey [4]. Notwithstanding, definite changes in fish communities in the Levantine ecosystem have been attributed to Lessepsian migrants. Thus long-term approaches are required to monitor of the exotics in proportion to local species; determine the seasonal and spatial distribution and status of the populations of alien species. Acknowledgements The authors greatly indepted to Prof.Dr.Erhan MUTLU. Prof.Dr.Gülsen ALTUG. Assoc.Prof.Dr.Saadet F. KARAKULAK and Assoc.Prof.Dr.Murat BILECENOGLU for their valuable comments and support and Captain Akin AKYAR for his help on the field works.

Abstract

Fatty acid, trace element and proximate compositions of male and female of blue crabs and swim crabs caught in Mersin Bay were investigated. The results of proximate analysis showed that there were variations in protein and moisture content of both female crabs and male crabs' meat of these two crab species (p<0.05). Saturated fatty acid (SFA) content was detected as 23.3%-24.8% in blue crabs whereas it was 24.7%-24.9% in swim crabs. Monounsaturated fatty acid (MUFA) content in the body of blue crabs (26.6%-29.6%) was higher than swim crabs (24.1%-25.9%). Besides, polyunsaturated fatty acid (PUFA) content of swim crabs (43.8%-45.3%) was higher than blue crabs (39.2%-42.8%) (p<0.05). It was also found that crab meat was rich in terms of trace element content, especially Cu, Zn, and Fe. *Keywords: Decapoda, Metals, Nutrients*

Introduction

Poturnid crabs, *Callinectes sapidus* and *Portunus pelagicus*, are the most important members of the estuarine food chain as while they feed on fish, aquatic vegetation, molluscs, crustaceans and annelids, they serve as preys to mammals, birds and fishes [1]. Seafood lipids are rich in n-3 PUFAs such as EPA and DHA. These fatty acids have a variety of health benefits, including prevention of sudden cardiac death [2] and chemopreventive effects of cancer [3]. The fat and fatty acid compositions of fish can vary depending on fish species, diet, gender, location and season of capture [4,5]. The objective of this study was to determine and compare trace element, fatty acid and proximate compositions of male and female blue crabs and swim crabs in Mersin Bay.

Materials and Methods

Poturnid crabs, C. sapidus and P. pelagicus, were caught by dip net from Mersin Bay, the coast of Northeastern Mediterranean, in March, 2008. In the fishing procedure, dip net which had mesh size of 32 mm was used. The morphometric measurements [carapace length (CL), carapace width (CW) and weight] of all samples were carried out. The morphometric measurements of crab carapace were done using a caliper. The mean CW and CL were 183.4-214.0 mm and 79.0-95.6 mm for blue crabs and 172.8-183.0 mm and 90.3-111.0 mm for swim crabs, respectively. The mean weights of blue crabs and swim crabs were between 180.8-238.6 g and 174.3-177.8 g, respectively. Crab samples were analysed in triplicate for proximate composition. Lipid content by the Bligh and Dyer [6] method, moisture content by AOAC [7] method, total crude protein by the Kieldahl method [8] and ash content by the AOAC [7] method. Fatty acid profiles of fat extracted from the blue crab samples were determined by gas chromatography (GC) of methyl esters. Methyl esters were prepared by transmethylation using 2 M KOH in methanol and nheptane according to the method decribed by Ichibara et al. [9] with minor modification. All samples were analysed three times for each metals with ICP-AES (Inductively Coupled Plasma Atomic Emission Spectrometry, Varian® model- Liberty Series II). The standard addition method was used to correct for matrix effects. The metal concentration (Cd, Cr, Pb, Cu, Fe and Zn) in tissue was recorded as μg metal/g dry weight [10]. Statistical analysis of data was carried out with the SPSS statistical program. ANOVA (Analysis of Variance) was used to evaluate the effect of gender on the fatty acid and proximate composition and trace element levels.

Results and Discussion

The results showed that the protein, lipid, moisture, and ash contents of female blue crabs and female swim crabs were not significantly (P>0.05) different. Protein contents of female blue crabs and female swim crabs were significantly higher (P<0.05) than those found in male blue crabs and male swim crabs. Moisture contents of male blue crabs and male swim crabs were significantly higher (P<0.05) than those found in female blue crabs and female swim crabs. This study shows that crabs caught from the Gulf of Mersin have high protein (21.4-22.5% for *C. sapidus* and 20.9–23.2% for *P. pelagicus*) and low fat contents (1.0–1.1% for *C. sapidus* and 1.2–1.3% for *P. pelagicus*). In this study, lipid values were higher than those reported by Gökoglu et al. [11] for the both crab species. *Fatty acids composition;* SFAs, MUFAs, PUFAs, PUFA/SFA, n-3 acids, n-6 acids and the n6/n3 ratio of male and female swim crabs and blue crabs' meat are presented in Table 1. The dominant SFAs were palmitic acid (12.8%-14.2%), and stearic acid (6.4%-9.0%) for both of the

crab species. Oleic acid (13.3%-14.8%) was the major MUFA in all crab meats, followed by palmitoleic acid (5.0%-8.7%) and octadecenoic acid (4.0-4.7%). The total PUFA value was the highest in meat of female swim crabs (43.75%), the lowest amounts (39.15%) were in meat of female blue crabs. EPA (20:5) and DHA (22:6) were PUFAs having maximal values. Statistically, there were no significant differences in Eicosapentaenoic acid (EPA) concentrations in body meat of male and female blue crabs (P>0.05). Besides, EPA concentrations in meat of female swim crabs were higher than those of the males (p<0.05). Trace element contents; the trace element contents of female and male of blue crab and swim crab are listed in Table 2. Cu, Zn, Fe contents of female blue crabs were significantly higher (P<0.05) than those found in male blue crabs. Cd, Pb, Zn contents of female swim crabs were significantly higher (P<0.05) than those found in male swim crabs. The concentrations of metals for muscle of crab are below those likely to cause a public health problem: 4 µg Cd/g (wet weight), 1.7 µg Pb/g according to the U.S. Food and Drug Administration [12] and 20 µg Cu/g and 50 µg Zn/g according to the Turkish Food Codex [13]. High Cu level doesn't directly affect human health. But the excess copper ve zinc is carried via the food chain to the upper trophic levels and creates important ecological problems.

THE EFFECTS OF SEASON AND SEX IN THE FATTY ACIDS AND PROXIMATE COMPOSITIONS OF COMMON CUTTLEFISH (SEPIA OFFICINALIS)

Yesim Ozogul ¹, Deniz Ayas ²* and Mustafa Kalay ² ¹ Cukurova University, Faculty of Fisheries, Seafood Processing Technology

² Mersin University - ayasdeniz@mersin.edu.tr

Abstract

The effects of season and sex on the fatty acids and proximate compositions of the mantle of the cuttlefish *S. officinalis* were evaluated. The results of the proximate composition showed that the level of protein contents of female of *S. officinalis* were significantly higher than those of male (P<0.05) for all seasons. In addition, lipid and moisture contents of female of cuttlefish were generally low compared to those of male cuttlefish. The fatty acid compositions of each sex and all seasons ranged from 29.38% to 32.51% saturated (SFA), 8.70-11.11% monounsaturated (MUFAs) and 48.23-54.57% polyunsaturated acids (PUFAs). The proportions of *n*-3 PUFAs (44.00-50.63%) were higher than *n*-6 PUFAs (3.38-4.25%) regardless of sex and seasons. *Keywords: Cephalopods, Nutrients*

Introduction Cephalopoda, one of the most important groups of marine invertebrates, are consumed throughout the world. Annual catch of cuttlefish ranged from 11,000 to 15,000 tons throughout the world and they occupies an important place among cephalopoda [1]. Bochemical contents of marine organisms have been reported to change due to seasonal changes [2,3,4]. Studies have been conducted on the nutrient value and fatty acid composition of cuttlefish [5,6,7]. In this study, the effects of season and sex in the fatty acids and proximate compositions of the mantle tissue of the common cuttlefish (*Sepia officinalis*) were investigated.

Materials and Methods

The common cuttlefish is generally caught in the Mediterranean and Eagen sea shore in Turkey. This species was caught in Mersin Bay with net in all seasons (except summer). Mantle which is the main edible portion of cuttlefish was homogenized and chemical analyses were done on this part of fresh samples. The analyses were performed at least in triplicate. Lipid content by the Bligh and Dyer [8] method, moisture content by AOAC [9] method, total crude protein by the Kjeldahl method [10] and ash content by the AOAC [9] method. Fatty acid profiles of fat extracted from samples were determined by gas chromatography (GC) of methyl esters. Methyl esters were prepared by transmethylation using 2 M KOH in methanol and n-heptane according to the method decribed by Ichibara et al. [11] with minor modification. Statistical analysis of Variance) was used to evaluate the effect of gender on the fatty acid and proximate composition and trace element levels.

Results and Discussion

Tab. 1. Seasonal changes in fatty acid composition of S.officinalis

Food Category (% by weight)	Identified prey items	Food Category (% by weight)	Identified prey items

(16.36%)	Octopus defilippi		Nephrops norvegicus
	Sepiolidae		Pagunus sp.
Polychaeta	Ambandisidan		Parapenaeus longirostris
(3.89%)	Aphroundae		Pasiphaeidae
Plantae	Ponidouia ocamica		Platysqutllotdes Itllyae
(0.06%)	Fosicionia oceanica		Sergestes sp.
Cannibalism (1%)	Scyliorhinus canicula		Squillidae

Fatty acid analyses; Table 1 shows the seasonal changes in fatty acid composition of male and female cuttlefish. The fatty acid compositions of each sex and all seasons ranged from 29.38% to 32.51% saturated (SFA), 8.70-11.11% monounsaturated (MUFAs) and 48.23-54.57% polyunsaturated acids (PUFAs). The major fatty acids found in cuttlefish were myristic acid (C14:0, 1.56-2.43%), palmitic acid (C:16, 16.38-19.24%), heptadecanoic acid (C17:0, 1.41-1.63%), stearic acid (C:18, 7.45-9.27%), oleic acid (18:1 n-9, 3.31-5.15%), linoleic acid (C18:2 n-6, 0.49-0.77), arachidonic acid (C20:4 n-6, 2.78-3.38%), cis-11-eicosapentaenoic acid (EPA, C20:5 n-3, 15.73-17.75%) and cis-4,7,10,13,16,19-docosahexaenoic acid (DHA, C22:6 n-3, 27.46-33.02%). These results were in agreement with those reported by Ozyurt et al. [7], Reale et al. [12], and Ozogul et al. [13]. The proportions of n-3 PUFAs (44.00-50.63%) were higher than n-6 PUFAs (3.38-4.25%) regardless of sex and seasons. This high PUFA level is similar to those reported [2,5,7,12,13]. The major polyunsaturated fatty acids of cephalopoda observed were EPA and DHA. In this study, the levels of DHA, which was recorded in autumn, spring and

winter, were 31.54%, 27.46%, and 28.70% for female cuttlefish, respectively, whereas its level were observed to be 33.02%, 29.23% and 28.70% for male cuttlefish. The EPA levels in female of cuttlefish mantle were found to be 17.75%, 16.26%, 15.73% and 13.9% while its level in male of cuttlefish were 15.85%, 17.22% and 16.80% in autumn, spring and winter, respectively. It is well known that the fatty acid profile of fish muscle reflects the content of the dietary lipid sources. Nutrient levels vary between species and even within species. Diet, size, age, reproductive status of fish, environmental conditions, and especially water temperature, influence lipid content and fatty acid composition of seafood.

Proximate analyses; Table 2 shows seasonal changes in proximate composition of male and female of cuttlefish. The results of the proximate composition showed that the lowest lipid content was obtanied from female in winter (0.74%) whereas the highest level of lipid was found in males in Autumn (0.94%). The lowest total mineral substance (TMS) content was obtained in Autumn (1.07-1.08%), whereas the highest level of TMS was obtained in Spring (1.73-1.75%) in both female and male. The lowest protein contents was also obtained in Autumn (16.96-17.33%). However, the protein contents did not change in both Spring (21.47-22.18%) and winter (21.64-22.01%) seasons. For all seasons, the level of protein contents of female of *S. officinalis* were significantly higher than those of male (P<0.05). In addition, lipid and moisture contents of female of cuttlefish were generally low compared to those of male cuttlefish.

A PRELIMINARY STUDY ON TWO SEAMOUNTS IN THE EASTERN MEDITERRANEAN SEA

Bayram Öztürk ¹*, Eda N. Topcu ¹ and Bülent Topaloglu ¹

¹ Istanbul University, Fisheries Faculty, Ordu cad. No 200. Laleli, Istanbul – Turkey / Turkish Marine Research Foundation (TUDAV) P.K: 10 Beykoz, Istanbul - Turkey - ozturkb@istanbul.edu.tr

Abstract

Two seamount plateau were sampled which are very little known in terms of deep sea habitat in the Eastern Mediterranean Sea. A total of 11 fish, 7 crustaceans and a cephalopod species were found between 880-1107 m depths. *Galeus melastomus* and *Squalus acanthias* were common species for fish and *Aristaeomorpha foliacea* inboth seamount areas for crustaceans. *Keywords: Eastern Mediterranean, Deep Sea Ecology, Biodiversity*

Introduction

In 2006-2007 and 2008, a three year survey was conducted in the Eastern Mediterranean Sea to better understand deep and high sea marine biodiversity. Samplings were performed by beam trawl in two locations in Eastern Mediterranean Sea. Finike Seamount were sampled at depths ranging from 880 to 1000m depths and Turgut Reis Seamount between 989 to 1107m depths in August 2008 period (Fig 1). Beam Trawls were conducted for sampling with a speed kept at 2,5-2,7 knots and lasted 30 minutes. The opening of net was 21.6 m with a mesh size of 22 mm. Samples were kept in Formalin.

Fig. 1. Map of the Eastern Mediterranean with locations of sampling stations.

Results and Discussion

A total of eight fish species, four crustaceans and a cephalopod species were found in Finike Seamount (Anaximander Seamounts) (Table 1). Majority of these fish were deep sea fishes. All crustaceans also known as deep sea decapods and P.longirostris and A.foliacea were commercially important species in the eastern Mediterranean Sea. A. veranvi, also a deep sea cephalopod, is a preferable prey of the striped and Risso's dolphins [1]. Mud volcanoes with a methane cold seeps community were reported from this area and this community is unique and quite different from all other known cold seep communities in that location [2]. This fragile ecosystem is under the threat of mainly bottom trawling. In Turgut Reis Ridge, only three fish and three crustacean species were found. All crustacean species were also of commercial importance (Table 1). Turgut Reis Ridge was also important in terms of deep sea fishes and crustaceans. This area is also under the threat of bottom trawling. Our suggestion is to designate this two sensitive seamount areas as high sea marine protected area or sensitive deep sea habitats such as Eratosthenes Seamount which is decided by GFCM recommendation 30/2006/3 that no fishing activities any more [4]. Ichthyofaunal richness is correlated with the intensity of research in the Eastern Mediterranean Sea [3]. More detailed and long term study is needed for the protection of these unique habitats in the Eastern Mediterranean Sea

THE CHRONICLE OF ALIEN SPECIES IN DODECANESE ISLANDS: A PATHWAY OF INTRODUCTION IN EUROPEAN COASTAL WATERS

Maria-Antonietta Pancucci-Papadopoulou¹* and Maria Corsini-Foka¹ ¹ Hellenic Centre for Marine Reasearch - apan@ath.hcmr.gr

Abstract

Alien species introduction was analysed from its starting in one of the hot-spot region of the Mediterranean Sea. Their impact is also discussed.

Keywords: Eastern Mediterranean, Biodiversity, Species Introduction, Aegean Sea

Our attention focuses on the Dodecanese Islands, as it is the closest to the coast of Asia Minor Hellenic area and the easternmost European waters significantly affected by the so called "biological pollution". Of the 192 alien species currently known from Greek Seas [1], 86 (44.8%) occur along the Dodecanese coasts, almost all (84) from warm/tropical waters: 6 by shipping, 3 by unknown vector, 1 via Dardanelles, 3 via Gibraltar and 71 via the Suez Canal (Fig. 1).

Fig. 1. Pathway of introduction

The first two lessepsian migrants were evidenced in Rhodes Island in 1894, the seagrass *Halophila stipulacea* and the macroalga *Hypnea cornuta*. Almost 40 years later (1930's) 3 Indo-Pacific fish species were recorded in the area, followed by other 5 during the 1940's. The first one, *Siganus rivulatus*, rapidly acquired commercial value. Thus, the corridor was open and changes in native communities and fishery activities started. During 1950's the first benthic invertebrate was recorded. A huge increase of alien species has been observed from the beginning of 1980s, after almost a century of "smooth" colonisation (Fig. 2).

Fig. 2. Trend of introduction

It must be noticed that this increase parallels the observed warming of the area, which showed an abrupt shift by the end of 1990's, resulting to more favourable conditions for the establishment of alien species. A strong correlation between alien species entry and climate warming has been detected [2]. During the 1980's the alien biota was increased by 2 polychaetes, 6 planktonic, 3 fish species and 1 gastropod (*Strombus persicus*, 1986), which quickly invaded all sandy bottoms of the Island. From then towards the introduction of alien species in the area assumed the character of invasion, with the addition of 13 new species during the 1990's and 36 from 2001 to 2009! Zoobenthos (38%)

and fish (37%) are the most important groups, followed by phytobenthos (17%) and plankton (phytoplankton 6%, zooplankton 2%). The most evident effects of new species entry can be detected at three different levels: biodiversity, economy and human health. Until now, evidence for endangerment or extinction of native species in the study area has not been detected, although this does not mean that it may not have occurred or may not be occurring. However, the 32 alien fish present (28 of Indo-Pacific and 4 of Atlantic origin), almost all well established, constitute approximately the 10% of the total ichthyofauna diversity [3]. From an economical point of view, few introduced species are locally exploited (S. persicus, S. rivulatus, S.luridus, Sphyraena chrysotaenia, Etrumeus teres) and recent colonizers (Sepioteuthis lessoniana and Upeneus pori) show a rapid increase. Fistularia commersonii, a piscivorous fish abundant and seriously affecting native species, is not appreciated, thus discarded. An example of invasive species provoking damages to biodiversity, economy and human health is the toxic fish Lagocephalus sceleratus, which evidences the huge dimension of the problem worldwide. The gradual tropicalization of the Mediterranean and the higher resistance to natural changes of tropical compared to native species lead us to believe that alien tropical species, now mostly affecting the Eastern basin, will gradually colonize the rest of the Mediterranean.

GROWTH RATES OF EARLY LIFE STAGES OF ENGRAULIS ENCRASICOLUS AND SARDINA PILCHARDUS IN THE ADRIATIC SEA (ITALY)

Monica Panfili¹*, Fortunata Donato¹, Elisabetta Betulla Morello¹ and Enrico Arneri¹

¹ ISMAR-CNR Sez. Pesca Marittima, Largo Fiera della Pesca, 60125 Ancona, Italy - m.panfili@an.ismar.cnr.it

Abstract

Early life stages of anchovy and sardine were collected in the Adriatic Sea during three seasonal surveys carried out between June 2007 and February 2008. Growth rates were estimated by daily increment counts on sagittal otoliths. Age estimates were made on late-larvae specimens, just before the transition from larval to juvenile stage. Growth of these vulnerable stages may be an important factor affecting recruitment success.

Keywords: Adriatic Sea, Pelagic, Larvae, Growth, Fishes

Introduction

Small pelagic fishes, especially anchovy *Engraulis encrasicolus* and sardine *Sardina pilchardus*, are important species in the Adriatic Sea, from both ecological and socio-economic points of views [1]. A major gap in the management of small pelagic fish stocks in the Adriatic Sea as well as in the whole Mediterranean Sea, is the limited knowledge of the basic aspects of early life stages. The stock biomass depends primarily on the strength of recruitment and on the survival/viability of early life stages in these pelagic species may be useful to understand the factors affecting year class strength and subsequent biomass of the adult population, as well as being essential for management purposes.

Materials and Methods

Three seasonal surveys of anchovy and sardine late-larvae were carried out between June 2007 and February 2008 by means of a pelagic trawl (mesh size 5 mm stretched) in two nursery areas along the Adriatic coast (off the Po river and in the Gulf of Manfredonia). In the laboratory, late larvae were measured to the nearest mm below (standard length, SL) and weighed with an accuracy of 0.01 g (TW). Sagittal otoliths preparation and interpretation procedures are described in [2]. The growth rates of sardine and anchovy late larvae were estimated by b^* age (days) where a would be the fish standard length at age 0 (i.e. the estimated length at exogenous feeding when the first increment is laid down) and b is the instantaneous growth rate of juvenile anchovy. Moreover, the allometric length - weight relationships were calculated for both species applying a nonlinear regression: $TW = a^*SL^b$. For anchovy, growth rates (mm·day⁻¹) and SL-TW relationships obtained in the two sampling periods (June and November) were compared, over a common size range (11 - 38 mm SL), by means of Analysis of Covariance (ANCOVA).

Results and Discussion

Anchovy larvae were collected in June 2007 (n = 50) in the Gulf of Manfredonia and in November 2007 (n = 78) off the Po mount. The June sample consisted of a slightly wider size range (SL: 7-38 mm) than in the November sample (SL: 11-40 mm). Sardine late larvae were caught in February 2008 only (n = 78) and SL ranged from to 18 to 35 mm. The relationship between standard length (SL) and age (days), obtained for the two species, are shown in Fig. 1 and 2.

Fig. 1. Age-SL relationship estimated for anchovy late larvae collected in June'07 (triangle) and November'07 (circle)

Fig. 2. Age-SL relationship estimated for sardine late larvae collected in February'08

The relationship SL-TW were described by the following equations: TW = $1.51*10^{-06}SL^{3.43}$, $r^2 = 0.98$ for June anchovy; TW = $7.93*10^{-07}SL^{-3.56}$, $r^2 =$ 0.94 for November anchovy and, TW= $3.81*10^{-07}$ SL $^{3.78}$, $r^2 = 0.84$ for sardine. The instantaneous growth rate estimated for sardine late larvae (0.20 mm day⁻¹) was lower than those estimated for anchovy (0.46 and 0.64 mm·day⁻¹ in June and November, respectively). Length-at-age of anchovy caught in November were significantly higher than those collected in June (F = 20.97; p<0.001) whilst no significant differences were found for growth-in-weight (F = 1.50; p = 0.22). These results obtained for anchovy partially disagree with the general pattern observed in another Adriatic area (Ortona) where the instantaneous growth rate picked in May and decreased in August and November [3]. Seasonal changes in environmental and trophic conditions largely affect instantaneous growth rate, indicating that the environment (e.g. food availability) was more favourable off the Po river mouth. Positive effects of temperature and food on the growth of fish are well documented [4], and in the case of anchovy the higher growth rate in November is probably related to trophic rather than temperature changes.

Abstract

The National Marine Park of Alonnisos in Northern Sporades was the first designated Marine Park in Hellas and is currently the largest marine protected area in Europe (approximately 2.260 Km^2). Aspects of the regional artisanal fishery were examined during the LIFE MOFI program. CPUE values exhibit great seasonal variations. These differences result from the seasonal landings of tuna, albacore and bogue which are being fished in vast quantities. Three distinctive fishing seasons have been identified regarding the target species. The main target species of the artisanal fishery was *B. boops*. *Keywords: Fisheries, Marine Parks, Aegean Sea*

Introduction

During the LIFE MOFI program field work has been conducted in order to accurately measure the actual intensity of seal-fishery interaction aboard local professional artisanal fishing boats in the National Marine Park (N.M.P.) of Alonnisos in Hellas. The purpose of this paper is to describe aspects of synthesis, effort, and seasonality of the artisanal fishery fleet within the area of the national marine park.

Materials and Methods

The work plan included the collection of 15 landings data of coastal fishery vessels per month for a period of two years which started in May 2006 and ended in May 2008. Discards were not included. All the sampling cruises took place in the waters within the park. For the grouping of coastal fishery and the evaluation of target species per month, CPUE values from all gears (kg/vessel/day) per species were used. The non parametric Kruskal-Wallis ANOVA by Ranks test was used to test for differences between monthly CPUE values. Cluster analysis was based on Bray-Curtis similarity indices on thirty species that their frequency of occurrence cumulatively counts for more than 90%. The species, which primarily account for the observed differences between fishing seasons, were defined by SIMPER routine.

Results and Discusion

During the survey, 355 interviews of boat owners were obtained and consist data for landed species. In total, 48 species were of commercial value in the local landings. However, 10 species dominate the catches and these account for 92,1% of the total quantity landed. Of these, 70,7% is represented by 3 species, namely *B. boops* (33,5%), *T. alalunga* (24,2%) and *T. thynnus* (13,2%). Seven species represent 21,3% of the total catches namely *P. elephas* (6,7%), *M. merluccius* (4,3%), *P. pagrus* (3,6%), *Scorpaena sp.* (2,2%), *M. surmuletus* (1,8%), *L. piscatorius* (1,4%), and *P. phycis* (1,1%).

The remaining 38 species consist of 8,1% of the total catches. The total CPUE (kg/day/vessel) from all gears, fluctuated between 11,8 kg/day/vessel in June and 125 kg/day/vessel in December for the period May 2006 – May 2007. For the fishing season June 2007- May 2008 CPUE values fluctuated between 16,8 kg/day/vessel in June and 177 kg/day/vessel in November.

Concerning the total CPUE, for the two fishing periods the non parametric Kruskal-Wallis ANOVA by Ranks test, indicates that there is statistical difference between months for the median CPUE values (H= 90.99 and p = 0.000) for the period 2006-2007. There are also differences for the period 2007-2008 (H= 71.692 and p = 0.000).

Outliers and extreme values were not often recorded for both fishing seasons. When they do these values are associated with the fishing of *T. thynnus* and *T. alalunga* which gives heavy animals and *B. boops* a species that gives large catches. However, lobster and hake fishing were responsible for some outliers. In Alonnisos, however, the daily catches considered to be highly influenced by both environmental and/or biological factors, concerning that the ability of the skippers was the same thought out the year.

Cluster analysis (fig. 1) indicated three groups of fishing seasons. The first fishing season consisted of the autumn months with the addition of December 2007. The second fishing season consisted the winter months of January and February of the years 2006-2007, and the third fishing season spring and summer months of the same years.

Simper analyses indicates a 58,41% average similarity for the first fishing season with *B. boops* (19,9%), *T. alalunga* (19%), *T. thynnus* (13,6%) primarily account for the observed similarity. The second fishing season indicates a 67.97% average similarity. *B. boops* (24%), *L. vulgaris* (14,3%), *S. maena* (13,7%) and *P.pagrus* (13,2%) are mainly responsible for 65,2% of the observed average similarity. The third fishing season indicates a 65,21% average

similarity with P. elephas (10,8%), B. boops (9,7%), P. pagrus (9,6%) and Scorpaena sp. (8,9%).

According to these results for all three fishing season, the main target species was *B. boops.* However important differences appear regarding seasonal differentiations. During the autumn months (Season 1) the fleet is focusing its efforts to the fishing of *T. thynnus* and *T. alalunga*, both seasonal catches in the area. During winter months (Season 2) the fleet is targeting mainly *B. boops.* Other species were considered either as accidental catches or occasionally targeted species by the fleet. During spring and summer months (Season 3) the fleet is diversifying the number of target species shifting on the fishing of more common coastal species in the area.

Such data provides a useful insight to regional fishing practices and contribute to determine conservation strategies and effective management measures that could be implemented for the preservation of the area.

MEGAFAUNAL ASSEMBLAGES IN THE DEEP WATERS OF THE NORTH AEGEAN SEA (HELLAS)

Anastasios Papadopoulos ¹*, Pavlos Vidoris ¹ and Argyris Kalianiotis ¹

¹ Fisheries Research Institute - apapadop@inale.gr

Abstract

The annual summer changes of the megafaunal assemblages from 6 sampling stations in the deep waters (>500m) of north and central Aegean Sea were studied for the period 2003-2006. Geographical differentiations occur both in the composition and species diversity between stations in the north and central part of the Aegean sea. These differences are attributed to the different geographical positions and the general oceanographic and circulation features of the areas. *Keywords: Deep Waters, Aegean Sea, Biodiversity*

Introduction

During the MEDITS program, annual bottom trawl surveys are conducted mainly from late spring to mid summer in the Mediterranean, in depths ranging from 10-800 m, in order to obtain estimates of abundance for a series of target species. However, little attention has been paid to the diversity and abundance of species and their relative assemblages in waters deeper than 500 m. The aim of this work is to describe aspects of the species assemblages and the biodiversity in the deep waters of the north and central Aegean Sea.

Materials and Methods

Samples from 6 stations in the depth zone of 500-800m were collected during the four years period 2003-2006 through MEDITS program. Standard net GOC 73 having a cod end mesh opening of 20mm (stretched) was used. For data analysis, the sampling year was noted as 3 for 2003, 4 for 2004, 5 for 2005 and 6 for 2006. All 6 stattions have depths between 500 and 600 m. Two of the stations (10 & 12) were located in Lemnos basin, one in Skyros basin (30), one between Skyros and Chios basins (28) and two in Chios basins (24 & 25). Catches of fish were identified to species levels for each haul. Cluster analysis was performed with PRIMER routine [1] using data transformed with Bray–Curtis similarity index. The differences were based on ANOSIM and SIMPER respectively. Biodiversity index was calculated using Shannon index.

Results

During the four years of sampling in these 6 stations, 3025 individuals were fished which belonged to 93 species. Of these 69 were fishes, 12 were cephalopods and 12 were crustaceans. Non-metric multidimensional scaling (MDS) ordination indicates that the stations were grouped based on their geographical position (Fig.1).

Statistical analysis indicated two groups that differed among them. Stations 10, 12, 28 and 30 constitute one (North) group and stations 24 and 25 the other (Central) group (ANOSIM: R global >0,75, p=0,001).

Simper analysis showed that five species are mainly responsible for the grouping of the North stations and these are *L. crocodilus, P. martia, N. sclerorhynchus, T. scabrous, A. hemigymnus, and L. dofleini* (Total contribution 72,88%).

Eleven species are responsible for the grouping of the Central group stations, *C. agassizi, C. caelorhincus, H. italicus, L. dofleini, P. longirostris, M. punctatum, H. mediterraneus, T. sagittatus, P. blennoides, P. cataphractum, N. norvegicus* (Total contribution 70,52%).

The average dissimilarity between the two groups is 78,78% with 23 species contributing 70,34% to that differentiation *C. agassizi, C. caelorhicus, T. scabrus, L. crocodilus P. martia B. glaciale H. italicus L. dofleini P. longirostris M. punctatum P. heterocarpus G. argenteus N. sclerorhynchus A. hemigymnus H. mediterraneus P. cataphractum P. sivado T. sagittatus S. veranyi P. blennoides N. norvegicus D. metopoclampus H. dactylopterus, G. melastomus.* The Shannon Winner diversity index was calculated based on the abundance of each species for each one of the stations during the four sampling periods. Values of the index for the North group fluctuated between 1,640 and 2,839 and between 2,821 and 3,420 for the Central group during the four years of sampling. The fluctuation of the index values indicates a differentiation in the biodiversity both between the groups as well as within the groups during the years of sampling.

These differences in assemblages and diversity may be attributed to the characteristics of the deep water that has been accumulated in each of the North–Central Aegean basins and vary according to the different geographical positions of each basin with respect to the formation sites and the general circulation features of the Aegean [2]. The same authors suggest that Lemnos and Skyros basins show almost identical behaviour.

The water volume below 500 m is almost the same for these two basins, they

probably share the same physical characteristics and that is why they support the same species assemblages.

On the other hand, Chios basin is by far the most prone to change. This must be attributed to its position. The major water exchange between the northern and southern parts of the Aegean take place over the Chios basin. Dense waters of high salinity and low temperature that filled the deepest parts of Chios basin, alter their characteristics through vertical diffusion as they mix with warmer and less saline intermediate waters [2].

This phenomenon over the Chios basin probably creates an environment that can favour a larger number of species with more diverse ecological attributes and that explains the higher values of Shannon diversity index. In summary, since assemblages in the north part of the Aegean Sea were always less diverse than the assemblages in the central part of the Aegean sea we assume that the composition of the communities reflect the ecological conditions at the two parts of the Aegean.

NEW DATA ABOUT POLYCHAETA COMMUNITIES FROM THE ST. GEORGE–VADU, ROMANIAN BLACK SEA LITTORAL ZONE

Gabriela Paraschiv 1*

¹ "Ovidius" University Constanza, Romania - gm_paraschiv@yahoo.com

Abstract

Based on a number of 449 collected samples, from a 0-28m-depth interval, from the St. George-Vadu Romanian segment of the Black Sea littoral, the main types of sedimentary habitats were identified and the characteristic Polychaeta associations. Dominant are the clay habitats, occasionally mixed with silt, in which populations of the following species can be found: *Melinna palmata* (from a depth of approx. 10m) *Euclymene collaris* and *Heteromastus filiformis* (from a depth of approx. 4m). The 1970s bibliography cites in these habitats, the *Nephthys hombergii* silt enclave.

Keywords: Black Sea, Polychaeta, Sediments

Introduction

The littoral segment St. George-Vadu represents an area of interest as it is directly influenced by the Danube and it includes dynamic sedimentary and erosion processes. The benthal communities are structured based on their affinities for one type of sedimentary habitat or another and based on the particular conditions of the life environment (hydrodynamic water mass, food resources). The Polychaeta group is well represented on all benthic biotopes on the NW Black Sea shelf, from the shallow water bottoms to the lower limit of benthic life (for Black Sea - the periazoic belt). This study was possible through the research program of the Project CERES 4-174/November 2004: The integrated geophysical-geoecological investigation of the St.George-Vadu littoral sector", accomplished by us in collaboration with INCD–GEOECOMAR, Bucharest.

Material and Methods

The quantitative samples collection started with August 2005 and 2006, at depth intervals of 0-28m, by means of Van Veen bodengreifer devices (surface 18x22cm). Based on the 449 quantitative samples, collected randomly, Polychaeta species were identified and a database set up. The ecological indexes for dominance and frequencies were calculated for different types of habitats. The granulometric analysis for fraction determination was realized according to the standard sedimentological method and the limits of the granulometric categories are: the sand/silt limit-0.063mm and the silt/clay limit-0.04mm (Wentworth method).

Results and Discussion

The structure of polychetes community from different habitats, after some authors it is considered to be an instrument that characterized local particularities linked to the benthic sub-layer habitats while other authors considered that the depth and the dynamic of water masses influenced this structure on a much larger scale than other factors. Keeping in mind the synergic action of these factors (benthic sub-layers and bathymetric) we have followed the structure of the Polychaeta community after particulars habitats from our research area: the first, in front of Danube Delta (St. George branch-Sacalin), second Sacalin Island-Portita and third Portita-Vadu. The littoral segment St. George-Vadu is characterized by an almost continuous disposition of the sediments habitats for the studied depth interval (0-28m). Still, various types of habitats are signaled, according to the dominant granulometric fraction (sand, silt, clay). Nearby the flowing mouth of the Danube/St, George branch, the benthal domain is dominated by the silt/clay habitats starting with the shallow zones (down to 25m). These compacted sediments at the basis of the sediment column (down to 20-25cm deep) display at the surface a slightly fluid layer with a significant percentage of detritus (particulate organic matter). This type of habitat was also found further south (Portita and Vadu) and in the sheltered area between shore and Sacalin Island (depths of over 10m). The list we drew up on the basis of the taken samples comprises a 28 Polychaeta species, 20 of which belong to the Palpata group (50% Spionidae and 25% Phyllodocidae) and the rest belong to the Scolecidae; a first analysis of this community indicates the detritivorous and suspensivorous as dominant. Scolecidae dominates the community of Polychaeta populations from clay substratum (8 species) from which 6 are Capitelidae: Capitella capitata (Fabr.), Capitella minima (Langerh.), Capitellides giardi (Mesnil.), (Langerh.), Heteromastus filiformis (Clap.), Capitomastus minimus Notomastus lineatus (Clap.). In the littoral sector between Sacalin Island and Portita, affected by a strong littoral current, the benthal domain (depths between 4 and 25-28 m) is dominated by mixed sediments - type NISIAR, while the Polychaeta community is dominated by Phyllodocidae (among which, Nephthys hombergii and the Nereidae species: Nenthes succinea or

Hediste diversicolor. The Prisor-Vadu sector low depth shore (0-5m) is characterized by sandy sediments, that era generally compacted; the Polychaeta community is relatively poor (populated only by 5 species, Spionidae being dominant).

Conclusion

The qualitative and quantitative analysis of the polychetes communities reveal that important changes have occurred in the community in the last decades and we cannot help observing that the changes have been brought about by the proliferation of sedentary, detritivorous and/or deposit feeding species on the one hand and the reduction in predatory forms on the other hand. In this research area, St. George - Vadu littoral segment, the benthic zoocoenosis suffered an important restructuration processes with the naturalization of the newly-penetrated bivalve Mya arenaria, and with the increase in the number of dams in the hydrographic basin of the Danube, which also affected the Polychaeta populations. In the 1970s, the Polychaeta community in the Delta Danube front was dominated by the species Nephthys hombergii - "Nephthys sediments enclave", [1]. The studies accomplished in the 1980s [2], [3], [4] signaled the expansion tendency of the sedimentary habitats with Melina palmate towards the shore, a tendency also confirmed by our studies. South to Portita, in the infralittoral layer corresponding to 3-6m depth interval, a biocoenosis was cited (with fine sands) in which Spio filicornis was dominant. Our studies of the sandy sediments show that the population of Spio is limited to a narrow strip parallel to the shore, in the depth interval 1-4m. The sedimentary substratum with mixed sandy, silt and clay from south to Portita, the Euclymene collaris and Heteromastus filiformis populations registered a extension from depths lower then 10m in the `70 to the depth 4-6m in present.

Abstract

The study of the benthic foraminifera assemblages in Thermaikos gulf (N. Aegean Sea) revealed the presence of 34 genera. The most abundant were *Ammonia*, *Quinqueloculina* and *Elphidium* which contributed to the 90% of the total 3,800 individuals. Their presence was particularly notable near the airport of Thessaloniki, where construction has disturbed the sediment and allowed the profusion of opportunistic species, though further investigation is required to confirm this assumption. *Keywords: Aegean Sea, Foraminifera*

Introduction

Foraminifera are the most abundant protozoa in the marine ecosystems and they play an important role in global geochemical cycles of inorganic and organic compounds [1], [2]. Due to their sensitivity to pollutants and the subsequent modification of their assemblages, they have been widely used in studies as pollution-indicators over the last decades [3]. In the present study, the composition of the benthic foraminifera communities is recorded for the first time in Thermaikos Gulf (N. Aegean Sea, Greece), which is heavily influenced by urban and construction development. This study was part of a research project (Operational Programme for Fisheries Sector 2000-2006).

Tab. 1. List of foraminifera genera identified in Themaikos gulf (N=number of individuals, Am=mean abundance, Dmp=Partial mean dominance, P=number of samples in which genus was found, F=frequency of genus in the total of samples)

	Eoraminifera genera	N	Am	Dmp	Р	F
1	Adelosina	122	20,33	0.03	3	0.50

Material and Methods

Six sediment cores (4 cm diameter) were collected seasonally (Autumn 2007 – Spring 2008) from 3 different sites at the inner Thermaikos Gulf [St1: Paliomana, (N 40°36,332' E 22°52,816'), St2: Airport (40°31,812' E 22°

57,740') and St3: Karabournaki (N 40° 35,001' E 22° 55,563')], at depths from 4 to 8 m. Overall, 3,800 foraminifera individuals were identified, including dead ones, which comprised about 80% of the total number. The dead assemblages were also considered, as sampling took place biannually and, therefore, the thorough study of the short life and reproduction cycles of these protozoa was hindered [4]. All individuals were identified at genus level, with the exception of the most abundant, which was *Ammonia beccarii* (Linné). Kruskal-Wallis and Fisher's LSD tests were employed to examine differences in abundance between the three stations [5].

Results and Discussion

Overall, 32 foraminifera genera were identified from 3,800 individuals; two additional genera remained unidentified. The most abundant was Ammonia, represented by A. beccarii, which made up for the 64% of the total number of individuals. Another two genera, Ouingeloculing and Elphidium showed high frequency in the samples. These three genera contributed up to 90% of the total number (Table 1). In general, the most frequent genera in this study (>50%) are also very common in other parts of the Aegean Sea [6]. The Kruskal-Wallis test (22.81, p<0.05) and Fisher LSD showed that there is a significant difference between the abundance of foraminifera at St2 and the other two stations. This station is near the Airport of Thessaloniki where large reconstruction has been taken place and the sediment disturbance is significant. Ammonia beccarii, which is an opportunistic and pollutant tolerant species [1], [2], showed its largest abundance at this station, as did the other two abundant genera, Quinqeloculina and Elphidium. However, in order to utilize foraminifera as indicators of disturbance in the marine environment further investigation of their assemblages, at structural and functional level, is required [2].

FISHERY ECOSYSTEM INDICATORS AND DYNAMICS IN THE MEDITERRANEAN FOR 1970-2005

Maria grazia Pennino 1* and Jose maria Bellido 1

¹ Instituto Español de Oceanografía. Centro Oceanográfico de Murcia - grazia.pennino@mu.ieo.es

Abstract

Though concerns about sustainability has been raised globally and ecosystem-based approaches have been proposed to manage fisheries, concepts such as "ecosystem health" and "ecosystem sustainability" are difficult to translate into operational objectives. The Large Marine Ecosystem approach can bring some light to this purpose, with the development of new ecosystem indicators to facilitate the understanding of the dynamics of the ecosystem. The "Mean Trophic Level" (MTL), the "Fishing Is Balanced" index (FIB), Pelagic/Demersal ratio (P/D) and the multispecies index of variability (SSD) are some of such indicators. These indices were utilised to examine the dynamics of the entire Mediterranean fishery ecosystem by analyzing the FAO database of fisheries landings from 1970 to 2005.

Keywords: Fisheries, Food Webs

Introduction and Methods

The present study aims to implement a LME approach in the Mediterranean Sea, that is one of the 64 Large Marine Ecosystems already identified [1]. The objective is to examine the Mediterranean fishery ecosystem in its whole in order to obtain an integrated insight of environmental and fishery issues. A priority to develop these new management strategies is to analize the dynamics and the changes occurring in the food chain over the time in the ecosystem. Therefore, there is a need for predictive indicators[2], which can be easily parameterised using easily accessible statistics [3]while communicating with a single number a variety of complex processes occurring within an ecosystem [4], such as those derived from the trophic level [5]. The study of MTL series of landings can describe the stages of exploitation of resources and analyze the state of the ecosystem relative to past periods for which there is no other data available except the amount of landings from fish markets [6]. In particular, according with others authors [7], in marine ecosystems, it would be possible to use the MTL of landings as an index of sustainability of the level of exploitation of fish resources and to analysis the phenomenon of the "Fishing Down the marine Food Webs" (FDFW) [6]. This is a gradual transition in landings from piscivorous, long-lived and high trophic level species to short-lived and low trophic level species as planktivorous pelagic fish and crustaceans and occurs because the species most susceptible to collapse are those of greater size with long life cycles, once these stocks will deplete, exploitation shall be directed toward smaller size species with a faster growth rate, and thus the mean trophic level of landings decreased [8]. We aim to examine the hypothesis of "FDFW" and changes in the Mediterranean ecosystem, analyzing FAO fisheries catches by 251 species from 1970 to 2005. The only analysis of the catch may not be sufficient to show the changes of the fishery ecosystem, but was accompanied by indicators such as: the Mean Trophic Level of landings (MTL), used to assess the effects of fishing activities at a ecosystem level, the "Fishing is Balanced" index (FIB), which allows to assess the stages of expansion or contraction of fishing pressure and bearing capacity exploited ecosystem [9], the ratio between pelagic and demersal organisms landed (P/D) which should provide information on the increase of nutrients in the basin and the multispecies index of variability (SSD) that show changes in the multispecies landings.

Results and Discussion

Mediterranean landings have increased from 300.000 in 1970 to 700.000 tonnes in 2005 with associated decrease of the MTL. In quantity terms, the proportion of the total marine fish landings which is accounted for by pelagic fish has risen from about 50% in 1970 to over 60% in 2005. The progression is remarkably sustained, possibly reflecting a shift in the fishery ecosystem. FIB index shows a negative trend in areas where landings and MTL decreases together, and a positive trends where there is increased fishing effort. The SSD index highlights that the abrupt increase in landings is accompained with major shifts in exploitation of target species. The P/D index shows a positive trend for all the years and in all divisions of the Mediterranean suggesting a clear predominance of pelagic on demersal fishes. Our analysis has revealed numerous ecosystem-level effects of fishing in marine ecosystems. We conclude that it is possible to conduct an innovative ecosystem assessment based on fishing resources in a system such as the Mediterranean Sea, characterized by high complexity and rather often low availability of information.

FIRST RESULTS ON THE MATURITY OF THE LESSEPSIAN MIGRANT *LAGOCEPHALUS SCELERATUS* (GMELIN 1789) IN THE EASTERN MEDITERRANEAN SEA

Panagiota Peristeraki ¹*, George Lazarakis ¹ and George Tserpes ¹ ¹ Hellenic Center for Marine Research - notap@her.hcmr.gr

Abstract

Analysis of the gonadosomatic index (GSI) of 94 specimens of the lessepsian migrant *Lagocephalus sceleratus*, recently invated to the Mediterranean Sea, suggest that reproduction of the species in the Mediterranean occurs in summer. GSI values start increasing at a total length of about 30 cm.

Keywords: Reproduction, Eastern Mediterranean, Suez Canal

Introduction. The Lessepsian migrant *Lagocephalus sceleratus* (Gmelin, 1789), also known as silverstripe blaasop, is an Indo-Pacific originated pufferfish of the family Tetraodontidae. The species has been recently introduced in the Mediterranean Sea through the Suez Canal [1, 2, 3] and has established populations in the eastern Mediterranean [4, 5]. *L. sceleratus* maybe a source of food poisoning with a high associated risk of mortality, as it commonly contains tetrodotoxin (TTX). The toxicity of the fish specimens inhabiting the E. Mediterranean has been also confirmed by recent studies [6, 7].

Materials & Methods. In the present study monthly data on size and maturity for 94 samples of *L. sceleratus*, have been analysed. Generalized additive model techniques [8] were used to analyze variations in gonadosomatic index (GSI) and the relative importance of total length (TL) and month of capture, in explaining those variations. The choice of the most appropriate link function and error distribution was made on the basis of residual plots. A Gamma error structure model accompanied by a log-link function was found to be the most appropriate for the analysis of the data. Model fitting was accomplished by means of the "mgcv" package [9] under the R language environment [10].

Fig. 1. GAM derived effects of total length (TL) and month on gonadosomatic index (GSI). Each plot represents the contribution of the corresponding variable to the fitted predictor. The fitted values are adjusted to average zero and the broken lines indicate two standard errors. The relative density of data points is shown by the "rug" on the x-axis

Results & Discussion. Analysis of deviance demonstrated that the effects of both the examined variables were highly significant (p<0.01). Plots of the standardized effects of the variables indicated that GSI starts increasing at a TL of about 30cm and reaches its maximum value around middle summer (Fig. 1). Those findings suggest that reproduction of the species in the Mediterranean occurs in summer

NOTE ON HISTORICAL AND PRESENT EXPLOITATION OF *CORALLIUM RUBRUM* (LINNEO, 1758) IN THE CENTRAL WESTERN MEDITERRANEAN

P. Pesci¹, R. Cannas¹, M. Follesa^{1*}, C. Pedoni¹ and A. Cau¹

¹ Department of Animal Biology and Ecology, University of Cagliari - follesac@unica.it

Abstract

The analyses of the landings and CPUE data from 1978 to 2005 for red coral in Sardinian seas (Central Western Mediterranean) were made. A statistical decrease in the landings can be observed. This reduction resulted very close to the decrease in the number of boats harvesting red coral. CPUE analysis at last allow to know that the average yearly amount of red coral landings by diver resulted steady with time.

Keywords: Cnidaria, Stock Assessment, Time Series, Western Mediterranean

Introduction

Red coral has been greatly exploited all over the Mediterranean Sea. The great exploitation of red coral made it a resource in danger according to many authors [1, 2, 3, 4, 5, 6]. Sardinia has a long history of red coral harvesting which led the adoption of a number of laws to manage this important resource. The most important rule established in 1989 in Sardinia (LR 30 maggio 1989, n. 23) banned the use of any towed gear to harvest red coral and imposed that only professional divers are allowed to pick up the coral manually. The aim of this work is then to evaluate if this resource in Sardinia has suffered overexploitation between 1978 and 2005.

Materials and Methods

The historical state of exploitation of the *Corallium rubrum* resource in Sardinian seas has been evaluated through the analysis of the data from FAO fisheries statistics. Yearly landings data (kg) from 1978 to 2005 were analyzed to find possible trends. Moreover, for the same period the analysis of the Catches per Unit of Effort (CPUE) has been made. The unit of effort here considered is the number of boats in which the "ingegno" was used for the period 1978-1989. The unit of effort in the following years is the number of divers manually harvesting the red coral. CPUE then represents the yearly mean of the red coral fished for unit of effort. Statistical trends were evaluated with the Spearman rank test [7].

Results and Discussion

FAO sources supply data for the red coral Sardinian landings from 1978 to 2005. A sharp decrease can be observed (Fig. 1). Spearman test indicates a statistically significant decreasing trend (P-value<<0.01). In fact from 1978 the data fall from more than 45000 kg to less than 5000 kg in 1990. After this 12 years decrease, however, a low steady state seems to be present (average of about 206 kg in the period 1989-2005).

Fig. 1. FAO landings data of *Corallium rubrum* for the sea around Sardinia (1978-2005)

This data alone however cannot be used as a sure assessment of a resource in danger. In fact if the number of boats used to harvest red coral is considered, a marked decrease of them can be noted. So the fishing effort has changed too with time and the decrease in the landed red coral does not necessarily indicate a decrease in its production. The CPUE can then be used to evaluate if the average of red coral landed by boats (or diver) has changed over time (Fig. 2).

Fig. 2. CPUE (kg) of Corallium rubrum in the seas around Sardinia (1978-2005)

From 1978 to 1988 both the ingegno and the manually harvesting were made. The latter became the only way of pick up coral in Sardinia since 1989. A certain decrease in the CPUE relative to the boats can be observed, however, the data of the CPUE by diver show a steady state (mean value = 184 kg, P-value>0.05). The average amount of red coral landed by diver seems not to be decreased with time in the analysed period. These analyses show that the amount of red coral by diver stayed constant with time without decreasing as should be the case if an overexploitation of the resource is present. The regional laws seem to work in a good way for prevent the overexploitation of this resource in Sardinia.

Abstract

Data from boat seine fishery in Greek waters have been analyzed to examine the effects of the time of fishing (before and after sunrise) and of the area on the catches. Data were collected on a monthly basis during the fishing period of the gear (10/2008-03/2009) in 14 different areas. The catch of *Spicara smaris*, the main target species of the gear, during hauls that took place before sunrise was 16%, whereas after sunrise was 48% of the total catch by weight. The catch of *Boops boops* and of all the "other species" before sunrise was 20% and 64% and after sunrise was 20% and 32%, respectively. *Keywords: Fisheries, Ionian Sea, Aegean Sea*

Introduction

Boat seine is a traditional fishing gear which operates in the Greek waters. Now days, there are about 475 vessels with license, 400 of which are active [1]. The fleet is composed of rather small and old vessels. In 2008, the average age of the fleet was 44 years old and 84% of the vessels were smaller than 13 m. The main target species of the fishery are *Spicara smaris*, *Boops boops*, and *Sardina pilchardus* [1, 2]. According to the Greek legislation, fishing is allowed only during daytime, extending one hour before sunrise until one hour after sunset. Fish behavior differs on a daily cycle and consequently the quantity and the composition of the catch is affected by the time of fishing [3]. In this study the catch composition of boat seine fishery before and after surise in Greece was examined in order to investigate if differences in the catch due to the time of fishing could be used for managerial purposes.

Material and Methods

From October 2008 to March 2009, observers accompanied professional boat seine fishing vessels on a monthly basis in 14 areas around Greece. The observers without interfering with the fishing operations recorded the number, the weight and measured the lengths of all the species. In total, 239 hauls were sampled, 25 of them took place before and 214 after sunrise. In all areas, 30 different vessels were sampled. The contribution of *S. smaris*, *B. boops* and of all the "other species" in the total catch by number and by weight, before and after sunrise, was estimated combining all the areas. For the areas with observations before and after sunrise, the composition of the catch by weight was estimated as well. As "before sunrise hauls" were considered these hauls when more than 50% of the tow took place before sunrise.

Results and Discussion

A total of 490,990 individuals (466,732 after and 24,258 before sunrise) were caught, weighting 7,323 Kg (6,800 Kg after and 523 Kg before sunrise).The proportion of *S. smaris* in the catch of the hauls before sunrise was 16.4% (by weight) and 28.1% (by number), of *B. boops* was 19.8% (by weight) and 13.7% (by number) and of the "other species" 63.8% (by weight) and 58.2% (by number) (Fig. 1). During the after sunrise hauls, the proportion of *S. smaris* was 48.1% (by weight) and 64.7% (by number), of *B. boops* 20.0% (by weight) and 12.9% (by number) and of the "other species" 31.8% (by weight) and 22.4% (by number).

The contribution of the "other species" to the total catch of the before sunrise hauls was higher than after sunrise, in all areas except Leykada (Fig. 2). In the latter, one of the main target species is *S. pilchardus* which was caught during the day. The contribution of *S. smaris* was higher in the after sunrise hauls in all areas except Leyvos. *B. boops* catch was higher in three areas before sunrise and

in the other three after sunrise.

Fig. 2. Boat seine catch composition before and after sunrise by weight per area.

Boat seine fishery operates in coastal waters (maximum distance from the coast about 800 m according to the Greek legislation) using a mesh size of 16 mm in the cod-end, which is not size selective. However, each haul, takes place in a restricted area and only above appropriate bottoms. Consequently, the gear could operate in a species selective way in order to reduce the fishing mortality on the stocks of species like *Mullus spp., Pagellus spp., Diplodus spp.* According to this study, restriction of the time of fishing, during only daytime, could result in an important reduction on the catch of the "other species" (32% by weight, 36% by number, and between 18% and 38% per area by weight).

Acknowledgements

This work is part of the research project "Assessment of the impact of boat seine fishery in the fisheries resources", financed by the Greek Ministry of Rural Development and Food. The authors thanks to the masters and the crew of the fishing vessels around Greece who participated in the project.

Abstract

One of the main issues related to net fisheries is that potentially commercial fish are discarded because they are partly or totally destroyed by scavengers while they remain on the nets in the sea. During trammel net selectivity experiments in Greece in summer 2004, observations on the condition of the fish after retrieval of the nets have been made. A qualitative "scale of damaged fish" (SDF) was created in order to record the condition of the fish according to 5 gradients: from 1: fully destroyed to 5: without any damage. The results related to hake and common pandora are presented. *Keywords: Ionian Sea, Fisheries*

Introduction

The Greek fishing fleet is characterized by an enormous number of small-scale coastal vessels, with high diversification of gears and techniques. Trammel nets are one of the most commonly fishing gears used by small scale fisheries along the Greek coasts. However, there are only sporadic attempts to study these fisheries [1], [2], [3]. In several métiers, the extended deployment (in time) of the nets in the water, the way of the fish capture and other characteristics of each haul (such as the depth), can lead to death of the fish in the nets. The fish caught, attract scavengers that feed on them and thus destroy the catch, causing subsequent discarding and uncounted mortality. The aim of this work is to study the discarding practice of trammel nets and introduce a scale of damaged fish.

Material and Methods

Experimental fishing trials with trammel nets of four different mesh size combinations took place in the Ionian Sea (Greece) along the west coasts of Peloponnissos, during June and July 2004. The mesh sizes used for the inner net were: 44, 56, 72 and 80 mm. All nets were made up of sheets of the four mesh sizes joined end to end to make up a fleet and arranged in random order. For each mesh size, a net of 500 m was used. A total of 76 sets of nets were followed. The nets were set during sunrise and retrieved in the following morning. The soaking time presented a mean value of 21 h (ranged from 12 to 24 h) while for two hauls the soaking time was 46 h. The number of specimens and the total weight per species were recorded and for each fish the total length was measured to the nearest mm.

One of the main problems of net fishery is that an important part of the catch (fish of commercial size) is destroyed by polychaetes or other marine organisms while the net remains into the sea. For the evaluation of the physical damages, the following "scale of damaged fish" (Table 1), was created in order to record the causes and the severity of the damages incurred, in relation to commerciality.

Tab. 1. Description of the Scale of Damaged Fish (SDF)

Scale	Description of damages	Commerciality	
5	No damages	Always	
4	Few damages, usually eyes and gills are eaten. Some small damages in the flesh caused by bites from cephalopods or other fish	Usually	
3	Medium extended damages, eyes, gills and part of the abdominal area eaten. Same damages in the flesh due to bites from cephalopods or other fish	No, private consumption or discarded	
2	Extended damages, eyes, gills and part or the whole of the abdominal area eaten. Severe damages in the flesh caused by bites from cephalopods or other fish	No	
1	Fully destroyed, only skin and skeleton remain. In many cases, species identification is difficult	No	

Results and Discussion

A total of 2.782 individuals were caught belonging to 76 species and weighting 315 Kg. Discarded fish composed 29% by number and 24% by weight of the catch. Discards were species with no commercial value, or commercial species, either because they were small sized or because their physical appearance (damages by other fish, polychaetes, cephalopods or on the winch during hauling) was appalling and they had no commercial value.

According to the scale presented above for the description of fish condition, 4.6, 5.9, 8.6, 8.1 and 72.7% of all the fish caught were classified in the gradients: 1,

2, 3, 4 and 5, respectively. The organisms that cause the damages differ and act in many ways; i.e polychaetes destroy first the eyes and the gills, then enter through the branchial opening and destroy the abdominal region, whereas the cephalopods remove the outer parts of the flesh.

Although detailed data per species are not presented here, significant quantities of commercial species are discarding due to damages caused by other species: 45% of common dentex, 40% of common pandora, 36% of common two-banded seabream, 30% of brown meagre, 20% of hake, 29% of common seabream, (upublished data). The differences that were observed between the species could be attributed to the resistance of the fish on the net, the time of capture, the visibility of the fish inside the water, etc.

The reason of discarding of the commercial species is almost always not the size but the condition of fish. Given that damages begin after the fish has died on the net, the soaking time is an important factor. A logistic regression analysis with the soaking time as single predictor reveals that this factor is significant in determining the discard probability (p-value=0.01, estimate=0.04, SE=0.01). The discarded common pandora and hake (Fig. 1) were well above the minimum landing size (MLS) and thus potentially marketable.

Fig. 1. A) Common pandora and B) hake landings and discards length composition from trammel nets, in Ionian Sea, June-July 2004

By cutting down the time of operation, the number of discards is expected to reduce. In Portugal, the length of time trammel nets and gill nets are permitted to remain in the water is limited in order to reduce spoilage and subsequent discarding of commercial species [4].

ASPECTS OF THE REPRODUCTIVE BIOLOGY OF THE SQUAT LOBSTER *MUNIDA RUTLLANTI* ZARIQUIEY ALVAREZ, 1952 (DECAPODA: GALATHEIDAE) IN THE ADRIATIC SEA

Mirela Petric ¹*, Josipa Ferri ¹ and Ivona Mladineo ² ¹ University of Split, Center of Marine Studies - mirela.petric@unist.hr

² Institute of Oceanography and Fisheries

Abstract

Reproductive biology of *Munida rutllanti* was investigated for the first time in the Adriatic Sea. Carapace length of males ranged from 10.5 to 21.5 mm, while in females it ranged from 11.2 to 19.4 mm. Sexual dimorphism was observed in seven morphometric characters. Ovigerous females were first observed in summer and later in autumn with higher frequency. Realized fecundity showed wide variation (273-3250 eggs) and positive correlation between the brood and female size. *Keywords: Decapoda, Reproduction, Adriatic Sea*

Introduction

Munida rutllanti Zariquiey Alvarez, 1952 is an Atlanto-Mediterranean species occurring from the nortwestern coast of Spain to Morocco and in the entire Mediterranean basin where is mostly found on muddy and shell-sand grounds of the continental shelf and upper slope. It constitutes well-established populations in the western Mediterranean and recently it has been more frequently reported from its eastern part. Due to its progressive spread, it is not surprising that this species has been reported in the Adriatic only after 2000 [1]. Despite the fact that *M. rutllanti* has been studied in other Mediterranean areas [2,3], we describe for the first time some biological parameters of this species from the eastern Adriatic.

Materials and Methods

The investigation was carried out in the eastern part of the central Adriatic Sea from May 2008 to April 2009 and total of 701 *Munida rutllanti* specimens were obtained. Samples were collected at depths from 110 to 200 m with commercial bottom trawl. Ovigerous condition of females was determined by presence or absence of eggs on pleopods. Ovigerous females were classified as 'non-eyed' (embryo without ocular pigment) and 'eyed' (embryo with ocular pigment) according to the stage of embryonic development. Fecundity was regarded as realized reproduction, which represents the number of eggs per clutch and was expressed by the regression equation of log-transformed number of eggs on carapace length at 'non-eyed' eggs of ovigerous females. To determine egg diameter, a subsample of 28 ovigerous females carrying eggs at the same stage of embryonic development was selected. Since the change in the allometry of cheliped growth represents the acquisition of secondary sexual characters, the same was used to determine size at morphometric maturity of males.

Results and Discussion

Carapace length (CL) of Munida rutllanti males ranged from 10.5 to 21.5 mm, while in females it ranged from 11.2 to 19.4 mm (Fig.1). Mean values of total length (TL), total carapace length (TCL), anterior carapace width (ACW), abdomen width (AW), cheliped length (ChL), propod length of cheliped (LCh) and propod width of cheliped (ACh) of males were statistically larger than of females (*t*-test: $t_{0.05} = 12.23$, p = 0.0005; $t_{0.05} = 6.01$, p = 0.0005; $t_{0.05} = 6.01$ 5.10, p = 0.0005; $t_{0.05} = 2.65$, p = 0.008; $t_{0.05} = 13.38$, p = 0.0005; $t_{0.05} = 13.38$ 13.28, p = 0.0005; $t_{0.05} = 14.39$, p = 0.0005, respectively). This evident sexual dimorphism was previously reported for this species and other members of Munida genus [4]. Throughout the whole year, ovigerous females were first observed during summer months and were represented by 27.45% among the females, of which 76.19% were carrying 'non-eyed' embryos. In autumn, 48.95% of total females were ovigerous and most of them also brood 'non-eyed' embryos. The smallest ovigerous female measured 11.3 mm carapace length which suggest 11 mm CL as the size at physiological maturity of females. Present results indicate a wide variation in realized fecundity from 273 to 3250 eggs (average 1182 eggs) with egg number increasing with female CL. The regression analysis of carapace length versus number of eggs is given with equation: $\log F = 0.718 + 0.1478 \log CL$, (R² = 0.507). The average fecundity value and observed egg diameter (0.28 - 0.46 mm) in this study are somewhat lower when compare to other Munida species [4,5]. Cheliped growth was negatively allometric for immature males and positively allometric for mature males with an inflexion point at a CL value of 13.9 mm which represents the morphological size at maturity. In this study, with 74.41% of males being morphologically mature, we assumed that they will ensure the next offspring production. Finally, there is an indication of an annual and seasonal reproductive cycle with distinct summer/autumn breeding period for M. rutllanti in the Adriatic Sea, however, only a further study based on monthly samples throughout at least a two-year period will provide a better understanding of seasonality of the reproductive cycle.

Abstract

Specimens of *Aristaeomorpha foliacea* caught in the Southern Tyrrhenian Sea were examined in order to validate the macroscopic scale used in MEDITS project to determine the ovarian maturity of this commercial shrimp. The scale was tested against a microscopic examination of ovarian samples.

Keywords: Crustacea, Decapoda, Reproduction, Tyrrhenian Se

INTRODUCTION The red shrimp *Aristaeomorpha foliacea* (Risso, 1826) is an economically important resource of the Mediterranean Sea, mainly found between 300 and 700 m depth. Studies on reproductive biology of this shrimp are usually based upon macroscopic observation of gonads [1,2,3]. The present work attempts to validate the macroscopic scale for maturity staging of *A. foliacea* currently used in MEDITS project [4] by histological examination of ovarian tissue.

MATERIAL AND METHODS Shrimps were caught by commercial trawlers in the Southern Tyrrhenian Sea, at a depth of 600 metres, between January and July 2009. Ovaries (n = 50) from formalin fixed specimens were dissected in the laboratory, and macroscopically staged for maturity, according to MEDITS scale, as follows: 1, immature; 2a, virgin developing; 2b, recovering; 2c, maturing; 2d, mature; 2e, resting adult. Ovarian samples were processed for histology and observed under the light microscope.

RESULTS AND DISCUSSION Histological analysis allowed to distinguish 5 types of cells: oogonia, OO (<10±0.11 µm), early primary oocytes, EPO (15-25 µm), late primary oocytes, LPO (25-85 µm), early vitellogenic oocytes, EVO (90-300 µm), and late vitellogenic oocytes, LVO (>300 µm). Stage 1 ovaries contained mainly oogonia and early primary oocytes, together with some late primary oocytes. Both 2a and 2b ovaries (Fig.1) contained oogonia and early primary oocytes in a germinative zone, as well as late primary oocytes, arranged in tubules, in a maturative zone. Stage 2c ovaries (Fig. 2A) contained both early and late vitellogenic oocvtes, besides EPO and LPO. Stage 2d ovaries were microscopically similar to 2c, except for one specimen, in which oocytes were found at a very advanced vitellogenic stage, with no nuclei, and a typical convoluted perivitelline space along the cell membrane (Fig. 2B), resembling the "cortical rods" described by Nazari et al. (2007) [5] in Farfantepenaeus paulensis, suggesting imminent spawning. No stage 2e individuals were found during the sampling period. Histological analysis confirmed the immaturity of stage 1 ovaries, and revealed no difference in the most advanced oocyte stage between 2a and 2b ovaries, which represent the same functional stage at different ages. Maturing (2c) and mature (2d) ovaries, which are clearly distinguishable macroscopically by colour, appeared histologically very similar, suggesting a fast achievement of yolk deposition in this species.

Fig. 1. Stage 2b ovaries of A. foliacea, with a germinative zone containing oogonia (OO) and early primary oocytes (EPO), and a maturative zone containing late primary oocytes (LPO)

Fig. 2. Stage 2c ovaries of A. foliacea with late vitellogenic oocytes (LVO) pilled up as coins in a single row (A); stage 2d ovary with advanced late vitellogenic oocytes characterized by a convoluted perivitelline space along the cell membrane (B)

BENTHIC VAGILE FAUNA ASSOCIATED TO COLONIZATION PROCESSES IN THE NORTHERN ADRIATIC CORALLIGENOUS HABITATS

Massimo Ponti¹, Federica Fava¹*, Roberto Gori¹ and Marco Abbiati¹ ¹University of Bologna - federica.fava8@unibo.it

Abstract

Benthic vagile fauna associated to colonization processes in the northern Adriatic coralligenous habitats was investigated by means of tiles field experiments carried out from August 2005 to August 2008 in three different rocky outcrops offshore of Chioggia characterised by different epibenthic assemblages. Although most of the single taxa didn't show a clear distribution pattern, as well as the species diversity indices, assemblage structures significantly differed among plots and between sites. The interaction between sessile and vagile fauna could play a relevant role in structuring the epibenthic assemblages. *Keywords: Adriatic Sea, Zoobenthos, Continental Shelf, Marine Parks*

Introduction

Numerous coralligenous rocky outcrops occur in soft silty-sandy sediments of the Northern Adriatic Sea bottom between 10 and 40 metres in depth, ranging in size from only a few to several thousands square metres, and raising between 1 and 4 metres from surrounding bottoms ([1]; [2]). The largest and better known outcrops are widespread offshore of Chioggia and Venice, between 18 and 30 m in depth and from 6 to 24 km from the coast and their ecological importance were recognised by the institution of a No Take Zone in 2002 ([3]). According to previous studies, epibenthic assemblages on subtidal hard bottoms offshore of Chioggia show high heterogeneity at a range of spatial scales, form 10s to 1000s of meters ([4]). The assemblages occurring on these outcrops could be clustered in three main typologies consistent with time and characterised by different abundance of algal turf, encrusting calcareous algae, encrusting and boring sponges and colonial ascidians ([4]). In order to assess the role of the recruitment processes in determining such variability, colonization patterns have been investigated in a long-term field experiment based on travertine tiles ([5]). The aim of the present study is to analyse the vagile fauna associated to the colonized tiles three years after their deployment.

Material and methods

Three study sites offshore of Chioggia, representing the three main hard bottom benthic assemblages identified in the previous study, were randomly chosen. Site P204 (6.6 km far from the coast, depth 20 m, 45° 12.665' N 12° 23.038' E) was dominated by algal turf and encrusting sponges, MR08 (14.6 km far from the coast, depth 22 m, 45° 13.825' N 12° 29.365' E) was characterised by red calcareous algae and colonial ascidians, while P213 (15.0 km far from the coast, depth 25 m, 45° 10.264' N 12° 30.999' E) presented intermediate abundances of algal turf and encrusting algae. In August 2005, three plots were randomly selected in each site, and for each plot sixteen travertine tiles (15.0 x 11.5 x 1.0 cm) were horizontally deployed in contact with the natural hard bottom. Three years after the deployment, tiles appeared indistinguishable from the surrounding bottom. In August 2008, four tiles for each plot were collected with the associated vagile fauna and preserved by 4% formaldehyde in separate plastic bags. Species were identified to the lowest possible taxonomic level and their abundance was estimated as number of individuals per sample. Differences between plots and sites were assessed by uni- and multivariate permutational analysis of variance (PERMANOVA, [6]).

Results

Overall 98 taxa were identified. Tanaidacea, Copepoda, *Bittium reticulatum*, *Leptochelia savignyi* and *Sillys* sp. were the most abundant taxa. Although most of the single taxa didn't show a clear distribution pattern, as well as the species diversity indices, assemblage structures significantly differed among plots and between sites. Vagile assemblages were correlated with those sessile colonizing the tiles. In particular, the gastropod *Bittium reticulatum* and the caprellid amphipod *Phtisica marina*, generally associated with algal turf and hydroids were more abundant in the site P204 dominated by a large amount of algae, while the isopod *Jaeropsis* sp., commonly found in the Mediterranean coralligenous habitats ([7]), was more abundant in the site MR08, characterised by red calcareous algae. Vagile assemblages appeared also correlated with depth, distance from the cost and spatial extent of the outcrops.

Discussion

The formation and maintenance of benthic assemblages on subtidal rocky bottoms largely depends by settlement and recruitment processes determined by the interaction of biotic and abiotic factors which operate at different spatial and temporal scales ([8]). Also post-recruitment processes including post-larval dispersion and intra- and interspecific interaction could play a relevant role ([9]). The analysis of the recruitment sequence of sessile species highlighted the importance of both early colonisation processes and following competitive interaction between species in structuring the epibenthic assemblages in the northern Adriatic subtidal rocky bottoms ([5]). The interaction between sessile and vagile fauna could also play a relevant, thought often largely neglected, role in structuring the epibenthic assemblages ([10]).

OVARIES DEVELOPMENT OF PARAPENAEUS LONGIROSTRIS (CRUSTACEA: PENAEIDAE) IN THE SARDINIAN WATERS

Cristina Porcu¹, Alice Gastoni^{1*}, Benedetta Podda¹ and Andrea Sabatini¹ ¹ Department of Animal Biology and Ecology – University of Cagliari - gastoni@unica.it

Abstract

In this paper, we report a description of female maturity stages of the deep-water rose shrimp *Parapenaeus longirostris* caught in the Sardinian waters between 250 and 440 m. Macroscopic and histological analysis were performed on 665 females. The observation on the ovaries leads to conclude that there are six stages of development. *Keywords: Decapoda, Reproduction, Western Mediterranean*

Introduction

The deep-water rose shrimp *Parapenaeus longirostris* (Lucas, 1846) is one of the most important commercial shrimps in many Mediterranean and Atlantic fisheries [1,2,3,4]. The aim of this paper is to identify and classify the maturity stages of females based on macroscopic and microscopic features of the ovaries.

Materials and Methods

Observations on the reproduction were made through monthly samples collected by commercial trawlers on epi-bathyal bottoms off Sardinian waters (central western Mediterranean Sea) between 250 and 440 m of depth. A total of 665 females were examined. Parameters recorded included carapace length (CL, mm) and sex; moreover, on the basis of size, shape and colour of gonads, the female maturity stages were defined. The ovarian tissues, preserved in salin formol 5%, were processed. Transverse sections (3.5 μ m) were stained with sodium iodoeosine and toluidine blue (Dominici's method) [5].

Results and Discussion

The specimens showed a range in size between 17.3 and 39.8 mm CL. Macroscopic and microscopic examination of the ovaries revealed six maturity stages:

Stage 1A (immature, virgin): typical of young immature specimens (17.3-18.1 mm CL). Thin and translucent ovaries with a tubular appearance and adherent to the dorsal portion of the digestive gland. A large number of oogonia, found grouped in the germinal zone, start to divide and can be observed at all stages of maturation. The primary oocytes (PO) with a large nucleus are visible.

Stage 2A (developing) / 2B (recovering): whitish or pale yellow ovaries, larger in volume than the previous stage ones. The paragastric lobes start to cover the sides, while the caudal extensions occupy all abdominal somites. These two stages differ only for the body size (2A: 20-24.1 mm CL; 2B: 25-38 mm CL). Microscopically, in the maturative zone, PO, surrounded by a monolayer of follicle cells, show a large nucleus with nucleoli flattened around the periphery.

Stage 2C (maturing): dark yellow-light green ovaries. Frontal lobes and caudal extensions are turgid and well defined (20.3-38 mm CL). From the histological analysis, besides all the previous cell types, primary (Y1) and secondary (Y2) vitellogenic oocytes were also visible. The first ones had a polyhedral shape with a nucleus containing several round nucleoli and the cytoplasm field with yolk granules and lipidic vesicles;

Stage 2D (mature): turgid ovary of different shades of dark green, completely developed occupy the entire thoracic cavity. The eggs are well visible (20.3-39.8 mm CL). All previous microscopic cells type are present. The nucleus of Y2 oocytes migrate to the peripheral zone and the ready-to-spawn oocytes show a characteristic margin of peripheral "rod-like bodies" [6].

Stage 2E (spent): green-brown ovaries that lose the characteristic turgidity of the previous stage and become flaccid (25.9-37.1 mm CL). Empty ovarian tissue and characterized by oocytes in reabsorbtion. The fully mature oocytes were still visible. The maturation process of *P. longirostris* ovaries exhibited progressive changes in color and volume from immature stages to mature ones. The gonad extends through the abdominal cavity since the first stage of the development.

Abstract

The problem of the biogeographical distribution of organisms is still connected to the distinction in the districts of the Mediterranean Sea. In this context, the Straits of Messina, as it has ecological features of significant interest that pose the questions and suggest biogeographical implications. The intense hydrodynamism, the low temperatures and the abundance of salts, transported to the surface from the deep water, make available a large amount of organic matter consumed by coastal populations. In this context, should be included repeated sightings of *Hexanchus griseus*, an abyssal species, which in the Strait is found at depths from 5 and 40 m, in special conditions of moon phase and current.

Keywords: Strait Of Messina, Biogeography

The biogeography distribution of marine organisms is linked to the subdivision into different districts of the Mediterranean basin. Nevertheless, the active interactions existing among several communities and their habitats reject such classical model of distribution. The Strait of Messina represents the junction of two basins, the Ionian and the Tyrrhenian Sea. Here, strong sea currents drive a complex displacement of water [1, 2]. Waters move between the two basins over a sill 70-110 meters deep, with a NW-SE oriented mouth. The sill morphology has a fundamental role not only for the hydrological regime of the Straits but also for the distribution of benthic populations occurring in this environment [3, 4]. Such hydrodynamism is responsible for the high biodiversity of the area. Intense strong currents and upwelling phenomena release a large quantity of organic matter that is used by coastal benthic populations. The peculiar morphologic, oceanographic and biological asset of the area determines an Atlantic-like ecosystem [5, 6]. In this particular environment has been repeatedly detected the species Hexanchus griseus (Fig. 1).

Fig. 1. Hexanchus griseus in the Giardini Naxos harbour

This species is a benthonic deep water shark that commonly lives between 700 -2000 meters; is one of the biggest sharks of the Mediterranean Sea that can reach 5 meters in length and 800 kg of weight [7]. In the Straits of Messina, H. griseus, during particular moon and tide phases, comes to shallow waters up to 15-30 meters of depth. During these periods, six-gill sharks have been commonly sought by scuba divers. From 1993 we had begun a visual scuba dive program of this species and were found numerous specimens including an adult female of 4 meters (Iaria pers. comm.). In 2007 Hexanchus griseus was sampled in an upwelling area south of the Straits of Messina (Giardini Naxos), under the framework of EU project ("Ge.In.Fa.Co. - individuazione e messa a punto di un modello per lo sviluppo sostenibile e per la gestione integrata della fascia costiera nell'area di Giardini Naxos - POR SICILIA 2000-We hypothesize that there is a strong correlation between vertical migrations of H. griseus and presence of a large quantity of organic matter and benthic organisms. Probably the species follows northern upwelling currents as well as other many species characteristic of the area. In the near future we aim to undertake a collaborative project of underwater tagging and photo-identification to gain insight on six-gill shark migration and distribution in the Mediterranean Sea 2006).

SYMBIODINIUM SP. CAN STAY ALIVE THROUGH THE GUT AND IN THE FAECES OF CNIDARIA PREDATORS. THE CASE OF CORALLIOPHILLA MEYENDORFFI AND ANEMONIA VIRIDIS.

Mathieu Poulicek ¹*, Stéphane Roberty ¹, Sylvain Plaza ² and Ophélie Ladriere ¹ ¹ Liège University, Marine Ecology unit, Chemistry Institute B6C - mpoulicek@ulg.ac.be ² STARESO, BP33, F-20290 Calvi (Corsica, France)

Abstract

The gastropod *Coralliophilla meyendorffi* is a common predator of the zooxanthellate anemone *Anemonia viridis*. Zooxanthella from the anemones are an important constitutent of the mollusc faeces. Cell integrity, occurence of flagellated forms, live/dead proportions and mitotic index of *Symbiodinium* collected from the faeces and cultivated in vitro were examined and compared to that of algae *in hospite*. The results show that most algae withstand digestive processes of the predator, staying alive and dividing actively in the faeces. Motile (lagellated) algae arise from dividing cells and escape the fecal pellets. Impact on coral bleaching recovery is discussed.

Keywords: Cnidaria, Dinoflagellates, Symbiosis, Predation, Fecal Pellets

Introduction

Many eukaryotic microalgae live in symbiosis with marine invertebrates. One of the most widely distributed and abundant intracellular algae are the zooxanthellae (dinoflagellates of the genus *Symbiodinium*) in symbiosis within cells of reef forming corals and of other cnidaria [1]. The increased frequency of disruption of this symbiosis (coral bleaching) is a major threat for coral reefs future [2]. In order to recover, bleached cnidaria can, either let proliferate the algae not previously expelled (5 to 25 % of the initial stock) or catch free *Symbiodinium* in the environment [3,5,7]. Both processes potentially result in algae community changes, favouring environmentally better adapted strains (adaptive theory of bleaching [8,9]). As "free" zooxanthellae are quite rare in the plankton [1], one can look for other possible sources of symbionts. Here we investigate the potential role of undigested algae embedded in the faeces of cnidaria predators as source of zooxanthellae for recolonization of bleached hosts.

Material and methods

In June 2009, 15 live Anemonia viridis (Forskal, 1775) and 15 Coralliophilla meyendorffi (Calcara, 1845) were collected by scuba diving (3-8 m depth) close to the oceanographic station STARESO (Calvi, Corsica) and kept separate for acclimatization during one month in free flowing aquaria in the laboratory under in situ light and temperature conditions (18 to 22°C, maximum light intensity 1970 lumen m⁻²). Experiments were performed in July 2009. Anemone extracted zooxanthellae were collected by gentle homogenization of 0.5 g (FW) of anemone tentacles in 10 ml of 0.2 µm filtered SW with a potter grinder, then purified from anemone debris by filtration (50 µm pore size) and centrifugation (500 x g), resuspended and cultured under in situ illumination and temperature in F/2 medium. Faeces zooxanthellae were recovered by grinding freshly collected faeces of Coralliophilla exclusively fed with Anemonia for 1 week, then purified and cultivated the same way. Algae density in culture was monitored in both cases for 12 days (5 replicates) by epifluorescence counts. Mitotic indexes (MI, as % of "doublets", N >500 cells) and % dead cells (Trypan blue permeation test, N>300 cells) were recorded every day at 9h00 in culture samples. Apparition of motile (flagellated) cells was monitored along nycthemeral cycles (during the log phase of both cultures) during 48 hours every 2 hours.

Results and discussion

Most zooxanthellae found in the faeces are alive (> 80 %) and able to multiply quickly. Actively growing cultures were obtained from algae either directly extracted from anemones or from faeces of *Coralliophilla* exclusively fed with *Anemonia viridis*. There are no significant differences between the kinetics of both growth curves : lag phase last approximately 6 days and logarithmic growth for another 6 days, culminating with densities around 200 to 250 10^3 algae ml⁻¹ (inoculum was 25 10^3 cell ml⁻¹).

The MI of faeces isolated algae is significantly lower than the MI of anemone extracted ones during the 3 first days of culture (0.8 to 1.2% compared to 2.0 to 2.8%) ; there is no significant difference during the following days. MI is classically low in zooxanthellae, close to 2 to 5 % of the population according to strains, light and nutrients supply [4,6]. Maximum MI occurs after 8 days of culture (2.9 to 3.4%). Division occur mainly during the very first hours of "light" period (from 6h30 to 9h00 in our conditions, 100 to 600 lumen m⁻²) and at dusk (18h30 to 21h00, 400 to 100 lumen m⁻²).

Division peaks were followed by apparition of motile algae (8h30 to 10h30 and from 20h30 to 21h30). There were virtually no flagellated forms during the night (light intensity < 50 lumen m⁻²), and very few ones (< 0.2 % during

the most illuminated hours of the day, > 600 lumen m⁻²). This conforms to previous observations under natural conditions [6]. Motile cells also escaped from undisturbed fecal pellets even if most cannot get free from mucous threads in which algae are embedded.

% dead cells was much higher just after isolation from *Coralliophilla* faeces (10 to 25% of the population at day 1) compared to anemone extracted ones (2 to 7%). From day 3 to day 12, the % dead cells in culture remained constant around 2% of the algae population for both conditions.

Conclusion

Most symbiotic zooxanthellae from Anemonia viridis consumed together with animal tissues by the gastropod Coralliophilla withstand digestion and are recovered alive, actively dividing and potentially motile in the faeces of the predator. Observations by Fit & Trench [5] on Cassiopeia scyphistome show that live Symbiodinium cells introduced in the coelenteron resist digestion by the cnidaria and are internalized (endocytosis) by endodermal cells. So, fecal pellets, once resuspended in the POM could be a source of algae for recolonization of bleached host. Moreover, flagellated cells produced by undigested zooxanthellae in faeces are another potential source as these motile algae are attracted to potential hosts [4], if freed from mucous threads. It should be quite interesting to check the hypothesis that faeces and fecal pellets of cnidaria predators may constitute a reservoir of live zooxanthellae able to be consumed and internalized during recovering phases post-bleaching.

THE CONTRIBUTE OF THE MANILA CLAM TO THE SECONDARY PRODUCTION OF THE BENTHIC COMPARTMENT IN THE VENICE LAGOON

F. Pranovi ¹*, P. Franzoi ¹, M. Pellizzato ², M. Zucchetta ¹ and P. Torricelli ¹ ¹ Environmental Sciences Dept., University Cà Foscari Venice, Italy - fpranovi@unive.it ² AGRI.TE.CO sc Ambiente Progetto Territorio

Abstract

A first attempt to quantify the contribute of the Manila clam (Ruditapes philippinarum) to the secondary production of the benthic compartment of the lagoon of Venice is described. The potential exploitable production, based on available data about the clams distribution and annual catches, has been estimated on a spatial basis within the main fishing grounds and compared with experimental data about the secondary production of the macrobenthic community of the lagoon, recorded in areas not interested by the clam harvesting activity.

Keywords: Bivalves, Alien species, Secondary Production, Lagoons, Adriatic Sea

Introduction

As previously described by other authors [1], the introduction of the Manila clam - Ruditapes philippinarum (Adams & Reeve, 1850) - in the lagoon of Venice and the subsequent demographic explosion directly affected the ecosystem functioning. Among the other effects, an increase of the benthic compartment production has been recorded, as reflected by the 40000 tons of catches per year reported at the end of the last century. Therefore, the voluntary introduction of the Manila clam represented the most successful event for the Italian shellfish aquaculture and, at present, Italy results to be the main clam producer in Europe. For this reason, this species can represent a good model to analyse ecological effects related to an alien species introduced for commercial purposes in a marine ecosystem. The aim of the paper is to use the secondary production as a proxy to assess the effects on ecosystem functioning due to the non-native species, Ruditapes philippinarum. By using available data from different sources, the clam potential exploitable production, for each one of the main fishing grounds, has been estimated on a spatial basis and compared with secondary production estimates for the macrobenthic community, experimentally obtained for different areas of the lagoon.

Material and methods

In the context of the present situation, characterized by local administrations efforts to enforce the management policy, allocating resources and fishermen in small portion of the lagoon, a lack of reliable and well structured databases about Manila clam have been recorded. To estimate the potential exploitable production on a spatial basis, the most recent biomass density data collected within the main fishing grounds [2, 3, 4,] were used as proxy for production distribution. Biomass values (wet weight, $g \cdot m^{-2}$) for each area were interpolated by using ordinary kriging on a 10 m square cells grid, after fitting the best model on the experimental variogram, using the 'gstat' library [5] of R software packages. For each area, a relative biomass index was then computed by dividing biomass of each cell by the total biomass of the area. The production distribution in each area was obtained by multiplying the annual production for the area by the relative biomass index. Estimated production values, transformed in ash free dry weight, were finally interpolated on a 100 m square cells grid. This interpolation was used to estimate the contribute of the Manila clam to the production of the benthic compartment by using, as reference, the mean value of 27.5 g AFDW m⁻² y⁻¹, recorded in areas outside clam fishing grounds and outside seagrass meadows [6].

Results and discussion

Obtained results highlight a significant contribution (from 1 to 4-5 times the value recorded outside the fishing grounds) of the Manila clam to the benthic compartment secondary production (Fig. 1). This could find explanation in terms of an optimization of the resources exploitation, as suggested by the bentho-pelagic coupling increase. The Manila clam is, indeed, characterized by a general 'rusticity'. Moreover, in the fishing grounds the population is maintained in the 'young phase' (with high r values) by the fishing activity itself. Finally, the presence of positive feedbacks with the fishing activity, due to the re-suspension of organic matter from the sea-bottom, has been described [7]. Estimates here presented, allowed for a first quantification of positive effects of the Manila clam on goods and services of the Venice lagoon, which in some way, represent the other side of the medal when assessing the global effect of non-native species on the ecosystem

functioning.

Fig. 1. Contribution of the Manila clam to Secondary Production of the benthic compartment. Data are expressed as percentage referred to the mean production experimentally recorded outside the clam fishing grounds

FISH ASSEMBLAGE OF THE MAR PICCOLO BASIN OF TARANTO (SOUTHERN ITALY): COMPOSITION AND STRUCTURE

Ermelinda Prato¹* and Ermelinda Prato¹ ¹ CNR-IAMC, U.O.S. Taranto - linda.prato@iamc.cnr.it

Abstract

The fish assemblage of the Mar Piccolo estuary was studied from September 2007 to August 2008. Using a 50m beach seine a total of 6796 fishes, mainly juveniles, belonging to 16 families and 28 species were caught at 10 stations. The highest number of species was caught during spring-summer months while the number of specimens was highest in summer and autumn months. The most abundant species were *Atherina boyeri* (32.1% of total individuals) and *Liza aurata* (28.3%). Statistically significant variations among sampling time were detected for fish abundance, number of species, Shannon's diversity, Evenness, Margalef's Richness and Simpson indices, (ANOVA; p < 0.001).

Keywords: Fishes, Ionian Sea, Lagoons, Biodiversity

Introduction

European Council Directive [1], indicated the fish communities as key biological component in the assessment of the ecological status of transitional water [2, 3]. Among the estuarines areas in the Mediterranen sea, the Mar Piccolo estuary is located on the Ionian coast of Taranto (Apulia region, Italy). The present work aimed at providing an upadated list of species taking into account also the structural approach. The specific objectives of this study were: 1) relationship between the principal abiotic factors with fish assemblages; 2) description of the fish communities from a taxonomic and structural point of view. Material and Methods Sampling was performed every month from September 2007 to August 2008 during daylight hours, in ten stations: three of which were situated in the 1st Inlet, and seven in the 2nd Inlet. At each sampling station three replicates were collected. The mean temperature (°C) and salinity were measured for each sampling time considering the stations pooled values as replicates. Fish samples were collected using a 50m beach seine with a height of 5m and mesh of 2mm. The mean fish abundance (number of individual), number of species and standing stock (grams of fish biomass) were calculated. Basic community index: Shannon-Wiener's diversity, Pielou's index (J), Margalef's richness index (d) and Simpson index were recorded. Two-way analysis of variance (ANOVA) was used to assess temporal differences in total fish community.

Results and Discussion

The water temperature followed a seasonal trend, with a minimum value in December (10.5 ±0.5°C) and maximum in August (25.5± 1°C). Salinity was lowest in January (35±1‰) and highest in October (36.8±0.5‰). Salinity was directly related to temperature (p<0.001; r= 0.71). Multiple regressions indicated that the number of individuals and standing stock, showed no significant relationship with environmental variables (p> 0.05). A total of 6796 fishes belonging to 16 families and 28 species were caught. The highest number of species was caught during spring-summer months, while the number of specimens was highest in summer and autumn months. The highest number of species recorded in spring shows that this ecosystem is an important spawning and nursery area. This ecosystem supported a number of species within of the European estuaries range, 14 (Essex Coastline, UK) and 110 (Thames) species with an average (\pm SD) of 53 \pm 20 in 38 European estuaries [4]. The most abundant species were Atherina boyeri (32.1% of total individuals) Liza aurata (28.3%), Symphodus cinereus (7.2%), Zosterisessor ophiocephalus (7.1%), Liza saliens (5.5%), Engraulis encrasicholus (2.7%), Symphodus tinca (2.6%) and Sparus auratus (2.5%). Fish abundance, number of species, Shannon's diversity, Evenness, Margalef's Richness and Simpson indices, revealed a highly significant variation among sampling time (ANOVA; p< 0.001). Mar Piccolo ichthyofauna includes marine euryhaline species that permanently live in the estuary, such as A. boyeri, Aphanius fasciatus, Z. ophiocephalus, Gobius niger, G. paganellus and Syngnathus acus. The ichthyofauna also includes juveniles of euryaline marine species for which this highly productive habitat provides a nursery ground (Sparus aurata, Dicentrarchus labrax, Diplodus vulgaris, Sarpa salpa, Mullus barbatus, Symphodus rostratus, S. tinca, S. cinereus, and almost all species of Mugilidae). The results obtained from this study provide a first contribute to knowledge of temporal patterns of structural fish assemblage in Mar Piccolo basin. However, due to anthropogenic pressures such as industry, fisheries and other maritime activities, it is necessary to protect and monitor this important fish habitat.

ALIEN INVASIVE SPECIES ESTABLISHED IN FOULING COMMUNITIES FROM CONSTANTA HARBOR, ROMANIA - A PILOT STUDY

Cristina Preda¹* and Marius Skolka¹

¹ Ovidius University of Constanta - preda_cristina2006@yahoo.com

Abstract

In this pilot study, we monitored alien invasive species established in benthic communities from artificial hard substrata in Constanta Harbor, Romania. Aspects regarding the biodiversity of fouling communities are presented as well as the situation of different invasive species in Constanta Harbor. The study was performed as part of the MODSIS project (MOnitoring and Detection System for Invasive Species) financed within IDEI program of the National Research, Development and Innovation Plan - PN II. *Keywords: Black Sea, Monitoring, Alien species, Biodiversity*

Introduction

Constanta Harbor is the largest port at the Black Sea, with a handling capacity of over 100 million tones per year. The total traffic increased from 43200 thousands tones in 2003 to 61800 in 2008 therefore increasing the risks of new alien species becoming established at the Romanian coast. The aim of this pilot study was to identify alien invasive species (AIS) "hot spots" in Constanta Harbor. We hypothesized that Constanta Harbor acts not only as a major gateway but also as an AIS reservoir.

Material and Methods

Three study sites in Constanta Harbor were selected taking in consideration the distance from the harbor entrance. First study site (S1) is closest to the entrance while the second (S2) and third (S3) are located inside the harbor (Figure 1). We collected monthly random samples from artificial substrata at 1 - 1,5 m depth from January till October 2009. Samples from ships hulls were collected occasionally in order to observe the community structure.

Fig. 1. Study sites in Constanta Harbor

Results and Discussion

We identified 67 macroinvertebrate species from fouling communities on artificial hard substrata, dominated by *Mytillus galloprovincialis* and *Brachyodontes lineatus*. Of these species, 44 are present in all sampling sites, 15 are current in two sites while 7 species occur only in one of the sites. Minor differences were reported between the qualitative structure of artificial and natural hard substrata communities [1] and also between the three sampling sites. AIS represent about 9%, all of them previously mentioned from the Romanian Black Sea Coast [2]. However, samples from ship hulls contain more alien species that represent a permanent source of potential settlers as is the case of other areas in the north-western Black Sea [3] (Table 1).

Tab. 1. AIS identified in samples

Species	Origin	Year of the first mention	Presence in fouling	Situation
Blackfordia virginica	North Atlantic	1940	S1	Established
Haliplanella lineata	North Atlantic	1960	S1.S2.S3	Established
Hvdroides elegans	Indo Pacific	?	Ships fouling	Accidental
Hydroides norvegicus	North Atlantic	?	Ships fouling	Accidental
Ficopomatus	North Atlantic	1954	Ships fouling	Accidental
enigmaticus			S2	
Doridella obscura	North Atlantic	1997	S1,S2,S3	Established
Mya arenaria	North Atlantic	1968	S2,S3	Established
Musculista senhousia	Indo Pacific	2004	Ships fouling	Accidental
Balanus improvisus	North Atlantic	1844	S1,S2,S3	Established
Balanus amphitrite	North Atlantic	1954	Ships fouling	Accidental
Sphaeroma walkeri	Indo Pacific	2004	Ships fouling	Accidental
Lepas sp.	Atlanto-	?	Ships fouling	Accidental
	mediterranean			
Rhitropanopeus harrisii	Indo Pacific	1950	S1,S2,S3	Established

Conclusion

The AIS identified in our samples are well integrated in the fouling communities therefore the harbor acts as an AIS reservoir for neighboring areas.

Abstract

A SSH (Suppression Subtractive Hybridization) cDNA library was constructed using samples collected from a continuous *Posidonia oceanica* meadow located in *Lacco Ameno* (Ischia, Gulf of Naples) at two different depths (-5 and -25 m). The aims are to identify differentially expressed genes associated with different light and temperature regimes and other potential stress-responsive gene networks important for adaptation. With ~1200 sequenced cDNA clones, 486 tentative unigenes were identified, of which only 28 are common to both shallow and deep libraries. Genes have been grouped in functional classes showing the highest differences between the two depths in primary metabolism, photosynthesis and stress defence genes. *Keywords: Genetics, Global Change, Phanerogams, Posidonia*

Introduction

Seagrass meadows are among the most productive ecosystems [1] with Posidonia oceanica being the most important species in the Mediterranean coastline. This species forms extensive mono-specific meadows that are extremely sensitive to medium-high levels of disturbance [2] and are being threatened by fast environmental changes caused by global warming and increasing human activities. Collectively, the forces impose a strong selective pressure to the long living P. oceanica meadows, particularly those found at the extremes of the environmental and geographic limits of the species. Being sessile, seagrasses can not easily disperse from a given locality and must therefore adapt to selective regimes and acclimatize to variations in local environmental parameters. The goal of this study it to distinguish differentially expressed genes associated with different light and temperature regimes and to identify potential stress-responsive gene networks. In order to do that, we built a SSH cDNA library between two different depths (-5 and -25 m) in a continuous P. oceanica meadow located in Lacco Ameno (Ischia, Gulf of Naples). Existing data suggest that clones growing at different depths are genetically isolated and that plants growing above and below the summer thermocline experience strong differences in light and temperature exposure [3].

Material and Method

After the stabilization of the summer thermocline (about -15m depth), shoots were collected above and below this thermocline by SCUBA diving from a meadow located in Lacco Ameno, Ischia (Gulf of Naples) in July 2008. Plants found at -5m (shallow station) and -25m (deep station) depth were sampled. Total RNA were isolated from leaf tissue using a modified hexadecyltrimertihyl bromide (CTAB) method; poly(A+) mRNA was isolated from the total RNA using the Dynabeads mRNA Purification kit (DYNAL BIOTECH), and forward and reverse SSH libraries were built using the PCR-select cDNA subtraction kit (Clontech, Palo Alto, CA). A total of 1920 random clones (960 from the shallow and 960 from the deep library) were sequenced in double-strand (Richard Reinhardt, MPI Molecular Genetics, Berlin, Germany). EST raw sequences were quality-trimmed and assembled into tentative gene clusters (TC) using CAP3 [4]. Putative functions of the identified tentative unigenes (TUG), were assessed by performing homology searches against the following databases: Gene Ontology(GO), SWISSPROT, NR -NCBI (blastx-step, e-value 0.001) and DrZompo (blastn-step).

Results and Discussion

The final assembly of shallow and deep ESTs includes 486 TUGs with a successful mapping of 2279 ESTs. 364 ESTs could not be assigned to the TUGs library. The percentage of TUGs common to both libraries (shallow and deep, S and D) was only 5.86% (28/486); 205 TUGs were found in S while 309 TUGs were found in D. TUGs have been divided in seven functional categories, the percent abundance of which differed in the two libraries. Transcripts for Protein Turnover and Respiration are more abundant in S, suggesting a more rapid metabolism at higher irradiance, while transcripts for the other five categories are more abundant in D (Fig. 1).

Fig. 1. Total number of ESTs assigned to functional categories. PM: Protein Metabolism; CC: Cell Component; T/PS : Transcription/Protein Synthesis; S/D : Stress/Defense; RE: Respiration; PH: Photosynthesis; PT: Protein Turnover

The presence of a higher number of transcripts assigned to Photosynthesis in the deep station is noteworthy, suggesting that a more complex and functional photosynthetic apparatus at lower irradiance is needed. Different stress responsive genes are present in the two libraries.

IMPACT OF ENVIRONMENTAL FACTORS ON THE DISTRIBUTION AND DENSITY OF FAN MUSSEL PINNA NOBILIS ALONG THE EASTERN AND SOUTH-EASTERN TUNISIAN COASTLINE

Lotfi Rabaoui ¹*, Sabiha Tlig-zouari ¹, Stelios Katsanevakis ² and Oum kalthoum Ben hassine ¹

¹ Faculty of Science of Tunis, University Campus, Biology department. El Manar 2092, Tunis – TUNISIA - Irabaoui@gmail.com ² Institute of Marine Biological Resources, Hellenic Centre of Marine Research, 46.7 km Athens-Sounio, 19013 Anavyssos, GREECE

Abstract

The distribution and density of Pinna nobilis was estimated along the eastern and south-eastern Tunisian coasts, with the use of a density surface modelling (DSM) approach. A marked relationship between the fan mussel density and two spatial parameters (depth and distance from a pollution source) was revealed. The adopted technique was found advantageous to better understand the ecology of the species.

Keywords: Pollution, Sampling Methods, Density

Introduction

Pinna nobilis is a Mediterranean endemic species. It is the largest Mediterranean bivalve which occurs in coastal soft-bottom areas, usually in association with seagrass meadows [1]. It is also one of the Mediterranean endangered species. To effectively protect this mollusc, it is necessary to assess the status and distribution of all major local P. nobilis populations.

Material and Methods

In the present study, a distance sampling method was applied to model the population distribution and density of P. nobilis along the eastern and southeastern Tunisian coastline (from Hergla to Elketef) taking into account spatial and environmental parameters. To do so, forty five line transects, perpendicular to the shoreline and extending from 0 to 6 m depth, were defined randomly along the study area; each line transect was marked every meter and divided into 8-m segments. After deploying the line, all detected P. nobilis individuals within 150 cm from the line were counted. For each observed individual, the following variables were recorded: the corresponding segment in which it was found, the perpendicular distance from the line $(= y_i)$, and the shell size $(= s_i)$, defined as the maximum dorso-ventral length of the shell. In addition, at the mid-point of each segment of the line transect the exact depth was measured. The dominant habitat type (H) of each segment was also recorded. Six different habitat types were identified: unvegetated sandy/muddy bottoms (UN), Posidonia oceanica beds (PO), Cymodocea nodosa beds (CN), Caulerpa prolifera beds (CP), Caulerpa racemosa beds (CR), and Zostera noltii beds (ZN).

For the detection function modelling, two functions were considered as candidate detection functions: the one-parameter half-normal $\hat{g}(y) = \exp\left(\frac{-y^2}{2\sigma^2}\right)$ function and the two-parameter hazard-rate function $\hat{g}(y) = 1 - exp \left[-\left(\frac{y}{\sigma}\right)^{2} \right]$ where σ is a scale parameter and b a

shape parameter. Considering different conditions, eight models were included in

the set of candidate models and the selection between them was based on the small-sample, bias-corrected form AIC_c of the Akaike Information Criterion. The population density of P. nobilis was modelled using the 'count method' of [2]. For that, one categorical and two continuous potential predictor variables were used: habitat type (H), depth (d), and the distance of each site (along the coastline) from the city of Gabes (x) respectively. Negative values were given to x's southwards and positive values for x's northwards of Gabes. With respect to the considered variables, eight models were used and model selection was done based on GCV score.

Results

A total of 318 fan mussel individuals were recorded in the line transects. The best model of the detection function among those tested (based on AIC_c) was the half normal function with no scale covariate. It is given by the equation $\hat{g}(y) = exp\left(\frac{-y^2}{2\sigma^2}\right) = exp\left(-1.602y^2\right)$, where distance from line (y) is in m. The best density model was the model which included univariate functions of

depth (d) and the distance from the city of Gabes (x). The expression of this model was $ln(E[\hat{n}_i]) = c + s_1(d) + s_2(x) + ln(\alpha)$, where c = -20.0, a = 18.4 m^2 , and the smooth functions s_i are given in Figure 1.

The fan mussel population density was zero at very shallow waters (<0.3 m depth) and was increasing within the depth range of this study (0-6 m). Zero fan mussel densities were observed near the city of Gabes. Population density increased with the distance from the city of Gabes and was higher in the south than in the north.

Discussion

Pinna nobilis density-depth correlation is well known with the fan mussel. Similar results were noted in Spain [3] and in Greece [4]. Regarding the relationship between the fan mussel density and the distance from Gabes city, this correlation could be attributed to pollution. Among the big cities located in the Gulf of Gabes (Gabes, Sfax, and Skhira), Gabes city is considered as the main source of pollutants, in particular phosphogypsum discharge in the open sea. According to figure 2, the farer from Gabes city the higher was P.nobilis population density. Almost all transects close to Gabes city had null densities. The absence of Pinna nobilis from the coast of Gabes and surrounding coasts is probably due to the large quantities of phosphogyps wasted from the industries of phosphoric acid and chemical products in the open sea since the seventies [5].

Fig. 1. Estimated smooth terms s(d) and s(x), for the best model of Pinna nobilis abundance in the study area. The smooth terms are given in the response scale and the corresponding 95% confidence intervals are given with dotted lines. A one-dimensional scatterplot is given at the bottom of each graph, using a vertical bar as the plotting symbol, to illustrate the distribution of available data

PERCNON GIBBESI (H. MILNE EDWARDS, 1853) IN LINOSA ISLAND TEN YEARS AFTER ITS FIRST RECORD

Paolo Raineri¹ and Dario Savini¹*

¹ Dipartimento di Ecologia del Territorio, University of Pavia, Via S. Epifanio 14 I-27100 Pavia - dario.savini@unipv.it

Abstract

An extensive survey conducted by visual census in summer 2009 by snorkelling and scuba diving reports a complete acclimation of the alien invasive grapsid crab *Percnon gibbesi* in Linosa Island (MPA Isole Pelagie, Sicily). The crab is distributed from 0-11 m depth along the whole littoral with the exception of one locality. Population density values ranges from a minimum of 1 to a maximum of 51 ind. per 10m² of seabottom.

Keywords: Decapoda, Islands, Sicilian Channel, Monitoring

Introduction

The alien crab *Percnon gibbesi* was firsty recorded in the Mediterranean in Linosa island in summer 1999 [1]. Since then it has been fastly spreading in several localities of the W and E Mediterranean [2] both by natural range expansion (water currents) and by anthropogenic vectors of introduction (ship ballast waters, fishing and recreational vessels). This algivorous species has been claimed to interact negatively with the native crabs community in the mediolittoral and upper infralittoral fringes, in particular with *Pachygrapsus marmoratus*, partially occupying its ecological niche [3,4]. The present poster reports results of a survey on *P. gibbesi* distribution and abundance in Linosa Island (MPA Isole Pelagie, Sicily) ten years after its first record.

Material and Methods

From 10/08-4/09/2009 the whole perimeter of Linosa island (about 11 km coastline) was surveyed by visual census (scuba diving and snorkelling) at a depth from 0-4 m. Presence/absence of *P. gibbesi* was reported in relation to habitat type (e.g. depth, sea bottom geomorphology, algal cover). Moreover, an estimate of population density was performed in 7 localities of the island (Fig. 1). Densities were estimated by counting numbers of crabs present on a 2 x 5m (10 m²) surface area of the seabottom (5 minutes search per 8 replicates). The non-parametric Kruskal Wallis test was used to compare median density values among sites [5].

Fig. 1. Geographical location of the sites surveied for *P. gibbesi* population density

Results and discussion

P. gibbesi was recorded along all the island littoral from 0-4 m depth except into one locality (Grotta dell'Amore; DDD= 35.871890N;12.853768E). Population density values were significantly (KS test: H = 40.9; Df = 6; p < 0.001) higher in S6 (Fili - DDD= 35.855214N;12.876449E; av density= 30 ± 22 ind. $10m^{-2}$) and S7 (Casotto – DDD= 35.855440N;12.866664E; av density= 51 ± 28 ind. $10m^{-2}$) (Fig. 2). The grapsid crab clusters in typical habitats constituted by large boulders encrusted with coralline algae (e.g. *Mesophyllum* sp; *Amphiroa* sp).

Fig. 2. Box plots of *P. gibbesi* population density values. The black points show mean density value per site. Boxes represent the 50% range of values. Whiskers represent the lower and the highest values and the lines inside the boxes represents the median value

It showed a continuous feeding activity near refugees constituted by holes and crevices in rocks. In various occasions it was found scavenging on *Pelagia noctiluca* and *Pachygrapsus marmoratus* carrions, as reported in other Mediterranean islands [6]. In conclusion, the survey identifed a well acclimated population of *P. gibbesi* in Linosa island, that in ten years has been able to colonize the whole superior infralitoral fringe, reaching higher densities $(30-50 \text{ ind} \cdot 10m^{-2})$ in localities characterised by a microhabitat of large boulders covered by coralline algae. Notwithstanding the species is mainly found in a depth range of 0-4 m, in agreement with the existing literature [4,6,7] we report also a population of the invasive crab at higher depth (10.7m), in a famous scuba diving site of the island (Manarazza - DDD = 35.874516N; 12.865639E). Future studies will consider interaction of *P. gibbesi* with native fauna (e.g. competition for space and food with *P. marmoratus, Eriphia vertucosa, Arbacia lixula, Thalassoma pavo, Coris julis*) and flora (e.g. herbivory rates on coralline algae), in order to estimate the environmental impact of this species.

CARACTERISATION DES PEUPLEMENTS ALGAUX ASSOCIES AUX TROTTOIRS A VERMETS EN ALGERIE

Chafika Rebzani Zahaf 1* and Amina Karali 1

¹ Faculté des Sciences Biologiques (FSB) Université Sciences et Technologie. Houari Boumedienne (USTHB), Alger, 16111, Algérie - chafikarebzanizahaf@gmail.com

Abstract

L'étude des différents types de bioconcrétions de la région de Tipaza a permis de localiser des trottoirs à vermets, des bourrelets à *Corallines* et des encorbellements à *Lithophyllum*. L'analyse de la biodiversité des trottoirs à vermets, effectuée en 2008-2009, a recensé au total 64 espèces floristiques.

Keywords: Biodiversity, Bio-Indicators, Phytobenthos, Zoobenthos

Introduction : Les bioconcrétionnements sont des biocénoses remarquables en Méditerranée. L'aspect écologique des trottoirs à vermets et la flore qui lui est associée sont étudiés. Ces formations biologiques sont rencontrées au niveau de l'étage médiolittoral inférieur et infralittoral supérieur sur les côtes rocheuses particulièrement de mode battu. Ces bioformations ont été signalées au niveau de la région de Tipaza par plusieurs auteurs, mais n'ont pas fait l'objet d'étude antérieure en Algérie. La présente étude concerne les types de bioconcrétionnements médiolittoraux et ceux de la partie supérieure infralittorale. Leurs localisations, leurs morphologies, ainsi que les espèces bioconstructrices et l'épaisseur de la couche édifiée ont été traités.

Matériels et méthodes

Les trois sites étudiés, Ain Tagourait, Kouali et Chenoua, sont localisés dans la partie Ouest de la région de Tipaza; cinq prélèvements ont été effectués en périodes estivale et hivernale (juillet-août 2008 ; janvier-février 2009). La méthode d'échantillonnage repose sur celle adoptée par Bellan-Santini [1] qui consiste en un grattage total jusqu'à la roche de surface (20x20 cm). L'ensemble de la récolte est versé sur un tamis de 1 mm de maille, recueilli, trié et conservé dans de l'eau de mer formolée à 4%.

Résultats et discussions : 1 - Les bioconcrétionnements : À Ain Tagourait, trois espèces bioconstructrices de trottoirs à vermets ont été observées : Dendropoma petraeum, Vermetus triqueter et Lithophyllum incrustans. À Kouali, deux types de constructions biologiques ont été observés : les trottoirs à vermets édifiés par les mêmes espèces rencontrées à Ain Tagourait et des bourrelets à Corallina elongata. Au Chenoua, les trottoirs à vermets rencontrés sont édifiés par Dendropoma petraeum et Neogoniolithon sp, des encorbellements à Lithophyllum lichenoides sont également observés. Les épaisseurs moyennes des trottoirs à vermets sont de : 4,58 cm à Ain Tagourait, 6,1 cm à Kouali et de 5 cm au Chenoua. Les phénomènes responsables des faibles valeurs des amplitudes horizontales des encroûtements sont : - une mince couche de vermets qui couvre les trottoirs en Algérie et en Sicile ; soit entre 5 et 10 cm d'amplitude horizontale [8] . Les résultats de l'étude montrent que le groupe des Photophiles Infralittoral Calme est aussi dominant que celui des Photophiles Infralittoral de mode Battu ; selon Molinier [7], plus la côte est battue, plus l'épaisseur des vermets est importante. Par conséquent, le faible hydrodynamisme ne favorise pas le développement des vermets ; - les espèces édificatrices des trottoirs sont très sensibles à la pollution, la présence massive de certaines algues dont les ulvales et les corallinales (Corallina elongata) indiquent une altération du milieu [5]; - les piétinements (public, pêcheurs, estivants et touristes), ces plates-formes sont en général très fréquentées. 2 - La flore : Les espèces algales déterminées sont aux nombres de 64 sur l'ensemble des trois sites étudiés ; 40 espèces appartiennent aux rhodophytes, 13 espèces aux chromophytes et 11 espèces aux chlorophytes pendant les deux saisons. Les espèces les plus représentatives sont les rhodophytes (Corallina elongata, Jania rubens) récoltées en épiphyte. Neogoniolithon sp est rencontrée uniquement au Chenoua, elle est en étroite association avec les Dendropoma petraeum pour édifier les concrétions. Hypnea musciformis est classée Photophile Infralittorale Thermophile par Boudouresque [3], elle forme des faciès et prolifère surtout en été. Selon Laborel [6], Bellan-Santini [2], Chemello [5], les espèces bioconstructrices de trottoirs à vermets sont apparentées à des eaux tempérées relativement chaudes. Pour les chromophytes, Cystoseira stricta forme des ceintures, et indique une eau pure, son recouvrement à Chenoua est moindre. Les chlorophytes (les ulves et les enteromorphes) se développent essentiellement à proximité des zones anthropisées ou fortement fréquentées. et sont donc des espèces indicatrices d'eaux polluées [1]. Les résultats du rapport R/P obtenus oscillent entre 2,62 à 3 et témoigneraient de la présence d'un peuplement à affinité relativement tempérée à chaude, cette affinité permet le bon développement des vermets.

Les bioconcrétionnements littoraux sont étudiés pour leurs intérêts écologiques et économiques, ce sont des processus très lents et rares en Méditerranée, ces biocénoses remarquables abritent une flore diversifiée servant de lieu de frayère et de nurserie pour de nombreuses espèces animales. Compte tenu de la lenteur et de la rareté de ces constructions biogéniques, le monitoring de ces peuplements semble indispensable à l'échelle méditerranéenne. Les trottoirs à vermets sont très sensibles à la pollution d'où la nécessité d'élaborer des plans de gestion et de conservation en rassemblant des données scientifiques précises et actualisées. La mise en place d'une base de données et d'une stratégie de surveillance, de conservation et d'un plan de gestion, sont indispensables. Dans une perspective préventive, il est nécessaire de procéder à la préservation de ces bioformations fragiles. Cette étude a permis de conclure que le site de Chenoua est le plus vulnérable. La biosurveillance, grâce à la cartographie de tous les bioconcrétionnements des côtes algériennes et aux mesures biométriques, reste le moyen le plus sur et le plus efficace pour la protection des habitats remarquables ainsi que des agents biologiques responsables de ces bioconstructions. Cette étude a révélé l'« état à temps zéro » et les mesures biométriques des trottoirs ; un suivi régulier de leur évolution ou de leur régression est indispensable à la sauvegarde et à la protection du patrimoine naturel de ces sites. Pour la conservation des types d'habitats marins naturels et remarquables et sur la base de critères méditerranéens, des fiches techniques d'évaluation écologique ont été établies pour chaque site. Ces fiches synthétisent les données scientifiques recueillies, et serviront à fournir des documents, à l'usage des gestionnaires, de prise de mesures de protection et de conservation.

Conclusion

BIONOMIE BENTHIQUE DES PEUPLEMENTS ICHTYOLOGIQUES DES FONDS CHALUTABLES DU SECTEUR ORIENTAL DE LA COTE ALGERIENNE

Wahid Refes ¹*, Nadia Semahi ¹ and Mostefa Boulahdid ¹

¹ Ecole Nationale Supérieure des Sciences de la Mer et de l'Aménagement du Littoral, 16000, Alger, Algérie - wrefes@hotmail.com

Abstract

Ce travail est une synthèse des observations réalisées sur la faune ichtyologique des fonds chalutables du secteur oriental de la côte algérienne au cours de la période 2005-2006. Il a permis de recenser 201 espèces de poissons, dont les peuplements ichtyologiques se structurent en trois unités bionomiques : le peuplement du détritique côtier à *Vidalia volubilis* ou à *Ophiura texturata* ; le peuplement du détritique du large à *Leptometra phalangium* ou à *Neolampas rostellata* ; le peuplement des vases bathyales à *Funiculina quadrangularis* et *Aporrhais serresianus* ou à *Isidella elongata* et à *Thenea muricata*. *Keywords: Algerian Basin, Fishes, Zoobenthos*

Introduction

À l'exception des travaux de Maurin *et al.* [1] sur la bionomie benthique des peuplements ichtyologiques du talus continental de la partie orientale de la côte algérienne (région d'El Kala, golfe d'Annaba, golfe de Skikda, golfe de Béjaïa), réalisés lors de la campagne de pêche du « Président Théodore-Tissier » en 1960, on ne recense aucun travaux sur cette thématique par la suite en Algérie. Cette étude présente une image récente et actualisée de la bionomie des peuplements ichtyologiques des fonds chalutables du secteur oriental de la côte algérienne.

Matériel et méthodes

Le secteur oriental de la côte algérienne s'étend de Cap Segleb (36°56'45''N – 8°36'57''E) à Cap Carbon (36°46'36''N – 5°06'27''E), il regroupe la région d'El Kala, le golfe d'Annaba, le golfe de Skikda, la baie de Jijel et le golfe de Béjaïa. Les résultats présentés sont des observations réalisées régulièrement et tout au long de l'année entre 2005 et 2006 lors de campagnes de pêche réalisées, à bord de chalutiers professionnels, par recensement des poissons et de la mégalofaune benthique accompagnatrice sur des fonds compris entre 22 et 795 mètres.

Résultats et discussion

Dans ce travail, les investigations, réalisées sur les fonds chalutables du secteur oriental de la côte algérienne entre 2005 et 2006, ont permis de recenser 201 espèces soit 29 Chondrichthyes et 172 Osteichthyes. Une classification ascendante hiérarchique est réalisée sur une matrice de 47 espèces constantes (B. boops ; C. conger ; M. merluccius ; M. barbatus ; P. acarne ; P. bogaraveo : T. trachurus : T. lvra) et communes (A. m. mediterranea : A. sphyraena; A. hemigymnus; A. laterna; A. rueppelli; A. cuculus; A. obscura; C. aper; C. rubescens; C. agassizii; C. linguatula; C. coelorhynchus; D. maroccanus; D. annularis; E. encrasicolus; E. denticulatus; E. spinax; G. a. argenteus; G. melastomus; H. d. dactylopterus ; H. mediterraneus ; L. caudatus ; L. boscii ; L. cavillone ; L. budegassa; M. scolopax; M. poutassou; M. surmuletus; P. erythrinus; P. blennoides; R. asterias; R. miraletus; R. oxyrinchus; S. pilchardus; S. aurita; S. scombrus; S. smaris; U. scaber; Z. faber) sur le suivi des 59 traits de chalut effectués lors des campagnes de 2005-2006, en utilisant la distance euclidienne et la méthode de Ward comme critère d'agrégation. Il ressort de cette analyse la présence de trois ensembles ichtyologiques : - un ensemble côtier entre 20 et 200 mètres comprenant le plateau continental et le bord supérieur du talus ; il est caractérisé par un cortège de 5 espèces constantes (M. barbatus ; P. acarne ; B. boops ; T. trachurus ; Trigla lyra) et 8 espèces communes (P. ervthrinus : A. m. mediterranea : E. encrasicolus : S. pilchardus; D. maroccanus; C. linguatula; M. surmuletus; Z. faber). - un ensemble profond entre 200 et 795 mètres ; il est caractérisé par un cortège de 13 espèces communes (E. spinax : G. melastomus : H. mediterraneus : C. coelorhynchus; E. denticulatus; L. caudatus; P. blennoides; R. oxyrinchus; C. agassizii; G. a. argenteus; H. d. dactylopterus; M. poutassou; A. hemigymnus). - un ensemble à large répartition bathymétrique ; il rassemble 3 espèces constantes (M. merluccius ; C. conger ; P. bogaraveo) et une espèce commune (L. cavillone). Ces observations confirment les résultats obtenus en Méditerranée par Stefanescu et al. [2] et Tserpes et al. [3]. Ils ont mis en évidence une forte relation entre l'assemblage des poissons et la profondeur. Il en est de même pour l'ensemble de la macrofaune et mégalofaune benthiques et démersales [4], [5], où la bathymétrie est un des principaux critères de ségrégation de l'organisation des peuplements. Par contre, une zonation géographique des peuplements ichtyologiques étudiés entre les différentes zones (région d'El Kala - golfe d'Annaba - golfe de Skikda - baie de Jijel golfe de Béjaïa) n'a pas pu être mis en évidence par rapport à l'ensemble des

traits de pêche réalisés dans le secteur oriental de la côte algérienne, malgré l'écart longitudinal entre la région d'El Kala et le golfe de Béjaïa de plus de 3°. Sur la base des travaux de Pérès et Picard [6], les fonds chalutables sont organisés en trois unités bionomiques de la côte vers le large : - le peuplement du détritique côtier à Vidalia volubilis ou à Ophiura texturata, où les espèces caractéristiques sont P. acarne et P. erythrinus, ainsi que les espèces B. boops, M. barbatus, M. surmuletus et Z. faber. - le peuplement du détritique du large à Leptometra phalangium ou à Neolampas rostellata, où les espèces caractéristiques sont M. scolopax et T. lyra, ainsi que M. barbatus. - le peuplement des vases bathyales à Funiculina quadrangularis et Aporrhais serresianus ou à Isidella elongata et à Thenea muricata, où les espèces caractéristiques sont C. agassizii, C. coelorhynchus, E. spinax, G. melastomus, H. d. dactylopterus, L. caudatus, M. poutassou et P. blennoides, ainsi que C. aper. Cette structuration bionomique, des peuplements ichtyologiques des fonds chalutables du secteur oriental de la côte algérienne, est liée essentiellement à la nature sédimentaire des fonds.

Abstract

Cet inventaire est une synthèse des travaux antérieurs et des observations originales réalisées sur la faune ichtyologique du secteur oriental de la côte algérienne, il a permis de recenser 302 espèces soit 1 Agnatha, 52 Chondrichthyes et 249 d'Osteichthyes. *Keywords: Algerian Basin, Biodiversity, Fishes*

Introduction

Ce travail présente un inventaire exhaustif des poissons signalés dans le secteur oriental de la côte algérienne.

Les résultats présentés sont des observations réalisées régulièrement entre 2000 et 2006 lors de campagnes de pêche et dans les ports de pêche, ainsi que les données bibliographiques de plusieurs travaux [1], [2], [3], [4], [5] et [6].

Résultats et discussion

302 espèces ont été recensées soit 1 Agnatha (1 famille), 52 Chondrichthyes (18 familles) et 249 Osteichthyes (88 familles). Les familles les mieux représentées sont les Rajidae (12 espèces), Serranidae (12 espèces), Sparidae (22 espèces), Labridae (19 espèces), Blenniidae (10 espèces) et Soleidae (11 espèces). Ces 6 familles représentent 28,48 % de la diversité spécifique du secteur oriental de la côte algérienne. Une compilation des données ichtyologiques recueillies sur l'ensemble de la côte algérienne [7] et [8] montre que les espèces signalées dans le secteur oriental de la côte algérienne ne représentent que 71,56 % des 422 espèces signalées sur l'ensemble de la côte algérienne, où les Agnatha, Chondrichthyes et Osteichthyes répertoriés représentent respectivement 50, 66,67 et 47,44 % et 72,81 % des espèces recensées sur l'ensemble de la côte algérienne. Liste des espèces: Agnatha : Petromyzonidae (P. marinus) - Chondrichthyes : Hexanchidae (H. griseus); Heptranchidae (H. perlo); Echinorhinidae (E. brucus); Squalidae (C. granulosus, C. uyato, C. coelolepis, D. licha, E. spinax, O. centrina, S. acanthias, S. blainvillei); Rhinobatidae (R. rhinobatos); Rajidae (R. alba, R. asterias, R. batis, R. brachyura, R. circularis, R. clavata, R. fullonica, R. miraletus, R. montagui, R. naevus, R. oxyrinchus, R. radula); Torpedinidae (T. marmorata, T. nobiliana, T. torpedo); Dasyatidae (D. centroura, D. pastinaca, D. violacea, G. altavela); Myliobatidae (M. aquila, P. bovinus); Mobulidae (M. mobular); Squatinidae (S. oculata, S. squatina); Alopiidae (A. vulpinus); Lamnidae (I. oxyrinchus); Scyliorhinidae (G. melastomus, S. canicula, S. stellaris); Triakidae (G. galeus, M. mustelus, M. punctulatus); Carcharhinidae (C. altimus, C. brevipinna, C. brachyurus, C. plumbeus, C. obscurus, Prionace glauca); Sphyrnidae (S. zygaena) ; Chimaeridae (C. monstrosa) - Osteichthyes : Anguillidae (A. anguilla); Xenocongridae (C. bicolor); Muraenidae (G. unicolor, M. helena); Nettastomatidae (F. oxyrhyncha, N. melanurum); Congridae (C. conger, G. mystax); Ophichthidae (E. myrus, O. refus, O. serpens); Dysommidae (D. brevirostre); Nemichthyidae (N. scolopaceus); Notacanthidae (N. bonapartei, P. rissoanus); Clupeidae (A. fallax, S. pilchardus, S. aurita, S. maderensis); Engraulidae (E. encrasicolus); Argentinidae (A. sphyraena, G. leioglossus, N. oblita); Gonostomatidae (M. muelleri); Sternoptychidae (A. hemigymnus); Chauliodontidae (C. sloani); Stomiidae (S. b. boa); Alepocephalidae (A. rostratus); Aulopidae (A. filamentosus); Synodontidae (S. saurus); Chlorophthalmidae (C. agassizii); Paralepididae (N. rissoi, P. c. coregonoides); Myctophidae (B. glaciale, C. maderensis, D. metopoclampus, E. rissoi, L. crocodilus, M. punctatum, N. elongatus, S. veranyi); Lophiidae (L. budegassa, L. piscatorius); Moridae (G. maraldi, M. moro); Gadidae (A megalokynodon, G. a. argenteus, G. mediterraneus, M. poutassou, M. d. macrophthalma, P. blennoides, P. phycis, T. m. capelanus); Merlucciidae (M. merluccius): Ophidiidae (B. robustus, C. laticeps, O. barbatum, O. rochei): Carapidae (C. acus, E. dentatus); Macrouridae (C. mediterranea, C. coelorhynchus, C. guentheri, H. italicus, N. aequalis, N. sclerorhynchus, T. trachyrhynchus); Exocoetidae (C. heterurus, E. volitans); Belonidae (B. b. gracilis); Atherinidae (A. boyeri, A. hepsetus); Trachichthyidae (H. mediterraneus); Zeidae (Z. faber) ; Caproidae (C. aper); Macroramphosidae (M. scolopax); Fistulariidae (F. commersonii); Syngnathidae (H. hippocampus, H. ramulosus, S. abaster, S. acus, S. typhle); Scorpaenidae (H. d. dactylopterus, S. elongata, S. loppei, S. notata, S. porcus, S. scrofa); Triglidae (A. cuculus, A. obscura, E. gurnardus, L. cavillone, L. dieuzeidei, P. cataphractum, T. lucerna, T. lyra); Dactylopteridae (D. volitans); Serranidae

(A. anthias, D. labrax, D. punctatus, E. aeneus, E. caninus, E. costae, E. marginatus, M. rubra, P. americanus, S. cabrilla, S. hepatus, S. scriba): Apogonidae (A. imberbis, E. denticulatus, E. telescopus); Pomatomidae (P. saltatrix); Echeneididae (R. remora); Carangidae (C. glaycos, C. crysos, L. amia, S. dumerili, T. ovatus, T. mediterraneus, T. picturatus, T. trachurus); Emmelichthyidae (C. cirrus, S. flexuosa, S. maena, S. smaris); Pomadasyidae (P. incisus); Sparidae (B. boops, D. dentex, D. gibbosus, D. macrophthalmus, D. maroccanus, D. annularis, D. c. cervinus, D. puntazzo, D. s. sargus, D. vulgaris, L. mormyrus, O. melanura, P. acarne, P. b. bellottii, P. bogaraveo, P. erythrinus, P. auriga, P. caeruleostictus, P. pagrus, S. salpa, S. aurata, S. cantharus); Sciaenidae (A. regius, S. umbra, U. canariensis, U. cirrosa, U. ronchus); Mullidae (M. barbatus, M. surmuletus); Pomacentridae (C. chromis); Cepolidae (C. rubescens); Mugilidae (C. labrosus, L. aurata, L. ramada, L. saliens, M. cephalus); Sphyraenidae (S. sphyraena, S. viridensis); Labridae (A. palloni, C. julis, C. rupestris, L. bergylta, L. bimaculatus, L. merula, L. viridis, L. fasciata, S. c. cinereus, S. doderleini, S. mediterraneus, S. melanocercus, S. melops, S. o. ocellatus, S. roissali, S. rostratus, S. tinca, T. pavo, X. novacula); Trachinidae (E. vipera, T. araneus, T. draco); Uranoscopidae (U. scaber); Blenniidae (B. ocellaris, C. galerita, L. nigriceps, L. pavo, L. trigloides, P. gattorugine, P. sanguinolentus, P. tentacularis, P. zvonimiri, S. cristata); Tripterygiidae (T. tripteronotus); Callionymidae (C. lyra, C. maculatus, C. risso, S. phaeton); Gobiidae (A. m. mediterranea, D. quadrimaculatus, G. cobitis, G. cruentatus, G. niger jozo, G. paganellus, L. friesii) ; Gempylidae (R. pretiosus); Trichiuridae (L. caudatus); Scombridae (A. rochei, E. alletteratus, S. sarda, S. japonicus, S. scombrus, Thunnus thynnus); Xiphiidae (X. gladius); Centrolophidae (C. niger); Nomeidae (C. gracilis); Stromateidae (S. fiatola); Tetragonuridae (T. cuvieri); Citharidae (C. linguatula); Scophthalmidae (L. boscii, L. whiffiagonis, P. m. maxima, S. rhombus) ; Bothidae (A. imperialis, A. laterna, A. rueppelli, A. thori, B. p. podas); Soleidae (B. profundicola, B. luteum, D. cuneata, M. ocellatus, M. variegatus, M. hispidus, S. impar, S. kleinii, S. lascaris, S. senegalensis, S. vulgaris); Cynoglossidae (S. ligulatus, S. nigrescens); Balistidae (B. carolinensis); Tetraodontidae (E. guttiferum); Molidae (M. mola).

Development

Abstract

Monthly sampling of picarel, *Spicara smaris*, was carried out from January to May 2003 in the Saronikos Gulf (Greece). The spawningfrequency was estimated at the peak of spawning (April-May 2003) by the use of post-ovulatory follicles, migratory-nucleus stage and hydrated oocytes. The percentage of the daily spawning females was found equal to 67.74%, which means that the female spawns every 1.48 days on average. Big females, which were predominant during the whole period except of May, accelerated their spawning rate in April forecasting thus the cessation of their spawning season. *Keywords: Aegean Sea, Spawning, Fishes, Demersal*

Introduction In the Eastern Mediterranean, picarel (*Spicara smaris* L.) is a commercial and popular species [1]. About half of total landings of this species catch is taken by beach seines, while the other half is distributed between trawlers and nets. Picarel is a multiple spawner [2] with a peak of spawning in the Saronikos Gulf in April-May [3]. In the present study the spawning frequency of picarel was estimated at the peak of spawning in the Saronikos Gulf (Aegean Sea, Greece). This indicator is an important reproductive variable and a crucial parameter for the spawning biomass estimation of the pelagic species [4].

Tab. 1. Spawning frequency of picarel *Spicara smaris* from at the peak of spawning in the Saronikos Gulf (Greece)

	Spawning on the night of capture			Spawned the night before the capture		Mature females	
	-	N		%	N	%	N
Sampling Date	New pofs (<24 h old)	Late MN stage oocytes	Hydrated oocytes		Pof 1 day old		
April 15	5	16	0	44.68	13	27.66	47
April 29	24	28	2	84.38	56	87.50	64
May 13	18	55	8	90.00	65	72.22	90
Total	47	99	10		134		201
Mean %				73.02		62.46	

Material and Methods Samples of picarel were monthly (Jan-May 2003) collected by beach seiners, trawlers and gillnets. Specimens were randomly taken from the catch, measured (total length) to the nearest mm, sexed and females were classified to reproductive stages according to Nikolsky's [5] scale. A total of 201 mature ovaries (greater than stage II) out of 419 females, were sectioned. The spawning frequency was estimated at the peak of spawning [4] and was based on the incidence of post-ovulatory follicles (pofs), migratory-nucleus (MN) stage oocytes and hydrated (H) oocytes [6]. The best indicator of the time of spawning may be the occurrence of females with both H oocytes and new pofs [7], because these females have been caught while spawning. In our case H oocytes although with no follicle along with new pofs were indeed found in the samples during night (caught by trawlers or nets). Since the MN stage lasts in a number of species for about 24 h [6], it was assumed that females, which contained late MN stage oocytes or H oocytes (still within their follicles) would spawn on the night of capture, while those females, which contained new pofs had already spawned at the same night. The use of post-ovulatory follicle method [6] can be applied when the age of pofs (based on the extent of their deterioration) is known. Pofs resembling to collapsed structures with however identifiable thecal and granulosa layers (old pofs) indicate that an individual female had spawned 24 h before sampling (pof 1 day), while bigger and very convoluted pofs with linearly arranged granulosa cells (new pofs) indicate that spawning has taken place at the night of sampling (pof < 24 h) [8]. The histological characteristics that were identified in the sections and were used for the estimation of the time of spawning were: late MN stage oocytes or H oocytes or new pofs indicated spawning on the night of capture, while pofs 1 day old indicated spawning occurred the night before capture. Analysis of variance (ANOVA) was performed for the comparison of means.

Results and Discussion During night samplings of picarel, the occurrence of both H oocytes without follicles and new pofs in the ovaries indicated that spawning was indeed in progress at that particular night [6]. Spawning during night is a reproductive strategy for achieving better survival since it provides protection from predators [9]. The histological characteristics which were used to assign the females spawning at the night of capture (i.e. late MN stage oocytes, H oocytes within their follicles, or new pofs) could have never been observed in any possible combination in the ovary of a femaly spawning at the night of capture. The fact that during night samplings late MN nucleus

stage oocytes, hydrated oocytes or new pofs were never met in the same ovary indicates the validity of the methodology followed. The percentage of females spawning on one of the two different nights (the night of capture and/or the night before) per sampling date are presented in Table I. It was found that 73.02% of the mature females spawned on the night of capture, while 62.46% spawned the night before. Variance of the monthly percentages was found to be homogeneous for the two spawning nights (P>0.05). Thus, analysis of variance of the percentage of females spawning per day (by month as a covariate) on spawning night indicated that the difference was not significant (F= 0.21; P=0.67). Subsequently, the mean of the two estimates gives the average percentage of the daily spawning females, which was found equal to 67.74%. This means that the female spawns every 1.48 days on average during the peak of spawning (15 April - 13 May: 28 days). Spawning females in April were significantly bigger in length than those caught in May (P<0.001). An increase of the spawning frequency more than two times was observed at the end of April (Table I). It seems that big females, which at that period are dominant, accelerate their spawning rate as they reach the cessation of their spawning season. Indeed in May only small females were left spawning, since picarel migrate immediately after spawning to the feeding grounds [10].

FEEDING SELECTIVITY OF SOME BENTHIC FISH FROM THE ROCKY BOTTOM OF THE ROMANIAN BLACK SEA COAST (AGIGEA AREA)

Irina Rosca¹*, Aliona Novac¹ and Victor Surugiu¹ ¹ Universitatea Alexandru Ioan Cuza Iasi - ada_iri@yahoo.com

Abstract

Three benthic dominant fish species were analyzed in the Agigea area of the Romanian Black Sea in order to quantify any forage selectivity or avoidance behavior of these fish. For this purpose items found in the stomachs of these fish were identified and compared, in terms of percent occurrence, to the corresponding values of the same species from random rocky bottom transects taken at the point of capture. The calculation of Ivlev's index indicated that amphipods and decapods were positively selected by the analyzed fish. Contrary to the literature sources, the data obtained assign the analyzed fish species to selective predators. *Keywords: Black Sea, Rocky Shores, Fish Behaviour, Zoobenthos*

Introduction

The round goby (*Neogobius melanostomus* Pallas 1814), the knout goby (*Mesogobius batrachocephalus* Pallas 1814), and the black scorpionfish (*Scorpaena porcus* Linnaeus 1758) are one of the main benthic feeders from the rocky seabed of the Black Sea. These species are considered to exhibit a generalistic feeding strategy with a relative broad niche width [1]. The aim of this project is to provide qualitative and quantitative data on feeding ecology of these fish species with special emphasis on their feeding selectivity.

Material and Methods

Fish were sampled with a trap net placed at a depth of 9.5 m and 12.5 m. For each species, 100 individuals were dissected and the gastrointestinal tracks were drawn and immediately preserved in absolute ethyl alcohol. The prey items were identified to the lowest taxonomic level as possible. The prey size also was taken into account [2]. In parallel, the macrofauna inhabiting rocky bottom, sampled using SCUBA diving from 0 to 16 m depth, was analyzed in order the establish community structure patterns in terms of species richness, abundance and biomass. Dietary preferences were calculated using Ivlev's selectivity index [3]. The values of 1 indicate the maximum preferences and selectivity towards a food item, those of -1 indicate the maximum avoidance, and 0 indicate the random feeding. Categories in the collected benthos were defined to correspond with the taxonomic levels identified in the guts.

Results and Discussion

The faunistic analysis of the 52 samples from the rocky bottom revealed the presence of 97 taxa, from which 88 were identified to the species level. Dominant groups as number of species were Polychaeta, Amphipoda, Hydrozoa, Decapoda and Turbellaria, which accounted for more than 50% of the total number of the species identified. The diet of analyzed fishes was based on gastropods, amfipods, bivalves, ispods and chironomid larvae. The round goby and the knout goby fed on 35% of the resources of the rocky benthos and the black scorpionfish on 29% of it.

Neogobius melanostomus
 Mesogobius batrachocephalus
 Scorpaena porcus

Fig. 1. Ivlev's selectivity index values for *Neogobius melanostomus*, *Mesogobius batrachocephalus* and *Scorpaena porcus*

The Ivlev's index indicated that the food items positively selected by the fish were mainly amphipods (>0.90)and decapods (>0.58)(Fig. 1). From the bivalves

only *Mytilaster lineatus* showed positive selection. Although the benthic samples revealed that *Mytilus galloprovincialis* is the dominant species, it presented negative electivity values for all the three species of fish analyzed (-0.85 for round goby, -0.69 for knout goby and -0.81 for black scorpionfish). The avoidance of this species may be due to either digestibility or their body size. Comparing the content of the fish guts with the macrozoobenthos from different depths, it has been observed that there are small differences, except those related to the bivalves *Mytilus galloprovincialis* and *Mytilaster lineatus*. The round goby and the knout gobyseem to avoid *Mytilaster* between 0 and 2 m depth (-0.455 and -0.001 respectively), but prefer it at greater depth (0.893 and 0.958 respectively). It is difficult to determine why a particular prey type is selected. We suggest that several of the important factors are prey size, mobility, type of fixing to substratum, activity and digestibility. Based on the obtained data it can be concluded that these fish species are selective feeders.

Abstract

Foraging specializations among marine mammals are susceptible to social transmission and could lead to the separation of distinct social units, thus increasing conservation challenges. We analysed the association patterns of the bottlenose dolphins population of the Bocche di Bonifacio International Marine Park to verify the existence of two distinct communities based on different feeding strategies. No correlation was found between the dolphin foraging tactics and community membership. Moreover, the population seems to be ruled by a random association strategy. For these reasons the managing authorities should treat this population as one entity and take effective synergic actions to ensure the conservation of this resource and its habitat. *Keywords: Cetacea, Marine Parks*

Introduction

Culturally differentiated communities among marine mammals populations are widely documented [1]. The transmission of cultural traits, such as peculiar foraging tactics, to preferred associates can trigger the development of behaviourally differentiated units belonging to the same population [2,3]. Bottlenose dolphins inhabiting the waters of the 'Bocche di Bonifacio' International Marine Park regularly interact with the trammel nets set by the coastal fisheries operating in this area. The purpose of this paper is to describe the patterns of associations of this bottlenose dolphins population and investigate whether the net-foraging behaviour is a cultural trait which influences the dolphin social structure distinguishing a community from another within the population.

Material and Method

From July 2006 to July 2008, 139 boat-based surveys, leading to 112 dolphin sightings, were made in the study area (408 km²). During each encounter date, sex and behaviour were recorded and 71 individuals were photo-identified and catalogued. Dolphins were categorized as 'trammel-feeders' (Tf) or 'non-trammel-feeders' (Ntf) based on whether they had ever been observed foraging on gillnets [4]. Association analysis were carried out on 23 animals sighted at least 5 times using the Half Weight Index of association [5] in Socprog 2.3. Firstly, the degree of social interaction between dolphins with different feeding habits was assessed. Secondly, the null hypothesis that individuals associate randomly was tested for the whole population and separately for each dyad.

Results and Discussion

Although within-classes associations (Tf-Tf = 0.13; Ntf-Ntf = 0.25) were higher than between-classes (Tf-Ntf = 0.06), the differences were not significant (t= 6.20, p=1, correlation coefficient= 0.38), highlighting that individuals significantly and frequently interact also with animals that have different foraging tactics. No evidence of significantly high associations coefficients was detected, since the standard deviations for both observed and randomly permuted HWI means had very similar values (P > 0.5). Furthermore, only one dyad showed a significant level of association (P > P)97.5), a value even lower than that expected if associations were completely random. In conclusion, the foraging specialization detected in the population cannot demonstrate the existence of culturally separated communities based on social learning of different feeding strategies. For these reasons the Bocche di Bonifacio dolphin society should be considered as one entity. Furthermore, since no significantly high or small associations indexes were detected either at population or at dyadic level, it can be inferred that this community lives in a fission-fusion society where companions are likely to be chosen randomly. These results represent important findings that the managing authorities of the Bocche di Bonifacio international Marina Park, namely the "Arcipelago of La Maddalena" National Park and the "Bocche di Bonifacio" Natural Reserve, should consider as fundamental assumptions when addressing the conservation issue of this biological resource.

ON THE TERMAL CONTROL OF COTYLORHIZA TUBERCULATA JELLYFISH POPULATION

Javier Ruiz^{1*}, Diana Astorga¹ and Laura Prieto¹

¹ Department of Coastal Ecology and Management, Instituto de Ciencias Marinas de Andalcía (CSIC) - javier.ruiz@icman.csic.es

Abstract

Cotylorhiza tuberculata is a jellyfish generating outbursts in the coastal lagoon of Mar Menor since mid-90s. Ups and down of the population proceeded along different years without a clear scientific understanding of its origin. In this manuscript we hypothesize that the tight control exerted by temperature on the life cycle of *Cotylorhiza tuberculata* is the origin of such fluctuations. Temperature triggers the strobilation process and cold waters generate high mortalities to the benthic phase. Modelling this thermal control results in simulations of medusa stocks closely resembling its weekly landings in the coastal lagoon. Conclusions derived from this closed population are a fore-signal of future evolution of jelly fish species in a Mediterranean with milder winters an longer summers. *Keywords: Medusae, Models, Coastal Processes*

The Mar Menor is a large (135 Km²) and shallow (3.5 m average depth) lagoon almost isolated from the western Mediterranean by a 22 Km long sandy bar. Progressive increase of both human pressure on the shores and agriculture forcing on the draining waters modified original communities during the 80s [1]. Parallel to this degradation, and coherently with an habitat-deterioration triggering of jellyfish blooms [2], *Cotylorhiza tuberculata* (CT) first appeared in the lagoon and started to build massive outbreaks in early 90s [3]. Highs and lows of CT abundance in the Mar Menor progressed since its first appearance without scientific understanding of the fluctuation origin. The societal alarm and the economic impact on bathing activities activated a program to extract medusa from the lagoon and generated a time series of capture per unit effort data.

A Bayesian model was implemented to assimilate these data in the mechanics driving the life cycle of exploited populations [4], The model tested the hypothesis that fluctuations have their origin in the tight control that temperature exerts on the life cycle of CT. Based on controlled experiments, all phases of the life cycle except strobilation and polyp mortality were found insensitive to the range of physical conditions present in the lagoon. Strobilation is triggered when the water temperature first rises over ~18°C with negligible ephira production later on. Therefore, the summer spam for the medusa phase can be accounted in terms of the time the lagoon is >18°C. Longer summers imply longer periods for medusa somatic growth and for population biomass to accumulate. Owing to the annual life-span of CT, polyps are responsible to transfer the population across winters but their survival is very sensitive to cold waters. Temperatures bellow 16°C result in mortalities that, when accumulated along the winter, heavily impact the remnants individuals available for strobilation and medusa generation in the subsequent summer. The model is then articulated on the basis of successive stages of polyp and medusa that alternate under the control of lagoon temperature and the progress of seasonal cycles. The simulated medusa stock in the lagoon reproduces an intra and inter-annual evolution coherent with the observed abundances of CT. This includes the massive outbursts during the long summers from 2000 to 2004 as well as the dramatic collapse of medusa population in 2005, after a previous very severe winter. The capacity of a thermally-forced life-cycle to explain in situ changes indicates the severe control that temperature exerts on CT abundance. Once the ecosystemdegradation conditions for jellyfish outbreaks are met, and the homeostasis of the system decreased, CT seems to fluctuate under the simple rule of the warmer the better.

Though the link between environment and scyphozoa populations has been extensively explored before (e. g. [5]) they mainly investigate statistical correlations between environmental indexes and jellyfish abundance rather than identifying the cause-effect control in the mechanics of jellyfish life-cycle and population dynamics. This mechanics offers a more solid ground to understand past periods of jellyfish occurrence and to project future expectations in a Mediterranean where milder winters and longer summer will modify the community balance of winners and losers.

SIX YEARS OF SURVEY (2004-2009) ON REPRODUCTION OF SEA TURTLES ON SHKAÏFATE BEACH, SYRIAN COAST (PROPOSED AS PROTECTED AREA)

A. Saad ^{1*}, A. Rees ², W. Sabour ³, A. Othman ³, C. Genaidi ³ and N. Alkhateeb ³ ¹ Tishreen University, Lattakia, Syria - adibsaad@scs-net.org ² Sea Turtle Prtoction Society of Greesce

³ Syrian Society for Aquatic Environment Protection, Lattakia, SYRIA

Abstract

Nesting turtles survey between 2004 – 2009 were conducted along the coast between Shkaifat and Snawbar (south of Lattakia city), along a 12.5 km stretch of coast. Results from the 2004- 2009 nesting season confirmed that a skaifat- snawbar beach near Latakia in Syria was an important nesting site for green turtles in the Mediterranean *Keywords: Beach, Conservation, Turtles, Levantine Basin, Monitoring*

Introduction

The presence of loggerhead and green sea turtles(*Chelonia mydas*) and loggerheadturtle (*Caretta caretta*), off the coast of Syria, was first reported by Gruvel [1], but nesting on the country's beaches was not indicated. The next turtle information to come out of Syria resulted from a rapid assessment survey in 1991 that identified low-level nesting concentrated on a beach south of Latakia City [2]. Local researchers noted incidental turtle captures in beach seines, and also observed turtles stranded along the coast [3]). Since 2004 a more extensive coastal survey was undertaken, primarily to better identify Syria's actual and potential nesting populations [4].

Martial and Methods

From last week of may to second week of October the 7.5 km beach between North Jableh and Snowbar, $35^{\circ}28'00"N$, $35^{\circ}51'45"E$ was surveyed in the earl morning for evidence of sea turtle nesting, nest hatching and events that may have affected the incubation of nests, such as inundation by storm waves or depredation. The adjoining beach to the north, from Snowbar to the river Al Kabir Ash Shamali next to Lattakia, 5 km to the north, was surveyed, as a continuation of the daily survey, 10 times at weekly intervals to record the same information.

Emergence tracks from adult turtles were checked for species and evidence of nesting and the track recorded as either a nesting or non-nesting emergence... Nesting species was determined by appearance of the track [5] and by maximum width of the track. In the eastern Mediterranean, loggerhead turtles are generally far smaller than green turtles , and hence their track widths are generally much narrower. Additionally nest excavation often afforded confirmation of species by identification of dead or live hatchlings or embryos . For determining the movement of sea turtles during and after the reproduction period, we tagged 64 individual during 2004- 2009 by metal tags contain the name and address of the teem leader.

Results and Discussion

During 2004, 2006, 2008 and 2009 we noticed 8, 15 and 21 nests in each kilometer (respectively) for the green turtle *Chelonia mydas*, as for *Caretta caretta*, we recorded many nests and spawning sites in the same beach, but in less number (Fig 1). During 2005 and 2007, the number of nest very lower (3 and 2 nest per km of the beach). These results indicate that this surveyed area is among the best sixth coastal zones suitable for the reproduction of the green sea turtles all round the Mediterranean coast. Syria may also play a significant role hosting foraging turtles, asloggerheads from both

Cyprus and Greece have been shown to forage in near shore Syrian waters [6]. Since green turtle *Chelonian mydas* nesting was discovered in 2004, repeated surveys have indicated that Latakia beach hosts a regionally important rookery. This, together with the presence of lower frequency nesting at a few other beaches places Syria as the third most important country, after Turkey and Cyprus, for green turtle nesting in the Mediterranean. Gerosa and Casale [7] indicate that interaction of sea turtles with fisheries in the Mediterranean is a major threat and that little is known of the level of incidental turtle captures in Syria. Since 2007. We undertaken a field work concerning this problem.

Fig. 1. Variation of the number of nest turtles : loggerhead and green) on Lattakia beach during six years of survey

IMPACT OF INVASIVE SPECIES ON THE BIODIVERSITY AND FISH STOCK; CASE STUDY: FISTULARIA COMMERSONII RUPPEL, IN THE SYRIAN COAST

Adib Ali Saad ¹* and Waad Georges Sabour ¹ ¹ Tishreen University- Lattakia, SYRIA - adibsaad@scs-net.org

Abstract

Reproductive cycle and feeding habit of bluespotted cornet fish *Fistularia Commersonii*, new lessepsian migrant was studied in the Syrian coastal water (Levantine Basin). *Fistularia commersonii* recorded for the first time in this area during 2001 has shown a rapid development among the ichtyofauna in the Eastern Mediterranean. It is carnivorous, and feed on many small fish species, such as *Sardinella* spp., *Sprarus spratus, Alosa fallax, Boops bops*.etc. 12-30 individual preys was found in the stomach of every specimen. The high fecundity rate, the long period of reproduction, (May–August) and its rapidly expanding population feeding on fish, make a decline of the biomass and causing damage and loss to fisheries yield. *Keywords: Life Cycles, Migration, Biodiversity, Fishes, Levantine Basin*

Introduction

During the nineties, a strange fish species of Indo-Pacific origin from family Fistularidae (cornetfishes) appears in the south-east Levantine Basin, the first record was reported by in the Palestinian coastal [1]. In July 2001 three specimens of Fistularia commersonii of total length (ST): 35.6; 77.8; 82.3 cm (SL) respectively was caught with beach seine in the seawater south Lattakia (35.44' N; 35.89' E) at a depth of 12 m. It was the first record of this lessepsian specis in the Syrian waters [2]. It was also reported in adjacent Lebanese coastal waters [3]. Two years later, it was observed with great number and became strong invader with regard to the increased percentage in the catch. Given the environmental conditions changes occurring in the Mediterranean and because of the connection between the Levantine Basin and the Red Sea through the Suez Canal, the East Mediterranean was subject to a big invasion of marine species. In the beginning this invasion was very slow because of the big difference in salinity between the both marine environments and because the high salinity of Bitter lake which constituted a natural barrier to the migration of marine organisms. Prior the construction of Aswan High Dam, the freshwater of the Nile during the flood, in reducing the salinity at the entrance Nord of the canal at Port Saïd, contribute to constitute a hyposaline seawater forming a barrier to this migration. After the functioning of the High Dam in 1965 and the stop of the flood, the salinity of the south-east corner of Mediterranean start increasing , making little difference in the salinity between the Red sea and East Mediterranean. The increased navigation through the Canal pathway during the last century and the global warming occurring word wide in the oceans inducing the rise of the Mediterranean water salinity have enhanced the Lessepsian migration process. The number of invasive fish species in the Levantine Basin reach to date 65 [4.5], from which 43 are recorded in the Syrian waters. [6] Fistularia commersonii is themore recent newcomer fish record in our water [2], measuring a total length of 29 cm. Afterwards the caught number by fish training nets increased progressively. In May 2003, 36 individuals measuring between 40 and 108 cm were caught in only one fish net. After this period, we observed increasing frequency of this invading species in the fishermen nets and with high number forming about 2-3% of the total net coastal catch. Given that the introduction of new species in the environment can surely affect in the marine biodiversity and in the competition of the biocoenoses and food, it is very important to know the behavior of reproduction and feeding of the newcomers in the local ecosystem in order to know it stock management and understand the relationship between themselves and between them and native species and thus knowing its role in the structure of the biodiversity in this ecosystem.

Material and methods

The study was performed in the coastal area of Lattakia along 80 km between Turkish border in the north and Banias in the south. A total of 460 specimens of Bluespotted cornet fish *Fistularia commersonii* were collected by beach seine and trammel net at depth of 2-20 m from August 2004 to September 2005. For each fish, the total length (TL) and standard length (SL) were measured to the nearest centimeter and total weight (W) to the 0.1 g. Sex and maturity were determined macroscopically. The weight of the gonad (Wg) was recorded to the 0.01 g. Spawning season was determined in using the monthly change of stages of maturation and the gonado-somatic index (GSI). Fecundity was estimated gravimetrically. In addition, the feeding habit was studied by analysis of food content in the digestive tube.

Result and Discussion

The GSI values of females were generally higher than those of males, but both

indices followed the same pattern. According to the examination of maturation stages and GSI values, Fistularia commersonii spawned in the Syrian coast from the second half of May until early August, with greatest intensity in June (Fig.1). The first sexual maturity of F. commersonii shows that 50% of females and males are sexually mature at standard length of 57.5 and 56 cm respectively . Males matured at smaller length intervals than females. Fecundity ranged between 355-697 eggs/g /ovary. This high fecundity rate contributes to increase the recruitment and juvenile population invade new ecological niches at the expense of native fish species. Certain negative impact on local fish stock through predation and feeding on small fishes was noticed (Fig.2). In studying the feeding regime and the dynamics of the reproduction, we conclude that Fistularia is a carnivorous predator feeding quasi exclusively on local fish, namely Sardinella aurita, Boops boops and Engraulis encrasicolus. The stomach content analysis has shown 20-25 fish individuals in one digestive. This may give an idea of the strong negative effect of thousands of Fistularia individuals on local living fish stock.

GEOGRAPHICAL AND BATHYMETRICAL DISTRIBUTION OF RED SHRIMPS IN SARDINIAN WATERS RELATED TO ENVIRONMENTAL CONDITIONS

Andrea Sabatini ¹*, Gloria Matta ¹, Francesco Palmas ¹ and Antonio angelo Pendugiu ¹ ¹ Department of Animal Biology and Ecology, University Of Cagliari - asabati@unica.it

Abstract

Red shrimps Aristaeomorpha foliacea and Aristeus antennatus are one of the most important and exploited resource in the western Mediterranean. The aim of this work is to evaluate the geographical and bathymetrical distribution of the two species in Sardinian seas and to identify a possible relationship with environmental conditions. We calculated the ratio between the two species and we compared ratio values with hydrological data (temperature and salinity) to establish how water masses properties influence species distribution. Our results indicate that A. antennatus prefers colder and less salty waters while A. foliacea prefers both higher temperature and salinity.

Keywords: Crustacea, Intermediate Waters, Western Mediterranean

Introduction

Red shrimps are mainly captured at depths between 400 and 800 m while unexploited below 900 m. In Sardinian waters we can find both species: in the southern and eastern parts *A. foliacea* is more abundant, while *A. antennatus* is more present along the northern and western coasts [1]. The spatial and temporal variability of these two species seems to be closely connected to hydrological and oceanographic factors and the distribution of red shrimps may be correlated to water mass properties such as salinity and temperature.

Materials and Methods

The biological data were collected in Sardinian waters between 1994 and 2006 during two annual trawl survey as part of the research projects Medits and Grund. Taking into account the number of individuals of *A. foliacea* (Af) and *A. antennatus* (Aa), logistic models were calculated fitting the ratio between the two species in function of depth:

Ratio = Aa/(Aa + Af)

Using logistic regressions, depth values for Ratio 0.5 (D_{50}), 0.25 (D_{25}) and 0.75 (D_{75}) respectively were calculated. D_{50} represents the depth in which the two species have the same abundance, D_{25} and D_{75} the depth in which the 25% and the 75% of individuals, respectively, are *A. antennatus*. Hydrographic data were extracted from the MEDATLAS database [2] and a mean value of temperature and salinity was considered. The data were correlated whit the correspondent ratio values for different Sardinian coasts between 400 and 800 m.

Results and Discussion

The logistic models obtained for Sardinian waters showed that in the northern and western Sardinia there is an equal occurrence of the two species at about 453 m and 478 m (D₅₀) respectively indicating a greater presence of *A. antennatus* in the whole depth range analyzed. The southern Sardinia is characterized by an extended presence of *A. foliacea* (D₅₀=612 m) while in the south-eastern Sardinia *A. foliacea* predominates over the whole depth range even below 650 m (D₂₅=647 m) (Fig. 1).

Fig. 1. Logistic models (Ratio values in function of depth)

These results showed that the ratio between the two species is very different among Sardinian coasts. The Regression Analysis, carried out fitting ratio values against hydrographic data, indicated that the ratio between the two species is correlated with environmental conditions (Fig. 2).

Fig. 2. Regression between Ratio values and (A) temperature and (B) salinity

Our results showed an already known bathymetrical distribution of the two species. The fluctuations in ratio and species distribution seem to be connected to environmental conditions and in particular to the circulation of intermediate water masses along Mediterranean coasts [3]. The comparison between hydrographic and biological data evidenced that both species seem to be connected to the peculiar features and fate of the LIW (Levantine Intermediate Water). In fact, in the eastern and southern part, LIW properties predominate and *A. foliacea* is the main species while in the western and northern sides of Sardinia LIW properties lose intensity in favor of *A. antennatus* which prefers colder temperatures and less salty waters.

SOME BIOLOGICAL PARAMETERS OF SPRAT SPRATTUS SPRATTUS PHALERICUS (RISSO1826) IN THE TURKISH BLACK SEA COAST

Hacer Saglam¹*, Ertug Duzgunes¹ and Nazli Kasapoglu¹

¹ Karadeniz Technical University, Faculty of Marine Science - hacersaglam@yahoo.com

Abstract

Some biological parameters of the sprat, *Sprattus sprattus phalericus*, collected from Turkish Black Sea coast between 2008 and 2009 were investigated. Sprat is an important food resource for many top predators. In present work, length frequency distribution, relationship between length and weight, sex ratio and condition factor of sprat have been studied. *Keywords: Black Sea, Biometrics, Pelagic*

Introduction

Black Sea sprat, *Sprattus sprattus phalericus*, is one of the most abundant small pelagic fish species in the Black Sea. It is an important food resource for many top predators. The sprat is a small, multiple (batch) spawning species with a protracted spawning season and a large number of spawning per year. According to 2006 fishery statistics, 7311 tons of sprats were harvested in Turkey of which 6681 tons were caught from the Black Sea and 630 tons from the Sea of Marmara [1].

Material and Method

Sprats were caught as by-catch in the purse seine fishery in 2009. The total length (L) and weight (W) were measured and sex was determined by gonads. The total number of investigated individuals was 334. The length-weight relationship was derived as $W=aL^b$, where W: weight (in g); L length (in cm), a: y-intercept and b: slope, characterizing the growth rate. The condition factors (CF) are computed by Fulton's index [2] as

 $CF = W*100/L^3$

where W is average weight and L is average length by size groups.

Results and Discussion

The sample was composed of 202 females ranging between 7.20 and 10.2 cm TLand 2.15 and 7.11 g, and 132 males ranging between 6.80 and 10.20 cm TL and 1.68 and 6.35 g. The sex ratio was significantly different from 1:1 (χ^2 =14.67; df=1; P<0.05). The input data for average lengths and weights of sprat are given in Table 1. According to data in Table 1 and using power function, the coefficients "a" and "b", characterizing weight-length relationship, have been estimated.

Tab. 1. Sprattus sprattus and some biological parameters

Parameters	F	М	Total
L±SE	8.74±0.042	8.69±0.053	8.72±0.032
W±SE	3.80±0.060	3.57±0.073	3.69±0.046
W=aL ^b	0.0066L ^{2.919}	0.0065L ^{2.911}	0.0070L ^{2.885}
r ²	0.87	0.85	0.85
CF (%)	0.518	0.494	0.507
n	202	132	334

Condition factor between differences between females and males was not significant in present study (P>0.05). The length frequencies of sprats are shown in Figure 1. The obtained results are not close to those, calculated by Sahin (1999) [3]. Sahin (1999) reported that the mean length values were 10.69 cm for both sexes in 372 specimens. According to our results, the average sprat length has been lessening in decade.

Fig. 1. Length frequency distribution of the sprat caught in the south-eastern Black Sea

INTERSTITIAL HARPACTICOIDS FROM THE SHALLOW WATERS OF THE ROMANIAN BLACK SEA COAST

Manuela Samargiu¹*

¹ Ovidius University, Faculty of Natural Sciences and Agricultural Sciences - manuelasamargiu@yahoo.com

Abstract

The study refers to a period of five years and the results regard a synecologic analyze of harpacticoids populations sampled from 11 sites with mobile substratum at 0 - 1 m depth, on a distance of more than 200 km along the Romanian shore, from Grindul Chituc to Vama Veche. Data about their abundance, density, frequency and ecological significance indices (WD %) are given, in order to emphasis the distribution of the characteristic species and their adaptive mechanisms. *Keywords: Black Sea, Copepoda, Infralitoral, Mediolittoral, Sediments*

Introduction

For marine waters of Romania, the data obtained between 1960 -1970, totalize 114 benthic harpacticoids species, associated with different characteristic biocoenosis. A first comprehensive list was done in 1959 [1] and after those three ample papers regarding pontic [2, 3] and Levantine [4] harpacticoids were published in 1960, 1962 and 1964. After more than 25 years, some ecological data of main harpacticoids species living on different kind of substrata were published again [5, 6].

Materials and methods

Quantitative sedimentary samples were taken using a corer with 7, 5 cm intern diameter. 11 sites (with three perpendiculars transects at 0, 0, 5 and 1 m depth) were seasonally investigated, during a period of five years. The samples have been preserved (4% formaldehyde solution or in ethanol 80%: glycerin in equal parts), washed and sieved by 160, 100 and 63 μ m mesh diameter. A Nikon SMZ-2T stereomicroscope and a Nikon E200 microscope were used for identification. The results were reported at m².

Results and discussions

The most encountered harpacticoids have the greatest abundances in 20 - 50 cm core horizon of the samples. Below this horizon we met extremely rare in corers, isolated examples of Arenopontia subterranea and Parastenocaris chappuisi. In two stations of the north sector Grindul Chituc (Lat. 44° N 47, 310; Long. 28° E 81,432) and Vadu (Lat. 44° N 35, 240; Long. 28° E 62,212) where sediments are consisting of fine and quartz sands eudominant species are Microarthridion littorale and Canuella perplexa, with great similarities regarding their abundances (A = 67 ind. \cdot m⁻²), frequency of 40 % and W = 11%. Harpacticus flexus (A = 51 ind. m^{-2} , F = 40 %, W % = 8, 98) and Halectinosoma abrau (A = 43 ind.·m⁻², F = 40 %, W = 7, 57) have dominant character in these sediments (the highest share at 0.5 m depth). At Navodari (Lat. 44° N 18, 707; Long. 28° E 37,913) and on Mamaia - Cazino (Lat. 44° N 14,297; Long.28° E 37,548) zones, 10 respectively 15 harpacticoids species were recorded with total abundances of 1306 and 580 ind. m^{-2} . For both zones M. littorale is on the first rank with high values of W = 19, 90% and 30%, frequency of 100%, and abundances of 260 and 174 ind.·m⁻² comparatively with the other species. Parathalestris dovi and Canuella perplexa are other dominant species. But for all mentioned species densities do not exceed 39 ind.·m-2. Longipedia minor, Tisbe furcata, Ectinosoma melanicepsTabacariei Lake flows into the sea we found occasionally isolated individuals of Itunella muelleri, Parastenocaris chappuissi and Onychocamptus mohammed. Total density of harpacticoids population recorded 67 ind.·m⁻². Constanta - Plaja Modern site (Lat. 44° N 10,718; Long. 28° E 39,452) represents the "border" between north sector and south sector of the Romanian littoral. The sands from the shallow waters have medium size (174 mm) particle diameter. 8 species were found at Constanta, H. flexus and M. littorale usually being more abundant in spring. D. tisboides with a very large eurytopic properties is considered here as subdominant. The endemic Mesochra pontica appeared in some samples from this area. Most species are quartered at 1 m depth. At Eforie Nord - Belona beach (Lat. 44° N 03,756; Long. 28° E 38,479) and Eforie Sud - Capul Turcului (Lat. 44° N 01,635; Long. 28° E 39,426) 14 species were recorded. Ectinosoma melaniceps take the first rank with a W of 27, 22 % and 29, 30 %, being euconstant and eudominant in both zones. As a typical interstitial form, Halectinosoma herdmani become one of the six constant and dominant species. S. pontica, Paralaophonte brevirostris, M. pontica, C. furcigera, Ameira parvula, Thalestris longimana and Parathalestris dovi are accessories coming, largely from higher infralittoral. Very abundant become at Costinesti (Lat. 43º N 56,896; Long. 28º E 38,292), Nitocra elongata being characteristic for coarse sands of this zone. Heterolaophonte stroemi paraminuta has a 100% frequency with 52 ind.·m⁻² abundances.A uniform distribution of encountered individuals in different depths it was observed. At Mangalia (Lat. 43° N 49,005; Long. 28° E 35,279) it was found 10 harpacticoids species, many of them with high abundances, very frequent (80 -100%) and with ecological significance indices values up to 24,78 as C. perplexa, H. herdmani, and N. elongata. Their depth preferences are here on 0, 5 m where the dynamic of the water is less felt at sediments level and the oxygen is still in optimum quantities. The situation is maintained in the final site, Vama Veche (Lat. 43°N 46,880; Long. 28° E 34,798) where middlittoral and infralitoral sands shelter 11 harpacticoids species. The total populations' abundances reach 809 ind.·m⁻², but with low densities, of 122 ind.·m⁻². The characteristic species are the same as in the former two northern sites, sharing the first five ranks, as eudominant and dominant, being encountered in all samples. As an accidental species was recorded Klieonychocamptus kliei ponticus, isolated in some samples.

Harpacticus littoralis and *Dactylopodia tisboides*, are accessory and receding species and *Schizopera pontica* is an accidentalone. In the next southern site, at Mamaia – Hotel Parc (Lat. 44° N 13,176; Long. 28° E 38,191), among the 13 recorded species, besides those already mentioned before, we can notice *Nitocra typica* as subdominant, with a uniform distribution in studied transects. In these interstitial spaces where the

Conclusions

- Five taxa - Canuella perplexa, Halectinosoma herdmani, Microarthridion littorale, Harpacticus flexus and Harpacticus littoralis consistently present in the north sites, are found in southern areas too, although their density in these biotopes varies from 5 - 35 ind.·m⁻².

- Some species which are accidentally in the northern sector areas become dominant in many stations of south region (for example *Ectinosoma melaniceps*, which reaches densities between 15 - 37 ind.·m⁻²).

- Typical endopsammic harpacticoids Arenopontia subterranea, Parastenocaris chappuisiOnychocamptus mohammed are adapted to mesoporal spaces, having filiform bodies and under 0, 5 mm lenght. But they are recorded as isolated, accidental species in Romanian Black sea shallow waters, and

TROPHIC RELATIONSHIP BEETWEEN LOLIGO VULGARIS AND POSIDONIA OCEANICA IN CATALAN WATERS (NW MEDITERRANEAN)

Pilar Sanchez ¹*, Montserrat Demestre ¹ and Silvia De Juan ¹ ¹ Institut de Ciències del Mar-CSIC - pilar@icm.csic.es

Abstract

The possible trophic relationship between *Posidonia oceanica* and the abundance of *Loligo vulgaris* in the Catalan coast (NW Mediterranean) was investigated. The results suggest that food source of *Loligo vulgaris* is closer to *Posidonia ocenica* than to phytoplankton.

Keywords: Behaviour, Cephalopods, Western Mediterranean

Introduction

L. vulgaris distribution extends along the eastern Atlantic, from the North Sea and British Islands (55° N) to the south-western coast of Africa (20° S), and also throughout the Mediterranean Sea (1). *L. vulgaris* distribution in the Mediterranean Sea, mainly concentrates in areas shallower than 100 m. It generally inhabits temperate waters. In the Mediterranean, *L. vulgaris* is mainly a by-catch of the multispecies bottom trawl fisheries, throughout the year. Near the coasts where it concentrates during autumn and winter for spawning, small-scale professional and sport fishermen usually target it using hand-jigs. Juveniles recruit to the fishery at approximately three-four months age (2). The purpose of this work is to study the possible trophic relationship between *Posidonia oceanica* and the abundance of *L. vulgaris* in the Catalan coast (NW Mediterranean).

Material and Methods

Sampling was carried out on board commercial trawlers on a monthly basis, from October 2003 to December 2005 in Roses, Blanes and Cambrils Catalonia ports (NW Mediterranean). The landings and landings-per-unit-effort, LPUE data were obtained from the DGPAM (General Direction of Fishing and Maritime Affairs) of the Catalan Government for the period 2000-2005. Data of stable carbon isotope are from th project "Avaluaciò de l'estat de les poblacions de *Loligo vulgaris* a Catalunya" financed by Autonomous Government of Catalonia. Isotopic value of *Posidonia oceanica* is -14.3 (s.d.=0.153) and for phytoplankton -23.6 (s.d=0.71).

Results and Discussion

LPUE data series showed a clear pattern of abundance from North (Llança) to South (Sant Carles) (Fig.1) being more abundant in the North and Central areas than on the South. It is well known that temperature is an important factor in the recruitment of the species (3) but not the unique. The distribution of Posidonia oceanica in Catalan waters is shown in figure 2. Posidonia meadows are more abundant in North and Central area of study. Our objective was to use stable carbon (C) isotope ratio of the mantle of Loligo vulgaris to typify the trophic state of the species and its relationship with Posidonia oceanica. Food sources were investigated using a mixing model based on phytoplankton and Posidonia oceanica source isotopic composition data previously obtained. Isotopic values of mantle of Loligo vulgaris varied between -17.3 (s.d. =0.2) in Cambrils, 17.4 (s.d.=0.1) in Blanes and -18.5 (s.d.=0.2) in Roses. Our results suggest that source of food of Loligo vulgaris is closer to Posidonia ocenica than to phytoplankton. This doesn't mean that Loligo eats directly on Posidonia but belongs to a tropic net where Posidonia is an important source of carbon.

THE PROJECT FOR-MARE: TRAINING AND RESEARCH IN MARINE PROTECTED AREAS, MARINE ECOLOGY AND GEOBOTANY STAGES

Dario Savini ^{1*}, Gilberto Parolo ¹, Chiara Lombardi ² and Anna Occhipinti ¹ ¹ Dipartimento di Ecologia del Territorio, Università di Pavia, Via S. Epifanio 14, I-27100 Pavia - dario.savini@unipv.it ² Centro Ricerche Ambiente Marino - ENEA, C.P.224, La Spezia, Italy

Abstract

The FOR-MARE project aims to create a network of expertises among Universities, Research Centres, Schools and Diving Associations in order to realize stages for students from University and teachers from primary and secondary schools. Its major objectives are: 1) expanding knowledge of the role of Marine Protected Areas (MPA); 2) promoting 'scientific tourism'; 3) helping MPAs in scientific data collection and monitoring programs.

Keywords: Marine Parks, Instruments And Techniques, Coastal Waters, Coastal Management, Monitoring

Marine Protected Areas (MPAs) represent a concrete effort of national administrations to preserve biodiversity and promote scientific research [1]. Currently, in Italy there are 20 MPA that care as a whole for about 184,000 ha of sea and 580 km of littoral. Notwithstanding their importance, Italian MPA are encountering a period of recession in relation to the world economic crisis, as they represent a "non productive sector of the national economy" in strict sense. The project FOR-MARE, namely translating from Italian to English: "Training and research in marine protected areas, stages of marine ecology and geobotany", born with the aim of broadcasting the role of MPA by creating "scientific tourism" in these areas. In June 2009 the Section of Ecology of the "Dipartimento di Ecologia del Territorio" of the University of Pavia promoted a first, pilot, taught course of Applied Ecology in the MPA of Isole Pelagie (Sicily) [2] in order to test a new teaching method in the field. Nineteen students from the University of Pavia with background experience in Biology, Ecology and Botany participated to this stage. In a week time (21/06-28/06/2009), students have been driven by teachers to prepare and present small scientific works on issues concerning population ecology of coastal marine organisms and terrestrial plants following a didactic scheme that consisted in:

1) providing theoretical knowledge by tutorial lessons;

2) conducting general surveys of the study area by snorkeling and trekking;

3) building up an experimental design (e.g. building also material used for visual census survey such as quadrats) (Fig. 1);

4) collecting biological and ecological information in the field using non destructive methodologies;

5) reporting scientific results to the public. The stage produced four small studies that provided new knowledge on local marine fauna and terrestrial flora: 1) Description and population structure of an unidentified actinia 2) Distribution and population density of the alien grapsid crab *Percnon gibbesi* 3) Morphometry and reproductive biology of *Pancratium linosae* (Amaryllidaceae) 4) Floristic characterization of the southern littoral of Linosa Island

All studies produced very interesting preliminary results, worth of scientific deepening. The first study led to the characterization of a peculiar population of the common actinia Cereus pedunculatus that in Linosa Islands was found only in a very restricted bathymetric range range (20-150 cm) of sheltered areas and is characterized by a dark -brown morph and small individuals (oral disc major axis < 5 cm). The second, revealed that the alien grapsid crab is the dominant crab species of the medium-superior infralittoral fringe; the highest density (51 \pm 28 ind. 10m⁻²) of *P. gibbesi* is found in partially sheltered localities characterized by a microhabitat of large boulders covered by coralline algae. The third, gave the benefit of the doubt on the correct taxonomic position of the island endemic sea-daffodil Pancratium linosae, that by morphometric analysis appeared more similar to the most common species Pancratium maritimum. Finally, the fourth and last study revealed the presence of 11 species of local flora, not mentioned in pre-existing floristical lists of the island and of a consistent population of the Eolian endemic species Limonium algusae never mentioned before. Results of the stage FOR-MARE strengthen once again the importance of volunteer based programs in scientific data collection as already pointed out by other ongoing international programs (e.g.Seasearch, UK; The International CIESM Jellywatch Program) [3,4]. A future aim of the FOR-MARE project is to establish a solid network of interest on the subject by involving administrators of the territory, universities and research institutes, schools, diving centers/associations and media.

Fig. 1. Students of the FOR-MARE pilot stage (Linosa Island, 2009) are building up survey instruments.

COMPARISON OF TRAWL SURVEY AND COMMERCIAL DATA ON SMALL PELAGICS FROM THE FAO **GEOGRAPHIC SUB-AREA 9 (WESTERN MEDITERRANEAN)**

M. Sbrana¹*, S. De Ranieri¹, A. Ligas¹, B. Reale¹, I. Rossetti² and P. Sartor¹

¹ Centro Interuniversitario di Biologia Marina ed Ecologia Applicata (CIBM), Livorno - Italy - msbrana@cibm.it ² Aplysia Soc. Coop. r.l., Livorno - Italy

Abstract

Trawl survey data on Engraulis encrasicholus and Sardina pilchardus have been compared with the official available statistics on landings in the FAO Geographical Sub-Area 9 (GSA9). A high correspondence between the two sources of data has been found for anchovy, while for sardine the two data series showed some differences with an evident decressing of the survey index and more fluctuating trend for landing data.

Keywords: Pelagic, Trawl Surveys, Fisheries, Ligurian Sea, Tyrrhenian Se

Introduction

Anchovy, Engraulis encrasicholus, and sardine, Sardina pilchardus, are two of the most important pelagic marine resources in the FAO Geographic Sub-Area 9 (Ligurian Sea and Northern and Central Tyrrhenian Sea). In this area a well developed fishery targeting them with purse seine is performed by the local fleets and by vessels coming from the south of Italy during the fishing season. Official statistics show that the biomass landed in this area represents a significant portion of the total landing registered in Italy for these two species. In spite of this, no specific scientific surveys have been carried out in the past in order to evaluate the biomass at sea and to collect information useful to assess the exploitation state of these two important resources. Since 1994, the GSA9 has been included in the MEDITS project for the evaluation of the demersal resources [1]. Although this survey is targeted to investigate species living near the bottom, the characteristics of the net employed (high vertical opening of the mouth) allow to regularly catch species living in the water column, as the small pelagics. The present study aims to compare the trends in biomass of the two populations with the commercial landings. A possible correspondence in the trends of the two data series will strengthen the possibility to use MEDITS surveys data also as valuable indicator of the abundance of small pelagic species.

Materials and Methods

The study was performed in the FAO GSA9, where the experimental trawl survey MEDITS has been carried out from the beginning of the project (1994) to the present. The gear used for the data collection is a bottom trawl designed for experimental fishing with scientific purpose [2]. The net vertical opening slightly higher (2.5 m) to that of the most common professional gears allows to significantly catch species less related to the bottoms like small pelagics. A cod end of 20 mm mesh size (stretched mesh) is employed. The experimental hauls have been allocated by means of a stratified sampling design with random drawing inside each depth stratum. Although the surveys cover the shelf and the upper slope from 10 to 800 m depth, the time series of mean biomass (kg/km²) were calculated for the macro-stratum 10-200 m, where the two investigated species are concentrated. A biomass index (kg/km²) has been computed according to Souplet [3]. Official statistics on commercial landings to be compared with survey data have been provided by the Italian Istituto Nazionale di Statistica (ISTAT) for the period 1994-2000 (www.istat.it); since 2001 the Istituto di Ricerche Economiche per la Pesca e l'Acquacoltura (IREPA) has been charged to monitor the economic aspects of the Italian fishing sector, including landing statistics (www.irepa.org). For each species, the two time series were analysed by means of the cross-correlation function [4].

Results and discussion

MEDITS data for anchovy shows high biomass indices of this species in the period 1999-2003, whilst the minimum values are observed in the last years. A similar trend of the total landing recorded in the GSA9 is found, with maximum biomass landed in correspondence to that estimated at sea. For this species a significant cross-correlation has been obtained (r = 0.54). For sardine the correspondence between experimental and commercial data is less evident. Landing statistics and trawl survey biomass estimations showed a very high parallelism just for the period 1994-1999. In the case of the trawl survey data, the trend is characterised by a drastic and continuous decrease; landing decreased till 1997 and high fluctuations of the values are observed in the period 2000-2008. For sardine the cross-correlation resulted not significant. The good correspondence between landing and survey trends supports MEDITS survey as a promising descriptor of anchovy abundance at sea, at least in absence of more precise data. In the case of sardine, the decreasing trend obtained from MEDITS data does not fully match with landing data. In spite of this, MEDITS could represent an useful source of information also for this species. However, it is important to take into account that sardine is not the target of the small pelagic fishery, thus is not landed on a regular basis. When anchovy is abundant, the fishermen avoid to land sardine and larger amount of the species is often rejected at sea.

REACTIONS OF BENTHIC PREDATORS TO MORTALITY EVENTS: A TIME-LAPSE APPROACH

Lucie Schiemer¹, Bettina Riedel¹, Martin Zuschin^{2*} and Michael Stachowitsch¹

¹ University of Vienna, Dept. of Marine Biology

² University of Vienna, Dept. of Paleontology - martin.zuschin@univie.ac.at

Abstract

The Northern Adriatic Sea is a case study for globally increasing coastal hypoxia and anoxia. We documented the course of events after experimentally induced, small-scale (0.25 m^2) mortalities here. The time-lapse camera revealed a clear sequence of predators and scavengers – fish, hermit crabs and gastropods – that removed the dead and decaying organisms within several days. Post-anoxia processes should be incorporated into management plans for sensitive areas.

Keywords: Adriatic Sea, Anoxia, Fishes, Mortality, Behaviour

Introduction

Hypoxia and anoxia are key, and increasing, threats to shallow coastal ecosystems worldwide [1]. The Northern Adriatic Sea is a recognized area for hypoxia- and anoxia-related community changes and mortalities [2]. Little, however, is known about immediate post-anoxia events and long-term recovery. We employed a new system (EAGU; Fig. 1) which creates and fully documents small-scale anoxia (50 x 50 x 50 cm) *in situ* [3]. The instrument combines photo-documentation with detailed chemo-physical analyses (sensor array) and allows the behaviors and mortalities of benthic organisms to be analyzed during and after oxygen depletion.

Material and Method

The EAGU device was positioned on a soft-bottom in 24 m depth (two deployments: August, September 2009) in the Gulf of Trieste, Northern Adriatic Sea. The system was initially positioned in a closed configuration (plexiglass chamber) over benthic organisms for 60 h to induce mortality. Then, the open configuration (aluminium frame) was used for another 2–3 d. The EAGU yielded ca. 6000 images which can be viewed and analyzed separately or as a film.

Fig. 1. Experimental Anoxia Generating Unit (EAGU) with instrument lid on plexiglass chamber. ch: camera housing, dl: datalogger, eb: battery, fl: flashes, os: oxygen sensor, sp: sensor port

Results and Discussion

The EAGU successfully created anoxia within three days, and most benthic organisms died. Analogous to dredge damage [4], the moribund/dead organisms attracted predators/scavengers, which removed most of the dead material within days. The analysis showed that fish (*Gobius niger; Diplodus vulgaris, Serranus hepaticus*) were the first post-anoxia visitors (after 9 min); their numbers gradually decreased during the deployment, suggesting that most of the suitable dead material was consumed early. The second and third group arriving were hermit crabs and gastropods. They mainly fed on remains not used by fishes (e.g. sponges, ascidians) (Fig. 2). After extreme events, measurements need to be taken to protect the remaining living marine resources.

Fig. 2. Three fish species initially attracted by benthic mortality (Gn Gobius niger; Dv Diplodus vulgaris, Sh Serranus hepaticus)

Abstract

Ce travail porte sur l'étude de la biologie et de la dynamique du copépode calanoïde *Copidodiaptomus numidicus* du réservoir Beni Mtir au cours d'un cycle annuel, qui s'étend du mois de mars 2005 au mois de janvier 2006. Les résultats montrent que les facteurs abiotiques et biotiques ont une influence sur la distribution de cette espèce. *Keywords: Copepoda, Zooplankton*

Introduction - Les copépodes sont constamment confrontés à des variations des facteurs abiotique et biotique, tels que la température, la quantité et la qualité de la nourriture rencontrée, qui peuvent agir sur leur croissance et leur reproduction ou sur le déroulement de leur cycle de vie [1]. Le copépode calanoïde *Copidodiaptomus numidicus* est l'espèce dominante du zooplancton de la plupart des réservoirs de la Tunisie [2]. Au cours de l'étude du zooplancton du réservoir Beni Mtir, nous avons noté l'importance quantitative de ce copépode calanoïde (64% du zooplancton total). L'objectif de ce travail est d'étudier la biologie et la dynamique du copépode *Copidodiaptomus numidicus* dans le réservoir Beni Mtir.

Matériel et méthodes - Site d'étude et stratégies d'échantillonnage : Ce réservoir a été construit en 1953, il est situé dans le gouvernerat de Jendouba entre 36°43'10" de latitude Nord et entre 08°44'10" de longitude Est à 30 Km de la ville d'Ain Draham, afflue de la rive Nord du fleuve Medjerdah, principal cours d'eau de la Tunisie. Cette retenue de barrage est alimentée par l'oued E'lil. Elle a un volume de 57,6 millions m d'eau pour une superficie de 310,6 ha et de hauteur maximale de 78 m. Le bassin versant couvre une surface de 103 km . Ce barrage est une source importante d'approvisionnement en eau potable de Tunis et de la production d'énergie électrique. Les prélèvements destinés aux analyses physico-chimiques et biologiques ont été effectués, selon une fréquence mensuelle de mars 2005 à janvier 2006 (sauf pendant les mois d'avril et de décembre à cause d'un problème logistique), sur toute la colonne d'eau (surface, 5m, 10m et 15m) au niveau de la station tour de prise. Analyses physico-chimiques et biologiques : La température de l'eau, le pH, les concentrations en oxygène dissous et la salinité ont été mesurés à l'aide d'une sonde multiparamètres de type Multi 340 i/SET. Les éléments nutritifs ont été dosés par colorimétrie en utilisant un auto analyseur de type 3. Les concentrations en chlorophylle 'a' ont été déterminées par spectrophotométrie après extraction à l'acétone 90%. Les échantillons de zooplancton ont été prélevés en utilisant un filet à plancton de type JUDAY de porosité 80 µm et préservés dans une solution de formol à 5%. Cette espèce a été identifiée selon Dussart [3].

Résultats et discussions - Le développement de l'espèce *Copidodiaptomus numidicus* est caractérisé par une densité maximale de l'ordre de 51,1 ind.l le 22 juillet 2005 (Fig. 1). Ce paroxysme est dû au développement le plus important des stades copépodites jeunes (C1, C2 et C3) (7,8 ind.l) et préadultes C4 et C5 (19,0 ind.l).

Fig. 1. Variation spatio-temporelle de la densité de *C. numidicus* dans le réservoir Beni Mtir

L'analyse en composantes principales de la matrice regroupant les paramètres physico-chimiques et biologiques permet de selectionner les deux axes qui ont le maximum de variance (Fig. 2). L'axe F1, qui extrait 38,26% de la variance, sélectionne positivement le groupement G1 constitué par la température, la conductivité, les concentrations de la chlorophylle 'a', les nauplii, les copépodites C4+C5, les mâles, les femelles ovigères et non ovigères. L'axe F2 qui extrait 21,76% de la variance sélectionne positivement le groupement G2 formé parles copépodites C1+C2+C3 et la salinité. Les résultats montrent que l'espèce Copidodiaptomus numidicus se développe essentiellement pendant la saison printanière et estivale. Tandis que les faibles densités ont été enregistrées pendant l'hiver (mois de janvier). Une corrélation positive a été mise en évidence entre les copépodites C4+C5, qui sont les plus abondants, et la température (r=0,850, p<0,05, ddl=16). De même, il y a une correlation significative entre cette espèce et les concentrations en chlorophylle 'a' (r= 0,837, p<0,05, ddl=16). La variabilité de la température de l'eau et les concentrations en chlorophylle-a affecte visiblement la dynamique et la reproduction des copépodes [4].

Fig. 2. Diagramme de l'analyse en composante principale : oxygène dissous (O₂), azote total (NT), phosphore total (PT), matières en suspension (MES), Chlorophylle-a (Chl-a)

Abstract

Two stations were selected in Çakalburnu Lagoon, Izmir, Turkey for determining amount of Tapes decussatus benthic juveniles. The maximum clam spat in St.1 and St. 2 were obtained 35 juvenile / 100 cm² (in November) and 15 juvenile / 100 cm² (in March), respectively. There was not detected any clam in February, April and June (St. 1) and in April and May (St. 2). Keywords: Bivalves, Aegean Sea, Recruitment

Introduction

The dynamics of planktonik larval populations have important implications for the life histories of marine benthic invertebrates [1]. An increased knowledge of bivalve larvae and settlement ecology will allow a better understanding of environmental processes that determine the magnitude of bivalve recruitment [2] and larval recruitment processes and survival of juveniles influence the bivalve population dynamics.

In Turkey, carpet shell clam, Tapes decussatus, is distributed along the all coastline except from Black Sea. Mainly, Tapes decussatus is collected from Izmir Bay, especially in Çakalburnu Lagoon and this species has a commercial value in Turkey. But production of clam is based on wild stocks and there is not any aquaculture facility. So amount of clam juveniles is important for natural stocks and sustainable production. This study was conducted for determining abundance of juvenile clam in Çakalburnu Lagoon, Izmir Bay, Turkey.

Material and Methods

Çakalburnu Lagoon (150 ha acreage) in Izmir Bay, Aegean Sea was selected for the study site, located at the south part of Izmir Bay (Fig. 1). The study was conducted in two stations in inside of lagoon. Field sampling was carried out monthly during a year. Environmental parameters such as temperature, salinity, chlorophyll-a, total particulate matter (TPM) and phytoplankton species were determined each month.

Benthic juvenile clam are aggregated largely with in the upper 1.0 cm of the sediment. Three sediment samples were collected at each station using a core sampler (5.0 cm diameter). The samples were fixed immediately with 5 % formalin and dyed with Rose Bengal to simplify sorting the specimens of settled bivalves under a loupe.

Fig. 1. Map of study site

Results and Discussion

Sea water temperature was between 13.2 °C and 28.6 °C throughout the study. Salinity value ranged from 36.1 ‰ to 38.5 ‰. Chlorophyll a value was determined between 4.71 $\mu g \ L^{-1}$ and 24.02 $\mu g \ L^{-1}$ in St. 1 and from 1.89 $\mu g \ L^{-1}$ to 58.40 mg L⁻¹ in St. 2. The average TPM concentration was found 11.19 mg L⁻¹ ¹ in St. 1 and 16.56 mg L⁻¹ in St. 2. Species belonging to Dinophyceae and Bacillarophyceae group were identified the most in terms of phytoplankton species composition in two stations. The maximum amount was obtained 35 juvenile / 100 cm² in St. 1 (in November) and 15 juvenile / 100 cm² in St. 2 (in March) (Fig. 2). There was not detected any clam in February, April and June (St. 1) and in April and May (St. 2) (p<0.05).

Newly settled of Manila clam in Tokyo Bay, Japan was observed mainly between May and October [3]. Our results showed similar to results of [3]. Moreover, in Nameishi, Japan, amount of Manila clam benthic juveniles was 90 ind. / 100 cm² [4]. Although our results lower than results of [4], Çakalburnu Lagoon was productive area for clam settlement.

Fig. 2. Amount of benthic juveniles in two stations

Abstract

The macrozoobenthos of Southern Black Sea coast (Turkey) was quantitatively investigated in May-July 1999. Samples taken at 39 stations (13-79 m depth range) provided the basis for the analysis of the distribution of 130 species and 6335 individuals of benthic invertebrates, as well as of their abundance and biomass. Most common species in the studied soft bottoms were, by numbers of individuals, *Melinna palmata, Lentidium mediterraneum, Lucinella divaricata* and *Chamelea gallina*. The polychaets *Micronephths* cf. *maryae, Aricidea fragilis mediterranea*, and *Chone filicaudata* for the entire Black Sea coast and *Eumida sanguinea*, *Mysta picta*, and *Prionospio*) *steenstrupi* represents new records for the Turkish Black Sea coast. *Keywords: Zoobenthos, Biodiversity, Black Sea*

Introduction

The Black Sea is the largest $(537, 000 \text{ km}^3)$ permanently stratified marine basin of the world [2]. In southern part coasts the shelf is only a narrow intermittent strip. Although the coastal area is free of hydrogen sulphide, concentrations increase rapidly under the thermocline due to the restricted circulation of deeper shelf water. Consequently, the number of macrobenthic species decreases rapidly with increasing depth. Zoobenthos of the Turkish sublittoral zone of the Black Sea has not been thoroughly investigated yet. The aim of this study is to determine the faunistic composition and the main macrozoobenthic communities occurring off the southern coast of Black Sea. The factors that may affect species distribution are also discussed.

Material and Methods

To analyse macrozoobenthos, at each station (total 39) bottom a single quantitative sample was taken using a van Veen grab (0.1 m²) (Figure 1).

Fig. 1. Map of the study area, indicating the sampling stations

All samples were washed through a 0.5 mm mesh sieve. Thereafter, all macrofaunal organisms were sorted using a binocular microscope, identified, counted and stored in 70% alcohol. Some physicochemical parameters were measured. Frequency index, percentages of animals in relation to total faunal abundances and biomass were calculated for delineating the community structures.

Result and Discussion

In the study region, the average oxygen level was 7.95 ml-1 between 10 and 25 m depth, and it dropped to 4.9 ml-1 at 25-50 m. At a depth of 50-80 m, average oxygen level was 1.25 ml-1. Temperature and salinity values were 15.9 C and 17.5 psu at 10-25 m, 8.8 C and 18.7 psu at 25-50 m, and 7.9 C and 18.9 psu at 50-80 m, respectively. The analyses of grab samples revealed a total of 130 benthic species belonging to Actinaria (one species, two individuals), Nemertini (one species, 10 individuals), Nematoda (one species, 17 individuals), Polychaeta (50 species, 3126 individuals), Phoronida (one species, 28 individuals), Pycnogonida (one species, three individuals), Crustacea (30 species, 490 individuals), Mollusca (42 species, 2373 individuals) and Echinodermata (3 species, 286 individuals). This study added three new records to entire Black Sea and 3 new records to inventory of marine fauna inhabiting the coast of Turkish Black Sea.Polychaeta accounted for 49.3% of total number of specimens, followed by Mollusca (37.4%) and Crustacea (7.9%). The dominant species in the area were Melinna palmata Grube, 1870 (28% of total individuals), Lentidium mediterraneum (8.5%), Lucinella divaricata (7.9%), Chamelea gallina (7.7%) and Aricidea fragilis mediterranea (5.9%), all comprising 83.5% of total specimens. Special attention should be paid to the distribution of the

opportunistic polychaet causing sediment bioturbation M. palmata. Gomoiu [3] deduced that the populations of M. palmata from the Romanian Black Sea shelf are able to process up to 4.8-9.6 kg of mud/m²/day. In our research we found that this species has a mean abundance of 450 ind. m⁻². Low dissolved oxygen values of lower layer and soft substratum of sediment resulted in wide distribution of M. palmata, adapted to these conditions. Molluscs were among the second abundant taxa, accounting for 32% of the total number of macrofaunal species. Among molluscs, gastropods dominate in species number (24 vs 18 of bivalve species), but bivalves are much higher as average density (534 ind. m-² vs 72 ind. m⁻²). The commonest bivalve, C. gallina (69%) had a highest frequency value of the 39 stations, followed by the bivalve, P. rudis (64%), the gastropod, Cyclope neritea (59%), respectively. Crustaceans are a qualitative and quantitative key component of the benthic fauna on soft and hard substrata [1]. In study area, Crustacea fauna was mainly composed of Amphipoda (70%), Cumacea (13%), Decapoda (10%), and Tanaidacea (7%), by numbers of species. Of the total of 30 benthic crustaceans, 15 species were encountered at a single station only. The commonest cumacean, Pseudocuma longicornis (37%) had a highest frequency value of the 39 stations, followed by the cumacean, Iphinoe tenella (33%), the amphipod, Ampelisca diadema (33%), the cumacean, Iphinoe elisae, and the amphipod, Perioculodes longimanus subsp. longimanus, respectively. The highest dominance value according to number of individuals was found for the cumacean, I. elisae (25%), followed by I. tenella (17%), the amphipod A. diadema (16%), the cumacean, P. longicornis (11%), and the amphipod, Bathyporeia guilliamsoniana (6%). Mutlu et al. [4] also mentioned that these same species were abundantly observed in this study area. Total numbers of species diversity for each group on the soft bottoms decreases with depth. Peaks of species diversity are at <50 m, in relatively shallow water zones: 10-25 and 25-50 m. Depth apparently has a major influence on the composition of the fauna, especially above the 50 m level. The most frequent species were M. palmata (present in 85% of the samples), Micronephths cf. maryae (72%), C. gallina (69%), Pitar rudis (Poli, 1795) (64%) and A. fragilis mediterranea (59%). Mollusca accounted for 76% of the total biomass in all samples, followed by Polychaeta and Echinodermata. The species with the highest individual biomass were C. gallina. Our investigations have shown that the abundance, biomass and ratio of zoobenthos in the biocoenoses mostly depend on the type of bottom sediments, physcochemical parameters and on the depth of the sea. This study provides useful information about the composition and distribution of benthic invertebrate fauna in Turkish Black Sea coast. Further investigations should be devoted to analyzing species relationships and resource partitioning between species to better understand the dynamic of zoobenthic assemblages.

TOWARDS INCREASING GELATINOUS PLANKTON BLOOMS IN THE MEDITERRANEAN. COMPARISON WITH THE BLACK SEA SIMILAR EVENT SCENARIO

Tamara Shiganova 1*

¹ P.P.Shirshov Institute of oceanology RAS - shiganov@ocean.ru

Abstract

During last years native gelatinous species considerably increased population size and distribution areas in the coastal areas of the Mediterranean Sea. Some of them expanded into the Sea of Marmara and even to the Black Sea. In addition non-native gelatinous species are recorded more and more often in the Mediterranean. We try to assume possible reasons based on nutrients concentration and climate shifts using the Black Sea scenario.

Keywords: Coastal Waters, Ctenophora, Medusae

In the Mediterranean Sea gelatinous species such as coelenterates and ctenophores increased their populations and areas of distributions during last years. Among them scyphomedusae Pelagia noctiluca, Cotylorhiza tuberculata, Rhisostoma pulmo. ScyphomedusaChrysaora hysoscella, and ctenophore Bolinopsis vitrea not only increased their areas of distribution but also expanded into the Sea of Marmara and even to the Black Sea [5]. Lessepsian migrant scyphomedusa Cassiopea andromeda established, spread over the eastern Mediterranean and penetrated into the Sea of Marmara [6]. The Black Sea invader Mnemiopsis leidyi, which was mainly observed in the Aegean Sea and did not create semi-reproductive population, in 2009 was recorded during all summer in new locations along the eastern and western Mediterranean Sea [1, 2, 3,7]. Spreading mucilage also increase in new areas. Although blooms of gelatinous plankton species have often been observed in the Mediterranean, particularly pronounced in the early 1980's, there is still almost no information about their effective causes, or of correlations which would enable prediction of their occurrence. Scenario of gelatinous plankton blooms in the Mediterranean has been compared with the Black Sea one. The Black Sea ecosystem resulted in nutrient pollution altered into a critically eutrophic in 1970s with catastrophic consequences and disturbed functioning. These conditions were favorable for the development of gelatinous plankton. First native gelatinous species began to increase their populations. Rising temperature in addition to disturbance are favored the naturalization of the gelatinous predatory warm-water ctenophore M. leidyi and its penetration into other seas of Mediterranean basin. It reached high abundances and affected all levels of the most ecosystems. Later on appearance in the Black Sea its predator warm water ctenophore Beroe ovata has facilitated ecosystem recovering. Since 1980s similar nutrient content alterations has been recorded in the coastal areas of Mediterranean linked to change their input from the rivers [4]. We assume that this factor together with temperature rise could be drivers of ecosystem change towards gelatinous blooms both native and nonnative.

Therefore the Black Sea example must be taken into consideration for understanding reasons of gelatinous plankton blooms in the Mediterranean Sea and focusing new research.

VARIATIONS SAISONNIERES DE LA BIOMASSE DE *NANOZOSTERA NOLTII* (HORNEMANN) TOMLINSON ET POSLUZNY DANS LA LAGUNE NORD DE TUNIS (TUNISIE SEPTENTRIONALE)

Abdessalem Shili ¹*, Naceur Ben Maïz ² and Charles François Boudouresque ³ ¹ Institut National Agronomique de Tunisie, 1082, Tunis - shili.abdessalem@inat.agrinet.tn ² Société de Promotion du Lac de Tunis, BP 36, Tunis El Bouhaira, 1080 Tunis Cedex, Tunisia ³ Centre d'Océanologie de Marseille, 13007, France

Abstract

Les Magnoliophytes marines sont réapparues dans la lagune Nord de Tunis après son assainissement et l'amélioration de la qualité de ses eaux. C'est le cas par exemple de *Nanozostera noltii* qui a proliféré, en premier lieu au nord-est de la lagune puis a progressé graduellement vers le sud-est. L'évolution saisonnière de la biomasse de *N. noltii* dans la lagune Nord de Tunis, montre des pics durant les saisons estivales et automnales. Les fluctuations ont été importantes surtout dans la station Nord-ouest où la biomasse totale de *N. noltii* a atteint un maximum de 420 g MS/m^2 .

Keywords: Phytobenthos, Biomass, Lagoons

Introduction

Suite à l'assainissement de la lagune Nord de Tunis, plusieurs espèces de Magnoliophytes telles que *Ruppia cirrhosa* (Petagna) Grande, *Cymodocea nodosa* (Ucria) Ascherson et *Nanozostera noltii* (Hornemann) Tomlinson et Posluzny (*=Zostera noltii* Hornemann) ont trouvé les conditions propices à leur développement [1]. *N. noltii* s'est développé en premier lieu dans le secteur Nord-est de la lagune, le plus influencé par les échanges avec la mer Méditerranée; puis progressivement, son aire de répartition s'est étendue jusqu'au secteur Sud-est. Cette espèce constitue des herbiers homogènes ou bien mixtes avec *Cymodocea nodosa* et *Ruppia cirrhosa*, surtout dans la partie nord de la lagune et avec la Chlorobionte, *Chaetomorpha linum* (O.F. Müller) Kützing, dans la partie sud de la lagune.

Materiel et méthodes

Nous avons étudié la répartition de *N. noltii* dans la lagune Nord de Tunis par observation le long de plusieurs transects nord-sud. Après localisation des herbiers à *N. noltii*, nous avons choisi deux stations au nord-ouest et au sud-ouest de la lagune pour l'étude de la biomasse. Dans chaque station, nous avons relevé la profondeur de l'eau et le recouvrement de *N. noltii* et de ses espèces accompagnatrices. Les prélèvements de biomasses ont été effectués, à raison de trois répliques par station, durant la période allant de janvier 1996 à janvier 1998 à l'aide d'un quadrat de 0,25 m². La masse sèche a été mesurée après séchage à 80 °C durant 24 h.

Résultats et discussion

La variation mensuelle de la biomasse de *N. noltii* montre des pics en été et en automne dans la station Nord-ouest de la lagune (fig. 1) où la biomasse totale a atteint un maximum de 420 g MS/m². En dehors de la saison printanière, les variations de la biomasse endogée suivent généralement celles de la biomasse épigée. Dans la station Sud-ouest de la lagune, *N. noltii* a essentiellement proliféré durant la deuxième année d'étude (1997). Son maximum de développement a été relevé au printemps avec 134 g MS/m². *N. noltii*, espèce euryhaline et préférant les faibles profondeurs et les fonds sablo vaseux [2], [3], a trouvé dans la lagune Nord de Tunis les conditions propices à son développement : faible turbidité et salinité dans les marges de ses tolérances. Elle s'est développée en premier lieu dans les zones Est, le temps de s'acclimater, puis a progressé et proliféré dans le secteur Sud de la lagune.

Fig. 1. Evolution mensuelle de la biomasse moyenne de *Nanozostera noltii* dans la station Nord-ouest de la lagune Nord de Tunis. La barre représente l'écart type. L'absence de barre indique un échantillon unique.

SPATIAL DISTRIBUTION OF CTENOPHORE MNEMIOPSIS LEIDYI IN AEGEAN SEA

A. Siapatis^{1*}, M. Giannoulaki¹, V. D Valavanis¹, A. Machias¹ And S. Somarakis¹ Hellenic Center For Marine Research - Siapatis@Ath.Hcmr.Gr

Abstract

The invasive ctenophore Mnemiopsis leidyi was accidentally introduced into the Black Sea in the early 1980s and it was first sighted in the Aegean Sea in the early 1990s. This paper presents the spatial distribution of M. leidyi in Aegean Sea during early summer 2004-2006 and 2008.

Keywords: Aegean Sea, Ctenophora, Plankton

Fig. 1. Distribution maps of *M. leidyi* (individual / m²) for June 2004, 2005 2006 and 2008 respectively.

Indroduction

The ctenophore Mnemiopsis leidyi is a voracious zooplanktivorous species

and its native habitat is estuaries and coastal regions along the eastern coast of North and South America. It was accidentally introduced into the Black Sea in the early 1980s [1] possibly with ballast water from ship coming from the northwestern Atlantic coastal region. The first occurrence M. leidyi in Aegean Sea was recorded during late spring-summer 1990 in Saronikos Gulf (45-75 ind m⁻², [2]). After 1991, M. leidyi swarms were observed in several coastal areas of the northern Aegean and few specimens were collected in offshore waters [3]. It is believed that the flow of Black Sea water mass to the northern Aegean Sea contributes to the dispersal of M. leidyi in the area. Materials and methods

Plankton specimens were collected during four research surveys during early summer in the northern Aegean Sea in June 2004-2006 and 2008. Sampling design was based on a grid of stations spaced on parallel transects that were approximately 10 nautical miles apart (Fig. 1). A total of 205 stations were located on 5 nautical miles intervals on each transect. Standard vertical plankton tows were made at each station, by a WP2 sampler (mouth opening: 0.255 m², mesh-size: 0.200-mm). M. leidyi specimens were identified and counted on board

Results and discussion

The spatial distribution of M.leidyi in Aegean Sea in early summer of 2004-2006 and 2008 (including both larvae and adult specimens) are shown in Fig. 1. Although its abundance and distribution shows a large degree of interannual variability, the highest abundances were observed in Thermaikos gulf and Strymonikos gulf where large rivers outflow. The lowest abundances were recorded in June 2005 (3 to 50 ind m⁻²), whereas the highest in June 2004 (4 to 188 ind m⁻²). The wider and most southern distribution (up to N. Evoikos Gulf) of the species was observed in 2006 and 2008 compared to the previous years. The percentage of occurrence of M. leidyi into the sampling stations increase during the years from 20 and 18% in June 2004 and 2005 to 37 and 50% in June 2006 and 2008. In June 2008 the highest abundances were observed in areas that have been characterised by Black Sea Water influence (e.g. Thracian Sea, Limnos-Imvros plateau), A spatial model has been applied based on Aegean Sea satellite data to determine the environmental conditions that characterize areas where M. leidyi is present and based on this to identify other potential areas that could support species presence in the Hellenic and Mediterranean Seas [4]. Furthermore, future work could involve examining whether the local conditions (e.g. temperature, salinity, prey's availability and/or predators' abundance) in the Hellenic Sea could favour Mnemiopsis successful reproduction, high populations or bloom levels during all year round that could possibly lead to an alteration of the food web in similar way to the case of the Black Sea.

OTOLITH MORPHOLOGY AND FISH SIZE RELATIONSHIPS FOR FIVE WRASSE SPECIES IN THE EASTERN ADRIATIC SEA

Frane Skeljo¹ and Josipa Ferri^{1*}

¹ University of Split, Center of Marine Studies - josipa.ferri@unist.hr

Abstract

Sagittal otoliths of five wrasse species, *Coris julis* (Linnaeus, 1758), *Symphodus tinca* (Linnaeus, 1758), *Symphodus cinereus* (Bonnaterre, 1788), *Symphodus ocellatus* (Forsskål, 1775) and *Symphodus rostratus* (Bloch, 1791) were described and compared using morphometric parameters. General otolith shape is the same for all wrasse species, although sagittal morphological variations between the species and different length groups were observed. Results for all investigated species showed that the otolith length is the best indicator of fish total length.

Keywords: Adriatic Sea, Teleostei, Biometrics

Introduction

Otoliths are one of the most useful anatomic fish structures in various studies because of their characteristics (size, morphological specificity and microstructure) and dependence of these properties on the variation in environmental factors [1]. Such applications are widely used by researchers studying feeding ecology of fish predators, although are not just limited to ichthyology. The adequate identification of fish prey from otoliths is essential in feeding studies, where the relationship between otolith length and fish length or weight given by specific regressions can also be used to estimate the prey size or mass. The aim of this study was to investigate otolith morphology of five wrasse species, establish the relationship between otolith size and fish size and to evaluate the usefulness of the otolith shape factors in separation of different wrasse species.

Materials and Methods

Fish samples were collected from the middle eastern Adriatic coast using a beach seine (mesh size 28 mm), from June 2009 to October 2009. The total length (TL) of each wrasse specimen was measured to the nearest mm, weight was measured to the nearest gram, and sagittal otoliths were removed, cleaned and stored dry for afterwards examination. Maximum otolith length (OL), width (h), thickness (d) and weight (OW) were taken for each otolith and its morphology was described [2]. A linear multiple regression model was fitted to the data in order to predict the total fish length from the length, width, thickness and weight of the otolith. The predictive regression equation took the form $Y = a + b_1x_1 + b_2x_2 + b_3x_3 + ... + b_ix_i$, where a=constant, b_n =regression coefficients and x_i =independent variables. Forward stepwise multiple regression (probability of alpha to enter <0.15) was used to determine which parameters would best predict total length in selected species.

Results and Discussion

In this study, otolith morphology of Coris julis (N=150) ranging from 5.5 to 21.5 cm TL, Symphodus tinca (N=144) ranging from 6.5 to 22 cm TL, Symphodus cinereus (N=127) ranging from 6.0 to 10.3 cm TL, Symphodus ocellatus (N=120) ranging from 5.8 to 9.5 cm TL and Symphodus rostratus (N=95) ranging from 7.2 to 11.5 cm TL was described. Based on changes observed in otolith morphology, four otolith categories for C. julis and S. tinca and two for S. cinereus, S. ocellatus and S. rostratus were distinguished. In general, otolith shape of investigated wrasse species is cuneiform while entire otolith margins are characterized only for C. julis and S. ocellatus. Anterior part of otolith, including rostrum and antirostrum is well developed in all species except C. julis, where antirostrum is poorly defined. On the other hand, S. tinca and S. cinereus otoliths have deep and acute notch and due to that can be easily distinguished from others. For all species, correlation between fish length and different otolith measurements was statisticaly significant at alpha level of 0.005, with otolith length showing the highest (0.70 - 0.96), and otolith thickness lowest (0.29 - 0.85) values of Pearson correlation coefficient. When a forward stepwise multiple regression model was fitted to the entire data set, the resulting equations excluded variables that did not significantly improve the regression: otolith width for S. cinereus, otolith weight for S. tinca, and both otolith thickness and weight for S. rostratus. For all equations, coefficient of determination (R²) was reasonably high, ranging from 59.5% for S. ocellatus to 93.4 % for C. julis (Table 1). However, using only otolith length as prediction variable produces linear regession equations with only slightly lower R^2 values for all analyzed species, except S. ocellatus (Table 2). Therefore, use of a multivariate model is probably not justified given the additional work required to measure several parameters, with only slight improvement in the precision of estimated fish length.

Abstract

L'étude de la maturité sexuelle chez *Caranx crysos* du golfe de Gabès (Tunisie) a montré que les mâles atteignent la première maturité sexuelle pour une longueur à la fourche (LF) de $210,2 \pm 0,6$ mm, alors que les femelles deviennent matures lorsqu'elles atteignent une longueur à la fourche de $222,3 \pm 0,4$ mm. Dans le cas des sexes confondus, la longueur à la fourche à la première maturité sexuelle est de $216,6\pm0,5$ mm. Chez *C. Crysos*, l'âge théorique de première maturité sexuelle serait de 3 ans pour les femelles et 2 ans pour les mâles.

Keywords: Reproduction, Fishes, Gulf Of Gabes

Matériel et méthodes

L'observation macroscopique de l'évolution des stades de maturation des gonades a été effectuée sur des critères morphologiques (coloration, consistance, importance de la vascularisation superficielle, forme, volume occupé par les gonades dans la cavité abdominale). L'ensemble de ces critères a abouti à l'établissement d'une échelle de maturité [1], [2]. L'examen des gonades mâles et femelles lors de la maturation et de la ponte a permis d'isoler trois classes d'individus ; - des individus juvéniles - des individus de tailles voisines et des individus adultes. Ainsi, les échantillons récoltés durant cette période ont été regroupés par classe de taille de 1 cm pour C. crysos. Nous avons dénombré pour chaque classe de taille, séparément, les individus matures et les individus immatures. Par la suite, nous avons calculé la proportion des matures par classe de taille durant la période située entre juin et août correspondant à la période de maturation chez cette espèce dans le golfe du Gabès. La taille de première maturité sexuelle qui correspond à la longueur pour laquelle 50% des individus sont matures a été déterminée en utilisant une fonction logistique qui relie les proportions d'individus mâtures à la taille du poisson. La fonction s'écrit sous la forme : P=1/(1 + e^{-r} (L-L50)), avec P : proportion des individus matures; L : longueur du poisson en cm ; r = constante de l'équation ; L_{50} = longueur à laquelle 50% des individus sont matures. En utilisant le logiciel "FSAS" [3], nous avons ajusté cette équation sur les données obtenues pour la maturité sexuelle chez C. crysos. Les résultats concernant les proportions des individus matures prédits (estimés d'après l'équation théorique) ont été analysés statistiquement par le test χ^2 qui est égal à : $\chi^2 = \sum (Mi-nPi)^2 / \sum nPi$, où Mi : nombre observé d'individus matures, nPi : nombre estimé d'individus matures. L'âge théorique à la première maturité sexuelle a été déterminé à partir de l'équation de Von Bertallanffy : $t = t_0 - 1/K$ Log $(L_{\infty}-L_t / L_{\infty})$ $L_t =$ longueur du poisson au temps t ; $L_{\infty} =$ longueur théorique pour un accroissement nul ; t₀ = temps théorique correspondant à L = 0 et k = constante de la vitesse de croissance.

Résultats

L'analyse des proportions d'individus matures de *C. crysos* (tableau1) montre qu'à une taille (LF) inférieure à 180 mm, aucun individu, quel que soit son sexe, n'est mature. Par ailleurs, tous les individus observés le deviennent à une taille (LF) supérieure à 250 mm chez les femelles et à 260 mm chez les mâles. Les plus petits et les plus grands adultes observés dans nos échantillonnages mesurent respectivement 182 mm et 358 mm chez les femelles et 181 mm et 351 mm chez les mâles. Les fonctions logistiques pour les femelles, les mâles et les sexes combinés sont déterminés et s'écrivent comme suit : P= $1/(1 + e^{0.7345} (L - 222.3))$ pour les Femelles, P= $1/(1 + e^{0.5125} (L - 210.2))$ pour Mâles et P = $1/(1 + e^{-0.5827} (L - 216.6))$ pour les sexes combinés.

- Les mâles de *C. crysos* atteignent la première maturité sexuelle pour une longueur à la fourche de $210,2 \pm 0,6$ mm (LT= 245,88 mm). Les femelles deviennent matures lorsqu'elles atteignent une longueur à la fourche de $222,3 \pm 0,4$ mm (LT= 259,79 mm). Chez les sexes confondus, la longueur à la fourche à la première maturité sexuelle est de $216,6\pm0,5$ mm (LT=253,12 mm).

- Dans le golfe du Mexique, les femelles de *C. crysos* deviennent matures pour la première fois à une taille de l'ordre de 267 mm de LF [4]. Les données observées s'ajustent bien au modèle logistique. Cette méthode s'applique donc à l'étude de la maturité sexuelle de *Caranx crysos* du golfe de Gabès.

-La fiabilité des résultats est justifiée par le test χ^2 . Les valeurs prédites sont presque identiques aux valeurs observées puisque le χ^2 théorique [5] et [6] est nettement supérieur (χ^2 théorique =22,36) au χ^2 observé (χ^2 observé, femelles=2,82<, χ^2 observé, måles =2,04 et χ^2 observé, sexes combinés=4,95). Dans le cas de *C. Crysos*, l'âge théorique de première maturité sexuelle a été estimé. La maturité sexuelle est atteinte à l'âge de 3 ans pour les femelles et 2 ans pour les mâles.

Abstract

L'analyse des caractères morphologiques de *Caranx crysos* du golfe de Gabès (Tunisie) a permis d'identifier l'espèce et la distinguer des autres espèces de poissons. L'étude numérique a montré un intervalle bien déterminé de chaque caractère étudié. De plus, le nombre de branchiospines diminue en fonction de la taille et de l'âge du poisson. L'étude biométrique chez les mâles, les femelles et les sexes combinés, a montré que les caractères métriques étudiés sont bien corrélés à la longueur totale et la nature de l'allométrie diffère suivant le caractère utilisé.

Keywords: Biometrics, Fishes, Gulf Of Gabes

Introduction

Caranx crysos (Saint-Hiliaire, 1817) est un poisson très répandu en Tunisie, notamment dans la région Sud du pays (golfe de Gabès) où leur importance commerciale augmente d'une année à l'autre. Dans ce travail, nous nous sommes intéressés à l'étude des caractéristiques morphologiques (numériques et métriques) de cette espèce.

Matériel et méthodes

L'étude a porté sur 270 spécimens de Caranx crysos de tailles (LT) comprises numériques, nous avons groupé les mâles et les femelles de cette espèce. Les caractères relevés et analysés statistiquement sont les suivants : le nombre de rayons aux deux nageoires dorsales (D1 et D2) ; le nombre de rayons à la nageoire pectorale droite (P) ; le nombre de rayons à la nageoire anale (A) ; et le nombre de branchiospines au premier arc branchial. Ensuite, nous avons analysé chaque caractère métrique chez les mâles (M), les femelles (F) et les sexes combinés de cette espèce. Ces caractères ont été relevés au millimètre près, à l'aide d'un ichtyomètre et d'un pied à coulisse électronique. Les différentes mensurations effectuées sont les suivantes : la longueur totale (LT) ; la longueur à la fourche (LF) ; la longueur standard (Lst) ; la longueur de la tête (T) ; la première hauteur du corps (H1) ; la deuxième hauteur du corps (H2) ; la longueur de la première nageoire dorsale (LD1) ; la longueur de la deuxième nageoire dorsale (LD2) ; la longueur de la nageoire pectorale (LP) ; la longueur prédorsale 1 (PD1) ; la longueur prédorsale 2 (PD2). Chaque caractère (C) a été décrit par un indice de proportionnalité (I) : I=C*100/LT, où C = caractère mesuré en mm et LT = longueur totale de poisson en mm ; et une fonction puissance (Y): Y= aX^{b} , où Y = caractère mesuré en mm (variable dépendante) et X = longueur totale en mm (variable indépendante). Après linéarisation de la fonction, les constantes a et b ont été calculées par la méthode des moindres carrés. Selon la loi de l'allométrie, b prendrait une valeur proche de 1. Pour tester cette valeur, nous avons utilisé le test "t" de Student : $t_{cal} = |b-1|/\sqrt{s^2_y(1-R^2)/s^2_x(n-2)}$; où $s^2_y = variance de la variable Y (en Log),$ s_{x}^{2} variance de la variable X (en Log), R^{2} = le carré du coefficient de corrélation, n = nombre d'individus examinés et n-2 = degré de liberté. Ensuite, nous avons comparé t calculé (t_{cal}) à la valeur théorique de t (t_{th}) à un seuil de 5% (Spiegel, 1991) [1].

Résultats

Etude numérique

Caranx crysos du golfe de Gabès possède deux nageoires dorsales séparées par une distance inter dorsale qui augmente avec l'âge (ID). La première dorsale (D1) est courte et épineuse, renfermant huit rayons durs ou épines. Au niveau de la deuxième nageoire dorsale (D2), le nombre des rayons mous varie d'un individu à l'autre et fluctue de 22 à 25. Comme chez tous les Carangidés, *C. crysos* du golfe de Gabès présente une nageoire anale (A) à deux épines coutres et isolées suivies d'un rayon dur et un nombre de rayons mous qui varie de 19 à 21. Les nageoires pectorales (P) sont longues, contenues 0,9 à 1,2 fois dans la longueur de la tête. Le dénombrement de rayons varie de 18 à 21 et il est indépendant de la taille. En revanche, le comptage de branchiospines a montré une diminution en nombre en fonction de la taille et de l'âge du poisson et ce nombre varie entre 33 et 42. En comparaison avec les études effectuées par Fischer et al. [2], les formules radiaires de *Caranx crysos* vivant en Méditerranée et en Mer noire et celle peuplant le golfe de Gabès sont identiques.

Etude métrique

Chez Caranx crysos du golfe de Gabès, les longueurs de la tête (T) et des hauteurs H1 et H2 et la longueur de la première nageoire dorsale LD1 évoluent

selon une allométrie minorante avec la longueur totale. Toutefois, la longueur de la nageoire pectorale (LP) évolue suivant une allométrie majorante. Par ailleurs, la relation entre la taille et les distance prédorsales LPD1 et LPD2 est isométrique. En revanche, la longueur de la nageoire dorsale LD2, varie suivant une allométrie minorante avec la taille chez les mâles, alors que la relation est isométrique pour les femelles (tableau 1). Par ailleurs, les relations entre les différentes longueurs du corps (LT, Lst et LF) montrent de bonnes corrélations justifiées par un coefficient de corrélation \mathbb{R}^2 qui varie entre 0,97 et 0,99. Les valeurs de la constante 'b' dans les différentes équations de croissance relative sont proches de l'unité. Chez les mâles, les femelles et les sexes combinés de *C.crysos*, la longueur totale (LT) crôît avec la longueur standard (Lst) et la longueur à la fourche (LF) suivant une allométrie majorante. La relation est minorante entre la longueur standard (Lst) et la longueur à la fourche (LF).

ROV OBSERVATIONS ON FISH AND MEGAFAUNA IN DEEP CORAL AREAS OF THE EASTERN IONIAN

C. J. Smith¹, C. Mytilineou¹, N. Papadopoulou¹, M. A. Pancucci-papadopoulou¹ and M. Salomidi¹* ¹ Hellenic Centre for Marine Research - msal@ath.hcmr.gr

Abstract

Under the EU CoralFish project, investigating cold water corals in the Eastern Ionian Sea, sonar targets were surveyed with a remotely operated vehicle at depths of 440-820 m. Information on the bathymetric range, habitat, behaviour, aggregation pattern and response to the ROV is reported for approximately 30 characterising megafaunal and fish species. *Keywords: Fishes, Crustacea, Deep Sea Ecology, Ionian Sea*

Introduction

The CoralFish project aims at assessing the interactions between deepwater corals, fish and fisheries, towards better ecosystem based management of European deep waters. Several areas in the North Atlantic and Mediterranean are being investigated. Rich coral communities have been described off the southeast corner of Italy [1]. Off the opposite side of this basin, in western Greece, sites are being investigated to identify and describe coral areas. Observations by remotely operated vehicle (ROV) on megafaunal organisms and their behaviour in their natural environment are reported.

Materials and Methods

The study area is situated off the west coasts of the islands of Cephalonia and Zakynthos (Greek Ionian Sea). Surveys were conducted between 300-2000 m depth in June 2009. Hull mounted multibeam sonar (Seabeam 2021 - 20 kHz) was used to map the general underwater topography, followed by deep tow operations (Geoacoustics Deep Tow 2000; Side scan 114/410 KHz; Subbottom Geochirp II, 1-12 kHz) in 4 selected areas. A DSSI Max Rover remotely operated vehicle (ROV) was used to make observations during 5 dives at 440-820 m depth on specific targets and target areas selected from the sonar records. The targets had high potential for deepwater coral occurrence. Live observations were made by scientists on board the support vessel and recorded material in the laboratory. Data analysis included species identification, depth range, habitat, behaviour, aggregation pattern and their reaction to the ROV.

Results

Various species of fish (Chlorophthalmus agassizi, Hoplostethus mediterraneus, Helicolenus dactylopterus, Pagellus bogaraveo, Polyprion americanus, Phycis blennoides, Chauliodus sloanii, Lampanyctus crocodilus, Nezumia sclerorynchus, Hymenocephalus italicus, Etmopterus spinax, Nettastoma melanurum, Bathypterois mediterraneus, Stomias boa), decapods (Aristaeomorpha foliacea, Aristeus antennatus, Plesionika giglioli, P. martia, P. edwardsii), cephalopods (Teuthoidea), anthozoa (Isidella elongata, Leiopathes glaberrima, Desmophyllum crystagalli, Funiculina quadrangularis) echinodermata (Stichopus regalis, Hymenodiscus coronata, Cidaris cidaris) and cirripedia were observed during the ROV surveys. Approximately 13 individual fish, 18 decapods, 2 cephalopods, 5 cirripedia and 47 corals have not yet been identified.

Depth range distribution: species were classified as found a) mainly <500 m depth (e.g. *C. agassizi*, *P. bogaraveo*), b) mainly between 500-700 m (e.g. *H. dactylopterus*, *H. mediterraneus*, *A. antennatus*), c) mainly >700 m (e.g. *I. elongata*, *L. crocodilus*, *C. sloanii*) and d) in the whole depth range (e.g. *F. quadrangularis*).

Habitat: species were separated into associated with a) mud (e.g. C. agassizi, I. elongata) and b) rocks (e.g. P. bogaraveo, D. crystagalli).

Behaviour: species were characterised as a) clearly benthic (e.g. I. elongata, C. cidaris), b) lying inactive or moving on the bottom (e.g. P. martia, P. giglioli, H. dactylopterus), c) staying just above the bottom, but in close relation with it (e.g. P. bogaraveo, P. americanus, H. mediterraneus, N. sclerorhynchus, H. italicus), d) lying on the bottom, but also swimming in the water column (e.g. A. antennatus, A. foliacea) and e) swimming in the water column (e.g. Teuthoidea).

Aggregation pattern: a) species presenting a schooling pattern (e.g. P. bogaraveo, P. gilioli), b) the solitary ones (e.g. P. americanus, C. sloanii) and c) those showing a dispersed pattern (e.g. C. agassizi, P. martia, H. mediterraneus).

Reaction to the ROV: species were distinguished as a) remaining inactive (e.g. *C. agassizi, P. martia*), b) reacting and leaving the area (e.g. *A. foliacea*), c) reacting, but without leaving (e.g. *H. dactylopterus*) and d) attracted (e.g. Teuthoidea).

Discussion

The results of the present study confirm the megafauna in the deep waters of the Ionian Sea [2]. More species were observed in the present work, probably related to the longer duration of the ROV surveys, the larger depth range and the larger geographical area studied. Although some of the information collected in this study is already known [3 and references therein], new insights were gathered regarding the behaviour of the species. The use of ROVs allows the behavioural study of deep-water species, however, light and noise disturbance need to be considered.

Acknowledgements : The authors would like to thank colleagues at HCMR in particular the geophysical team and ROV support team as well as the captain and crew of the RV Aegaeo. The CoralFish project (http://eu-fp7-coralfish.net/) is funded by the EU and Greek General Secretariat for Research & Technology.

Abstract

This paper provides information about morphological differences between individuals live and dead green turtles (Chelonia mydas) hatchlings on Samandag beach in Turkey. A total of 146 hatchlings, taken equally from both live and dead, were examined for the morphological differences. The dead hatchlings had smaller all carapace length, fore limp length, hind limp length from both side and lower weight than live hatchlings.

Keywords: Turtles, Eastern Mediterranean

Introduction

Body size and shape have important physiological, evolutional and ecological for sea turtles [1]. The morphology of hatchlings can increase or decrease possibility of their surviving [2]. Generally bigger hatchlings are more talented swimmer and can escape from predators [3]. Hatchling's morphology of sea turtles can be affected from both genetic and maternal characteristic and environmental factors [3,4]. The differences among the size of the hatchling sea turtles can be caused from the structure of hydric and thermal characteristics of surroundings of nest in incubation duration [4,5]. The aim of this study was to evaluate morphological differences between individuals' live and dead green turtles (*Chelonia mydas*) hatchlings on Samandag beach in Turkey.

Material and methods

Data were collected on Samandag Beach (36° 7.500' N 35° 55.100' E) Northern Mediterranean Sea in Turkey during the 2008 and 2009 nesting seasons. A total of 146 hatchlings, taken equally from both live and dead, were measured and 8 measurements were taken (Figure 1) using manual callipers accurate to 0.1 mm. Measures of straight carapace length (SCL), straight carapace width (SCW), curved carapace length (CCL), curved carapace width (CCW), fore limb length (FLL) from both left and right, hind limb length (HLL) from both left and right, weight between live and dead hatchlings were compared [6,7].

Fig. 1. Measures of straight carapace length (SCL), straight carapace width (SCW), curved carapace length (CCL), curved carapace width (CCW), fore limb length (FLL) from both left and right, hind limb length (HLL) from both

Results and Discussion

The dead hatchlings had smaller SCL (U= 960,00, Z= -6,73, P= 0,000), SCW (U= 1002,00 Z= -6,553, P= 0,000), CCL (U= 1722,00, Z= -3,726, P= 0,000), CCW (U= 1272,00, Z= -5,524, P= 0,000) and lower weight (U= 875,00, Z= -7,040, P= 0,000) than live hatchlings (Table 1). Furthermore, there was significant difference between hatchlings from those in hatchlings from both FLL and HLL for both side, dead hatchlings had smaller left FLL (U= 972,00, Z= -6,699, P= 0,000), right FLL (U= 923,00, Z= -6,901, P= 0,000), left HLL (U= 1863,00, Z= -3,213, P= 0,001) and right HLL (U= 1850,00, Z= -3,274, P= 0,001) than live hatchlings (Table 1).

Peters and Verhoeven (1992) [8] found that there was a significant difference between the sizes of live and dead the loggerhead turtles and suggested that smaller hatchlings were weaker. Similarly, Ozdemir et al. [2] have found that carapace of loggerhead dead hatchling is smaller for SCL and their weightiness is less than loggerhead live hatchling. Whereas; Loughron et al. (2000) [9] found that there was no significant difference between live and dead hatchlings for SCL, SCW and weight of the green and loggerhead turtles. The larger size may allow hatchlings to escape gape-limited predators, swim faster and to successfully handle larger prey items hatchlings i.e "the bigger is beter" [10]. Generally bigger hatchlings can escape from predators [3]. However, survival of hatchlings can affect negative effect such as its time to leave from the nest of hatchlings, pollution status on beach and amount of light.

Tab. 1. Summarized statistics of the variables taken for live hatchlings and dead

SUMMER FISH LARVAL ASSEMBLAGES IN FOUR AREAS OF THE CENTRAL MEDITERRANEAN

Joan Miquel Sorell¹, Patricia Lastra¹, Patricia Reglero¹ and Mari-Luz Fernandez De Puelles¹* ¹ Instituto Español de Oceanografía - mluz.fernandez@ba.ieo.es

Abstract

Our study confirms that several tuna species spawn in the central Mediterranean, especially in the vicinity of island. Tuna larvae were found in the four areas sampled (Eolias, Cabo Passero, Malta and Aegean Sea) and represented between 18% and 90% of the total abundance. The high larval abundances and occurrence of *Thunnus alalunga* shows that our sampling period coincided with the spawning peak of this species. Other larvae also found in the assemblages included meso-batipelagic, small pelagic and coastal. *Keywords: Ichthyoplankton, Fishes*

Introduction

The Mediterranean Sea is an important spawning area for different fish species. The aim of this study is describing the fish larval assemblages in four different areas located in the Central Mediterranean Sea complementing previous surveys in other Mediterranean locations paying special attention to tuna larvae [1]. The presence of larval stages of fish will provide valuable information to describe summer spawning areas for different species in the Central Mediterranean Sea.

Material and Methods

Icthyoplankton samples were obtained within the framework of the oceanographical survey Marviva Med during summer 2008 in four areas in the Central Mediterranean: Eolias (24 stations, from 15th July to 19th July), Cabo Passero (8 stations from 24th-25th July), Malta (5 stations from 25th-26th July) and Aegean Sea (14 stations, from 5th to 11st July). Surface hauls were conducted at 1 m depth using Bongo 90 net equipped with 500 microns meshes. Stations were sampled during daytime and night. Samples were conserved in ethanol. Once in the laboratory, the fish larvae were sorted out and identified to the lowest taxonomic level possible, generally, species level.

Fig. 1. Fish larval species sampled in each area (Cabo Passero, Malta, Aegean Sea, Eolias). Numbers represent the percentage of each species in relation to the total larval abundance in each area. Only species representing more than 2% of the total abundance were included. All stations within areas were pooled together

Results and discussion

Six species of *Scombridae* were identified but their presence in the different areas differed. Eolias was the area with higher diversity of *Scombridae*, being all species represented, including *Euthynnus alletteratus* which was only found herein, but excluding *Katsuwonus pelamys* that was only found in Malta. *Thunnus alalunga* and *Auxis rochei* were found in all four areas. However, only *Thunnus alalunga* was represented in abundances higher than 2% of the total abundance in each area. In Malta, the larval assemblage was clearly dominated by two species, *Thunnus alalunga* and *Auxis rochei*, representing around 90% of the total abundance of the fish larval species identified. *Xiphias gladius*, a species included in the red list of UICN, was found in three areas except in Cabo Passero. Inversely, *Thunnus thynnus* was found in Cabo Passero and in Eolias. Larvae of large and medium pelagic species have been found in large quantities also in other areas of the NW Mediterranean Sea, defining specific larval

assemblages [2], as in our case occurred in Malta. Our results suggest that the different areas sampled in the Central Mediterranean Sea are spawning areas for Scombridae fish and, taking into account the high larval abundances and occurrence of Thunnus alalunga, that sampling period coincided with the spawning peak of this species. Larval assemblages were composed by fish groups other than large pelagics. In Eolias, the community was dominated by Thunnus alalunga and Chromis chromis (a coastal species). Other medium pelagic fish larvae such as Auxis rochei was also found in the area. Mesobatipelagic fish species followed in importance. The coexistence of these different groups of larval species has been described in the NW Mediterranean [3] suggesting some similarities in the larval assemblages of NW and central Mediterranean. In the Aegean Sea, meso-batipelagic fish larvae dominated the community represented by Ceratoscopelus maderensis, Cyclotone pigmaea and Hygophum sp. *Thunnus alalunga* was also represented in the community. Ceratoscopelus maderensis and Lampanyctus pusillus, belonging to the mesobatipelagic species, dominated the assemblage. Our study confirms that several tuna species spawn in the central Mediterranean, especially in the vicinity of island, and co-occur with larvae of other species.

ASSESSMENT OF MARINE PAINTS BASED ON TUBEWORMS AND SEPIA SHELL

Aida Tadros^{1*}, Manal El naggar¹ and Fatma Zaghloul¹

¹ National Institute of Oceanography and Fisheries (NIOF) - BT_AIDA@yahoo.com

Abstract

Two Marine paints were prepared with the same formulation except one based on tubeworms (AF_t) and the second contains *Sepia* shell (AF_s). The two paints together with their blank (B) were applied on unprimed steel panel and immersed in seawater. The biological investigation of the coated surfaces showed (AF_s) inhibits heterotrophic bacteria, actinomycetes and the sulfate reducing bacteria after 21 days of immersion with 43%, 25% and 64%, respectively, compared to (B). After 70 days of immersion (AF_s) was free from diatoms, primary stages of macroalgae and the polychaet larvae while primary stages of macroalgae were formed on (B). *Keywords: Diatoms, Fouling, Bio-Accumulation, Chemical Analysis*

Introduction

The immersed surfaces in marine environment are usually rapidly colonized by microorganisms, includes attachment of bacteria, diatoms, fungi, and protozoans. These are often followed by the settlement of algal spores and larvae of macro invertebrates. The colonization process is termed biofouling [1]. This study aims to evaluate the antifouling property of tubeworms and Sepia shell as natural pigments for marine fouling control.

Each of tubeworms and Sepia shell was incorporated individually in similar marine paint formulation. The paints were applied on unprimed steel panels, immersed in Eastern harbor (EH) and their coated surfaces were biologically assessed.

Material and Methods

Tubeworms have been collected from (EH) and *Sepia* shell is available and easily obtain. Both washed with tap water, distilled water, dried at 70 °C and grind till fine particle size $<71\mu$ m using sieves.

Chemical analysis; the total C% of tubeworms and *Sepia* shell was measured in Micro-analytical Center, Fac. of Sci. Cairo Univ.

Spectrophotometer measurement; 0.1g of each of tube worms and sepia shell in 50 ml D.W. was stirred and the spectrum of each solution was measured after 2, 4,7,8,9, and 10 days.

Marine paint formulation was prepared with a composition of oil binder 25, iron oxide 10, zinc oxide 24, and complementary pigments 13. Tubeworms and/or *Sepia* shell were added with 25 % in the paint. The two paint formulations together with the blank were applied on unprimed steel panels 10X10X0.5cm, hanged in a frame and immersed in EH. The condition of the surfaces was followed photographically and biologically inspected [Figs 1&2]. The microbiological examination for heterotrophic bacteria, actinomycetes, sulfate reducing bacteria and marine fungi and the biological investigations for diatom and zooplankton population were carried out for the biofilms formed on (B), (AF_t) and (AF_s) coated steel panels according to the APHA, 1995 [2].

Results and Discussion

The four different microbial communities were monitored after 7, 14, 21 and 21 and 28 days. The diatom and zooplankton formed on the coated surfaces were examined and identified after 70, 85 and 95 days.

The C% was found to be 12.22 % and 13.82% for tubeworms and sepia shell respectively. The spectra of the tubeworms after 8 days showed two absorption bands at 385 nm and 370 nm respectively, while the aqueous medium of the *Sepia shell showed* one absorption band at 270 nm.

The coated steel surfaces were inspected in triplicates for heterotrophic bacteria, actinomycetes and marine fungi after 7, 14, 21 and 28 days of immersion. The data indicated that the maximum inhibition for heterotrophic bacteria, actinomycetes and the sulfate reducing bacteria was observed after the 21 days of immersion on (AF_s) . They were significantly inhibited by 43%, 25% and 64%, respectively, compared to (B). After 14 days of immersion the marine fungi showed to be inhibited by 14% on (AF_t) compared to (B).

The results of the biological investigation after 70 days of immersion showed primary stages of macroalgae were formed on (B). Rare numbers of diatoms (*Navicula, Cosinodiscus* and *Thalassionema nitzschioides*) and rare numbers of zooplankton species (copepoda, protozoa, and free living nematode and spionoid larvae of polychaet) were recorded on (B) and (AF_t). These species were attached to the coated surfaces from the surrounding seawater, while (AF_s) surface was free from diatoms, primary stages of macroalgae and the polychaet larvae. After 85 and 95 days of immersion, frequent forms of primary stages of macroalgae and rare diatom species (*Skeletonema, Nitzschia closterium & Navicula*) were formed on all examined steel coated panels (B, AF_t and AF_s) and a detection of only one polycheat larva was observed after 95 day on each examined coated panel. (AF_s) steel coated surface showed better fouling control

than (AFt) over a period of 100 days of immersion.

Abstract

Remarkable changes in the benthic communities of Venice lagoon were observed between 2002-2007. The temporal evolution was characterized by a general increase of species richness, numerical abundance, biomass and diversity. There was a rapid change between 2002 and 2003, with an increase of abundance and biomass in the seaward zones of the lagoon. After such a change, these zones stabilized, while for the inner zones the recovery continued in 2007. The communities of the internal areas shifted from an organic-adapted community towards a more marine community. Spatial patterns and typical transitional gradients were evidenced each year. The role of main hydrogeological drivers is also briefly discussed. The study underlines the importance of considering physiographic zones in describing benthic dynamic.

Keywords: Lagoons, Monitoring, Biodiversity, Sediments

We demonstrate changes in the benthic macroinvertebrate community of the Venetian Lagoon between 2002-2007 Sixty stations distributed all over the lagoon were sampled in May-June of 2002, 2003 and 2007 ("MELa Project" Magistrato alle acque di Venezia / Consorzio Venezia Nuova). A zonal approach was adopted, by which changes in benthic communities structure are referred to the different physiographic zones composing the lagoon ecosystem (Rochford, 1951, Roy et al., 2001, Tagliapietra et al., in press). Five physiographic zones were identified: the Marine Tidal Deltas, close to the three sea inlets, the Central Basin and the Sheltered Lagoon, located on the middle ranges of the lagoon and two landward zones; the Fringe zone and the Bayhead Estuary. The temporal evolution was characterized by a general increase of species richness, numerical abundance, biomass and diversity. Both the total number of species and the average number of species per station increased, this trend being more pronounced in the Fringe zone and Bayhead Estuary. The highest species richness was found in 2007 (255 species). The first two years were characterized by a higher number of organic-tolerant species, whereas 2007 presented more sensitive ones. There was an increase of individuals from 2002 to 2003 in all zones, especially in the Sheltered Lagoon. Such an increase was also observed in 2007, but only for the Marine Tidal Delta and the Fringe Zone. Numerical abundances were dominated by polychates and amphipods, being typically higher in the inner zones because of the occurrence of opportunistic species. Also the biomass increased considerably from 2002 to 2003 in the Marine Tidal Delta and the Central basin. In 2007, the increase involved in the inner areas such as the Fringe Zone and the Bayhead Estuary. Minima were recorded in the Sheltered Lagoon. Biomass was dominated by bivalves. Exception to this trend was observed in the Central Basin with a reduction of both abundance and biomass in 2007 compared to 2002-2003. Temporal changes in dominant taxa were reflected in the trophic composition that shifted towards filter feeders. The diversity followed the species number and therefore decreased along the transitional gradient from sea to land. The biomass diversity showed a progressive increase mainly in the inner typologies, as the Fringe zone and the Bayhead Estuary. In every year, species richness correlated mainly to residence times and salinity, then to turbidity and sediment texture. Similarly diversity indexes correlated to species number although with lower coefficients. The environmental variables had a relatively low correlation with similarity matrices of both abundance and biomass. The role of turbidity and sediment organic matter in structuring the lagoon benthic assemblages was also important; as an example in the areas with high turbidity the community is less rich than that expected and characterized by organic-tolerant species. In the multivariate analysis performed on the abundance, the 2007 samples resulted quite different from those of 2002 and 2003 which largely overlapped. The community structure of the internal areas showed a progressive shift towards the Marine Tidal Delta structure. The shift towards a Marine Tidal Delta community structure was more evident for the Fringe Zone samples, especially for those of the Lido Basin. In this context the Bayhead Estuary stations kept their individuality. Biomass showed a temporal evolution similar to that of abundance. In conclusion, we found a rapid change between 2002 and 2003 with an increase of the vigour (abundance and biomass) in the seaward zones of the lagoon. The Marine Tidal Delta areas, after a rapid change, stabilized, while for the inner zones the recovery continued in 2007 with the exception of the Sheltered Lagoon. In 2007 the general overview pointed at an increase of diversity all over the lagoon. This increase was not followed by an increase of vigour in the Central

Basin where a sensible reduction of both abundances and biomass was recorded. Our study underlines the importance of considering physiographic zones in describing benthic dynamic.

Abstract

A recent ROV exploration of the deepest part of Montecristo Island (Tyrrhenian Sea) documents the occurrence of an extensive crinoid facies dominated by *Leptometra phalangium* (Müller J., 1841). This Atlantic-Mediterranean crinoid forms dense populations up to 10 individuals /m² all around the island in a depth range between ca. 110-130 m, preferentially settling on coarse detrital bottoms. *Keywords: Tyrrhenian Se, Echinodermata, Zoobenthos, Biodiversity, Bio-Indicators*

Introduction

The tiny island of Montecristo is located in the eastern Tyrrhenian Sea at 42° 19.9'N, 10°18.5'E. Montecristo is part of the Tuscan Archipelago National Park since 1971. A programme designed at the non-invasive exploration of the flanks of Montecristo island was launched in 2008 to check for the possible presence of deep water corals down to its deepest stretches. Two exploratory surveys were conducted in summer 2008 onboard the m/b *Angélique 1945*, using the Remote Operating Vehicle (ROV) *Prometeo Flat Platform 6+* and the *Global Vision* Video Camera (VC), operated by ROBOMAR sas & Co (Fig.1). The ROV exploration identified and documented for the first time the presence of an extensive crinoid *facies* all around the island starting from 108 m down to a maximum depth of about 132 m.

Fig. 1. Island of Montecristo. Map of the surveys

Results and discussion

The most successful transects were carried out at the sites of Punta Rossa, Punta Forata and Punta del Diavolo where the ROV imaged a seabottom characterized by the absolute dominance of crinoids. Spot checks conducted using VC at other locations around Montecristo further confirmed the ubiquity of such crinoid facies that results therefore the most relevant one inhabiting the coarse circalittoral detrital seabottom encircling Montecristo. At the time of our diurnal survey the quasi totality of crinoids were very active in feeding. Since no seabottom sampling was allowed beside corals (not encountered during our ROV investigations) the taxonomic recognition of the crinoid was performed using the video documentation (Fig. 2).

Fig. 2. The ROV during the operations and two snapshots of the "Crinoid garden" taken by the ROV's video equipment

The crinoid has been identified as *Leptometra phalangium* (Müller J., 1841). This is a common echinoderm distributed in the Eastern Atlantic Ocean and Mediterranean Sea ([1], [2], [3], [4]). In the Mediterranean *Leptometra* is well known to contribute to circalittoral communities, and is widespread in the Tyrrhenian Sea, including other sectors of the Tuscan Archipelago ([2]).

Acknowledgements : Thanks are due to the Park authorities for granting permission to work in the waters of Montecristo. SCUBA divers Michele Ghirelli and Antonio Sperottihelped with ROV buoyancy calibration.

RECENT DATA IN THE HARD BOTTOM COMMUNITIES FROM THE ROMANIAN BLACK SEA COAST

Adrian Teaca¹, Tatiana Begun¹, Marian traian Gomoiu¹ and Victor Surugiu^{2*} ¹ National Institute of Geology and GeoEcology – GeoEcoMar, Constanta Branch ² Universitatea Alexandru Ioan Cuza Iasi - vsurugiu@uaic.ro

Abstract

The authors present the qualitative and quantitative modifications of hard bottom associated fauna from the Romanian littoral, based on the analyses of 203 quantitative samples collected between 2001 - 2004. There were identified 152 taxa, with average density of 1,300,000 ind.m⁻² and the average biomass of 17,000 g.m⁻². Comparing with '60-'70 period, the actual quantitative structure is five to ten times higher, while from qualitative point of view, the situation is still almost the same. *Keywords: Biodiversity, Zoobenthos, Rocky Shores, Black Sea*

Introduction

The hard substratum from the Romanian littoral occupies a small area of about 70 km². Subsequently, the coastal works and protective dikes construction led to the increasing of areas with hard substratum and expansion of artificial epibiont system even more than that of natural one. The improper analysis of hard bottoms in the past have imposed a sporadic character of the studies, the latest known studies have been made in '60-'80 period [1, 2].

Material and methods

During the period 2001 - 2004, 203 quantitative samples of fauna from hard bottom have been collected from 10 stations distributed along the Romanian littoral, by means of SCUBA and free diving. In each station were taken quantitative samples from 3 depths (0, 1, 2 m). The vertical distribution of the benthic populations was analyzed based on samples collected from 9 depth intervals (0-16m) in Agigea area. The collecting method consisted in scraping of quadrate of 400 cm² surface (Fig.1).

Fig. 1. Map of the investigated area with locations of sampling sites (Southern part of the Romanian Black Sea coast)

Results and discussions

The analyses of the samples helped identify 152 taxa (147 species). The polychaets (49 species) and the amphipods (21 species) were dominant in the qualitative structure with a share of 50 % of all found species. Qualitative structure of the taxonomic group is composed as follows: Porifera – 4 species, Cnidaria – 13, Turbellaria – 6, Nemertina – 4, Polychaeta – 49, Mollusca – 13, Halacaridae – 2, Bryozoa – 5, Crustacea – 50, Tunicata – 1 and non identified taxa/group - 5.

In the superior infralittoral (1 to 4m deep), 136 species were recorded, in the mediolittoral 89 taxa and 85 taxa in the infralittoral (6 to 16 m deep).

Based on studies performed, it was concluded that the rock mussels' biocoenosis ranging between Cape Midia and Vama Veche, represents, in fact, a biocoenotic unity. Uniformity of structure and development are preserved in all analysed locations. The share of common species is about 85 % by abundance, due to 20 dominant species present in all locations.

According to depth the structure of rocky fauna varies significantly. The forming of associations in mediolittoral, having as dominant species the crustaceans *Hyale perieri*, *Echinogammarus olivii*, *Jaera nordmanni*, *Xestoleberis aurantia* and *Xestoleberis decipiens* is based on their affinity for the phytal substratum. The species grouping in the superior infralittoral based on coenotic affinities evinced the presence of an association numerically and as biomass dominated by *Melita palmata - Microdeutopus gryllotalpa - Amphitoe ramondi - Alitta succinea - Pilumnus hirtellus*. The dominant association in infralittoral is constituted within a nucleus of 4 species after density: *Melita palmata – Microdeutopus gryllotalpa - Jassa ocia - Stenothoe monculoides* and 10 species after biomass: *Gonothyraea loveni*, *Alitta succinea*, *Platynereis dumerilii*, *Cryptosula pallasiana*, *Balanus improvisus*, *Melita palmata*, *Microdeutopus gryllotalpa*, *Jassa ocia*, *Athanas nitescens*, *Pisidia longicornis* (Bray-Curtis similarity) [3].

The trend of increase in the number of taxa with depth show biggest jump in the range 0 - 8 m of about 40 species from 0 m to 80 species at 8 m.

The average density was about $1,300 \times 10^3$ ind.m⁻² and the average biomass was about 17×10^3 g.m⁻². The numerical dominants are represented by worms (580,000 ind.m⁻²) and crustaceans (650,000 ind.m⁻²) and as weight by molluscs (19,500 g.m⁻²), crustaceans (215 g.m⁻²) and worms (35 g.m⁻²). Meiobental segment represents 87 % of the total average density while the biomass of macrobental forms over 99 %.

Relationship between numerical abundance and maximum weight of benthic fauna on natural hard bottoms and artificial hard bottom is 1:3 for density and 1:3.6 for average biomass.

Number of crustaceans species reported amounts to 50 (except the copepods) value that is superior to those cited in 1975 - 1995 period [2]. The current qualitative structure could be compared with that described for the Agigea rocky associations in 1961 [1].

The abundances are at least 5 to 10 times higher compared to those of '60s -'70s. The average density of 280×10^3 ind.m⁻² from Agigea in `70 years have been much lower than in 2003 - 2004 period which was $1,300 \times 10^3$ ind.m⁻². Comparative analysis shows a profound destabilization of the population equilibrium, characterized by domination of worms by late of `80s (72 %) at the expense of other groups (Crustacea 17 %). The current state of benthos associated with hard substrate falls within the normal evolution (e.g. 38 % worms, Crustacea 54 %) compared with that of '60 period [1].

Taxa whose actual number reported in very low or none in previous years and which now form well contoured populations at Romanian seaside are *Opercularella lacerata* (F-25 %), *Ventromma halecioides* (F-30 %), *Tergipes tergipes* (F-50 %), *Ericthonius difformis* (F-40 %), *Jassa ocia* (F-50 %), *Siriella jaltensis* (F-20 %), *Athanas nitescens* (F-60 %), *Eriphia vertucosa, Palaemon adspersus* (F-20 %), *Pisidia longicornis* (F-70 %). Rare species with single occurrence cited as missing in recent years are *Limapontia capitata*, *Cymadusa crassicornis*, *Brachynotus sexdentatus*.

QUALITATIVE AND QUANTITATIVE ASSESMENT OF THE MACROBENTHIC POPULATIONS OF **CRUSTACEANS FROM THE NORTH - WESTERN PART OF THE BLACK SEA**

Adrian Teaca¹, Tatiana Begun¹, Marian traian Gomoiu¹ and Victor Surugiu²* ¹ National Institute of Geology and GeoEcology – GeoEcoMar, Constanta Branch ² Universitatea Alexandru Ioan Cuza Iasi - vsurugiu@uaic.ro

Abstract

The paper presents the crustaceans' populations state in period 2003 - 2008. The total number of species was 66, approximately 60 % of the total number of species recorded in the NW Black Sea during the period 1960 - 1970. The most abundant crustacean was the opportunistic species Ampelisca sarsi.

Keywords: Crustacea, Zoobenthos, Black Sea

Introduction. Marine diversity is often a scope of environmental research especially within the framework of global environmental changes. The pontic crustaceans' fauna, although in small number of species, represent a complex group with a definitory importance in the benthic biocoenosis, from the limit of breaking waves zone to periazoic level. The state of any benthic community in the NW Black Sea region represents the "mirror" of ecological changes along the time, reflected in the "inventory" of the biota quality and quantity, published in the last 10 years in several papers [1, 2]. Nevertheless, researches referring to the crustaceans' population especially from the Romanian Continental shelf are very scarce.

Materials and Methods. In the period 2003 - 2008, a number of 437 quantitative benthos samples were collected between 0 - 213 m depths by means of the van Veen-type grab, box corer and multicorer. The offshore samples were collected during several cruises (R/V "Akademik" 2003, 2006, R/V "Parshin" 2005, R/V "Poseidon" 2008, R/V "Mare Nigrum" 2006, 2007 and 2008), while the inshore samples during several national projects covering only the sedimentary substrata. The sampling was done with 0.1 $\rm m^{-2}$ van Veen grab, or by 0.25m^{-2} box corer and 0.15 m^{-2} multicorer.

Results and Discussion. The analyses of the samples helped identify 66 species (Cirripedia - 1, Amphipoda - 35, Cumacea - 8, Mysida - 3, Tanaidacea - 2, Isopoda - 6 and Decapoda - 11), approximately 60 % of the total number of species recorded in the NW Black Sea and 65 % in the Romanian littoral zone during the period of "ecological prosperity" (Fig. 1). The mean abundance of the crustaceans' populations was 1,156.9 indv.m⁻² for density and 5.78 g.m⁻² for biomass. There are some differences in the spatial distribution of crustaceans in the NW Black Sea. The average density and biomass decrease as far as water depth decrease according to a logarithmic relation (Density - $R^2 = 0.84$; Biomass - $R^2 = 0.93$), from 1,806.5 ind.m⁻² at 0-20 m depth, to 13.3 ind.m⁻² at 111-130 m for density and 9.27 g.m⁻² at 0.03 g.m⁻² for biomass (Fig. 2)

Fig. 1. The number of species of macrobenthic crustaceans' distribution in the NW Black Sea region

Fig. 2. The numerical abundance of macrobenthic crustaceans' distribution in the NW Black Sea region

The deep zone typical populations of crustaceans are stationated at 50 - 81 m deep. As the depth increases, the effectivenesses and the number of species decreases progressively. The dominant species in offshore zone are: Ampelisca sarsi (F-50 %), Perioculodes longimanus (F-46 %), Phtisica marina (F-44 %), Apseudes acutifrons (F-32 %), Balanus improvisus (F-32 %), Apherusa bispinosa (F-30 %), Iphinoe elisae (F-30 %), Microdeutopus versiculatus (F-29 %), Caprella acanthifera (F-27 %), Corophium runcicorne (F-25 %) and Eudorella truncatula (F-25 %). The populations from bathimetric interval 0 -20 m are more heterogen realising the passage from littoral associations of sandy substratum to the muddy ones. The average density value recorded in the littoral zone exceeds 1,860 ind.m⁻², being four times higher than in the deep zone associations (455 ind.m⁻²). These great values are explainable by the intercalation of two great biocoenotic associatons: faunistic association on the hard substratum and those from sedimentary substratum (implicit the spreading of hard substratum species in the structure of sedimentary associations) and also by the structure of littoral populations dominated in majority by the A. sarsi (F-55 %, 1,300 ind.m⁻²), B. improvisus (F - 35 %) and Iphinoe maeotica (F-25 %). Zernov's Phyllophora Field became one of the most outstanding examples concerning the ecosystem degradation and biodiversity losses. The knowledge of the Phyllopora association state represents the key to the ecosystem recovery valuation. Without considering the modifications suffered, the maximum diversity of crustaceans (32 species) remains within the initial areal with Phyllophora due to habitats' variability (macrophytes, mussels clumps) (Fig. 1). Concluding, the observations made show a major restructuring of the existent populations through the great number of constant species, which dominate the benthic biocoenosis.

BIODIVERSITY PATTERNS OF DEEP-SEA BENTHIC MEGAFAUNA ON WESTERN AND CENTRAL MEDITERRANEAN BASINS

Samuele Tecchio¹*, Eva Ramírez-llodra¹, Francisco Sardà¹ and Joan baptista Company¹ ¹ Institut de Ciències del Mar (CSIC) - tecchio@icm.csic.es

Abstract

Abundance, biomass and diversity patterns of bathyal and abyssal Mediterranean megafauna were analysed. Sampling was conducted with a bottom otter-trawl at depths ranging from 600 to 4000 m in the western Balearic Sea, the western Ionian Sea, and the eastern Ionian Sea. A general decline in diversity with depth along the three zones was found, while influence of geographic area was less marked.

Keywords: Biodiversity, Deep Sea Ecology, Western Mediterranean, Ionian Sea

The Mediterranean deep-sea environment is an optimal natural laboratory to study ecological processes. Commercial trawling reaches depths of 900 m maximum, allowing for studies of non-impacted environments below this depth. Knowledge of benthic megafaunal diversity and its patterns of variation between basins is at present very scarce.

Fig. 1. Map of Mediterranean Sea, with sampled areas indicated

Megafaunal samples were collected in 26 OTMS trawls between 600 and 4000 m during a trans-Mediterranean cruise (June 2001, Fig. 1). The western Balearic basin, the western Ionian sea and the eastern Ionian sea were investigated. The megafauna was identified to species level, counted and wet weighted $(\pm 1 \text{ g})$. A faunal list was compiled, indicating occurrence of each species in each zone. Species richness, Shannon-Wiener H', Margalef's diversity and Pielou's evenness indexes were calculated for each sample. Similarity of community structure amongst samples from all geographic areas and depths was visualised with a non-metric multidimensional scaling (MDS). Two-way similarity percentages (SIMPER) statistical routine was conducted, using "depth" and "basin" as crossed factors and Bray-Curtis measure as similarity [2].

The most speciose groups were Actinopterygii (45% of species), crustaceans (32.4% of species) and Chondrichthyes (7.8% of species). Across the whole dataset, Margalef species richness index shows a significant decrease with depth and negative linear correlations between species richness and depth were found for each of the three zones considered separately. Pielou's index increased with depth in the western Balearic basin, with an abrupt decrease at 1230 m caused by the abundance peak of the fish *Alepocephalus rostratus* in the western Balearic. A similar pattern was present in the western Ionian, with a decrease of the index at 1500 and 1700 m caused by the spiderfish *Bathypterois dubius*. The biology of this species is more adapted to the scarce trophic resources, although the exact reasons for this dominance of *B. dubius* are, at present, not described. Species evenness at the two abyssal depths was low compared to the rest of the western Ionian basin. In the eastern Ionian Sea, the evenness index showed an inverted V-shape pattern. Shannon-Wiener index, along with standardized biomass, are shown in Fig. 2.

According to SIMPER analysis, dissimilarity in community composition between the western Balearic basin, the western Ionian and the eastern Ionian, across all depth ranges, is mainly caused by the fishes *A. rostratus* and *C. mediterraneus*, the shark *C. coelolepis* and the decapods *A. antennatus*, *P. typhlops*, and *G. longipes*. The MDS showed a clear depth zonation. The trawls at 600-800 m grouped together, confirming the *middle slope* subdivision [3]. The depth range 1000-1700 m showed the higher dispersion between trawls, as previously reported for fishes and crustacean assemblages in the Mediterranean. The deepest assemblages at 1700-3000 m, along with the two trawls conducted at 3300 m and 4000 m in the central Ionian abyssal plain, grouped together,

suggesting that below 1500 m there are no major changes in assemblages structure with depth. The three zones exhibited a comparable species richness down to 1500 m depth, but after this limit only the western Balearic basin maintained a Margalef index of above 2.0, while in the Ionian basins (both western and eastern) values decreased rapidly. We suggest that higher surface productivity and coastal input of the western Balearic basin supply the necessary energy to sustain a diverse community at lower depths in this zone. In the more oligotrophic Ionian Sea, organic matter arrival to the lower slope and deep basin is reduced, forcing a decrease in diversity earlier in the depth range.

OSMOTIC STRESS EFFECTS ON THE BIOCHEMICAL COMPOSITION OF THE DIGESTIVE GLAND OF THE SCALLOP FLEXOPECTEN GLABER

K. Telahigue ¹*, I. Rabeh ¹, I. Chetoui ¹, N. Ghazali ¹, D. Boussoufa ¹, M. S. Romdhane ² and M. El Cafsi ¹ ¹ Faculté des sciences de Tunis - k_telahigue@yahoo.fr

Abstract

This study refers to the biochemical composition of the digestive gland of *Flexopecten glaber*. Results show that the hyposmotic and the hyper-osmotic stress induce a decrease in the total content of glycogen and lipids. The osmotic stress induces an increase of the polyunsaturated fatty acids and the (n-3) group; mainly the C18:3n-3 and C18:4n-3. Conversely the EPA (C20:5n-3) decreases as a response to any variation of salinity around the optimal salinity rate (35 psu). Keywords: Bivalves, Physiology, Aquaculture

Introduction

The digestive gland plays an important role in the physiology of the mollusk bivalves. This organ is mainly involved in the storage of lipids and glycogen ([1], [2], [3]). In this study we investigated the effects of salinity variation on the biochemical composition (glycogen, lipids and fatty acids) of the digestive gland of the scallop F.glaber.

Material and Methods

Individuals of F.glaber were acclimated for 3 weeks under constant temperature (15°C) and different salinity rates (25, 30, 35 and 40 psu). Scallops were fed a monoalgal diet based on Isochrysis galbana. The total glycogen was analyzed according to the enzymatic method [4]. Total lipids were extracted according to Folch et al. method [5]. Fatty acid methyl esters were obtained according to [6] and analyzed on a HP 6890 gas chromatograph. Statistical analyses were carried out using the software-program Statistica 6.0. Data were analyzed for significant differences of means, ANOVA, and inspected by Duncan test at the level of 5%.

Results and Discussion

Results showed that total glycogen and lipids contents of the digestive gland decrease significantly mainly at 25 psu (2.66 mg/g and 60 mg/g respectively) and 40 psu (2.22 mg/g and 64mg/g respectively) in comparison with the optimal salinity of 35 psu (3.95 mg/g and 81mg/g respectively). Concerning fatty acids, we noted that the elevation (40 psu) and diminution (25 psu and 30 psu) of salinity induce an increase of the åPUFA (Polyunsaturated fatty acids) as well as the åMUFA (Monounsaturated fatty acids) and a decrease of the åSFA (Saturated fatty acids) compared to the control salinity (35 psu). We also noted an elevation of the a(n-3) and a(n-6) under hyposmotic and hyperosmotic stress. We recorded that the osmotic stress induces an increase of the C18:3n-3 (from 0.7% at 35 psu to 6.25% at 30 psu and 4.66% at 25 psu) and the C18:4n-3 (from 2.24% at 35psu to 12.59% at 40 psu and 10.45% at 30 psu). Conversely we noted a significant diminution of the EPA (C20:5n-3) from 7.08% at 35psu to 3.42% at 40 psu and 3.48% at 25 psu. Recorded results are linked with the role played by the PUFA (mainly n-3) in the regulation of permeability and fluidity of the membrane; specially the EPA which may serve as a substrate for prostaglandin biosynthesis as a stress response [7].

COMPARATIVE FATTY ACIDS PROFILES OF *FLEXOPECTEN GLABER* DIGESTIVE GLAND UNDER STARVATION AND MONOALGAL DIET CONDITIONS

K. Telahigue ¹*, I. Chetoui ¹, I. Rabeh ¹, M. S. Romdhane ² and M. El Cafsi ¹

¹ Faculté des sciences de Tunis - k_telahigue@yahoo.fr

Abstract

The starvation effects on the fatty acids composition of the digestive gland of the scallop *Flexopecten glaber* were underwent in this study. Results show that food deprivation induces a diminution of the amounts of the EPA (C20:5*n*-3) and the DHA (C22:6*n*-3) as well as the n-3/n-6 ratio. Meanwhile, a selective retention, in terms of increase of percentage, of the AA (C20:4*n*-6) in unfed specimens is recorded.

Keywords: Aquaculture, Bivalves, Physiology

Introduction

In scallops, the digestive gland is the most important organ involved in lipids reserve storage [1, 2]. The fatty acids composition of the digestive gland essentially depend on the food availability [3]. In this study we compared the fatty acids profile of the digestive gland of *Flexopecten glaber* under two nutritional conditions to asses the effects of the food deprivation on fatty acids composition of this organ.

Materiel and Methods

Tow groups of 6 individuals of *F. glaber* were acclimated for 3 weeks at constant temperature $(15^{\circ}C)$ and salinity (35 psu). The first lot was fed a monoalgal diet based on *Isochrysis galbana*; whereas the second group was starving. Total lipids were extracted according to the Folch method [4]. Fatty acid methyl esters were obtained according to [5] and analyzed by a HP 6890 gas chromatograph. Statistical analyses were carried out using the software-program Statistica 6.0. Data were analyzed for significant differences of means and inspected by Duncan test at the level of 5%.

Results and discussion

Results, reported on the table 1, show that under food deprivation the Saturated Fatty Acids decrease in general; the most pertinent diminutions concern, however, the Myristic acid (C14:0), the Palmitic acid (C16:0) and the Stearic acid (C18:0). Also, under the same starvation condition, a significant decrease of the n-3 polyunsaturated fatty acids is recorded (from 23.45% in the fed lot to 7.52% in the unfed lot). Oppositely, an elevation of the n-6 polyunsaturated fatty acids is observed (from 4% to 19.42% respectively). Consequently, the deprivation effect is the decrease of the n-3/n-6 ratio. Within the Polyunsaturated Fatty Acids decrease trend, the most important starvation effects are observed for EPA (C20:5n-3) and DHA (C22:6n-3) amounts. Contradictory, the amount of AA (C20:4n-6) is maintained at significantly higher level. This phenomenon of selective retention of the ALA, which is involved in the prostaglandin synthesis [6], would correspond to a survival strategy and a mean to stand starvation stress adopted by the mollusk. Similar results were recorded in neutral lipids of starved mussels [7].

MAY THE IDEA OF PARTITIONING THE PELAGOS SANCTUARY IN AREAS OF SPECIFIC INTERESTS SOLVE THE PROBLEM OF HOW TO PROTECT 100,000KM2? THE SPERM WHALE CASE

Paola Tepsich ¹*, Massimiliano Rosso ¹, Maurizio Wurtz ² and Aurelie Moulins ¹

¹ CIMA Research Foundation - paola.tepsich@cimafoundation.org

² Dipartimento di biologia - Università di Genova

Abstract

The 2009 acoustic "scan" realized inside the Pelagos Sanctuary aimed to get information on the sperm whale distribution. Results indicate some aggregations and specifically close to hotspots determined by a previous study. This information can be used to concentrate mitigation effort needed for Pelagos Sanctuary's efficiency.

Keywords: Deep Waters, Cetacea, Ligurian Sea

Introduction

The establishment of the Pelagos Sanctuary is the first step that aims to focalize on the necessity to protect the cetacean and their ecosystem. However, its efficiency depends totally on the proposed mitigation instruments and on our knowledge of the different cetacean populations inhabiting the area. Indeed, the northwestern area being extensively used by maritime transport, fisheries, militaries as well as the coast, conflicts of interests slow down the processes of protection. At the same time, 8 species of cetaceans are considered as commonly seen in the Pelagos Sanctuary and the area is used differently by each one of them [1]. A possible alternative is to partition the Pelagos area in particular specific areas where one specific risk has to be solved for a specific species. Based on the 2009 "scan" realized for the ISHMAEL project inside the Pelagos Sanctuary, the study discusses the obtained sperm whale distribution according to hotspots previously characterized.

Material and methods

In 2009, a large "scan" of the Pelagos Sanctuary was realized by two vessels: *Menkab*, the research boat of the *Biology Department* of the *University of Genoa* and *Halifax*, the sailing boat of the NGO *Participe Futur*. The "scan" focuses on the area encompassed by the 500m and 2500m isobaths organized in 597 acoustic stations. On each station, we use an omni-directional hydrophones (with a range of about 3 NM from the station) to detect sperm whales. In some cases after the positive detection on *Menkab*, it has been decide to localize the animal with a prototype 3-D hydrophone in order to test the capacity to find the animal and continue eventually with photo-id protocol. Visual detection was also performed between the acoustic stations with 4 trained observers watching the 360° around the boat.

Fig. 1. Distribution of the initial 597 acoustic stations (small dots), 294 have been checked (white dots), 42 resulted positive to sperm whale presence (black dots). Isobaths of 1000m and 2000m are represented

Results and discussion

During 2009, about 294 acoustic stations where performed: 52 by *Halifax* in 18 days and 242 by *Menkab* in 23 days; however, only 189 were performed on the

597 initial positions. In total, 42 were positive with sperm whales; 14 amongst postive stations are considered to detect different individuals (12 stations in the northern part of the sanctuary and 2 off Corsica; fig. 1). The probability to hear sperm whale is 0.06. The estimated number of animals encountered is 17 whales while 8 have been sighted. According to the 4 hotspot obtained by [2], 4 of the 12 stations of the northern part of the Pelagos Sanctuary are inside or close three of the hotspots. This result seems to confirm that specific areas are inhabited repeatedly by the species and thus this information can be used to design areas with major attention.

Abstract

Species composition, abundance and biomass distribution of mesozooplankton species with depth were studied in the Levantine basin (eastern Mediterranean) within the framework of SESAME (Southern European Seas: Assessing and Modelling Ecosystem changes). Copepods were found to be the dominant group at all depth layers sampled during both sampling periods. Mesozooplankton biomass and abundance varied between 2.2-18.1 mgm⁻³, 72.28-757.55 ind.m⁻³ in April 2008 and 0.98-4.67 mgm⁻³ and 99.54-492.52 ind.m⁻³ in October 2008, respectively. Mesozooplankton biomass and abundance tend to decrease with depth. *Keywords: Levantine Basin, Biomass, Zooplankton , Eastern Mediterranean*

Introduction

Mediterranean and particularly the eastern Mediterranean is considered to be one of the extreme oligotrophic regions in the world, in terms of both primary productivity and chlorophyll *a* concentrations (1). Zooplankton form an important link in the pelagic food web due to the transfer of energy from unicellular algae to higher trophic levels (2). Studying zooplankton communities are especially crucial for not only detecting ecological changes and understanding the functioning of pelagic ecosystems, but also in terms of fisheries. The aim of this study was to determine the vertical distribution of mesozooplankton biomass & abundance and species composition in the oligotrophic Levantine basin.

Material and methods

Mesozooplankton samples were collected from standard layers (0–50, 50–100, 100–200 m), with the aid of a WP2 closing net of 200 μm mesh size during daytime (06:00-18:00) from the Levantine basin (Fig.1) in April and October 2008. All samples were split into two halves for the estimation of biomass (dry weight) in one and

for species identification in the other.

Fig. 1. Location of the sampling stations in the Levantine Basin

Results and Discussion

A total of 145 taxa were identified from the basin. Copepods were found as the dominant group at all layers during both sampling periods. In April 2008, copepods and siphonophorans were generally more abundant in the layer 0-50m (except E30N00), whereas, doliloida and appendicularians in layers 0-50 and 50-100 m, ostracoda in layers 50-100 and 100-200 m were found more abundant. In April, Calocalanus styliremis, Clausocalanus jobei, C. parapergens, C. paululus, Lucicutia flavicornis, Mecynocera clausi, Paracalanus dunudatus, P. nanus, Farranula rostrata, Oithona plumifera, O. setigera, Oncea media groups, Oncea mediterranea dominated the top 50 m whereas C. contractus, Ctenocalanus vanus, Haloptilus longicornis, L. flavicornis, M. clausi, P. denudatus, P. nanus, F. rostrata, O setigera, Oncea media groups became dominant in the layer 50-100 m. Finally copepod species namely H. longicornis, O. setigera, Mormonilla minor and O. mediterranea dominated the layer 100-200 m . In October 2008, copepods, chaetognaths, siphonophorans and cladocerans were more abundant in the layer 0-50 m, while Ostracoda was found higher in the 50-100 m depth range.

Appendicularians were more abundant in the layers 0-50 and 50-100 m. In general, *Clausocalanus furcatus, C. paululus, C.pavoninus,O. plumifera* in the layer 0-50 m., *C.contractus, C styliremis ,C. pavo, C. jobei, O. setigera, F. rostrata* in the layer 50-100 m and *C. paululus, H. longicornis, M. clausi, P. denudatus, O. setigera, M. minor* in the layer 100-200 m were found abundant copepod species. Changes in mesozooplankton biomass and abundance at stations during April & October 2008 are shown in fig2. In April 2008, mesozooplankton biomass and abundance varied from 2.20 mg m⁻³ (F50N00, 100-200 m) to 18.10 mg m⁻³ (E30N00, 50-100 m) and from 72.28 ind (G10N00, 100-200m) to 757.55 ind m⁻³ (E30N00, 50-100 m), respectively. Mesozooplankton biomass and abundance in October 2008 found to vary from 0.98 mg m⁻³, 99.54 ind m⁻³ (E30N00, 100-200 m) to 4.67 mg m⁻³, 492.52 ind m⁻³ (E10N00, 0-50 m), respectively. Mesozooplankton was more abundant in April than in October and both biomass and abundance values tend

to decrease with depth.

Fig. 2. Changes in mesozooplankton biomass and abundance in all sampling stations

A PRELIMINARY STUDY ON THE MACROZOOBENTHIC INVERTEBRATE FAUNA OF TWO BANKS IN THE NORTH AEGEAN SEA

Bülent Topaloglu¹*, Bayram Ozturk¹, Eda n. Topçu¹ and Onur Gönülal¹

¹ Istanbul University, Fisheries Faculty & Turkish Marine Research Foundation - topalbl@istanbul.edu.tr

Abstract

In this study, two high sea banks on the North Aegean Sea were sampled. The Johnston Bank has 41 m. depths with coralligenous habitat and The Sinaya Bank has 130 m. depths with mud-sandy habitat. Totally 2288 individuals belonging to 51 taxa in Johnston Bank and 490 individuals belonging to 17 taxa in Sinaya Bank were sampled. We assume that The Johnston Bank is an important spawning ground for many benthic species and needs protection. *Keywords: Aegean Sea, Zoobenthos, Eastern Mediterranean*

Introduction

Benthic studies in the North Aegean Sea are mostly on communities and species check-list [1], [2], [3]. The Aegean Sea has several banks what makes it very important for benthic biodiversity. However, the studies on these banks are limited. The characteristics of the benthos of Bruker, Mansell and Stocks banks were comparatively studied [4] and the most complicated trophic structure was found at the Stocks bank whereas the simplest one was near the Lesbos Island. A recent study was conductedon the habitat structure and biological characteristics of a maerl bed off the northeastern coast of the Maltese Islands [5]. Two stations were monitored to study temporal variation in species diversity. The maerl bed proved to have high species diversity with 244 animal and 87 algal taxa recorded; *Bittium latrelli* was the dominant taxa.

Material and Methods

Two high sea banks were studied at the North Aegean Sea. The Sta.1 is known as Johnston Bank at 41 m depth surrounded by depths of 200-500 m. The Sta.2 is known as Sinaya Bank at 130 m surrounded by depths of 200-300 m (See Map.1). The samples were taken by dredge with 2 knot speed during 10 minutes at the end of November 2008. The water temperature, salinity and dissolved oxygen were measured by SeaCat 19plus CTD profiler. The samples were counted, identified and fixed.

Fig. 1. Map of the sampling stations (revised from http://odv.awi.de)

Results and Discussion

Totally 51 taxa were sampled at the Sta. 1 and 17 taxa at Sta.2. At the Sta.1, *Gammarus locusta* was the most dominant species with 26,75 % followed by *Bittium latrelli* with 24,56 %. At the Sta.2, *Parapenaeus longirostris* was the most dominant species with 69,39 % (See Table 1.). Water temperature was measured as 16,55 °C at the Sta.1 and 16,27 °C at the Sta. 2. The salinity was 39,2 ‰ and dissolved oxygen was 6,5 mg/l at the both stations. According to the results, the oceanographic conditions were almost similar at Sta.1 and Sta.2 but the main differences are depth and habitat structure. The main habitat of Sta.1 is coralligenous with 41 m. whereas it is sand-mud in Sta.2 with 130 m. The dominant species at the Sta.2 (*P. longirostris*) is consistent with [3], and that of Sta.1 (*B. latrelli*) is coherent with [5]. Beside this, the number of collected individuals is 2288 belonging to 51 taxa at the Sta.1 were observed in juvenile stage. Coralligenous habitats are important in terms of marine

biodiversity and an action plan for these habitats in the Mediterranean Sea was prepared by RAC/SPA [6]. These high sea banks should be protected from the bottom trawling and similar harmful fishing activities. We assume that Johnston Bank could be set as a marine protected area as it is an important spawning ground in the Northern Aegean Sea and a coralligenous habitat. More detailed studies are needed in the high sea part of the Aegean Sea.

EXPLOITATION PATTERN OF THE MEDITERRANEAN FISHERIES

Athanassios c. Tsikliras ¹*, Anny Dinouli ¹ and Konstantinos i. Stergiou ²

² Laboratory of Ichthyology, Department of Zoology, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract

The annual landings of the Mediterranean fisheries were analysed for the period 1970-2005 and classified into exploitation categories based on the shape of the catch curve and the year of overall maximum catch. In 2005, about 22% of the Mediterranean fisheries are characterised as crashed, 39% as overfished, 23% as fully exploited, whereas developing fisheries were confined to less than 16%. These results, although encouraging compared to available global estimates, sound the alarm of fisheries sustainability, and ask immediate conservation and management measures.

Keywords: Fisheries, Conservation

Introduction

Despite the long history of fisheries exploitation of the Mediterranean Sea, data concerning stock assessment are lacking or sporadic, thus inducing a strong impediment for the management of this large marine ecosystem as a whole. Existing stock assessment attempts concern a low number of species, when compared to the multispecies assemblages exploited (i.e. more than 150 commercial species). In contrast, the long time-series of landings available, offer a useful and cheap, yet in some cases unreliable, background information for evaluating the status of fisheries, as well as their ecological footprint [1]. The aim of the present work was to assess the exploitation status of the Mediterranean fisheries stocks for the period 1970-2005 using the methodology of [2], and compare them with the corresponding global trends and/or similar work performed elsewhere.

Materials and methods

The annual landings, expressed as live weight equivalent of catches, have been recorded since 1970 for the Mediterranean and the Black Sea (FAO area 37) by the General Fisheries Commission for the Mediterranean (GFCM) [3]. The GFCM catch data refer to the legal and reported large- and small-scale fisheries, excluding discarded catch, illegal, unreported, recreational and sport fishing. Catch statistics were extracted from the GFCM dataset for all available records or stocks (=species-area combinations). The annual status of fisheries (1970-2005) was classified into one of the following four categories: developing, fully exploited, overexploited, and crashed [2]. The classification is based on the relationship between the catches of a given year compared to the year of overallmaximum catch. Thus, in a developing fishery, the year of catch is before vear of maximum catch, and catch is less than 50% of the overall maximum catch; in a fully exploited fishery the catch is greater than 50% of maximum catch; in an overexploited fishery, the year of catch is after year of maximum catch, and catch is between 10% and 50% of the overall maximum catch; and in a crashed fishery, the year of catch is after the year of maximum catch, and catch is below 10% of the overall maximum catch.

Results and Discussion

Based on the overallmaximum landings, which varied among stocks, in 2005 (the most recent year available), 336 out of the 1480 stocks analysed can be classified as crashed (22.7%), 583 as overfished (39.4%), 335 as fully exploited (22.6%) and 226 as developing (15.3%). In the 1970s, the majority of the stocks were largely underexploited and most fisheries (around 80%) were developing (Fig. 1). Only a few stocks were overexploited and even fewer can be characterised as crashed. Over the last 20 years, however, an increasing percentage (averaging 19.6% for 1996-2005) of stocks suffers from overexploitation. The cumulative percentage of overfished and crashed stocks increased dramatically from 10% in 1977, to 20% in 1987, 30% in 1990, 40% in 1995, 50% in 2000 and 60% in 2005. Interestingly enough, the percentage of fully exploited stocks has remained rather unchanged since 1970 (averaging 23.6±2.52% for 1970-2005). The degree of exploitation of the Mediterranean fisheries is disappointing compared to previous estimates for the area (74% of the Mediterranean stocks are either fully exploited or overexploited: [4]) but encouraging compared to the current global pattern (the developing fisheries are less and the overexploited/crashed ones are more: [5]), the NE Atlantic and the North Sea (in 1999, 50% of fisheries were overfished or collapsed: [2]).

Fig. 1. Trend in the status of Mediterranean marine fisheries resources (1970-2005) based on FAO statistics (status definitions adopted by [2])

Since traditional management schemes seem to have failed to prevent exhaustion of the marine resources, future management should be directed towards reducing fishing effort and excluding large areas from fisheries exploitation.

TRENDS IN TROPHIC LEVEL OF FARMED FISH IN MEDITERRANEAN COUNTRIES

Athanassios Tsikliras ¹*, Eleni Tsalkou ¹, Daniel Pauly ² and Konstantinos I. Stergiou ³ ¹ Department of Ichthyology and Aquatic Environment, University of Thessaly - tsikliras@uth.gr ² Sea Around Us project, Fisheries Centre, University of British Columbia, Vancouver, B.C., Canada, V67 1Z4 ³ Laboratory of Ichthyology, Department of Zoology, School of Biology, Aristotle University of Thessaloniki, UP Box 134, Thessaloniki, Greece

Abstract

The mean trophic level (τ) of the Mediterranean farmed fishes (i.e. excluding crustaceans, cephalopods and bivalves) was estimated on a country basis for the period 1950-2004. Overall, τ increased from a mean value (±SD) of 2.68 (±0.044) for 1950-1959 to 3.21 (±0.031) for 2000-2004, thus confirming that the Mediterranean food webs, overall, are being farmed up. However, the pattern was not uniform across countries; France, Italy Turkey and Israel are farming progressively higher trophic level fishes, while the mean trophic level of farmed fish is declining in Greece, Egypt and Croatia. The overall trend toward farming farming up should be reversed, because it implies non-sustainable pressures on Mediterranean ecosystems. *Keywords: Aquaculture, Fisheries, Fishes, Food Webs*

Introduction The trophic level (τ) of fisheries landings and mariculture production has been used to evaluate both their status and that of their supporting ecosystems, notably by testing whether marine food webs are fished down [1] or farmed up [2]. The selective removal of large, high trophic level organisms by fishing lowers their relative contribution to the landings, which are progressively dominated by small fishes, while their mean trophic level declines. The opposite occurs when the contribution of large, high trophic level organisms produced by mariculture operations increases, and hence the mean trophic level of their aggregate output increases. Both processes are indicators of absent sustainability and ecosystem health; the latter poses additional economic and ethical concerns [2]. The aim of the present work was to assess the extent of farming high-trophic level fishes across the Mediterranean and identify which countries and species contribute to the overall farming up trend of the Mediterranean aquaculture, recently demonstrated to occur based on aggregated data [2].

Materials and methods The marine and brackish water aquaculture production of fishes (i.e., excluding crustaceans, cephalopods and bivalves) of the Mediterranean and the Black Seas was extracted from the GFCM (General Fisheries Commission for the Mediterranean) dataset for the period 1950-2004 [3]. The mean weighted τ [4] for each year was calculated for the Mediterranean part of each of the countries with such production, based on specific estimates of τ taken from the literature, or from FishBase (www.fishbase.org).

Results and Discussion Overall, τ increased from an average value (±SD) of 2.68 (± 0.044) for 1950-1959 to 3.21 (± 0.031) for 2000-2004, thus confirming that the Mediterranean food webs are being farmed up and that farming up is the result of culturing high trophic level fishes. This confirms the trend established by an earlier analysis of the farming-up effect in the Mediterranean [2]. However, the absolute values of τ are not straightforwardly compared, as their pertained to a shorter time period (1970-2004), and were based on more aggregated data. The main fish culturing Mediterranean countries for 2004 were Greece (65000 t), Turkey (47000 t), Egypt (43000 t), Italy (14000 t), France (5000 t), Croatia (4000 t) and Israel (3000 t), From these countries, Turkey (mean $\tau \pm SD=3.46\pm0.001$), France (mean $\tau \pm SD=3.50\pm0.015$), Italy (mean $\tau \pm SD = 3.36 \pm 0.116$) and Israel (mean $\tau \pm SD = 3.45 \pm 0.005$) are progressively culturing higher trophic level fishes, whereas Greece (mean $\tau\pm$ SD=3.44±0.001), Egypt (mean $\tau\pm$ SD=2.40±0.204) and Croatia (mean $\tau \pm SD=3.48\pm0.007$) are not (Figure 1, mean τ refers to 2000-2004). The rate of τ increase is higher in Italy (0.15 per decade) and Turkey (0.05 per decade) compared to France (0.015 per decade) and Israel (0.02 per decade) and is mainly attributed to the increasing percentage of cultured seabass (Dicentrarchus labrax) and seabream (Sparus aurata). The declining percentage of low trophic fishes in the Mediterranean aquaculture may enhance this trend in the future. It should be noted that the effect of bluefin tuna (Thunnus thynnus) fattening [5] was not yet identifiable in the 2004 dataset. As noted earlier [2], the farming of seabass and seabream, and the fattening of bluefin consume far more fish (sardine, anchovies, etc.) for feed than these operations produce, which thus contribute to reducing the net supply of fish available for human consumption. Along with the many environmental problem caused by the farming of carnivorous fish, this argues for a need to return to more sustainable forms of mariculture, notably bivalve aquaculture, which has a long tradition in the Mediterranean.

Fig. 1. Mean weighted trophic level variability of the Mediterranean cultured fishes for the main producing countries (1950-2004). The four bottom panels (Egypt, Italy, Croatia and Total Mediterranean) are not in the same scale.

FEEDING GUILD COMPOSITION OF A GASTROPOD MACROBENTHIC COMMUNITY IN THE NORTH AEGEAN SEA

Irini Tsikopoulou ¹*, Chryssanthi Antoniadou ¹, Eleni Voultsiadou ¹ and Chariton Chintiroglou ¹ ¹ Department of Zoology, School of Biology, Aristotle University of Thessaloniki - etsikopo@bio.auth.gr

Abstract

The aim of this study was to examine temporal changes in feeding type composition of a macrobenthic gastropod community in Thermaikos Gulf, north Aegean Sea. Throughout the sampling period a gradual increase in the abundance of carnivores was observed, which implied a natural or anthropogenic disturbance in the area during the study period. *Keywords: Aegean Sea, Gastropods, Mollusca*

Introduction

Hydrodynamics and other environmental parameters may induce temporal and spatial changes in feeding guilds composition in marine sediments, eventually modifying the structure of macrobenthic communities [1]. Moreover, trophic type composition of benthic mollusc communities has been used as indicator of environmental stress induced by organic enrichment [2]. This study investigates temporal modifications of macrobenthic mollusc communities in the north Aegean Sea on the basis of feeding guild composition.

Materials and Methods

Three annual samplings were carried out from summer 2001 to winter 2004. Three vertical transects along the NE coasts of Thermaikos Gulf were set up and six stations were selected for benthic macrofauna sampling using corers, at depths between 3 and 10 m. Gastropods were classified into five feeding guilds: carnivores, detritus feeders, herbivores, suspension feeders and parasitic species ([1], [2], [3], [4]). The non-parametric Kruskal–Wallis test was used to confirm or reject the null hypothesis that the distribution of each feeding type was the same during the sampling period [5].

Results and Discussion

In total, 6931 gastropods were collected and identified in 62 species. Of these, 33 were assigned to carnivores, 14 herbivores, 7 detritus feeders, 2 suspension feeders and 6 parasites. The different feeding guilds were unevenly distributed in the three sampling periods in terms of numbers of individuals and species richness (Figure 1). The abundance of carnivores increased though time (H_{kruskal-Wallis}= 45.02; p<0.01), whereas species richness did not follow a specific pattern (Hkruskal-Wallis= 65.07; p<0.01). Adversely, detritus feeders showed a decreasing trend in their abundance (Hkruskal-Wallis= 59.15; p<0.01) but there was no specific pattern in species richness (Hkruskal-Wallis= 32.94; p<0.01) (Figure 1). The increasing dominance of carnivores against detritus feeders might be a result of natural or anthropogenic disturbances in the sampling area [1], thus confirming the observations of Antoniadou et al. [6] who attributed such changes to the increase of organic pollution in the northern transect of the study area. In conclusion, the feeding guild composition of a macrobenthic gastropod community can be a useful tool for biodiversity studies and monitoring surveys in marine coastal ecosystems.

Abstract

This document gives an overview of the EUSeaMap project and its part in the implementation of the EC policies involving marine habitat mapping. The EUSeaMap project will produce broad-scale predictive habitat maps for over 2 million square kilometres of European seabed covering four geographic areas of the European seas: Celtic, North, Baltic and western Mediterranean seas. Some preliminary results for the western Mediterranean are given. Keywords: Mapping, Models, Western Mediterranean

Marine habitat mapping is required for the implementation of various EC Directives and Regulations in that it is the baseline for environmental assessment and monitoring requirements as well as for the enactment of protection measures for marine habitats and species. In its Blue Book on an integrated maritime policy for the European Union, the EC proposed to take steps towards building a network that "assembles fragmented and inaccessible marine data into interoperable, contiguous and publicly available data streams for complete maritime basins". EUSeaMap is a preparatory action, funded by the DG MARE, that is functional to the setting up of this European network through the creation of models capable of predicting seabed habitat maps. The project aims to provide a tool for marine spatial planning by Member States and at the same type supports the implementation requirements of the Marine Strategy Framework Directive. The EUSeaMap is run by a consortium of partners (BLST, Denmark; DHI, Denmark; IFREMER, France; IEO, Spain; ISPRA, Italy; SEPA, Sweden) led by the Joint Nature Conservation Committee (UK). The project is based on the habitat modelling approach developed within the framework of the previous INTERREG IIIB-funded MESH [1] and BALANCE [2] projects, and will develop a common methodology for broad-scale seabed habitat mapping across Europe, using the EUNIS classification (http://eunis.eea.europa.eu/) across four marine studyareas covering over 2 million square kilometres of Europe's seabed: the Celtic, North, Baltic, and western Mediterranean Seas. The EUNIS habitat classification scheme, originally developed in 1996 by the EEA, has recently incorporated several marine habitat lists developed at biogeographic levels. Such is the case for the North Atlantic habitats, identified by Connor et al. [3], which have been incorporated into EUNIS. Similarly, a list of benthic Mediterranean habitats adopted under the framework of the Barcelona Convention [4], has also been incorporated into EUNIS [5]. To this effect, EUNIS represents a univocal comprehensive system for the identification and classification of marine habitats across European seas, a long needed measure as pointed out by several authors [6].

The project will introduce better quality habitat maps through the use of bestavailable data and refined modelling processes. It will make the digital map layers available to stakeholders and develop an on-line mapping tool to display the layers. Attention will be focussed on assessing the benefits and constraints of a broad-scale habitat map with respect to higher resolution maps produced from detailed survey data, and demonstrate how the Marine Strategy Framework Directive Annex III requirements can be used in characterising the marine environment. This exercise will allow estimation of the effort required to develop complete broad-scale coverage of waters surrounding the European continent as well as higher resolution ones. The EUSeaMap will utilise GIS software to model seabed habitats through the assembling and integration of several layers representing abiotic parameters (sediment, bathymetry, light, wave and tidal energy at seabed, salinity at seabed, temperature at seabed, dissolved oxygen, ice cover, stratification). Careful selection and analysis of ecologically relevant thresholds will be performed for each abiotic parameter in every region. Through the expert application of the EUNIS classification scheme, combinations of these parameters will be used to predict habitats at the high level habitats of EUNIS (levels 3 and 4). The approach will also quantify the degree of confidence of the generated maps. This will be done both on the basis of the source of each data layer used, and through the use of fuzzy boundaries for habitats, according to our knowledge of the required conditions for a given habitat to occur. The array of abiotic parameters used to

model habitats will vary according to each study area.

In the western Mediterranean sea the following parameters will be used: sediment, bathymetry, light, energy at seabed, temperature at seabed. Since the nature of the broad scale map determines a pixel size of analysis of 250 m, it is expected that at least 15 habitat types, according to the EUNIS classification, will be modelled in this basin. The habitats expected to be modelled for the Mediterranean (see Table 1.) are distributed as follows: 3 in the infralittoral zone, 7 in the circalittoral, 4 in the bathyal and 1 in the abyssal zone.

Tab. 1. List of the Mediterranean habitats to be modelled.

EUNIS Habitat code	Eunis name (in parenthesis eventual notes)	RAC/SPA Code [4]
A3	Infralittoral rock and other hard substrata	III6
A5.23	Infraittoral fine sands	111.2.
A5.28	Infralittoral Mediterranean biocenosis of superficial muddy sands in shettered waters	111.2.3.
A4.26	Mediterranean coralligenous communities moderately exposed to hydrodynamic action (we intend Coralligenous beds)	IV.3.1
A5.51	Maerl beds (we intend Rhoddliths beds in general)	VI.2.2.1; VI.2.2.2
A5.46	Mediterranean biocoenosis of coastal detritic bottoms	IV.2.2.
A5.38	Mediterranean biocoenosis of muddy detritic bottoms	IV.2.1.
A5.39	Mediterranean biocoenosis of coastal terrigenous muds	IV.1.1.
A4.27	Faunal communities on deep moderate energy circalittoral rock	IV.3.3.
A5.47	Mediterranean communities of shelf-edge detritic bottoms	IV.2.3.
A6.1	Deep-sea rock and artificial hard substrata	V.3.
A6.51 A6.511	Mediterranean communities of bathyal muds Facies of sandy muds with Therea muricata	V1.1. V1.1.1
A6.3	Deep-sea sand	V2
A6.52	Communities of abyssal muds	VI.1.1.

EUSeaMap will produce a modelled EUNIS habitat map, harmonised across the four regions, as well as associated confidence layers available through a purpose built webGIS. The webGIS will comply with INSPIRE standards and the layers will be available for viewing through WISE-Marine on its inception. The project will assess the feasibility and work resources required to extending the modelling process to other regions of Europe to produce broad-scale EUNIS habitat maps. Furthermore, it is proposed to provide generic resource requirements for new remote and ground-truth survey, probably per unit area, adjusted to suit the different major zones for survey.

PHYLOGENETIC RELATIONSHIP AMONG THE BLACK SEA ALOSA SPECIES FROM MTDNA ND5/6 SEQUENCES

Cemal Turan ¹*, Deniz Erguden ¹ and Funda Turan ¹

¹ Fisheries Genetic Laboratory, Faculty of Fisheries, Mustafa Kemal University - cturan@ymail.com

Abstract

Phylogenetic relationships among five species of *Alosa (Alosa maeotica, A. tanaica, A. caspia, A. immaculata* and *A. fallax nilotica*) was examined with sequence analyses of mtDNA ND5/6 region. In pairwise comparision, the highest genetic differences were observed between *A. caspia* and *A. tanaica* (0.691), and lowest between *A. maeotica* and *A. tanaica* (0.491). In minimum evolution tree, two phylogenetic nodes were detected; in the first node, *A. maeotica* and *A. tanaica* grouped together which were sister group to *A. f. nilotica*. In the second node, *A. caspia* and *A. immaculata* grouped together. *Keywords: Genetics, Teleostei, Black Sea*

Introduction

Shad (*Alosa spp.*) is one of the most important fish resources and have high economic value in the world [1]. Shad species are commonly found in the Black Sea and represented with four species and one subspecies [1,2]. *Alosa maeotica, Alosa tanaica, Alosa immaculata, Alosa caspia* are distributed in the Black Sea. *Alosa fallax nilotica* is distribution in the Black, Marmara, Aegean and Mediterranean Seas. Knowledge on phylogenetic relationship among these species is important to elucidate evolutionary history and genetic relationships among these species. In the present study it is aimed to elucidate phylogenetic relationships among *Alosa* species with sequence analyses of mtDNA ND5/6 region.

Material and Methods

Speciments of A. maeotica, A. tanaica, A. caspia, A. immaculata and A. f. nilotica were collected from the Black Sea. The samples were placed individually in plastic bags, and kept frozen at -40°C until the molecular analyses. Total genomic DNA was extracted from a peace of fin tissue (approximately 2 $\,\mathrm{mm^2})$ using Midi DNA isolation Kits. The amplification of the mitochondrial ND5/6 gene was performed using PCR with a profile of 94°C for 4 min, followed by 35 cycles of 94°C/30s strand denaturation, 52° C/20s annealing and 72 °C/1 min 30 sec primer extension, and a final 7 min elongation at 72°C. Purified DNA (3-5 µl) was sent to IONTEK for sequencing, using primers (F: 5'-AAC AGT TCA TCC GTT GGT CTT AGG-3' and R: 5'-TAA CAA CGG TGG TTC TTC AAG TCA-3'). Sequences were aligned and ambiguous bases resolved by eye using Sequencer v.4.5 (Gene Codes Corp.). The initial alignments of partial 16S rDNA sequences were performed with Clustal W program [3] and final alignment was completed manually with BioEdit [4]. MtDNA sequence data were analyzed to assess levels of pairwise nucleotide variation and to determine nucleotide composition for each taxon using Mega 4 [5]. The molecular phylogenetic tree was constructed using the three distinct phylogenetic approaches: a distance-based method using neighbor joining (NJ), [6] a cladistic approach using the maximum parsimony (MP) criterion, and minimum evolution (ME). The reliability of the inferred phylogenies was evaluated using the bootstrap method [7] with 1000 replicates. One species, Engraulis encrosicolusrom, were included as an out group taken from GenBank (NC003097).

Results and Discussion

There were 888 variable and 16 conservative nucleotides of which 857 were parsimony informative over 904 bp. Examination of the gene fragment reveals a lack of guanin (T; 18.1%) and abundance of adenine (A; 30.3%). The mean nucleotide diversity (*Pi*) was found to be 0.516. For congeneric comparisons of genetic distance (Kimura two parameter), the highest genetic differences were observed between *A. caspia* and *A. tanaica*, and lowest between *A. maeotica* and *A. tanaica* (Table 1). The three different phylogenetic approaches (NJ, MP, ME) resulted in similar tree topologies and the clades are well supported (Fig. 1). In minimum evolution tree, two phylogenetic nodes were detected; in the first node, *A. maeotica* and *A. iamaculata* grouped together. Similarly Faria et al [8] also clustered *A. caspia* and *A. immaculata* together and found close relationship for these two *Alosa* species in the Black Sea using ND1 and Cytochrome b genes.

Abstract

Diel changes were investigated in fish assemblages associated with shallow seagras (*Posidonia oceanica*) and bare sand in two southern Adriatic Sea coves. Habitat related differences in assemblages were strong day and night, and were greater than diel changes. The seagrass associated assemblages remained similar day and night and consistently differed from sand associated. In contrast, the assemblages over sand varied on a diel basis as larger individuals of several species (e.g. *Atherina boyeri*, *Sarpa salpa*, *Conger conger*) that resided over other habitats during the day, were caught at night. Both habitats were utilized by newly recruited juveniles of economically important species and their habitat associations generally did not differ on a diel basis. Hence, both habitats are considered important to the fisheries of southern Adriatic.

Keywords: Fishes, Biodiversity, Adriatic Sea

Introduction

The shallow-water vegetated inshore areas generally support different and more diverse and abundant fish assemblages than non-vegetated habitats, as well as being considered more important as nursery areas for juveniles of many economically important species [1]. This phenomenon is classically explained by considering the high structural complexity of such vegetated (mainly seagrasses) systems, which are able to fulfill the role of nursery areas in providing shelter and food to a great number of littoral fish species [2]. These conclusions have primarly been based on daytime sampling programmes, even though many littoral species of fish display strong diel rhythms of activity and diel changes in habitat-usage by fishes have been documented [3]. Thus, decision about the relative importance of different habitats to fishes based solely on daytime sampling are often equivocal. The objective of this study was to examine diel changes in the fish assemblages associated with the shallow seagrass (*Posidonia oceanica*) and unvegetated (bare sand) habitats.

Material and methods

Monthly samples of the shallow-water fish assemblage were collected with a small beach seine (mesh size 8 mm at outer wings and 4 mm at the bag end, knot to knot) between May 2007 and April 2008, every 4-h over 24-h period (daily samples were taken at 08.00, 12.00, 16.00h; while night samples at 20.00, 24.00, and 04.00h) in the two different areas; Donji Molunat (N 42° 27'27,5"; E 18°25'34,5") and Prapratna (N 42°48'58.1"; E 17°40'50.6") coves, southern Adriatic Sea. The substratum in Donji Molunat is shallow seagrass (*Posidonia oceanica*) while in Prapratna cove is clean sand. Sampling depth ranged from 4.0 to 0 m. The fish data were analysed using the PRIMER software package. Data were transformed for presence/absence and the Bray-Curtis similarity matrix was used to generate 2-dimensional ordination plots with the non-metric multidimensional scaling (nMDS) technique [4].

Results

A total of 64231 fishes comprising 83 species was caught; 12429 fishes (67 species), occurred over seagrass, whereas 51802 fishes (58 species), occurred over sand. Most fish were juveniles, mainly young-of-the-year, amounting a total of 89%. The dominant species of Donji Molunat, Boops boops (48,85%), Coris julis (7,65%), Pagellus bogaraveo (6,64%), Sardina pilchardus (5,72%) and Prapratna cove, Boops boops (57,21%), Atherina boyeri (19,70%), Sardina pilchardus (19,70%) and Sarpa salpa (6,60%) were caught in consistently higher numbers and biomass in different time of diel period. A greater number of species was caught over seagrass than over sand, day (52 vs. 48) and night (55 vs. 50). However, more individuals tended to occur over seagrass (9467) than sand (4627) during the day. At the assemblage level, slightly more individuals over seagrass were caught during daytime, whereas in Prapratna Bay dominated nighttime assemblage in both terms. Non-parametric Spearman's correlation test showed no signifficant correlation on composition and abuundance between these coves (r_s=0,210, p=0,187). The nMDS plot shows clear separation of the investigated areas (Fig. 1).

Discussion

The ichthyofauna was generally more diverse over seagrass than over sand both day and night, and more fish generally occurred over seagrass than over sand during the day, as reported elsewere [5]. The habitat-related differences in the fish assemblages were because many species consistently occurred in only one habitat, or were predominantly caught in one habitat, both day and night. Different types of fishes were generally associated with the two habitats, as discussed by [5,6]. The structure of the seagrass-associated assemblages did not differ substantially between day and night, as observed in other parts of the world [7]. However, significant diel change in the structure of the sand-associated assemblages was evident, which was primarly due to the influx of several species over sand at night. Changes in assemblage structure observed were caused by shifts in abundance of a particular species rather than by their presence and/or absence. In spite of diel changes in some species occurrence in both coves, no strong evidence for the existence of distinct day and/or night communities was detected. The predominance of juveniles in the catches indicate that these coves serve as nursery and feeding grounds.

Abstract

Deeply contrasting coastal / open ocean ecosystems have been investigated in the April and October 2008 cruises of the R/V BILIM during the SESAME project, covering the Cilician Basin, a north-south transect of the Levantine Basin, the Aegean coast of Turkey, the Turkish Straits System (TSS), and finally a transect arching over the mid-section of the Black Sea starting from the Bosphorus and extending east. Earlier work in April 2007 in the Turkish Straits and a repeated earlier cruises in the Cilician Basin since 2005 have provided additional data. Physical, chemical and biological oceanographic measurements and satellite data provide a basic description of the state of the different ecosystems, ranging from oligotrophic open waters to eutrophicated coastal / shelf areas supplied with water and nutrients from the large rivers. *Keywords: Circulation, Straits And Channels*

The Black Sea, a land-locked deep basin occupied with brackish waters, possesses distinctly different biochemical properties due to the presence of oxygenated in the upper layer and sulfide-bearing waters below a depth of 100-150 m and a transition zone in between (1). Comparison of the new and historical data sets indicates long-term changes in Black Sea upper layer chemistry. In this period, the nitrate stock of the upper layer has increased by 2-3 times as silicate stock displayed an opposite trend in the upper layer down to onoxic intreface since the 60's [2-3]. Thus, nitrate/silicate ratio decreased drastically in the upper layer throughout the basin [4]. However, there has been a slow increasing trend in the surface silicate values in the last decade, suggesting progressive changes in the Black Sea ecosystem. The suboxic zone, having distict chemical features, remained enlarged since 80's. Present results demonstrate that regionally variable vertical features of nutrients and dissolved oxygen remained similar in the western cyclonic gyre since 80's. However, lateral intrusion of oxygenated and nutient rich Bosphorus plume into the intermediate depths of SW shelf zone appears to modify basic features that appear in the westen cyclone. Depth integrated primary production rates ranged between 16 and 45 mgC.m-2h-1 in the eastern and western Black Sea stations in April and September 2008. A highly significant correlation exists (P = 0.001 n = 59 r= 0.59) between total chlorophyll and primary production rates. In-situ chlorophyll values were higher in spring than in fall. Concentrations ranged between up to 5 μ g/L in spring-08, and 1.6 μ g/L in autumn-08.

Fig. 1. Surface distribution of phytoplankton abundance (cells/l) in April and September 2008

In the Cilician basin of NE mediterranean, river discharges with large nutrient loads make eutrophic nearshorewaters of Mersin Bay. Upper layer of the Levantine Sea are depleted in nitrate and phosphate during the year, excluding the Rhodes cyclonic gyre in winter months. Nitrate/PO4 molar ratio has remained almost constant at levels of 25-28 during the last two decades, implying P-limited primary productivity in the euphotic zone as experienced in recent studies in the region. However, present POM data show that C/N ratio in the oligotrphic sea is very similar to the classical Redfield ratio, but lower than the those estimated for the more productive Black Sea ecosyetm during SESAME surveys. Primary Production (PP) rates ranged from 3.5 in the offshore to 40 mgC.m-2h-1 in nearshore waters of Mersin Bay enriched by river and domestic discharges. Phytoplankters were found overhelmingly abundant in shallow shelf waters under direct influence of river discharges in the Cilician basin and least in highly oligotrophic offshore waters in the Levantine basin. The mesozooplankton biomass and abundance decreased with inceasing depth (down to 200 m) in the Levantine Basin during study periods.

With the onset of stratification in fall, bacteria dominated the upper layers more efficiently compared to the spring period.

In the two-layer Marmara Sea ecosystem, the productive upper layer water is

depleted in nitrate and phosphate; however, an enrichment is recorded in the Marmara-Bosphorus Junction due to intensive mixing of counterflows with different nutrient properties. Therefore, the euphotic zone is more productive and has higher algal biomass and POM than Black Sea open waters. Its lower layer are hypoxic levels of DO (between 30-100 μ M), enriched in nutrients but with much lower N/P ratios (8-10) than in the oxygenated NE Mediterranean deep layer, due to denitrification in oxygen-depleted bottom waters of Marmara basin. Peak values of chlorophyll were measured in the Sea of Marmara and the Black Sea were also significantly high.

Maximum heterotrophic bacterial and cyanobacterial abundance and biomass were observed in the sea of Marmara during fall with values ranging between 2.6x10^6 cells/ml and 14.4 µgC/l for heterotrophic bacteria and 2.1x10^5 cells/ml and 25.3 µgC/l for cyanobacteria. In contrast lowest levels were attained during fall in the Levantine Basin with values ranging between 1.5x10^2 cells/ml and 0.02 µgC/l for heterotrophic bacteria and 1.5x10^2 cells/ml and 0.02 µgC/l for cyanobacteria and 1.5x10^2 cells/ml

SOMATIC AND GONADAL MOSAICISM DETECTION IN CULTURED FISH BY RAPD-PCR

Irem Uzonur ¹*, Kubra Sari ¹, Tugba Senel ¹ and Arzu Erol ¹ ¹ Fatih University, Biology Department - iuzonur@fatih.edu.tr

Abstract

DNA samples of organs and tissues from cultured fish: *Oncorhynchus mykiss*, *Sparus auratus* and *Dicentrarchus labrax* have been analyzed by PCR amplification with random primers. Among the 20 random 10-mer nucleotide primers tested, four that yield stable, well reproducible profiles of amplification products were chosen for further genome-wide mosaicism analysis. With these primers, the differences in the RAPD profiles of some tissues were detected in several individuals. These differences were associated with the modification of mobility or with the gain/loss of the fragment in the RAPD profile and could be caused by either genomic rearrangements or mutations involving the regions of DNA-primer pairing. Different epigenetic factors may also contribute to this process.

Keywords: Aquaculture, Fisheries, Fishes, Genetics, Monitoring

Introduction

The random amplified polymorphic DNA (RAPD) method has initially been used to detect polymorphisms in genetic mapping, taxonomy and phylogenetic studies and later genotoxicity and carcinogenesis studies. Despite its extensive use, this technique has also attracted some criticisms, mainly for lack of reproducibility [1]. RAPD assays have a great potential for the detection of DNA effects, alterations and damages including DNA adduct formations, breaks, point mutations, large rearrangements, and other changes, such as structural distortions induced by chemical or physical agents following the direct and/or indirect interactions with the genomic DNA. It has proven to be an efficient molecular tool for the identification of differences among natural populations, when provided with reliable reference samples [2-4]. Molecular evaluation of DNA effects by RAPD profiling can be a method capable of identifying environmental threats earlier than the used standard methods. Traditional approaches to the assessment of the impact of pollution on aquatic communities have generally been based on ecological criteria, such as changes in biomass, diversity and in species composition, whereas genetic changes may occur in natural populations as well as aquacultured organisms exposed to pollution. Many of the pollutants found in aquatic environments are known to be genotoxic and carcinogenic, and may interact, directly with DNA or after metabolic activation [5, 6]. Genotoxicity is an organism-specific and quantitative measure of the potential of a particular environment that causes damage to a cell's DNA. Target organ genotoxicity in this context can be defined as how target organs' DNA responds to genotoxicants [3, 4].Somatic mosaicism and gonadal mosaicism as an extension of the phenomenon imply the presence of genetically different cell lines in a single organism. Our work relies on RAPD analysis to show the extend of the somatic and gonadal mosaicism in freshwater cultured Oncorhynchus mykiss and mari-cultured Sparus auratus and Dicentrarchus labrax to be a basement for further epigenetic and genetic work that is to be done to improve fish-culture work quality.

Materials and Methods

A comparative analysis was carried using RAPD assay to assess the genotypic differences among the same fish's various organs/tissues. Furthermore, inter and intra-tissue variations were assessed together by an improved RAPD approach proposed in this work to detect target organ genotoxic effects on various organs and tissues of aquacultured fish: *Oncorhynchus mykiss, Sparus auratus* and *Dicentrarchus labrax*. Genomic DNA was isolated from dissected organs of the three mentioned cultured fish. Their genetic diversity has been assessed by RAPD-PCR and intra-specific genetic variation detection due to intrinsic and extrinsic factors realized as somatic and gonadal mosaicism were shown with xn replicates of RAPD-PCR using primers OPA-8 and OPB-18. The combination of these methodologies enabled the detection of various RAPD profile changes in the DNA as a mosaicism of tissues/organs extracted separately, when the RAPD-PCR mastermix with the same organ's/tissue's DNA was aliquoted into multiple tubes and thoroughly assayed together under identical conditions.

Results and Discussion

Preliminary data obtained in this work show that the RAPD profile changes of various tissues (Figure 1, liver, muscle, gonad respectively for two different primer OPA-8 and OPB-18) of the same aquacultured fish can easily and reliably be monitored for various DNA effects described as somatic and gonadal mosaicism which might be an early indication for the heritable in the case of gonadal mosaicism and genotoxic, mutagenic and carcinogenic potentials of the cultured fish populations with variable target organ genotoxicities detected as somatic mosaicism.

Hellas

Abstract

The edible holothurian, *Holothuria tubulosa*, was studied over a two-year period at the Dodecanese, South Aegean, in order to estimate the population density and biometry. Dense populations of the species were found at 3 islands, in shallow waters and very sheltered bays, in proximity to aquacultures. The biometric variables of the studied population differed among the islands; this pattern was linked to the trophic status of each area and the local fisheries. Considering the small size of the studied population and its low density, compared with other Mediterranean sites, it seems that *H. tubulosa* has been over-exploited at the Dodecanese. *Keywords: Density, Biometrics, Echinodermata, Aegean Sea*

Introduction

The Atlanto-Mediterranean holothurian, *Holothuria tubulosa*, is among the most conspicuous benthic invertebrates in the shallow sublittoral zone [1], commonly forming dense populations in meadows and sheltered bays. It is a selective epibenthic deposit feeder, highly contributing to the recycling of bottom detritus [2]. The species is exploited in the Mediterranean, either as fishing bait or as food source [3, 4], and is currently studied for its bioactivity with promising results for the treatment of inflammatory disorders [5]. In the Aegean Sea *H. tubulosa* is harvested and utilized as fishing bait at the Dodecanese, whereas it is commercially exploited in some Turkish areas [6]. *H. tubulosa* has been well studied in the western Mediterranean and the Adriatic [2, 4, 7]. However, relevant data for the Aegean populations is missing; the existing information is limited to the geographic and bathymetric distribution of the species [1]. Taking into account the above, the aim of the present work is to contribute to the study of *H. tubulosa* population in the Dodecanese, South Aegean Sea.

Materials and Methods

The study was conducted at the Dodecanese, South Aegean Sea, where 26 stations on nine islands were randomly located (Figure 1).

Fig. 1. Study area indicating sampling stations and relative abundance of *H. tubulosa*

Sampling, i.e. experimental fishery, was practiced by scientists and sponge fishermen by diving down to 20 m depth, in two consecutive years (2007 and 2008). 40 specimens were randomly collected from each station, in order to estimate the main biometric characteristics of the species (L = length, D = width, W = drained weight, Wg = gutted weight). Prior to biometrical analysis the specimens were relaxed in seawater containing 7.5% MgCl₂ at 0°C, for 24 hours, to enhance the measurements homogeneity [8]. Population density was estimated through fishing effort, according to an index of relative abundance ranging from 1 to 7. One-way ANOVA was used to test for spatial differences for the estimated biometric variables of the species.

Results and Discussion

H. tubulosa was recorded at 18 stations, in shallow waters (less than 10 m depth) and in very sheltered bays, generally having low density (Figure 1). Dense populations were only observed at three islands: Agathonissi, Arkoi and Pserimos, where the species was found in proximity to aquacultures. A

moderate dense population was also observed in Astypalea, where sampling took place in a very sheltered bay, in which organic input accumulates. These results may be explained by taking into account the oligotrophic nature of the Dodecanese area [9], which creates constraints on the holothurians feeding. As a result, the *H. tubulosa* population can thrive only in areas with high organic inputs. Moreover, in this area the species has been harvested over a long period, a fact that also precipitates the reduction of the population density.

Overall, 350 individuals of *H. tubulosa* were measured. Their size ranged from 4.13 to 19.7 cm in length and from 1.99 to 8.6 cm in width, with a mean at 10.26 \pm 2.78 cm and 3.82 \pm 0.88 cm, respectively. Their biomass ranged from 29.14 to 350 g for drained and from 20.3 to 164.43 g for gutted weight, with a mean at 104.59 \pm 44.7 g and 61.89 \pm 23.25 g, respectively. Significant spatial differences for the biometric characteristics of the species were recorded (p<0.01) with high values at Agathonissi and low at Pserimos.

These results can be related to differences in local environmental conditions, mainly with respect to the trophic status of each area combined also with the effect of local fisheries. Unfortunately, there is no relevant data about the fishery of *H. tubulosa*. Considering the much smaller mean size, comparing to the usual one which approximates 20-25 cm in length [3], and the low density values observed, it seems that *H. tubulosa* has been over-exploited at the Dodecanese.

FACTORS AFFECTING DISCARDING IN THE EAST MEDITERRANEAN TRAWL FISHERY

Vassiliki Vassilopoulou¹* and John Haralabous¹

¹ Hellenic Centre for Marine Research - celia@ath.hcmr.gr

Abstract

Analysis of data from on-site sampling of trawl fisheries in the central Aegean by observers on-board fishing vessels was conducted to determine the relative importance of certain factors (fishing and temporal) affecting discarding. A significant positive correlation was found to exist between the mean discards and the mean catch weight. Catch quantities and species composition in the catch appeared to have the highest impact on discard patterns.

Keywords: Aegean Sea, Demersal, Fisheries

Introduction

Discarding at sea occurs mainly in multi-species fisheries, such as those operated in the Mediterranean, where it is perceived mainly as throwing away unmarketable by-catch species, and/or undersized individuals of target species. In Greek waters, higher amounts of discards are generated by bottom trawlers [1], and total quantities produced annually have been estimated to range between 13,500 and 22,000 t [2]. Understanding the factors that determine what and how much is discarded is fundamental if we are to propose mitigation tools for fisheries management [3]. This study aims to contribute to the knowledge of discarding patterns and factors affecting them in east Mediterranean trawl fisheries.

Material and Methods

Data analysis was based on fishery records taken in 2004 and 2005 by observers on-board commercial trawlers on quarterly intervals except for the summer, when according to the Greek legislation trawlers operation is prohibited. All vessels were operating routinely in the central Aegean Sea and they were distinguished into two different segments on the basis of their size (>24m and <24m). Fieldwork at each haul comprised the recording of the fishing duration, the species composition and the total catch. Then for each species, values of both the marketable and the discarded fraction of the catch, number of fish, total weight and fish length were recorded. Haul data were subsequently aggregated at the daily trip level, mean values per fishing hour of discards and catch weight were estimated and further analysed through General Linear Model Analysis of Variance (GLM ANOVA). The dependent variable was the mean absolute values of discards per fishing hour; the fixed factors were the fleet segment, the species caught and the quarter of the year; the mean total catch per fishing hour was used as a covariate. The impact of each significant source of variation was studied through the value of partial η^2 (higher η^2 value implies higher effect).

Results and Discussion

Our results showed that on average 36.6% of the trawl catch was discarded per fishing trip. The latter value is lower than the mean discarded quantity mentioned in a previous study in Greek waters [2] and is possibly related to the implementation of the 40 mm cod-end mesh size in trawls the last few years. In the North Sea the introduction of certain technical measures which included increases to cod-end mesh size have been proven effective in reducing discards [4]. On the other hand, in the Baltic Sea cod fishery the enforcement of gear related technical measures was not successful due to poor compliance by fishers who did not accept the subsequent large short-term catch losses [5].

Fig. 1. Relation between mean discards and mean catch per hour (in kg) from trawlers in Central Aegean in 2004-5 by trip sampled.

Great variation appeared between mean discards and mean catch portions among trips, although a significant positive correlation (r=0.708, p<0.05) was found between the two parameters (Fig.1). Similar results were obtained in other studies [2], [6], while there were also cases where discard rates were found to be unrelated to the amount caught [7]. GLM ANOVA results revealed that the factors used in the current analysis explained about 75% of the total variability of discard quantities (Table 1). Mean catch per hour had the highest impact on discards (partial $\eta^2 = 0.418$). Concerning the main effects in the model, species had a higher impact than quarter of the year and fleet segment. Discard patterns can be highly variable and are initially affected by catch compositions, which are determined by environmental and social (regulatory, behavioural) factors, but are ultimately controlled by the fishing vessel crews, who are influenced by landing constraints and economic forces [8].

FIRST RESEARCH SIGHTINGS OF FIN WHALES (*BALAENOPTERA PHYSALUS*) IN COASTAL WATERS OF THE MALTESE ISLANDS, CENTRAL-SOUTHERN MEDITERRANEAN

Adriana Vella ¹*

¹ Conservation Biology Research Group, University of Malta - avel@cis.um.edu.mt

Abstract

Fin Whales (*Balaenoptera physalus*) have been recorded in coastal waters of the Maltese Islands for the first time between July and August 2007 during ongoing cetacean scientific surveys, at an average distance from the Maltese coasts of about 4kms and in waters of average depth of 167 meters. This first coastal Fin whales' approach, recorded as part of a long-term cetacean research, in the central-southern Mediterranean region encompassing a research area of 100,000km2, since 1997, may indicate range expansion or redistribution of some Fin whales in the Mediterranean or a singular event. Investigating the reasons behind these approaches and planning conservation measures for such presence in high vessel traffic regions of the Mediterranean is necessary. *Keywords: Cetacea, Conservation, Coastal Waters, Monitoring*

Introduction

Though Fin whales (Balaenoptera physalus) have been studied extensively in the North West of the Mediterranean, with a particular focus in the Ligurian Sea and in the Pelagos Cetacean Sanctuary [1,2,3,4,5], relatively fewer other Fin whale sightings and studies have been reported from elsewhere in the Mediterranean [6,7]. One such study suggests a winter feeding ground for Mediterranean Fin whales, observed close to the Island of Lampedusa in February. Here the Fin whales were observed to feed on different prey and to spend their time in shallower waters than those in the Ligurian Sea [8]. These observations were taken to suggest a seasonal shift in ecology and geographic distribution among Mediterranean Fin whales. However, the number of individuals sighted close to Lampedusa in winter was smaller than that estimated in the Ligurian sea in summer. As studies in the Ligurian Sea started to extend into the autumn and winter months it was observed that indeed the number of Fin whales decreased drastically in this region only between November and January [9]. These observations still leave questions on what may be redistributing some Fin whales while not others at different times of the year, and where such redistribution is taking place. Though various researchers reveal relationships between Fin whale distribution and environmental factors [4,5], it is still difficult to predict such distribution with synergistic impacts of increasing number of factors, including noise pollution and possible changes in climatic conditions. This would indicate the need for long-term monitoring of various regions of the Mediterranean in order to assist in the conservation management of such IUCN declared Endangered species.

Fig. 1. Aerial photo of Fin Whale just under the water surface close to Maltese Islands

Methods

The Maltese Cetacean Research Project, ongoing in the central and southern Mediterranean Sea in an research area of 100,000Km2, around the Maltese Islands, since 1997 by the author, utilizes both aerial and marine field research surveys, to investigate cetacean abundance and distribution [10]. The Research methods adopted are those described in Vella [10]. This paper focuses on the first recorded sightings of Fin whales in coastal waters (within 5km distance from the coast) around the Maltese Islands.

Results and Discussion

A total of five Fin whale sightings were recorded in coastal waters around the Maltese Islands between July and August 2007. Out of these, four sightings in July were of single Fin whales (spotted on different days, but appeared to be the same individual residing in the same area for at least a week) and one sighting in August included two individuals (sighted once as this was followed by days with strong winds).

Cetacean projects need to focus on local to regional areas in their conservation research and management, so as to promote the long-term and dedicated yearround research and monitoring required for reliable and accurate data on these long-lives species. This first coastal Fin Whales' approach recorded in the central-southern Mediterranean region ,as part of an extensive dedicated research, may indicate range expansion or re-distribution of this species in the Mediterranean. Of course sustained research effort would allow for corroboration of these first observations. Investigating the reasons behind these approaches and planning conservation measures for such presence in high vessel traffic regions of the Mediterranean is necessary.

Tab. 1. Main observations and records linked to the first Fin whale sightings close to the coast of the Maltese islands.

Period of sightings close to Maltese Islands:	2nd week of July to 2 nd week of August 2007
Average Distance from coast:	4.04 km (St. Dev = 2.09), range 2.5 to 7.5km
Average depths at sightings:	167.6 m (St. Dev = 47.71), range 85 to 200m
Other cetacean species in the area:	Common Dolphins (Delphinus delphis)
>Fishing activities in the area:	small tunas and swordfish

BLUEFIN TUNA CONSERVATION RESEARCH IN THE CENTRAL-SOUTHERN MEDITERRANEAN SPAWNING AREA

Adriana Vella 1*

¹ Conservation Biology Research Group, University of Malta, MSD 2080, Malta, Italy - avel@cis.um.edu.mt

Abstract

Bluefin tuna (*Thunnus thynnus*) has been caught in the Maltese Islands since 1748. By 1995, when the Japanese bought bluefin tuna (BFT) caught by Maltese fishermen, the effort increased dramatically, however limited by the artisanal long-line gear used. Total BFT long-line fisheries landings have followed an over-all decline from a peak of 353,014kg in 1995 to 227,008kg in 2006. Close to 400 BFT specimens were sampled during six years to study variations in sizes, sex ratios, biogeographical characteristics and molecular genetics using microsatellite loci. This study's results indicate decreasing average BFT catch body size and an increasing sex bias for females. A significant genetic heterogeneity, FST value of 0.018 (P=0.015), was found among the BFT sampled in the spawning and fishing region south of the Maltese Islands.

Keywords: Conservation, Pelagic, Fisheries

Introduction

Tuna has been caught in the Maltese Islands with traps since 1748. However this fishing method was finally replaced with long-line, initially as a by-catch in the swordfish fisheries prior to fine-tuning gear for Bluefin tuna in 1995, when the Japanese bought Bluefin tuna caught by Maltese fishermen. Bluefin tuna fishing is now a seasonal activity for Maltese Fishermen undertaken between May and mid July. Each fishing expedition involves on average 4 days of effort with 40 to 50 miles of long-line, set at least three times, each extending down to 100m with bait which is mostly imported Mackerel. Boats utilized for this fishing measure between 10 to 26m. The increase in purseseine fishing effort in the Central and Southern Mediterranean Area can jeopardize the survival of the species population and the livelihoods of Maltese long-line tuna fishermen if continued unchecked [1]. Vessels from Malta and Tunisia found themselves being joined by Italians, Spanish, French and recently increasing Libyan fishing vessels. The sudden increase in exclusive fishing zones by Tunisia and Libya further proves the increasing desire to increment the income from this fish species. In order to better understand the Bluefin tuna population structure and diversity found south of the Maltese islands, this study was started in 1998 [2,3] so as to undertake the microsatellite population genetics study presented here. This study has recently extended its sampling range West ward and East ward so as to expand on the results obtained so far.

Materials and Methods

Three hundred and eighty specimens of Bluefin tuna caught during the Maltese tuna long-line fishing season between 1998 and 2004 were measured (fork length and weight), sexed, and tissue sampled. DNA extraction from the proteinase carried out using the stored tissues was K/phenol/chloroform /isoamylalcohol method [4]. Microsatellite analyses protocols and primers used for this study were adapted from Takagi et al. [5]. PCR DNA amplification was carried out in an Eppendorf Mastercycler Gradient thermocycler. A 50ul reaction was used containing around 50ng DNA, 1µM of each primer, 5ul of buffer (consisting of 10 mM KCl, 10 mM (NH4)2SO4, 20 mM Tris-HCl, 2.0, mM MgSO4, 0.1% Triton X-100, pH8.8), 200 µM dNTPs, 3.5units of Taq DNA polymerase (New England Biolabs). 7.2ug of BSA was also added later. Each primer set had a flourescent label on either the forward or the reverse. The primers for the four loci considered included: tth01-TET: tth04-FAM: tth06-HEX: tth07-FAM. The temperature profile used involved an Initial denaturation for 5 min at 94°C, followed by 35 cycles of 1 min at 95°C, 1 min at 50°C, and 1 min at 74°C followed by a final extension of 10 min at 72°C. Allele frequencies were calculated as: number of the allele / total number of alleles (for that particular locus). Heterozygosity observed (Ho) and expected (He) were calculated using Arlequin ver.3: Ho is the number of heterozygotes observed as a ratio of the total number of individuals, while He is the expected number of heterozygotes if the total number of individuals were at Hardy-Weinberg equilibrium (HWE). Fixation index (FST) was used to measure Bluefin tuna population differentiation based on genetic polymorphism data, such as microsatellites. This statistic compared the genetic variability within and between populations. FST was calculated using Arlequin ver.3. This analysis was important in order to investigate the presence or absence of any significant differences between the various allele frequencies amongst Bluefin tuna from different sampling areas south of the Maltese Islands.

Results and Discussion

Bluefin tuna landings have increased through the years. However a decline in

recent years is also noted though fishing efforts have increased. Between 1999 and 2004 on alternative years one may note a progressive increase of % females with the highest (70%) in 2004 showing a high bias toward females. Body size investigation indicates a clear reduction in the average size of the sampled individuals in 2003 and 2004. A close positive logarithmic relation between body size (kgs) and fork length (m) with a high R squared value of 0.86 was obtained. On investigating the genetic distance between samples caught during the six year study period (1999-2004) from three locations south of the Maltese Islands, genetic diversity between individuals sampled from regions A (SW of the Maltese Islands) and C (SE of Maltese islands) was found to be significant on a pairwise test: FST = 0.018 (P = 0.015). The molecular genetics analyses results for Bluefin tuna in this study show the number of alleles per microsatellite locus within samples varied from 5 for Ttho1 in the three locations to 13 for Tth07 in location B (situated between A and C). Allele richness per locus and sample varied from 3.894 at locus Tth01 in location C to 10.2 at locus Tth07 in location B. Average observed heterozygosities varied between 0.368, in location C at locus Tth01, and 0.925, in location C at locus Tth04. The expected heterozygosities varied between 0.536, in location C at locus Tth01, and 0.885 in location C at locus Tth07. The genotype distribution at loci Tth06 and Tth07 in location C deviated significantly from Hardy-Weinberg expectations (HWE) and thus were removed from subsequent analyses with the consequence that the FST value increased further in its significance.

Investigating the genetic distance between samples from the different locations South of the Maltese Islands during the six year study period (1999-2004) indicated an FST which varied from 0.018 (P=0.015) to 0.025 (P=0.012), when removing the two loci in location C found to be significantly deviating from the HWE obtained in this study. This clearly shows a significant difference between Bluefin tuna sampled in different locations in the Maltese Fishermen's fishing grounds thus requiring further conservation research and management considerations.

A PRELIMINARY STUDY OF THE BLUNTNOSE SIXGILL SHARK, *HEXANCHUS GRISEUS*, IN THE CENTRAL MEDITERRANEAN REGION, AROUND THE MALTESE ISLANDS

Noel Vella¹* and Adriana Vella¹

¹ Department of Biology, University of Malta - noel.vella@um.edu.mt

Abstract

Research on *Hexanchus griseus* (Chondritchthyans: Hexanchidae) has been ongoing since 2004, including various conservation assessments of the direct-catch fisheries and by-catch landings of this species by Maltese fishermen. Results on the number, morphometrics, sex, distribution and genetics analyses of the specimens caught allows for a long-term conservation management plan for this species and for sustainable fisheries to be set. The genetic analyses of various mitochondrial loci would determine this species' population structure.

Keywords: Elasmobranchii, Fisheries, Conservation

Introduction

Conservation risk assessments of elasmobranchs indicate that this group consists of some of the most threatened marine species, where *Hexanchus griseus* is one such case [1,2,3]. IUCN has assessed *Hexanchus griseus* as nearly threatened both on a global and regional level [4,5]. Although this species is cosmopolitan, there have been no detailed assessments on its population structure and data is scarce at the global level [4]. However records of *Hexanchus griseus* landings in Malta show that there has been a constant increase in the catches between the mid-1980s to the mid-1990s, coinciding with an increase in the fishing effort within the same period [1]. Such increase is then followed by a significant sharp decline in the catches between 2004 and 2008 being that of 3917kg per year [6]. Such decline can be partially attributed to overexploitation of the areas being fished, highlighting that this slow growing shark species needs detailed dedicated research to protect the species, its habitat and sustainable fisheries depending on this resource.

Materials and Methods

This study has collected detailed records of the characteristics of this species specimens' landed since 2004. Over 435 individuals landed by fishermen at the Malta fish market were sampled till 2008. The most common fishing gear used to catch *Hexanchus griseus* is bottom longlines (97.6%), where this species is caught either as a target species or as by-catch. Statistics show that 73% of the landed *Hexanchus griseus* [6] were caught between January and April, with a peak in landings between February and March. Such seasonality is observed because during these months several fishermen exploit deep water species, but throughout the rest of the year they change the fishing gear to target more commercially important species.

Results and Discussion

The female proportion is significantly larger than that of males for the sampled individuals, which corroborates other findings [1,7,8] where similar ratios were observed on smaller sample sizes in the Mediterranean region. Analyses of the total length of the recorded specimens were also conducted. Females ranged between 74cm and 400cm, with a mean body length of 270cm (St. Dev. 63.5cm), while males ranged between 106cm and 356cm, with a mean body length of 246cm (St. Dev. 39.1cm). In this study two females (total body lengths: 397cm and 400cm) had developing ova, the latter having over 350 developing ova with a diameter between 5mm to 53mm. With regards to males, a total length of 270cm marked the point where they had either nearly or fully calcified claspers that were as long as the tip of the pelvic fin. This indicates that the size of maturity of the Central Mediterranean specimens is very similar to that observed in other Mediterranean regions [9], in which case it can be concluded that the specimens collected in this study were mostly inveniles and with only one record of a new born. No records of any gravid female have been obtained from either specimens investigated during this study nor from experience of the interviewed fishermen. This observation may indicate various regional scenarios: 1) fishing methods are targeting immature individuals, 2) mature individuals do not occur in Central Mediterranean or 3) the population has been exploited in a way that only immature specimens are left, since individuals reach sexual maturity quite late in their life-cycle.

Preliminary population genetics are giving further insight on the population structure of this exploited species within this region, so as to be in a better position to understand the status and requirements of the species and its conservation.

DO THE TECHNICAL CHARACTERISTICS OF THE TRAWLERS CONTROL BOTTOM TRAWLING ACTIVITY IN THE GULF OF GABES (TUNISIA)?

¹ UMR 5244 CNRS-EPHE-UPVD Biologie et Ecologie tropicale et méditerranéenne - marion.jarraya@univ-perp.fr

² INSTM, Sfax, Tunisie

Abstract

In the Gulf of Gabès, bottom trawling is a highly developed fishery but is still poorly known. The aim of this study was to identify this fishery by determining the technical characteristics of the trawlers, their production, fishing area and target species, using a typological approach based on multivariate analyses of landings data. Four fishing strategies are defined (caramote prawn and fish fishery, fishery of the species destined for exportation -essentially rose shrimp- and non selective fisheries) showing that differences in fishing tactics are mainly due to differences of exploited areas which depend themselves on the technical characteristics of the vessels. *Keywords: Fisheries, Gulf Of Gabes, Coastal Management, Gis, Analytical Methods*

Introduction

The Gulf of Gabès is the most important fishing area in Tunisia (southwestern Mediterranean Sea) and bottom trawling is the most predominant fishing activity in this area. Fisheries management not only requires the knowledge of the biological and the dynamics parameters of the resources but also to identify the characteristics of the fleets. Many authors have tried to establish a typology of the trawling activity ([1], [2],[3]), but in this region, it is still poorly known. The purpose of this study is to identify the effects of the technical characteristics of the fleets and the prospected areas on the trawlers productions.

Material and methods

Two data sets were available: one from national statistics of Tunisia, and the other one from individual on-site interviews of the trawlers captains in the Sfax harbour. The data were collected during 3 months from February to April 2008, and were related to the technical characteristics of the boats. The quantity of the species caught was also estimated. A typology of the fleet was used to identify several metier (a gear associated with a fishing practice) to explore potential relationships between the technical characteristics of the trawlers and the species caught. The methodology employed to reach theses objectives consist in multivariate data analyses which are more and more employed in the fisheries sciences ([4],[5]). Cartographic representations of the metiers were also performed using a Geographical Information System (G.I.S).

Fig. 1. Activity areas of the different trawler groups operating in the gulf of Gabès

Results and Discussion

Fleet structure and eploited species.: The data collected by the Statistical Service of the General Direction of Fishing and Aquaculture show an increase of engine power of the trawlers (and indirectly of fishing effort) in the lasts decades. A total of 88 trawlers were prospected (33% of the trawlers of the area). The average total length, GTR and engine power were estimated and the main exploited species were characterised. *Typology of the active fleet and activity areas of each métier*. The typological analysis of the trawlers showed the existence of 4 fishing strategies (métier) (Table 1) and the activity areas of the trawlers for each metier were represented using a GLS.(Fig. 1). The first target caramote prawn and cuttlefish. This métier is practiced by old trawlers with low engine power and low autonomy at sea. The second métier is composed by the youngest and less selective trawlers; involving an important number of sailors. The third is fishing. The units belonging to this group

have the best technical characteristics (big boats with highest engine power and gross tonnage) and operate at deep sea and their interest is to prolong duration of the outing to take advantage of the trip. The fourth métier is fishing for export (species like rose shrimp, common octopus, musky octopus, and european squid). The units linked to this activity are the longest trawlers with an important crew number. They are the freezer trawlers. This type of activity requests big units and an important number of sailors to carry out the operations of sorting, conservation and packaging of the species caught. It is a new fishery and results from diverse economic (poor profitability of the traditional fisheries) and biological factors (weak fish production due to over exploitation of the stocks).

Tab. 1. Description of the four métiers in regard with the technical characteristics of the boats and the landed species

							- So 1.5 (1)

Conclusion

This study indicates that the technical characteristics of vessels command the fisheries strategies and therefore the exploited species. The role of the technical parameters in the identification of the different métier has not been mentioned in the national studies implying a typology of the travlers. The most mentioned factors are the seasonality ([6]) and the fishing zone ([7]). The results of the two approach (cartographic and statistic) show a good concordance, might be a good basis for the management of the fishing activity in the gulf of Gabès.

SEA WATER PILING: TRADITIONAL OR ALTERNATIVE MATERIALS? AN INTEGRATED BIOLOGICAL AND ECOTOXICOLOGICAL EVALUATION IN VENICE LAGOON (ITALY)

A. Volpi Ghirardini ¹, C. Losso ¹, G. Libralato ^{1*}, M. Zanella ¹, E. Keppel ², M. Sigovini ² and D. Tagliapietra ² ¹ Environmental Sciences Department, University of Venice, Campo della Celestia 2737/b, 30122, Venice, Italy -

Abstract

Wood has been traditionally used as piling material in estuarine and marine coastlines. Recently, in Venice lagoon, timbers turn-over accelerated not only due to water mechanical action, but also to the increase of their biological degradation operated by wood borers. The need to guarantee navigation safety and increase environment protection determined the identification of a series of traditional add-ins and alternative piling materials. The aim of this study was to verify through some *in situ* and *ex situ* experiments the ecotoxicological viability of the proposed piling materials as well as to fill the gaps in the knowledge about the distribution and ecology of the main species of wood boring invertebrates in order to supply policymakers and stakeholders with a series of scientific criteria to manage the timbers turn-over phenomenon.

Keywords: Bio-Accumulation, Ecotoxicology, Lagoons

Large amounts of wood have been used over the centuries for piles, docks and bulkheads for developing estuarine and coastal areas. Wood is a particularly useful building material as it is a renewable resource, with relatively low harvesting costs and excellent strength-to-weight properties [1]. Timbers for piling purposes are frequently treated in order to retard or prevent decay due to wood-boring organisms such as fungi, molluscs and crustaceans [2]. Recently, in Europe traditional timber species started to be substituted not only by tropical ones, but also by a wide series of treated wooden-based materials as well as completely artificial ones. Indeed, they are supposed to be more resistant to water mechanical action and wood-boring agents, lowering the related management costs, but with unknown environmental implications. In Venice Lagoon, wood is extensively used for maritime works, especially mooring piles and navigation channel marks (named "briccole") (approximately 7,000). In addition to the degradation caused by natural and man-made physical factors, timbers are characterized by strong biotic degradation phenomena. It has been estimated that along the shipping channels there are about 22,000 wooden piles constituting the briccole and between 5,000 and 10,000 wooden piles are present for boats mooring. Each year, a large number of them must be replaced. Recently, it was observed that their turn-over increased, probably as a consequence of a higher biological activity of marine wood borers such as the molluscs Bankia carinata, Lyrodus pedicellatus, Nototeredo norvegica and Teredo navalis, the isopods Limnoria lignorum and L. tripunctata and the amphipod Chelura terebrans. The problem of protecting wooden constructions in the Lagoon is of considerable interest mainly for navigation safety and environment protection as well as under the economical viewpoint. Various solutions were suggested such as the use of high durability essences, the application of physico-chemical protections or the opportunity to take into consideration alternative materials (e.g. plastics or recycled plastics). The aim of the currently ongoing research study is to assess a discrete set of piling materials (n = 16) in order to verify their durability towards mechanical water stress, their sea water ecotoxicity and the potentiality for wooden ones to be biologically degraded, considering both in situ and ex situ experimental activities.

Fig. 1. The investigated piling materials (# 16) present leachates with various toxicity levels towards saltwater biota.

In situ experiments have been set up to obtain bioaccumulation data from active and passive biomonitoring using mussel exposure, to characterize and evaluate the intensity of wood borers attacks on lagoon scale, to define a preliminary model of habitat suitability and to increase the ecological knowledge of the main species of wood boring invertebrates. Ex situ activities have been scheduled to assess the potential ecotoxicological hazard of leachates generated by piling materials under various exposure conditions considering a battery of sensitive seawater toxicity testing species (i.e. bacteria, algae, molluscs and crustaceans). The final aim is to supply policymakers and stakeholders with a series of scientific criteria in order to manage the phenomenon of timbers turn-over and, specifically, to compare the usage of traditional and alternative piling materials as well as other protective add-ins.

BATH SPONGES FROM A MARINE PROTECTED AREA IN THE AEGEAN SEA

E. Voultsiadou ¹*, C. Antoniadou ¹, T. Dailianis ¹, D. Vafidis ² and C. Dounas ³

¹ Department of Zoology, School of Biology, Aristotle University, Thessaloniki, Greece - elvoults@bio.auth.gr

Abstract

Diversity and density of bath sponges have been investigated in eleven localities inside and outside the area of the National Marine Park of Alonissos and Northern Sporades (NMPANS). The species *Hippospongia communis* (Lamarck, 1814) and *Spongia officinalis* (Linnaeus, 1759) were recorded. Dense populations of the latter, consisting of moderate-sized individuals, were detected exclusively in the core of the Marine Protected Area (MPA). Considering the dramatic decline of Mediterranean commercial sponge populations during the last 20 years, due to the combined effects of successive disease outbreaks and unregulated fishing activities, the remarkable sponge abundance recorded suggests that protection conditions may be considerably in favour of the viability of sponge populations.

Keywords: Porifera, Sporades Islands, Marine Parks, Density, Conservation

Introduction

Five sponge species of the family Spongiidae have been traditionally harvested in the Mediterranean Sea ([1]). During the last decades periodic disease outbreaks have decimated their natural populations ([2]) and along with unregulated harvesting have caused a severe decline in bath sponges catch. In Greece, a large area of the north Aegean, covering 2.220 km², has been assigned as a Marine Park since 1992, constituting the largest MPA in the Mediterranean Sea ([3]). Before the imposition of the protective measures, the area was regularly exploited by sponge fishermen, while afterwards only sporadic, unauthorized harvesting of bath sponges occurred, mostly outside the core of protection.

Materials and Methods

The study was conducted in summer 2008, at 7 stations set inside the established Marine Park and 4 stations in adjacent unprotected areas (Figure 1). Sponge population density was estimated by scientists accompanied by sponge fishermen diving down to 50 m, as the number of individuals encountered per length of investigated area (N/km). In total 130 randomly selected sponge individuals were measured for their dimensions in three axes and their product was used to estimate sponge size in liters.

Fig. 1. Study area indicating sampling stations and estimated population density of sponge species (So: *S. officinalis*, Hc: *H. communis*)

Results and Discussion

The two most common Mediterranean bath sponge species, *H. communis* and *S. officinalis*, were recorded exclusively inside the core area of the Marine Park on rocky bottoms and *Posidonia*meadows; the former in low abundances, and the latter with dense populations at most occasions (Figure 1). *S. officinalis* varied in size from 0.27 to 7.2 liters, and its population consisted mostly of moderate-sized individuals. The size of *H. communis* individuals varied from 1.6 to 21.2 liters, exhibiting a wider range of size distribution due to the presence of few large-sized individuals (Figure 2).

Although preliminary, the present data suggest that protection measures may be considerably in favour of the viability of sponge populations which thrive inside the MPA, in contradiction with the unprotected areas surveyed in this study as well as other Aegean areas open to uncontrolled sponge fishery ([4]). In other Mediterranean areas over-exploitation and disease incidences have also led to a decreasing trend in sponge abundance and size ([1]), while recovery was observed in MPAs ([5]). However, the low population density values in one studied station of the core area and the complete absence of the two species from other stations in protection zone A suggest that the protection scheme *per se* cannot safeguard the existence and robustness of commercial sponge populations. The systematic comparison of sponge communities between protected and unregulated areas, as well as the investigation of the particular environmental conditions in the North Sporades Archipelago will further elucidate the reasons of these findings.

Abstract

Calanus helgolandicus s.l. genetic differences have been identified for the first time between and within European basins, as well as a decrease of prosome length with latitude. Our study explores the population structuring of this key species in relation to morphology, genetics and hydrography.

Keywords: Copepoda, Biogeography, Hydrography, Genetics

The marine copepod *Calanus helgolandicus* is of considerable importance in the marine food web. It plays a critical role in marine ecosystems as a grazer of microplankton and as a major food source for commercially important fish. The distribution of *C. helgolandicus* in European waters covers a wide range of habitats, from open ocean to coastal environments. Recent studies [1, 2] have shown that *C. helgolandicus* is sensitive to changes in climate. Its distribution range and abundance has increased as European waters have warmed over recent decades. Building on the network of laboratories created by *Bonnet et al.* for their review on *C. helgolandicus* (2005), we collected samples in 95% ethanol from 19 European sites (figure 1).

Fig. 1. Map of the stations. Different shades indicate different genetic regions: Fjords, NE Atlantic, Tyrrhenian Sea, Adriactic and Ionian Seas, Mljet lakes, Aegean Sea, Black Sea

To reveal barriers to dispersal within this species' distribution range (including the closely related *C. euxinus* from the Black Sea) we compared morphological (prosome and urosome length) and genetic (mitochondrial 16S rDNA gene) structuring of populations and linked these with sea surface temperature and other hydrographic features. *Calanus* populations showed high levels of genetic diversity and strong population genetic structuring with six major groupings: (1) NE Atlantic and Tyrrhenian Sea, including the subgroup (2) northern fjords, (3) Eastern Mediterranean, which contained subgroups (4) seawater lakes of Mljet island in the Adriatic Sea and (5) Aegean Sea, and (6) Black Sea. Morphological structuring is congruent with the genetic groupings within the E Mediterranean. However, groupings differed within the Atlantic, where latitude (i.e. temperature) appears to affect morphology more than gene flow. *Calanus* populations from the Mljet lakes, Aegean Sea and Black Sea are isolated at the genetic, morphological and hydrographical levels and might represent incipient species.

DIET OF THORNBACK RAY (*RAJA CLAVATA* LINNAEUS, 1758) IN SAROS BAY (THE NORTH AEGEAN SEA)

Cigdem Yigin¹* and Ali Ismen¹

¹ Çanakkale Onsekiz Mart University, Fisheries Faculty, Department of Fishing and Processing Technolog - cyigin@hotmail.com

Abstract

Food composition of thornback ray (*Raja clavata*) was studied in Saros Bay (North Aegean Sea). A total of 121 thornback ray were caught and examined. Stomach samples from 68 females (10,7-88 cm TL) and 53 males (14-76 cm TL) were examined. Of the stomachs examined, 116 (96%) were full and 5 (4%) empty. A total of 511 prey items, belonging to 6 prey taxa, were counted. Crustacea were the most important component in the diet of *R. clavata* with IRI% of 74.78. Other main prey items found in the stomachs were pisces (IRI%=18.59),nematoda (IRI%=5.98),cephalopoda (IRI%=0.08),annelida (IRI%=0.03) and mollusca (IRI%=0.01).

Keywords: Diet, Elasmobranchii, Aegean Sea

Introduction

Elasmobranch fishes are among the top predators in the marine environment and thus play an important role in marine ecosystems, potentially regulating, through predation, the size and dynamics of their prey populations [4].The aim of this study was to examine the feeding habits of thornback ray caught in Saros Bay (The North Aegean Sea).

Material and Methods

Specimens were collected by using commercial trawl between February 2005 and December 2006 in the Saros Bay. The trawling was done daytime and nighttime at depths ranging from 0 to 500 m. In the laboratory, identification of ingested prey was carried out to the level of species.Stomach content was analyzed using the percentage frequency of occurrence (F%), numerical percentage (N%), percentage by weight (W%), the index of relative importance (IRI), and percent of IRI (IRI%) for each prey type [1,2].

Results

Stomach samples from 68 females (10.7-88 cm TL) and 53 males (14-76 cm TL) were examined. Of the 121 stomachs examined, 116 (96%) were full and 5 (4%) empty. A total of 511 prey individuals was identified (Table 1), crustacea were the most important component in the diet of *R. clavata* with IRI% of 74.78. Pisces were second in importance, IRI% of 18.59. Besides nematoda, cephalopoda, annelida and mollusca with IRI% of 5.98, 0.08, 0.03 and 0.01 respectively were minor prey. As compared with IRI% values between sexes, there were not significantly difference in composition of the diet of male and female thornback rays (P = 0.801).

Discussion

The nature of the ingested food depends, first on the morphology and feeding behavior of the fish, and secondly, on the composition and amount of food available. The flat body and ventral mouth of the skates suggest a benthic feeding habit [3]. In this study, the results demonstrated that *R. clavata* feed on benthic prey items, variations in the Index of Relative Importance (IRI%) among the prey groups showed that crustaceans were the most important component in the thornback ray.

Abstract

Recent surveys along the Mediterranean coast of Turkey have documented the rapid expansion of populations of tropical alien species such as Amphisorus hemprichii, Percnon gibbesi, Aplysia dactylomela, Septifer forskali, Diadema setosum, Apogon smithii, Apogon quecketii, Nemipterus randalli and Vanderhorstia mertensi. Keywords: Eastern Mediterranean, Fishes, Mollusca, Foraminifera, Crustacea

The sublittoral macrofauna of the Mediterranean coast of Turkey was studied in May 2008 and July 2009. Eight bottom trawling sessions were performed at depth of 20-off Iskenderun and Antalya. The population increase of Apogon smithii, and Nemipterus randalli were noteworthy (Table 1). The Red Sea cardinal fish A. smithii was first recorded from Turkey during this study and seven individuals were collected in Iskenderun Bay in 2008 [1], which constituted only 0.003 % of the total biomass. A year later, its percentage increased almost hundred fold (0.29 %). Although an increase was observed also in the populations of A. quecketii, it was not significant, indicating that these Apogon spp. may have different ecological characteristics. An even more dramatic expansion was observed in the Indian Ocean threadfin bream N. randalli. In 2008, it constituted 0.01 % of the total biomass in Iskenderun Bay, whereas in 2009 it was already 1.86 %. A lesser but still prominent increase was observed in Antalya (0.02 % in 2008 vs 1.1% in 2009).

Tab. 1. Biomass percentage of the species observed in 2008 and 2009

	Iskend	derun	Ant	alya
	2008	2009	2008	2009
Apogon smithii	0,003	0,29	-	-
Apogon quecketii	0,03	0,04	-	-
Nemipterus randali	0,01	1,86	0,02	1,1

In the framework of a marine biodiversity project, 113 stations off Kas (Antalya) have been regularly monitored by SCUBA diving from June 2002 to August 2009, 15 alien species have been recorded [2-6]. The populations of the foraminiferan Amphisorus hemprichii, brachyuran crab Percnon gibbesi,, sea hare Aplysia dactylomela, bivalve Septifer forskali and the slender shrimpgoby Vanderhorstia mertensi expanded remarkably. Both population density and their occurrence increased significantly (Table 2). Amphisorus hemprichii has been first recorded in the Mediterranean from 21 stations off Kas in 2002 [5]. One year later it spread to all 113 stations, and was found off Bodrum and Datça in the Aegean Sea as well.At present, the species occurs from Antalya to Bodrum on the southwestern coast of Turkey. Five years after it was first reported in Iskenderun Bay, Septifer forskali reached Antalya Where it was recorded in four stations in 2006, 84 stations the next year and 113 stations two years later. in the populations of Percnon gibbesi, Aplysia dactylomela and Vanderhorstia mertensi expanded as well, but since these species need specific habitat types, they cannot inhabit all the sampling sites. However, the stations in which they are observed cover the entire region, indicating that these species also successfully invaded southwestern coast of Turkey. Not all alien species are invasive: two individuals of the needle-spined urchin Diadema setosum have been recorded off Kas in 2006 [3], but no other specimen was sighted since.

Tab. 2. The number of stations off Kas where alien species were observed 2002 - 2009

		Number of stations									
	2002	2003	2004	2005	2006	2007	2008	2009			
Amphisorus hemprichii	21	113	113	113	113	113	113	113			
Percnon gibbesi	0	0	0	0	2	3	5	25			
Aplysia dactylomela	0	0	0	0	0	1	3	10			
Septifer forskali	0	0	0	0	4	84	113	113			
Diadema setosum	0	0	0	0	1	0	0	0			
Vanderhorstia mertensi	0	0	0	0	0	0	1	24			

In the past decade we have witness the rapid expansion of some thermophilic alien species along the coast of Turkey. It would be of interest to management to learn whether this could be ascribed to qualities inherent to these particular species, or to changes in the receiving environment.

Abstract

Primary production and phytoplankton composition have been studied seasonally between September 2008-April 2009 at two shelf stations in the Cilician basin of NE Mediterranean. Depth integrated primary production rates varied between 0.048 and 1.6 mgC.m⁻³h⁻¹ at the two shelf stations (30 and 200 m deep). Picoplankton (0.2-2.0 mm) dominated primary production in winter, replaced by larges sized cells (>5 mm) in spring. Total chlorophyll-a concentrations decreased from a high level of 0.93 μ g/L in the nearshore to a low level of 0.02 μ g/L in offshore waters throughout the sampling period. Primary production data were consistent with total chlorophyll-a and particulate organic carbon measurements.

Keywords: Primary Production, Chlorophyll-a, Coastal Waters, Eastern Mediterranean

Introduction

The eastern Mediterranean waters are known to be ultra-oligotrophic [1], with $PO_4 < 0.02 \text{ mM}$ and $NO_3 < 0.3 \text{ mM}$ in the upper mixed layer in summerautumn, chlorophyll-a being below 0.05 mg/L in the deep basin. The daily rates of primary production varied from 38.5 to 250 mgC m⁻² d⁻¹ in the Cilician basin in 1991 and 1992 [2]. Recent daily rates calculated for the offshore and near shore waters varied in the range 6.0±3.1 and 180±176 mgC m⁻³ d⁻¹ [3]. Typical phytoplankton blooms were observed during early spring (February - March), exhibiting a pronounced subsurface maximum below the thermocline during summer [2].

Material and Methods

Two shelf stations (the shallow one: 30 m deep; the other 200m), located in the Mersin Bay of the Cilician basin (Fig. 1) were visited in September 2008, February and April 2009. To measure total and size fractioned primary production, ¹⁴C added seawater samples were incubated *in situ* during midday for about 2-3 hours. Chlorophyll-a was measured by the conventional fluorometric method; particulate organic matter (POM) by a CHN analyzer, nutrients by a multichannel auto-analyzer, ¹⁴C counts by Perkin Elmer Tricarb 2810 TR scintillation counter.

Fig. 1. Sampling stations visited in the Cilician basin

Results

In the Cilician basin, Primary Production (PP) rate was as low as 0.048 mgC.m⁻³h⁻¹ in offshore, increasing to 1.6 mgC.m⁻³h⁻¹ in near shore waters of Mersin Bay fed by river and domestic discharges. In the nutrient-depleted Cilician basin, PP was dominated by picoplankton (0.2-2.0 mm) in February and by larger cells (>5 mm) in April 2009. A highly significant correlation exists (P = 0.01 n = 48 r = 0.604) between total chlorophyll and PP rates. Total chlorophyll concentrations increased from a low level of 0.02 µg/L in the offshore to 0.9 µg/L levels in nearshore waters of the Mersin bay (Cilician basin) throughout the sampling period. POM data have also displayed similar spatial variations whereas the nitrate and phosphate were almost consumed in the upper layer due to limited inputs from external and internal sources.

Fig. 2. Total PP rates $(mgCm^{-3}h^{-1})$ measured in the Cilician basin in 2008-2009

Abstract

Present study has been carried out in 34 trawling stations in the Sea of Marmara between 1992-1995, fish stocks and distribution has been investigated using trawling gear and the effect of physico-chemical conditions monitored. The fishes have been separated from trawl material and distributions, stock size and conditions have been investigated. Hake biomass was highest whole year and its percentage in total economical demersal fish stocks was around 50-60 % annually. Cod biomass was following the hake, especially its stock size has been gradually increased by years and its percentage was around 15-20 %. *Keywords: Demersal, Fishes, Stock Assessment*

Introduction

The Sea of Marmara is the second fishing ground after Black Sea with respect to fishing in Turkey. The annual average fishing has been 87.04 % in the Black Sea, 7.58 % in the Sea of Marmara, 3.57 % in the Aegean Sea, and 1.50 % in the Mediterranean Sea [1]. The general problems of the Sea of Marmara are the intense population and industrial areas on the shores, resulting organic and inorganic pollution and the interaction of the eco-systems of two different seas. This type of pollution is an important reason for the narrowing of species distribution areas. The rapidly growing industry, the related increase in population, the distribution of port services and all discharges from the land into bays and gulfs, which are the most productive regions of sea eco-systems, are leading to an increase in pollution. Therefore, degradation can be observed in very important egg-laying areas. The situation experienced in the gulfs of Izmit, Gemlik and Bandirma is one of the best examples. In this way, new stock areas disappear every day, because of insufficient precautions, and stocks and fishing are affected negatively as a result. Detailed studies on biomasses and stocks, based on numeric data remain insufficient in regards to the sea life of the Sea of Marmara that is significantly important on fishing activities.

Materials and Method

Sampling studies have been made at a total of 32 stations in the summer and winter seasons between 1992-1995, taking into account the depth scale ratios of the Sea of Marmara. During the research, demersal fish distribution was observed in different ecological regions in the Sea of Marmara. Therefore, 4 sub-regions were specified and the stock values were calculated.

Region I comprises the Southeast part of the Sea of Marmara. The line drawn between the south exit of the Bosphorus and approximately Bozburun constitutes the border of this region. Since this region comprises gulfs and shores with heavy industrial activities, the water here is affected by industrial waste and this region constitutes the most polluted and unproductive region of the Sea of Marmara (20-110 m = 289.3 km^2).

Region II comprises mainly the northern part of the Sea of Marmara. It stretches from the south exit of the Bosphorus to Mürefte. This region is not appropriate for trawl fishing and its eastern part is subject to limitations stemming from the nature of the ground, the vessel circulation and industrial waste (20-110 m = 1056.0 km^2).

Region III comprises mainly the southern part of the Sea of Marmara. This region contains very appropriate places for trawl fishing (20-110 m = 1863.0 km²).

Region IV comprises the Southwest part of the Sea of Marmara. Although the region's surface is relatively small, it is the most productive part of the Sea of Marmara according to 1993 data (20-110 m = 1538.8 km^2).

Results and Discussion

The hake alone represents 56 % of the total catch between 1992-1994. Decreasing to catch trend to 33% in the winter of 1994 was determined while it was 81 % in the summer of 1993. In the winter of 1995, sudden increase of all fish stocks were determined again. Consequently, the proportion of the hake to the total catch increased to 48 % parallel to the increase in all other fish stocks. Generally, hake could be seen in between Büyükçekmece and Marmara Ereglisi in the northern, Erdek Gulf and the entrance of the Dardanelles in southwestern and the northwest of Imrali Island in southern Sea of Marmara.

Distribution of cod was slightly difficult to observe in the northern part. However in the summer of 1992, it has been observed a slight availability in Marmara Ereglisi. In 1995, species distribution observed in a change of its location to the east for cod stocks and in the same period main distrbituion area was recorded at the entrance of Izmit Gulf. The actual distribution area of this species is southeastern and southern Sea of Marmara where the Mediterranean current is very effective at the bottom (Dardanelles and Bay of Erdek).

Evaluation of the bimass ratio of hake and cod amongst other species, opposition of bimass values and distributinal aspects was recorded between those two species that shares nearly the same habitat. While hake biomass in total fishing amount decreased, cod biomass was detrmined in increasing trend and vice versa. Similar feeding strategies is evaluated for the most important reason of this situation. Both hake and cod are known as predators. It has been considered as an important result that distributional effects and food availability between those two species and its relation in fisheries.

STUDIES ON THE BIOLOGY OF THE VULNERABLE FISH APHANIUS FASCIATUS NARDO 1827 (CYPRINODONTIDAE) AT THE GHADIRA WETLAND IN THE MALTESE ISLANDS

Marion Zammit-mangion ¹*, Charles Gauci ² and Mark Gauci ² ¹ University of Malta, - mzam1@um.edu.mt

² Birdlife Malta

Abstract

A population of *Aphanius fasciatus* Nardo 1827 from a wetland community in the Maltese islands was sampled for four months. The sex and juveniles ratios, reproductive state and lengths were studied. The population showed an abundance of females (3:1), a relatively high investment in juveniles and sustained reproduction typical of fish species that inhabit harsh environments. In this study females were found to be slightly shorter than males.

Keywords: Fishes, Growth, Lagoons

Introduction

Over the last decade and largely in response to human pressure A. fasciatus Nardo 1827 has disappeared rapidly from the Maltese Islands, so that it is now properly recorded at just two geographically isolated sites occupying a total of 0.15km²(1). Despite the fact that locally it is classified as vulnerable there are few scientific studies on the biology of this organism. This paper provides information on A. fasciatus from one of the above sites, the Ghadira wetland in Mellieha. The site consists of land nestled between two hills and just inland of the sea at Mellieha bay. The wetland consists of a central saline pool that rapidly becomes hypersaline during the peak summer months. To the west of the pool lies a freshwater reservoir which is considerably deeper than the central pool. A total of 841 fish were sampled four times between June and October 2008 using baited minnow traps in the saline waters of the central pool and in the freshwater reservoir (over 2.5m in depth). A shallow channel maintains connection between the two in the summer months. Abiotic factors were monitored throughout this period. Identification of the adult fish was facilitated by the sexual dimorphism exhibited by males and females of the genus Aphanius. Juveniles were identified as being 27mm or under in size.

Results and Discussion

At the wetland the females were more abundant and overall a sex ratio of 3:1 was recorded. The higher ratio of females is typical of fish species that inhabit harsh environments where greater investment in reproductive capacity is necessary. Similar ratios were oberved in other studies on killifish in lagoon habitats which indicates that the Greek and Maltese habitats are exposed to similar abiotic features such as hypersalinity and high temperatures (2). Females exhibited sustained reproductive behaviour with swollen bellies typical of pregnant fish from April through to late October while temperatures remained warm and favourable. The ratio of juveniles to adults was 1:1.3 or approximately 50% of the total population which is again indicative of high investment in the generation of juveniles. Females were slightly shorter (54.4mm SD8.6mm) than males (57.6mm SD 8.9mm). The mean size of the killifish reported at the Ghadira wetland is larger than that reported in other studies on similar habitats (2) and a contributing factor is the freshwater reservoir where the mean size of fish is considerably larger (60.5mm) than in the central saline pool (42.4mm). While the population in the central pool remains vulnerable as they are exposed to extreme abiotic conditions, the freshwater reservoir offers a reserve for the adult killifish where conditions are more favourable. The conservation of this part of the reserve is therefore critical to the survival of the population.

Abstract

La palourde *Ruditapes decussatus* (bivalve, Veneridae) est la seule espèce de coquillage officiellement exploitée en milieu naturel sur les côtes tunisiennes. Néanmoins, en l'absence d'informations concernant son stock nous avons mené cette étude. L'exploitation de la palourde dans le gouvernorat de Sfax est réalisée dans des zones de production dont la délimitation est effectuée par l'administration (Direction Générale de la Santé Animale). Des campagnes de prospection, durant l'année 2004, ont permis l'échantillonnage de palourdes et nous avons calculé l'abondance et les biomasses dans chacune des six zones de production de la côte régionale de Sfax. *Keywords: Bivalves, Biomass, Population Dynamics*

Résultats et Discussion

Le volume du sédiment prélevé par échantillon correspond à une surface d'un quadra de 0,25 m² et une hauteur de sédiment de 30 cm. Deux quadras simultanés sont effectués par station. Les échantillons au nombre de 552, réalisés dans 271 stations situées sur 47 radiales le long de la côte de Sfax (Figure 1), ont été tamisés sur place sur un maillage de 2 mm de côté. Ayant recours à la méthodologie utilisée dans l'évaluation du stock des palourdes du bassin d'Arcachon [1] et des populations de bivalves dans le golfe Normandbreton [2], nous avons calculé l'abondance, en nombre d'individus et les biomasses en Kg ainsi que leurs écarts types associés (Tableau 1), de la population de *R. decussatus* dans chaque zone de production (de S1 à S6) tout en respectant la délimitation administrative.

Fig. 1. Distribution des zones de production de la palourde dans la région de Sfax

L'abondance relative de *R. decussatus* dans la région de Sfax varie d'environ 3,2 à 121 millions d'individus, avec des écarts types respectifs de 1,4 x10⁶ à 56,2 x10⁶ (Tableau 1). Les zones de production situées au nord de Sfax présentent les plus faibles valeurs et sont moins riches en palourdes. En effet, dans les deux zones S1 et S2, respectivement 13,5 % et 9,6 % des stations uniquement comprenaient des palourdes. Par contre, les zones S5 et S6, situées au sud de la région de Sfax, sont les plus densément peuplées avec respectivement 43 et 121 millions d'individus. Malgré une abondance moindre, la région S3 détient une valeur de biomasse supérieure à celle en S1. Les palourdes rencontrées dans les prélèvements en S3 sont plus âgées qu'en S1, elles ont des tailles plus grandes.

Tab. 1. Abondances(T_i), biomasses (B_i) et écarts types (ET) de la palourde dans la région de Sfax

	-				
Zone	B _l /m ²	т _і ×10 ⁷	न (T)_	Ві ×10 ⁴	ET (Bi)
	(g/m²)	(ind)	×10 ⁷	(Kg)	×10 ⁴
S1	1,9	2,4	1,2	7,2	3,8
S2	3,1	0,3	0,1	0,9	0,4
S3	28,2	1,6	0,3	9,4	2,8
S4	11,7	1,3	0,3	4,1	0,8
S5	17,7	4,3	2,1	14,1	6,6
S6	132,1	12,1	5,6	33,3	12,9
total	11,9	22,1		69,1	

Les résultats de l'étude de l'abondance et des biomasses moyennes par m² rejoignent ceux mentionnés ci-dessus, soit S6 la strate la plus peuplée et S1 la strate la plus pauvre en individus de la région ayant respectivement des densités moyennes de 48 et 0,648 individus/m² et des biomasses de 132 et 1,921 g/m². Hormis la zone de production S6 (132 g/m²), comparées à d'autres régions dans le monde, on peut considérer que les valeurs trouvées pour la biomasse et l'abondance sont relativement faibles par rapport à celles obtenues dans le bassin d'Arcachon en France (128 g/m²) [1], (0,4 individu/m², 2g/m²) [2] et en Algérie dans le lac El Mellah (atteignant 528 individus/m²) [3]. Ces mêmes auteurs remarquent également une variation importante selon les strates observées. Cette répartition est à mettre en relation avec le type de substrat et les conditions environnementales [4]. En conclusion, l'évaluation menée durant la période d'étude n'est que relative et il convient de tenir compte de la variabilité interannuelle de la distribution spatiale des gisements pour définir les modalités d'exploitation.

Abstract

Un total de 80 espèces ont été identifiées : 47 *Rhodophyta* (59%), 16 *Ochrophyta* (20%), 15 *Chlorophyta* (19%) et 2 *Magnoliophyta* (2%). Six pourcents du nombre total des espèces inventoriées sont des espèces exotiques d'origine Indo-pacifique dont une est signalée pour la première fois en Tunisie (*Acrothamnion preissii*) et 28 espèces sont nouvelles dans la région d'étude. *Keywords: Algae, Alien species, Biogeography*

Le littoral tunisien est largement ouvert à des influences variées de part sa position charnière entre les deux bassins, occidental et oriental de la Méditerranée et la morphologie de ses côtes. Cela laisse supposer la présence d'une macroflore benthique où se côtoient des groupes biogéographiques très différents. Cependant, les travaux sur la macroflore benthique de la Tunisie sont rares, ponctuels et fragmentaires dans le temps mais aussi dans l'espace [1]. Dans l'objectif de connaître la grande diversité de la macroflore benthique des côtes tunisiennes, nous avons entrepris l'étude des caractéristiques systématiques et écologiques du macrophytobenthos de la frange littorale nord-est de la Tunisie, localisée au nord du golfe de Tunis. L'étude porte sur un ensemble de trois sites, répartis le long du littoral Nord et Nord-est des côtes tunisiennes : Bizerte, Cap-Zebib et Raf-Raf, situés entre les parallèles 37°17'17'' et 37°16'57'' Nord et les méridiens 10°13'57.9'' et 10°14'10.5'' Est. Les prospections ont été réalisées selon un plan d'échantillonnage mensuel, durant une période s'étalant de juillet 2005 à juillet 2006 (inclus) et à une profondeur variant de zéro à dix mètres. L'analyse de l'ensemble des prélèvements nous a permis d'identifier au total 80 espèces comprenant 47 Rhodophyta, 16 Ochrophyta, 15 Chlorophyta et 2 Magnoliophyta.

Chlorophyta : Acetabularia acetabulum, Bryopsis duplex, Caulerpa racemosa var. turbinata-uvifera, Caulerpa racemosa var. cylindracea, Cladophora prolifera, Cladophora hutchinsiae, Codium bursa, Codium fragile, Codium vermilara, Dasycladus vermicularis, Enteromorpha linza, Flabella petiolata, Halimeda tuna, Ulva rigida, Valonia utricularis.

Ochrophyta: Cladostephus hirsutus, Colpomenia sinuosa, Cystoseira mediterranea, Cystoseira compressa, Dictyopteris membranacea, Dictyota dichotoma var. dichotoma, Dictyota dichotoma var. intricata, Dictyota linearis, Ectocarpus siliculosus var. siliculosus, Ectocarpus fasciculatus, Padina pavonica, Sargassum vulgare, Scytosiphon lomentaria, Sphacelaria rigidula, Stypocaulon scoparium, Taonia atomaria.

Rhodophyta: Acrothamnion preissii, Asparagopsis armata, Aglaothamnion caudatum, Aglaothamnion tripinnatum, Amphiroa rigida, Antithamnion heterocladum, Callithamnion corymbosum, Callithamnion tetragonum, Ceramium bertholdii, Ceramium ciliatum, Centroceras clavulatum, Ceramium diaphanum var. diaphanum, Ceramium gracillimum, Ceramium flaccidum, Ceramium secundatum, Champia parvula, Chondria coeruslescens, Compsothamnion thuyoides, Corallina elongata, Crouania attenuata, Dasya hutchinsiae, Erythrotrichia bertholdii, Erythrotrichia carnea, Erythrocladia subintegra, Fosliella farinosa, Goniotrichumm alsidii, Griffithsia opuntioides, Herposiphonia secunda f. secunda, Heterosiphonia crispella, Hypnea cervicornis, Hypnea musciformis, Hypoglossum hypoglossoides, Jania rubens, Laurencia obtusa, Laurencia papillosa, Lithophyllum incrustans, Mesophyllum lichenoides, Nitophyllum punctatum, Peyssonnelia dubyi, Peyssonnelia squamaria, Phyllophora crispa, Pleonosporium borreri, Polysyphonia sertularioides Polysiphonia opaca, Pterocladia capillacea, Rytiphlaea tinctoria, Sphaerococcus coronopifolius. Magnoliophyta: Cymodocea nodosa, Posidonia oceanica.

Sur l'ensemble des espèces inventoriées, les *Rhodophyta* constituent le groupe le mieux représenté avec 59% de l'ensemble des espèces recensées, les *Ochrophyta* et les *Chlorophyta* occupent la seconde position avec respectivement 20% et 19% du nombre total des espèces. Par ailleurs, le rapport R/P (Rhodophyceae/Phaeophyceae) [2], calculé pour l'ensemble des sites étudiés est de 2.9 et reflète un caractère d'affinité tempérée, correspondant au bassin occidental. De plus, le regroupement des espèces inventoriées en fonction de leurs affinités biogéographiques [3-4], nous a permis de constater que l'élément Atlantique est dominant avec 45%, suivi de l'élément Cosmopolite avec 34% puis de l'élément Méditerranéen avec 11%. Les espèces à affinité tropicale représentent, quant à elles, 10% et sont formées par 6% pour l'élément indo-pacifique et 4% pour l'élément pantropical. La macroflore benthique de la région étudiée est donc un mélange hétérogène, constitué par plusieurs espèces d'affinités diverses. Parmi les espèces inventoriées, cinq d'entre elles retiennent notre attention, en raison de leurs caractères exotiques et leur origine Indo-pacifique [4], soit: (1) *Caulerpa racemosa* var. *turbinata-uvifera*, (2) *Caulerpa racemosa* var. *cylindracea*, (3) *Asparagopsis* sp, (4) *Codium fragile* et (5) *Acrothannion preissii*. Ces espèces exotiques représentent tout de même 6 % du nombre total des espèces inventoriées. En outre, dans cette étude, nous signalons pour la première fois *Acrothannion preissii* sur les côtes tunisiennes. En conclusion, le nombre d'espèces inventoriées dans ce travail (80 espèces) représente 19.32% de la flore marine connue à ce jour sur le littoral tunisien et reporté par Ben Maïz [1]. 28 de ces espèces sont mentionnées pour la première fois dans le secteur d'étude et dont une est nouvelle pour la Tunisie.

A COMPARISON OF THE PRECISION OF RED MULLET (*MULLIDAE*) AGE DETERMINATION BY THE USE OF DIFFERENT BONY STRUCTURES AT THE STRAIT OF GIBRALTAR REGION

Abdelaziz Zoubi¹*, Abdeljaouad Lamrini², Abdellatif Berraho¹ and Allal Hamouda² ¹ Institut National de Recherche Halieutique - abdelaziz_zoubi@hotmail.com

² Institut Agronomique et Vétérinaire Hassan II

Abstract

The goal of this study was to determine the most reliable bony structures (scales, whole and broken otoliths) for ageing the striped red mullet at the strait of Gibraltar region. The results showed for all structures a high percentage of agreement between the young individuals age readings carried out by observations of whole and broken otoliths; the age determined for old individuals by scales and whole otoliths seemed underestimated.

Keywords: Strait Of Gibraltar, Fisheries, Population Dynamics, Growth

Introduction

The striped red mullet (*Mullus surmuletus* Linnaeus, 1758), is one of the most commercially important fish species targeted by trawl fishery at the Moroccan waters. The area of study extends from the Strait of Gibraltar to Larache region. The accumulating evidence that scales can provide unreliable estimates of age has forced fishery scientists to use other calcified structures, especially otoliths [1]. Thus, the specific objectives of this study were to determine the precision of age estimated for this species using different hard structures.

Materials and methods

The samples of data used in this study were collected in 2005 by commercial category (small, medium and big), using a stratified random sampling of monthly commercial landings of trawlers made at the fish auction of Larache.

Samples of 114 individuals, ranging in size between 12 to 28 cm, were measured by their fork length to the nearest centimetre. In the laboratory; fish scales and sagittal otoliths by length class of 1 cm were removed from each fish and were washed and stored dry [2]; for age determination, Scales, whole and broken otoliths through the focus were illuminated with reflected light and were examined under a dissecting microscope with a dark background [3].

The readings were done without knowledge of scales or otoliths reference (length). All samples of scales and otoliths were interpreted separately three times. If all the three readings are different, the material is rejected. Only complete hyaline zones were counted using Guidelines for pattern interpretation generally based upon standardized interpretation presented in the CARE Age Reading Manual [4].

Several measures were used to determine the precision (reproducibility) of ages assigned using these structures. The Percent of Agreement (the percentage of age readings that agree with the modal age which represents the age for which most readings agree), the standard deviation (sd) and the coefficient of variation (CV =100 x sd/mean) [5], were used. Age readings were analyzed with a spreadsheet developed by Guus Eltink [6].

Results

The results show that the Percent of Agreement (P.A.) decreased for all structures over age 5 and indicate that precision (CV) between readings using whole otoliths remains slightly high as assigned ages increased (Table 1). For the scales, whole and broken otoliths CV's increased with increasing fish age, indicating that readings agreement decreased as fish grew older. However, the age reading agreement for whole otoliths kept high even for older individuals.

Tab. 1. Comparison of readings P.A. and CV among ages assigned using scales, whole and sectioned otoliths for two groups of striped red mullet

Age/	Sample	Scales		Whole	otoliths	Broken otoliths		
Structure	size	PA (%)	CV	PA (%)	CV	PA (%)	CV	
Fish with age less or equal to 5 years	75	67.04	14.98	82.52	11.86	95.14	5.13	
Fish with age greater than 5 years	39	59.17	26.45	68.72	21.15	83.46	10.48	

Discussion and Conclusions

The results of the study show that the determination of age by the use of whole otoliths and scales is less precise by comparison to that estimated from broken otoliths. In general, we found that broken otholith yielded the most precise age estimates for red mullet. Whole otoliths was equally useful for ageing the species but only for individuals not old (less or equal to 5 years);

over this age, the ages determinations using both scales and whole otoliths are underestimated by comparison with broken otoliths. Studies have consistently shown higher precision in ages assigned with otoliths than with scales in walleyes [7].

THE GEAR SELECTIVITY EFFECT ON GROWTH PARAMETERS OF AXILLARY SEABREAM, PAGELLUS ACARNE (SPARIDAE) AT THE MOROCCAN WESTERN MEDITERRANEAN

Abdelaziz Zoubi ¹*, Abdeljaouad Lamrini ², Allal Hamouda ² and Yassine Zahri ¹ ¹ Institut National de Recherche Halieutique - abdelaziz_zoubi@hotmail.com

² Institut Agronomique et Vétérinaire Hassan II

Abstract

We examined the effects of gear selectivity on the estimation of growth parameters of Axillary seabeam from western Mediterranean. For longline and trawl nets, there were differences between the von Bertalanffy growth estimates derived from the two fishery's mean values of length-at-age. For longline fishery, a selectivity-related bias in the estimation of growth parameters was recorded, yielding unrealistic estimates of t₀.

Keywords: Fisheries, Fishes, Growth, Western Mediterranean

Introduction

The axillary seabeam, *Pagellus acarne* (L.) (Sparidae), is widely distributed along the continental shelf at the Atlantic and Mediterranean waters [1]. Abundant in Moroccan Mediterranean waters, this species is commercially exploited at depths between 80 and 150 meters by longliners (up to 20 % of landings in weights) using gill nets and hooks and also with trawlers by means of deep trawl net (about 80 % of landings in weights) [2].

Materials and methods

The area of study covered the sparidae fisheries located at the Strait of Gibraltar region of Morocco which extends from M'diq to Larache. The samples of data were collected in 2004 and 2005 at the fish auction of Larache by using a stratified random sampling of Axillary seabream monthly landings of travlers and longliners .

Samples of 510 individuals, ranging in size between 10 to 28 cm fork length were measured to the nearest centimeter; for age determination, 5 scales by length class of 1 cm, were removed, washed, viewed with a magnification of 50x; fish were considered to be 1 year old after the formation of the first winter ring. Fish age was determined by two different readers with no knowledge of fish length or month and gear of capture. If the two readings agreed, then the age was adopted as definitive. If the two readings differed, the scale was omitted from further analysis.

The Von Bertalanffy theoretical growth parameters and the corresponding variances were estimated separately for trawl and longline fisheries by using FISHPARM program [3]. To test for the selectivity effect on the estimation of growth parameters, we undertook a comparison of the growth parameters derived separately from data of trawl and longline fisheries and the corresponding variances. The Hotlling's T^2 test [4], was also used to compare the parameters of both fisheries.

The three theoretical Von Bertalanffy growth parameters and the corresponding variances were estimated separately by type of fishery (Table 1).

Tab.	1.	The	Von	Bertalanffy	growth	parameters	(L _∞ ,	К,	t _O)	with	the
corre	spoi	nding	varia	nces estimate	d by type	e of fishery					

V	Sample	Length	Age interval		L		к	to	
rear	size	Interval		value	variance	value	variance	value	variance
				Tra	wl fishery	10-14-2-2		11. 11. 11.	
2004	780	10 - 28	0 - 8	34,82	1,42	0,152	0,00172	-1,942	0,24
2005	809	(cm)	(year)	33,63	2,10	0,187	0,000557	-1,889	0,0529
				Long	gline fishery			10.035	Constant Section
2004	198	21 - 29	4 - 8	32,58	7,55	0,146	0,00276	-4,071	2,66
2005	205	(cm)	(year)	32,74	13,8	0,137	0,00359	-4,495	3,40

Results and Discussion

Results showed that trawlers caught fish with ages ranging between 0+ and 8 years; in contrast, longliners were targeting only bigger fish of age 4 to 8 years. Moreover, we found significant differences for all three growth parameters obtained by type of fishery (Hotlling's T² test, P <0.001). The examination of the parameters of growth obtained in table 1, shows a t₀ strongly negative; by comparison to trawl fishery, the variances associated with the estimated parameters of growth for longline fishery are rather high. Therefore, it appeared that the t₀ parameter is very sensitive to the first age groups. In fact, gear selectivity can influence estimates of growth parameters [5]. It is difficult to obtain samples representative of the population's age structure when using a single gear because of the size selectivity of most gears [6]. To allow for obtaining more reliable estimates of growth parameters of a stock, the data representing the whole range of fish length should be used [7].

MITIGATING THE IMPACTS OF COASTAL DEFENCE MEASURES

Laura Airoldi ¹* and Shimrit Perkol-Finkel ¹ ¹ University of Bologna - laura.airoldi@unibo.it

Abstract

Defense measures have a strong impact on species composition, abundance and diversity of coastal marine environments. Understanding the factors controlling these impacts is crucial for proper management of coastal areas. We show results of field studies aiming at developing means for promoting the growth of desirable species and for controlling the spread of invasive species on coastal man-made structures

Keywords: Adriatic Sea, Coastal Management, Species Introduction, Biodiversity, Coastal Engineering

Evidence for severe loss of marine habitats is increasing worldwide, stirring concern because of their recognized ecological and economical values (1). Recent estimates suggest that > 60% of native habitats may have been lost throughout history in many coastal areas of the planet (2). Losses have resulted from natural and particularly from anthropogenic factors driving marine systems through thresholds of degradation (3). Losses are ongoing at accelerating rates and overall benefits of current protection measures are low. Urbanization is one of the leading causes for habitat and species loss in coastal waters. Today 22,000 km² of European coastlines are covered by urban marine structures and further development is expected (2). Such structures are often built on sandy bottom where they generate changes in species composition, abundance and diversity. Understanding the factors controlling such changes is crucial for proper management of coastal areas. The current research aims at outlining a new approach of sustainable management of urban marine structures, by incorporating ecological knowledge of their functioning and of the appropriate scales, spatial and temporal, of management. We show results of past and ongoing experimental field work which specifically dealt with: 1) analyzing the impact of coastal artificial structures on native assemblages, 2) monitoring the spread of nuisance or invasive species on coastal artificial structures, and 3) developing means for promoting the growth of desirable species. These studies have been done along the 190 km of coastal defence and other armoured urban infrastructures along the Italian North Adriatic Sea. Results show that the proliferation of coastal defense measures causes a disruption of native soft-bottom environments and unnatural changes to the composition, abundance and diversity of native assemblages. Proliferation of coastal defense structures can also have critical impacts on regional species diversity, removing isolating barriers, favoring the spread of non-native species and increasing habitat heterogeneity (4, 5, 6). In order to provide advice about how to mitigating the impact of these measures on the environment, we tested the feasibility of promoting the growth of desirable native species on urban marine structures, using the canopy-forming alga Cystoseira barbata as model species. We documented the ongoing loss of this species in native habitats in this region in relation to severe anthropogenic disturbances, and their replacement by opportunistic species of lesser habitats complexity. We estimated natural recovery potential by in-situ monitoring of subsequent recruitment, survival and growth patterns of C. barbata juveniles, and tested the potential for urban armoured structures to provide additional suitable substrata for this species. Transplantation experiments demonstrated that Cystoseira has the potential to grow on urban structures, but its success is influenced by several factors, including wave exposure and herbivorous pressure. Urban marine structures do not function as natural habitats. Advancing our understanding of the impact of urban structures on natural habitats, and increasing our ability to control their assemblages is of prime importance in light of the continuous proliferation of these artificial habitats. Management for these artificial habitats should be specifically adapted, aimed at increasing their ability to sustain various ecological and biological applications, for example, by managing their prevailing assemblages. Finally, we suggest that instead of relying on the construction of new artificial reefs for restoration and enhancement, ecologists, engineers and decision makers should consider maximizing the ecological functioning of existing man-made structures. Abstract

Here we report the results of a field experiment designed to identifying and quantifying possible local changes in sedimentary environments and associated assemblages related to the deposition of two common but different types of detritus produced by hard bottom species (green algae and mussels) along the coast of the north Adriatic sea. *Keywords: Adriatic Sea, Detritus, Sediments, Artificial Reefs*

Coastal marine landscapes have been profoundly altered by the introduction of a variety of human-made artificial structures, such as seawalls, dykes and breakwaters, ([1], [2]). There is mounting evidence that these structures may profound change the environmental and ecological condition of the coastal ecosystem ([3], [4], [5], [6]). However, the broader ecological consequences of these man-made structures that could extend the foot print of their impact are poorly understood. These artificial structures could have important consequences for the functioning of coastal system through the spatial subsidy of detrital material that is sloughed off the artificial structure and changes productivity, nutrient cycling, detrital pathways in the adjacent softsediments. We designed an experiment to identify and quantify possible changes in sedimentary environments and associated assemblages related to the unnatural, considerable amount of detritus produced by hard bottom species associated to the urban structures. The study was carried out along the sedimentary coasts of the North Adriatic Sea (Italy). In this area >190 km of artificial structures, mainly grovnes and breakwaters, seawall and jetties, have been built along 300 km of naturally low sedimentary shores causing severe loss and alterations of shallow sedimentary habitats [3]. We first identified and quantified the type, amount and distribution of detritus produced by dominant hard-bottom species on the structures. We then carried out a field experiment to analyse the effects of detritus from different organisms (i.e. Ulva spp, vs Mytilus galloprovincialis) on surrounding sedimentary environments and associated assemblages. We predicted different effects of these two forms of detritius because of the different nature in the organic material (specific gravity and chemical content) and the provision of shell material associated with mussel deposition. Mussels and Ulva were collected from artificial breakwaters located in Lido di Dante (44°22'59"N, 12° 19'19''E). Mussels were frozen for 24 hours while Ulva stored at 4° for 24 hours to quickly obtain fresh detritus, therefore disposed into net bags (60x60 cm, mesh size 1 cm) to be used in the experimental treatments. The experiment was set up on soft bottoms at about 50 m apart from any artificial structure and at a depth of 4 m which is similar to the depth of soft-bottoms surrounding the nearby structures. Treatments included: addition of detritus from Ulva spp (500 g wwt), addition of detritus from mussels (3 kg wwt). unmanipulated controls and a procedural control (empty nets). The amount of detritus in each treatment was chosen based on previous field observations. Twelve plots were established for each treatment. Sampling was done 2 days, 7 days and after 21 days after the deposition of the detritus to follow the temporal trajectories of the effects. Each time 4 plots of each treatment were randomly selected and sampled destructively. Variables measured in each plot included: soft-bottom macrofauna, macrofauna directly associated with the detritus, total organic matter, chlorophyll a and sediment grain size. Detritus originated from *Ulva* spp. and mussels had significant and different effects on macrofauna. These effects included both changes in the composition and distribution of the macrofauna in the sediments and effects related to the colonization of detritus by rich assemblages (particularly amphipods). Strong effects were evident 2 and 7 days after the beginning of the experiment, but weakened by 21 days. This suggests very rapid breakdown and assimilation of this material into the benthic foodweb. Some of the major changes were related to few families of amphipods that showed the highest abundance in Ulva treatments after 7 days of the starting of the experiment. Our study suggests that mounds of detritus produced by organisms associated to marine artificial structure can affect the structure of native soft-bottom assemblages. This effects become particularly significant if scaled up in areas, such the North Adriatic Sea, which is highly affected by marked eutrophication processes, frequent storm events and high temperature that could enhance detritus deposition around more than 300 km of coastline protected by artificial

structures.

THE DEVELOPMENT OF A VULNERABILITY INDEX FOR BEACH EROSION, BASED ON A SEDIMENT BUDGET APPROACH

George Alexandrakis ¹*, Serafim Poulos ¹ and Adonis Velegrakis ²

¹ Department of Marine Science, University of the Aegean, University Hill, Mytilini 81100, Greece

Abstract

The present contribution presents an erosion index for the beach zones based on a conceptual sediment budget model; the latter involves the identification of littoral cells, sediment sources, throughouts and sinks of sediment. For the development of the index the aforementioned parameters are ranked in a homogeneous way and interrelated mathematically. The produced index values quantify relatively vulnerability to erosion along the beach zone.

Keywords: Coastal Processes, Erosion, Shoreline Evolution

Introduction

The difficulty to predict coastline changes is due to the range and the frequency of processes that affect coastal areas and the closely coupled links between sea-level rise and other processes driving coastal change. Over the past decade, the Coastal Vulnerability Index has been developed for the assessment of coastline changes due to a potential sea level rise. This index aims to classify the potential effects of sea-level rise on open coasts using the physical characteristics of the coastal system (for details see Gornitz and White, 1992), providing basically a rank-based vulnerability assessment and comparative classification of the various coastal stretches.

The aim of this contribution is the development of an index dedicated to the assessment of vulnerability in the case of beach zones developed in microtidal environment but experiencing significant nearshore hydrodynamics including relative sea level change.

The BVI method

Concept: The proposed beach-zone vulnerability index (BVI) is based on a numerical approach of the parameters governed the sediment budget of beach zone and its evolution. Thus, variables that form the beach vulnerability index includes: (i) long-shore sediment transport; (ii) cross-shore transport; (iii) riverine inputs; (iv) relative sea level change (tectonic and climatic); (v) wave run-up; and, (vi) aeolian sediment transport. It is worth mentioned that the calculation of the aforementioned variables incorporates the estimation of other important parameters, such as granulometry, significant wave height and the gonorphological characteristics of the beach zone, like beach slope, beach profile length

Calculation: For the calculation of each variable the simplest possible available equation has been chosen; these are presented below:

(I). Longshore sediment transport is given by Komar's (1998) equation:

 $Q_1 = 1.1\rho g^{\frac{3}{2}} H^{\frac{5}{2}}_{b} cos(a_b) sin(a_b) \quad (1)$

where, Q: potential volumetric longshore transport rate (m³/day), ρ : water density; g: the acceleration of gravity; H_b: breaking wave height, a_b: wave crest angle at breaking.

(II) Crosshore sediment transport is provided from the Bailard and Inman's (1981) equation:

$$\begin{split} Q_1 &= \rho C_D u_b^{-3} \left\{ \frac{\varepsilon_B}{tan\phi} \left(\psi_1 + \frac{2}{3} \delta_u - \frac{tan\beta}{tan\phi} u_3^{*} \right) + \frac{u_b}{w_s} \varepsilon_s \left[\psi_2 + \delta_u u_3^{*} - \frac{u_o}{w_s} \varepsilon_s u_3^{*} tan\beta \right] \right\} (2) \end{split}$$
where, $\varepsilon_{\mathbf{B}}$: 0.2; $\varepsilon_{\mathbf{S}}$: 0.025; $\mathbf{C}_{\mathbf{D}}$: dragging coefficient; \mathbf{w}_s : sediment fall velocity;

where, ϵ_B : 0.2; ϵ_S : 0.025; C_D : dragging coefficient; w_s : sediment fall velocity; φ : the angle of repose; β : the beach slope; u_b :near bed water velocity; ρ : water density; and, ρ_s : density of sediment. $\delta_u, \psi_1, \psi_2, \psi_1, u_3^*$ and u_5^* cross-shore velocities depending from the significant wave height (Bailard ,1982).

(III) In the case of data absence, riverine sediment inputs maybe calculated with the use of Hovious' (1998) equation:

 $lnE = -0.416lnA + 4.26 \cdot 10^{-4}H + 0.15T + 0.095T_R + 0.0015R + 3.58$ (3) Where, E: sediment weight gr/m²; H: maximum elevation of the drainage basin;

T: mean temperature; T_R : temperature range; and, R: river run off. (IV) The effect of relative sea level rise variable is calculated from Bruun's

(1962) semi-empirical relationship: $R = s \left(\frac{L}{B + h_c} \right)$ (4)

where, S: relative mean sea level rise, in cm; L: profile length; B: berm height; and, $h_{c}{:}closure\ depth.$

(V) The wave run-up R is given from CERC (1984) in the case of: $P_{1} = 0.2911 \text{ f} \cdot \frac{9.17}{2} \text{ c} \cdot$

breaking waves, $R = 2.32 H_o \xi_o^{0.17}$ (5a) and, non-breaking waves, $R = H_o \sqrt{2\pi} \left(\frac{\pi}{2B}\right)^{\frac{1}{4}}$ (5b) where, Ho: offshore significant wave height; B: Berm height, and $\boldsymbol{\xi}\!\!:$ the Irribaren number.

(VI) The aeolian transport variable is provided by Hsu (1986) equation:

$$q = V_a P_a \left(e^{-0.63 + 0.91D} \right) \sqrt{\frac{U_x}{gD}}$$
 (6)

where, q: sand transport rate, in gm/cm/s; u^* : shear velocity; g: acceleration of gravity; D: mean sand grain diameter; Va: air kinematic viscosity; and, Pa: air mass density.

The index is applied in a beach zone that is divided alongshore into a grid at distances according to the required accuracy. Subsequently, the required data set is obtained either by the use of numerical models (eg. wave heights, breaking height and angle) or by data that are collected by field measurements. **Ranking index variables:** It is based on the assumption that the potential maximum value reflects 100% of the variable; this maximum value will be calculated obviously by applying the maximum values for the parameters that are included in the corresponding equations. Numerical values of variables will be also transformed into percentages ranging between 0.00 and 1.00, while those variables that are associated with addition and/or removal of sediment from the beach zone (e.g. cross-shore sediment transport will be signed as either negative or positive.

Output: The index will be calculated as the geometric mean value of the six (6) variables for each grid cell of the beach zone. This will highlight not only the most vulnerable parts of the beach zone to erosion, but also the principal variable being responsible for the highest vulnerability; thus, the physical process(es) mostly responsible for the erosion could be identified.

THREE-DIMENSIONAL MATHEMATICAL MODEL TO SIMULATE GROUNDWATER FLOW AND MASS TRANSPORT IN COASTAL AQUIFER SYSTEM OF ANNABA, EASTERN ALGERIA

Badra Aoun Sebaiti ¹*, Erick Carlier ¹ and Azzedine Hani ¹ ¹ Ecole Universitaire Polytechnique de Lille - aounsebaiti-badra@hotmail.com

Abstract

On the coastline of the Seybouse low plain, the gravel aquifer is characterised by a high conductivity. In order to determine the origin of this salinity, a monthly monitoring of the groundwater chemistry was conducted between February and December 2006. The collected basic data were used for the preparation of a groundwater flow and mass transport model for the quantitative assessment of impact of human influence on contaminant dispersal in the watershed. *Keywords: Algerian Basin, Models, Pollution, Salinity*

The potentiometric surface in the Seybouse basin, which covers an area of 264 $\rm km^2$, has declined significantly since 1978. Earlier studies in this area (1-3) have shown that i) groundwater is used intensively near the coast; ii) the decrease of water levels creates piezometric depressions and the extension of zero level towards the south (Fig. 1); iii) the dip of the gravel strata is mainly towards the sea; and iv) the steady decrease of hydrochemical features from the sea to the continent on about 15 km (Fig. 2).

Fig. 1. Variation of piezometric levels between 1978 and 2006

Fig. 2. Variations of hydrochemical features. Graphs for chlorides, sodium, Strontium and EC from the sea to Dréan, in southern sector

A transient multilayer model has been developed to synthesise the hydrologic data and study the regional changes in aquifer interactions caused by changes in discharge. The model consists of two layers, the first corresponding to the alluvial phreatic aquifer and the second to the deep confined aquifer, and it is calibrated against the steady state groundwater heads recorded before 1983. Model verification was done by history matching over the period 1978-1996. Under steady-state conditions, the correspondence between simulated and observed water levels is generally good (average difference of 0.4 m). For the deep aquifer, the simulated time-series hydrographs closely match the recorded hydrographs for most of the observation wells. For the alluvial aquifer, the recorded hydrographs cover only a short time period, but they are reproduced. The model indicates that groundwater pumping induced a decrease in natural discharge, a downward leakage in most of the basin and a continual water-level decline. The model has also been applied to the analysis of recharge impact. Simulating the behaviour of the system over the period 1978-1996 without pumping indicated small changes in hydraulic head. These results show that the groundwater reservoir has a low recharge, but excellent hydraulic properties; a solute-transport model was used to study aquifer contamination from salty intrusion in coastal sectors; it was extended to the year 2010 by simulating an optimistic hypothesis that maintains present pumping until 2010. The model indicates that the head decrease of the alluvial phreatic and deep confined aquifers will be 4 m and 5 m respectively. The simulated piezometric

distribution illustrates the vulnerability of the aquifer in coastal sectors where flows with an important concentration of chloride may be observed, especially towards the Salines wells field. The solute concentration in the deep confined aquifer will increase from 1 g.L (prior 1996) to 5 g.L in 2010 m.

SPATIO-TEMPORAL CHANGES IN STRUCTURE AND FUNCTION OF THE COASTAL ECOSYSTEM IN THE NE BLACK SEA

E. Arashkevich ¹*, V. Chasovnikov ¹, V. Kremenetskiy ¹, S. Mosharov ¹, A. Nikishina ¹, L. Pautova ¹ and K. Soloviov ¹ ¹ Shirshov Institute of Oceanology, Russian Academy of sciences - aelena@ocean.ru

Abstract

We present hydrophysical, chemical and biological data obtained in the different seasons in the coastal zone of the NE Black Sea in 2007-2009. Spatial changes in chemical parameters (nutrients, DO, H2S) as well as in primary production, Chl a, POC, phyto- and zooplankton distributions are discussed in relation to hydrophysical conditions and the influence of coastal run-off. Seasonal peculiarities of ecosystem structure and function are described. *Keywords: Black Sea, Coastal Systems*

Introduction

The pelagic ecosystem of the coastal area is characterized by a high spatiotemporal variability caused by the complicated physical, chemical, and biological processes running in this region [1]. To a great extent, this variability is related to the presence of fronts, eddies, filaments, etc, which control the intensity and directions of the along- and cross-shelf transport [2], [3]. Meanwhile, the hydrophysical processes occurring near the shore and over the continental slope cause a great diversity of scenarios, which switch depending on wind forcing and the regional climatic changes on both temporal and spatial scales [4], [5]. This study was performed in frame of EU project SESAME and aimed to investigate the coastal ecosystem function and crossshelf exchange in the NE Black Sea.

Material and methods

In 2007-2009, monitoring of seasonal variations in physical, chemical, and biological parameters was performed in the coastal region off Caucasian coast. Data were collected along a transect from the shore to deep basin in three seasons, spring, summer, and autumn. CTD-profiling (by SBE 19plus probe) along with chemical (nutrients, DO, H2S) and biological (primary production, Chl a, POC, phyto- and zooplankton) sampling were done at three key stations located over the inner-shelf (25 m isobaths), middle-shelf (55 m isobaths) and continental slope (1000 m isobaths). Horizons for hydrochemical and biological sampling were chosen according to *in situ* CTD-profiles.

Results and discussion

The high amplitude of seasonal variations in the surface temperature (up to 19°C) caused the drastic changes in the structure of pelagic ecosystem. In winter/spring, the seasonal maximum of nutrients as well as Chl-a and primary production (PP) was observed in the upper 10-m layer. After the thermocline formation, the depletion of nutrients in the upper layer led to decrease in Chla concentration and PP. Species composition of phytoplankton showed significant seasonal changes with predominance of dinoflagellates in spring, coccolitophorids in summer, and diatoms in autumn but this pattern could vary from year to year. There was a slight tendency to the decrease of nutrients and phytoplankton concentration in the inshore-offshore direction, however the difference was insignificant. This finding suggests an intensive cross-shelf exchange in the study area. PP varied from 210±60 mg C/m² day in spring to 175±30 mg C/m² day in autumn. Two peaks of zooplankton abundance were observed in spring and autumn at all locations but their intensity differed in the different years. No obvious relationship between phytoplankton concentration and zooplankton biomass were found. The effect of gelatinous top-predators (medusas and ctenophores) on the total zooplankton biomass was insignificant at short-time, monthly, and interannual scales (ANOVA, F=2.34, p=0.1). The surface-dwelling zooplankton populations showed more prominent response to both hydrophysical changes and biological (food and predations) factors.

ETUDE COMPARATIVE DU RYTHME DE L'ACTIVITE LOCOMOTRICE DE *TALITRUS SALTATOR* ISSU DE DEUX PLAGES TUNISIENNES: BIZERTE ET GOLFE DE GABÈS

Amel Ayari 1* and Karima Nasri-Ammar 1

¹ Faculté des Sciences de Tunis, 2092, Tunisie - ayariamel@gmail.com

Abstract

L'amphipode supralittoral, *Talitrus saltator*, considéré comme bioindicateur de la stabilité des plages sableuses, a fait l'objet de plusieurs recherches concernant l'étude du rythme locomoteur. Notre étude a pour objectif de caractériser le rythme de l'activité locomotrice de ce talitridé au niveau de deux plages géomorphologiquement différentes. L'étude du rythme de l'activité locomotrice des animaux expérimentés a révélé plusieurs différences statistiquement significatives. Par ailleurs, les différences observées sont expliquées comme stratégie adaptative aux changements environnementaux. *Keywords: Crustacea, Gulf Of Gabes*

Introduction

L'activité locomotrice présente une dépendance directe aux fluctuations des facteurs environnementaux qui sont considérés comme des synchroniseurs ou "Zeitgeber" [1]. En effet, le rythme circadien est entrainé par l'alternance jour/nuit [2] et le rythme circatidal est synchronisé par le flux et le reflux des marrées. Le but de ce travail est de comparer les caractéristiques du rythme endogène de *Talitrus saltator* au niveau de deux plages géomorphologiquement différentes.

Matériel et Méthodes

Un total de 30 individus ont été collecté, durant la saison automnale, aussi bien au niveau de la plage de Bizerte (37°19'N-9°51'E) qu'au niveau de la plage du golfe du Gabès (N 33° 52' 34,0''; E 10° 07' 38,8"), cette dernière présente une amplitude des marées considérée comme la plus importante dans le bassin méditerranéen (jusqu'à 2,2 m). L'activité locomotrice a été enregistrée en plaçant, individuellement, les spécimens dans des boites d'enregistrement ou actographes. Ces derniers sont placés dans une enceinte climatique qui permet de contrôler aussi bien la température que la photopériode. Les individus de *Talitrus saltator* ont été maintenus sous une température constante de 18 \pm 0.5°C. Ces spécimens ont été d'abord, soumis à la photopériode naturelle (LD) du jour de la collecte puis ils ont été maintenus en libre cours (obscurité continue : DD).

Résultats et discussion

L'activité locomotrice des spécimens de Talitrus saltator, testés dans cette expérience, a révélé un rythme circadien proche de 24h avec une composante circatidale d'environ 12h (Tableau 1). L'étude de la rythmicité des individus a montré qu'au niveau des deux plages de Bizerte et du Gabès, la rythmicité circadienne est la plus prononcée quel que soit le régime photopériodique imposé (LD ou DD) ; la rythmicité circatidale est plus marquée au niveau de la plage du golfe du Gabès (Figure1). L'analyse des actogrammes en double plot, ainsi que les courbes d'activité locomotrice moyenne par heure et par jour, ont permis de mettre en évidence trois types de profils : unimodal, bimodal et plurimodal. Le rythme locomoteur des individus issus de la plage de Bizerte décrit un profil bimodal qui est le plus observé sous alternance lumière/obscurité. Par contre, en obscurité continue, le profil plurimodal est le plus dominant. Les individus collectés au niveau du golfe de Gabès présentent une activité locomotrice de type plurimodale quel que soit le régime photopériodique imposé. L'étude des caractéristiques du rythme de l'activité locomotrice (période circadienne, période circatidale, temps d'activité et déphasage Af) a montré qu'en obscurité continue, la population de Talitrus saltator, provenant de la plage de Bizerte, présente un allongement d'une heure de la période circadienne ; alors que, la période circadienne obtenue chez les individus issus de la plage du golfe de Gabès reste inchangée sous les deux régimes photopériodiques [LD] et [DD]. Une différence hautement significative a été révélée entre les périodes circadiennes des deux populations (Tableau1). De plus, l'analyse statistique par le test Wilcoxon a révélé des différences significatives entre les périodes circatidales des deux populations, quel que soit le régime photopériodique imposé (Tableau1). L'analyse des temps d'activités n'a révélé aucune différence significative (Tableau1). Enfin, la majorité des individus de la population du Gabès présente un retard de phase alors qu'une avance de phase est observée pour Talitrus salator collectée au niveau de la plage de Bizerte. La différence entre les déphasages moyens des deux populations est hautement significative (Tableau1).

CHANGES IN THE MACROALGAL ASSEMBLAGE OF THE UPPERMOST INFRALITTORAL FRINGE FOLLOWING A POINT OIL SPILL IN THE GRAND HARBOUR, MALTA

Marthese Azzopardi^{1*} and Patrick J. Schembri¹

¹ Department of Biology, University of Malta, Msida MSD2080, Malta - marthese.azzopardi@um.edu.mt

Abstract

The uppermost infralittoral rocky shore macrophyte assemblage at Rinella Creek in the Grand Harbour, Malta was sampled in June 2002. Two days later, approximately 3.5 tonnes of oil were accidentally released at this site and the oil on the shore was cleaned up with steam. The site was visited 16 times over a period of 14 months to record the recolonisation process. Multivariate community analysis showed that the community had recovered within a year from the incident.

Keywords: Algae, Petroleum, Pollution, Rocky Shores

Introduction

On 24 June 2002, ~3.5 tonnes of oil were accidentally released from a discharge pipe on the shore by the Tank Cleaning Facility at Rinella Creek, within the Grand Harbour, Malta, resulting in an oil slick that extended from the point of discharge to approximately mid-way across the creek. The spill was contained by booms and the oil was removed within three days. Serendipitously, the shore at the spill site had been sampled two days prior to the spill, as part of another project. When the site was re-visited two days post-spill, the rocky shore was being cleaned of oil using steam. Drastic changes in the shore community as compared to conditions pre-spill were immediately evident, including bleaching of the dark band of supralittoral cyanobacteria, discoloration of mediolittoral macroalgae, and mass mortality of the mediolittoral fauna.

Methods

Five replicate 0.5 m x 0.5 m quadrats were placed at random in each of the supralittoral, upper and lower mediolittoral and uppermost infralittoral zones at Rinella Creek and the percentage cover of each species of macroalga was recorded. The site was visited 16 times over a period of 14 months to record the recolonisation process, however, no data were collected on two occasions due to bad weather. The quadrats were placed at exactly the same position during each sampling visit. The results presented here are for the macroalgae of uppermost infralittoral fringe (sea-level to 50 cm water depth).

Results & Discussion

Throughout the study period, 17 macroalgal taxa were recorded from the infralittoral fringe, comprising 5 Chlorophyta, 4 Phaeophyta and 8 Rhodophyta. Of these, 7 were perennials and 10 annuals. Eight species were filamentous, 6 were erect and 3 were encrusting. The lowest number of species recorded was 3, on the second visit and the highest was 11, a year after the spill. Prior to the spill, the macroalgal assemblage comprised 9 species, of which Corallina elongata and Cystoseira compressa were dominant in terms of percentage cover (87% and 16%, respectively); encrusting algae (two species of Lithothamnion and Neogoniolithon notarisii) had a 6.6% cover and all remaining species < 2%. Post-spill, the encrusting algae were not recorded from the study area in 57% of the visits, however, in the last visit (August 2003) they had not only reappeared, but had a percentage cover of 8.6% which was more than the pre-spill value. During the second (July 2002) and third (August 2002) post-spill visits, Cladophora sericea had 100% cover, but this value decreased until it was not recorded from the sixth visit (September 2002) onwards. In the last visit, two species, Dictyota sp. and Gigartina acicularis, that had not been present pre-spill or in subsequent sampling sessions, were recorded with a cover of <1%. In the last sampling session (August, 2003) 11 macroalgae were present of which, Corallina elongata and encrusting algae had the highest percentage cover: 59% and 8.6%, respectively. All macroalgae had a heavy epiphytic cover of diatoms, mainly Coscinodiscus spp., and Ceramium gracillimum. Although Corallina elongata was the only species present throughout the entire study period, its percentage cover varied and ranged from a minimum of 34.2% in August 2002 to 100% in May 2003. Also, bleaching of C. elongata was observed during August and September. NMDS ordination (Fig. 1) showed a clear cyclical pattern, indicative of macroalgal community recovery after one year from the incident, a result confirmed by the RELATE procedure for cyclicity in PRIMER version 6 [1] (Rho = 0.448, P = 0.1%). The Shannon-Wiener index H' (Fig. 2) calculated for each sampling visit decreased by the second visit (first post-spill visit) but a year later, it was restored to its original value.

Fig. 2. Mean value and 95% confidence intervals of Shannon-Wiener index for each sampling visit at Rinella Creek.

ASSESSMENT OF THE ECOLOGICAL STATUS OF MALTESE COASTAL WATERS USING THE RHODOPHYTA/PHAEOPHYTA MEAN RATIO INDEX (R/P RT. I.)

Marthese Azzopardi 1* and Patrick J. Schembri 1

¹ Department of Biology, University of Malta, Msida MSD2080, Malta - marthese.azzopardi@um.edu.mt

Abstract

Macroalgae from seven sites along the rocky upper infralittoral of Malta and Gozo were sampled in the spring, summer and winter seasons of 2003 and 2004. The aim was to apply the Rhodophyta/Phaeophyta mean ratio index (R/P rt. I.), a biological index which makes use of macroalgae, to discriminate between the sites, which are subject to different degrees of anthropogenic stress and which were therefore expected to have a different ecological status as defined by the EU's Water Framework Directive. The R/P rt. I. generally discriminated between sites, however, two sites gave anomalous results. *Keywords: Algae, Coastal Waters, Rocky Shores*

Introduction

Benthic macroalgae are a reliable indicator of the trophic status of coastal waters and are one of the Biological Quality Elements for the evaluation of ecological quality required by the European Union's Water Framework Directive (WFD, 2000/60/EE). The aim of the present study was to apply the Rhodophyta/Phaeophyta mean ratio index (R/P rt. I.) [1], a biological index which makes use of macroalgae for the implementation of the WFD, to discriminate between seven sites in Malta, which are subject to different degrees of anthropogenic stress and which were therefore expected to have a different ecological status. Site locations included the Malta Freeport (a large transhipment centre), the Grand Harbour (considered highly eutrophic), and a reference site in Gozo.

Methods

Seven shores around Malta were selected to have the same substratum type and comparable slopes but different degrees of anthropogenic impact. Site selection was based on the results of a long-term monitoring programme of local inshore waters based on measurement of levels of nutrients, chlorophyll a and water transparency as indicators of environmental quality [2]. Five replicate 0.5 m x 0.5 m quadrats were placed at random in the upper infralittoral fringe (the zone from 0-50 cm depth) at each site and the percentage cover of each species of macroalga present was recorded three times a year in 2003 and 2004. For each site, the R/P rt. I. was worked out in three different ways, (i) for each season separately in 2003 and 2004, (ii) combining the annual seasonal data so as to produce a single value for each year, and (iii) over the whole two-year period. The results were analysed using non-metric multidimensional scaling (nMDS) and cluster analysis based on the Bray-Curtis similarity measure, and Principal Components Analysis (PCA). Computations were made using the PRIMER (ver 6) suite of programs [3].

Results & Discussion

PCA ordination based on environmental variables (Fig. 1) clearly distinguished the sites with PC1 and PC2 collectively explained 77.3% of the variation; PC1 appeared related to chlorophyll a content and BAC, and PC2 to dissolved phosphate. The sites could therefore be arranged in a series with Qbajjar as the reference site and, in order of deteriorating water quality, St. Paul's Bay, Marsascala-J, St. Angelo, Manoel Island, Birzebbuga and Marsascala-W. In total, 86 taxa were recorded, comprising 19 Chlorophyta, 24 Phaeophyta, 42 Rhodophyta and 1 Heterokontophyta. For each site, the same ecological status was obtained in 2004 as in 2003 when considering the respective annual macroalgal datasets. A cluster analysis and nMDS ordination were made on the percentage cover of Rhodophyta and Phaeophyta over the two-year period (Fig. 2). Three clusters resulted: (1) Qbajjar, St. Paul's Bay and Manoel Island with 'high' ecological status, (2) Marsascala-J and -W with 'low' status, and (3) St. Angelo and Birzebbuga with a 'bad' status. The St. Angelo site gave a consistently 'bad' status in all seasons during both years, due to a lack of Phaeophyta at this site. The same site groupings were obtained when calculating the R/P rt. I. Generally, the R/P rt. I. varied with season, for example, the ecological status for St. Paul's Bay was 'moderate' in spring 2003, 'bad' in summer and 'high' in winter. It may be concluded that the R/P rt. I. discriminated between sites, however, Marsascala-J and -W gave anomolous results since a 'moderate' ecological status was expected from the physico-chemical analysis and based on expert judgment; these sites had a high percentage cover of Chlorophyta, which distorted the index.

Fig. 1. PCA ordination of the sites based on mean values of salinity, temperature, dissolved nitrate, dissolved phosphate, Beam Attenuation Coefficient (BAC) and chlorophyll *a* content, recorded between 1998 and 2003 as given in [2]. (Q – Qbajjar; P – St. Paul's Bay; J – Marsascala-J; B – Birzebbuga; A – St. Angelo; M – Manoel Island; W – Marsascala-W).

Fig. 2. Hierarchical group-average linkage clustering plots for the percent cover of Rhodophyta and Phaeophyta.(Site codes are as in Fig. 1)

Abstract

La région centre de la côte de l'Algérie a été exposée à plusieurs phénomènes naturels désastreux : séisme, sécheresse et inondation. Ces phénomènes ont des effets sur le trait de la côte ; dans certaines régions, il a avancé par contre, dans d'autre il a rétréci. En premier lieu nous avons tracé le trait de côte à différentes dates sur la base d'images satellites. Deux régions d'étude ont été analysées sur site.

Keywords: Coastal Waters, Deep Waters, Erosion, Sediment Transport

Introduction

La problématique posée est l'étude du recul et l'avancement de trait de côte dans la région Algéroise. Notre étude a porté sur la baie d'Alger et celle d'El Djamila, car dans ces deux baies, l'érosion et l'accrétion des plages ont pris de l'ampleur ces dernières années, surtout au niveau de l'érosion côtière. Ce phénomène devient une préoccupation environnementale majeure qui touche toute la façade centre de la côte algérienne. Pour cette étude, nous avons choisi des plages qui sont cibles de ces deux phénomènes.

Matériel et méthodes

Trait de côte. Pour réaliser les traits de côte nous avons utilisé des images hautes résolutions SPOT PANCHROMATIQUE pour les années 1988 et 1997. Nous avons transformé les images directement en trait de côte à partir d'un ensemble d'applications séquentielles effectuées sur la base de la morphologie mathématique. D'autre part des images du GOOGLE EARTH PRO sont utilisées. Pour cette partie, nous avons assemblé des images captées par écran en utilisant le logiciel Corel Draw. Pour réaliser cette opération nous avons utilisé environ 120 photos. L'ensemble des images est mis en table par le SIG MAPINFO9. Nous avons tracé le trait de côte par numérisation. Les trois traits de côte sont géolocalisés par rapport à des points fixes. L'analyse diachronique du trait de côte nous a permis de connaître l'état de changement et localiser les zones de grand intérêt [1], [2].

Cartes lithologiques, cartes des pentes et cartes des longueurs d'ondes de la houle. A partir des cartes géologiques nous avons réalisé des cartes de lithologie côtière. Grâce aux cartes topographiques, nous avons déterminé la distance entre le trait de côte et l'isobathe 10 m, cette distance est horizontale et perpendiculaire au trait de côte, la pente de chaque carreau a été calculée (chaque 250 m). On peut calculer la longueur d'onde des vagues sur une distance de 50 m à partir du trait de côte.

Commentaires des cartes. La carte lithologique montre l'existence de deux formes de lithologie côtière : des sables et galets qui sont des roches sédimentaires meubles, facilement transportables par les courants et les vagues. Ces sables forment la plage Est et la plage Ouest de Sidi Fredj. A l'arrière de ces plages on trouve des dunes actuelles, ces ensembles sont alimentés par l'Oued Béni-Messous et celui du Mazafran. L'isobathe des 10 m est très proche du trait de côte, en revanche, au niveau de la plage Est et de la plage Ouest cet isobathe s'éloigne du rivage. Ceci explique l'existence des fortes pentes face à la presqu'île de Sidi Fredj (des valeurs supérieures à 4 % sont enregistrées au carreau 23). Les faibles valeurs sont enregistrées au niveau des deux plages. Les zones de fortes pentes se caractérisent par des houles avec des longueurs d'ondes très élevées, elles subissent donc une houle de forte énergie, au contraire des zones à faibles pentes (plages) qui sont face à une houle d'énergie moins importante à cause de l'amortissement de l'énergie de la houle par le fond. La dureté du gneiss lui permet de résister à l'érosion causée par l'hydrodynamisme marin, par contre les sables des plages s'érodent facilement [3]. La plage Ouest est caractérisée par un degré d'érosion très élevé car elle est exposée à des houles, plus importantes et les plus violentes en période hivernale, qui viennent de l'Ouest et du Nord-ouest, contrairement à la plage Est qui est à l'abri des houles violentes et exposée à des houles de direction nord-est.

Accrétion côtière. Le site choisi dans cette étude, est une plage qui fait partie de la baie d'Alger et plus précisément se trouve dans la localité de Rais Hammidou du côté ouest de la baie. Nous avons pris des photos du transport sédimentaire ainsi que les mouvements des apports terrigènes véhiculés par les houles aboutissant à la formation des dépôts sédimentaires, généralement du sable varié - cette plage est sous la forme d'une baie semi-fermée qui piège le sédiment transporté par les vagues et les houles-. L'organisation des structures sédimentaires, d'autant plus variées que les forces en jeu sont diverses et

changeantes [4]. De ce fait les structures sédimentaires les plus nombreuses et diversifiées s'observent sur les marges de la plage, où les influences climatiques, hydrologiques, biologiques, sont les plus actives et variables. La plage Ouest est caractérisée par un degré d'érosion très élevé car elle est exposée à des houles, les plus importantes et les plus violentes en période hivernale, qui viennent de l'ouest et du nord-ouest, contrairement à la plage Est qui, à l'abri des houles violentes et exposée à des houles de direction nordest, n'est pas soumise à l'érosion marine.

Conclusion

Pratiquement, les zones côtières sont confrontées à des problèmes d'érosion et d'accrétion côtière. Ces problèmes pourraient s'accroître dans le futur en raison du changement climatique. Grâce à la télédétection spatiale, la détection des zones confrontées à ce problème peut s'effectuer rapidement. Les sorties sur terrain permettent une modélisation sous SIG et développer une analyse future. Cela permet une meilleure gestion du littoral et une protection durable du trait de côte.

DONNEES ECOLOGIQUES SUR LA NOUVELLE ESPECE *POMATIAS ELEGANS* (GASTEROPODE, PROSOBRANCHE, *POMATIIDAE* MULLER, 1774) TROUVEE AU NORD DE LA TUNISIE

Monia Ben Romdhane ¹*, Chahrazed El Hedfi ¹ and Mohamed Ben Salem ¹ ¹ Faculté des Sciences de Tunis, 2092, Tunisie - romdhanmonia@yahoo.fr

Abstract

Les variations mensuelles de la structure de la population de *Pomatias elegans* révèlent une dominance des femelles par rapport aux mâles ($X^2 = 5.36$). Les individus immatures présentent deux pics très nets au printemps et en automne, le premier pic est le plus élevé. L'espèce est rare en hiver et en été, mais elle est présente en automne et au printemps. Le sex-ratio global est biaisé en faveur des femelles.

Keywords: Mollusca, Reproduction

Introduction

Les Prosobranches terrestres n'ont fait l'objet d'aucune étude en Tunisie, et s'avèrent par conséquent extrêmement mal connus [1], [2]. La signalisation d'une nouvelle espèce au nord du pays améliore nos connaissances et augmente le nombre d'espèces de prosobranches terrestres tunisiens [3]. La répartition de *Pomatia elegans* est plus étendue en Europe (en Espagne [4], en France [5], en Italie [6] ainsi qu'en Turquie [7]). En Afrique, elle a été récemment signalée, seulement en Tunisie. Ce travail apporte des données à la connaissance de l'écologie et de la biologie de cette espèce.

Matériel et méthodes

Le site d'étude est situé au nord-est de la Tunisie (Raf-Raf : 37°11' ; 10°11'), les escargots sont prélevés à la main de leur milieu naturel. Pour chaque sortie, on compte le nombre de femelles, de mâles ainsi que celui des immatures ; puis on les place dans des récipients numérotés et étiquetés. Au total, l'effectif des individus collectés est égal à 203 spécimens. A ces individus nous avons appliqué le test Chi $2(\chi^2 = \sum_{i=1} x (a_1 - a_i)^{2/} a_i$ au seuil 5%), l'abondance relative AR (AR% = ni x 100/ N) et la fréquence d'occurrence F (F = n x 100/N).

Résultats et discussion

La structure de la population de Pomatias elegans

L'effectif total est de 203 spécimens dont 23.64 % mâles, 34.48 % femelles et 41.87 % indifférenciés. Faible en hiver (17 individus), le nombre s'élève à 109 individus au printemps avec un maximum en mai (41 individus). Pendant la période estivale, nous avons collecté uniquement 12 individus, alors qu'en automne, l'effectif augmente à 64 dont 28 sont des indifférenciés. Les variations mensuelles montrent une dominance des femelles par rapport aux mâles (70 femelles par rapport à 48 mâles). Cette dominance est nette dès le mois de février et durant le printemps. Les immatures présentent deux pics très nets au printemps et en automne, le premier pic est le plus élevé (Fig. 1).

L'abondance relative et la fréquence d'occurrence

L'abondance relative de la population de *Pomatias elegans* est faible en hiver ainsi qu'en été, à l'exception du mois d'août (0 individu). Les valeurs de l'abondance relative sont inférieures à 5 %, l'espèce est donc rare. En revanche, l'abondance relative augmente régulièrement pendant les mois du printemps (20,2 % en mai), mais elle reste toujours inférieure à 30 %. *Pomatias elgans* est considérée comme une espèce présente pendant les saisons printanière et automnale. La valeur de la fréquence d'occurrence est égale à 91,66 %, l'espèce est commune.

Le sexe- ratio

La valeur calculée de X^2 global (5.36) est supérieure à la valeur de X^2 théorique, l'écart entre les proportions des mâles et des femelles est significatif. Pendant l'hiver et l'été, le sex-ratio est biaisé en faveur des femelles, par contre, il est respecté au printemps et en automne.

Abstract

The diatom genus *Pseudo-nitzschia* includes several species capable of producing the neurotoxin domoic acid, the causative agent of Amnesic Shellfish Poisoning (ASP). The scope of this study was to identify species present in the Bay of Kotor, SE Adriatic Sea from the samples collected during the 2008/2009 survey. TEM examination revealed presence of four morphotypes: P. *pseudodelicatissima*, P. cf. *pseudodelicatissima*, P. *calliantha* and P. *subfraudulenta*. *Keywords: Diatoms, Adriatic Sea, Phytoplankton*

Introduction

Marine planktonic pennate diatoms of the genus *Pseudo-nitzschia* are widespread and abundant in coastal and oceanic waters all over the world. The genus has received much attention following the discovery that some species are capable of producing the neurotoxin domoic acid, the causative agent of Amnesic Shellfish Poisoning (ASP). There are a few reports about occurrence and ecology of these diatom species from the southern Adriatic coastal waters [1] but none from the Bay of Kotor, a deeply indented bay located in the south eastern coast. This paper represents the first detailed report on findings of Pseudo-nitzschia species in this area.

Material and methods

Sampling was carried out seasonally in 2008/2009 at three stations in the innermost part of the Bay of Kotor. Water samples were collected with Niskin bottles and sub-samples for phytoplankton analysis preserved with neutralized formaldehyde at a final concentration of 1.4%. Phytoplankton composition was identified and enumerated according to Ütermohl. Transmission electron microscope (TEM) observations were made by deposition of acid cleaned material onto firmware metal grids and examination with a Zeiss EM10A microscope.

Results and discussion

The Pseudo-nitzschia species found in the Kotor Bay were identified with light microscopy as members of the P. delicatissima and P. seriata group, based on their valve width $(1.5 - 2.8 \,\mu\text{m} \text{ and } 4.3 - 6.7 \,\mu\text{m}, \text{ respectively})$. The cell ends in girdle view were pointed and elongated in the former morphotype therefore it was identified as P. pseudodelicatissima species complex. The latter was designated as P. subfraudulenta species from the P. fraudulenta/subfraudulenta group based on the shape of the valve which was more linear in the mid valve than lanceolate [2]. The cell length range was 85.6 - 195.6 um. The overlap of cell ends was 1/6-1/4 of cell length. Upon TEM examination, specimens showed 13–17 fibulae and 22–28 striae in 10 μ m. The central larger interspace was present and had the width of 5 valve striae. Each stria was biseriate with roundish poroids divided in several sectors separated by smooth space (6 - 7 in 1 µm). The ultrastructural features of the frustules confirmed the species as P. subfraudulenta (Hasle) Hasle (Fig. 1. A). Based on the ultrastructural features visible in TEM, P. pseudodelicatissima-like specimens were attributed to three distinct morphotypes. Only one morphotype was present in the samples collected in the spring period and together with P. subfraudulenta in autumn and winter samples. The cell length range of these cells was $14.3 - 76.8 \,\mu\text{m}$ and they overlapped in chains in 1/10- 1/5 of cell length. Valves had 18 - 22 fibulae and 38 - 40 striae in 10 µm with presence of the central interspace. Each stria was ornamented with square poroids (5 poroids in 1 µm) split into 7 - 10 sectors with central sector present in more than 70% of the poroids. According to these features cells belonging to this morphotype were ascribed to P. calliantha Lundholm, Moestrup et Hasle (Fig. 1. B). Second and third morphotype co-occurred in the samples with measured cell length range of $38.9-144.1\ \mu\text{m}$ and overlap 1/12-1/7 of cell length. The shape of the valve was more linear in LM therefore it was not identified as P. cuspidata which has more lanceolate shape of the valves [2]. In TEM specimens of the second morphotype were designated as P. pseudodelicatissima (Hasle) Hasle emend. Lundholm. Hasle et Moestrup (Fig. 1. C). Cells had 40 - 44 striae and 22 - 26 fibulae in 10 $\mu m.$ Striae were uniseriate with 4 - 6 oval to square poroids in 1 µm. In more than 50% of poroids hymen was divided into two large parts. However, in the same samples specimens were present with higher percentage of poroids divided into more sectors (4 - 6). These are not typical features of P.

pseudodelicatissima and these cells had 40-44 striae and 20-22 striae per 10 μ m. Given the possibility that these specimens belong to different species this third morphotype was refered to *P*. cf. *pseudodelicatissima* (Fig.1. D).

Fig. 1. TEM images: (A) P. subfraudulenta, (B) P. calliantha, (C) P. pseudodelicatissima(D) P. cf. pseudodelicatissima

P. pseudodelicatissima (both second and third morphotype) was found only in the summer with cell concentrations in surface waters of 1.2×10^5 cells L⁻¹ and it contributed up to 70% of the microphytoplankton. P. *fraudulenta* and potentially toxic P. *calliantha* [4] were present in lower concentrations during the rest of the year with abundances up to 10^4 cells L⁻¹ constituting up to 29% and 50% of microphytoplankton, respectively. The cell numbers and environmental parameters for each season are given in Tab 1.

Tab. 1. Seasonal range (min - max) and mean±SD of physical and biological parameters. For all abundance values minimum was 40 cells L⁻¹.

Pseudo-nitschia calliantha, a species for whom the production of domoic acid is well documented [3], represents frequent component of the Kotor Bay phytoplankton assemblages. Blooms of this species are known from Italian coastal waters [1] as well from the middle eastern Adriatic coast [4] and despite the fact that in this investigation it was not recorded in high abundances, it is most likely that blooms of this species occur in these waters. Examination of *Pseudo-nitzschia* species distribution and related environment factors that affect their abundance are therefore essential for predicting potentially harmful algae blooms in the area as it sustains active shellfish farming.

DIVERSITÉ MORPHOMÉTRIQUE DE *PATELLA CAERULEA* (LINNAEUS, 1758) DU LITTORAL ROCHEUX DES CÔTES TUNISIENNES

Jihen Boukhicha¹, Sabiha Zouari Tlig¹* and Oum Kalthoum Ben Hassine¹

¹ Unité de Recherche de Biologie, Ecologie et Parasitologie des Organismes Aquatiques, Campus Universitaire de Tunis, El Manar I,

2092, Tunisie - s.zouaritlig@gmail.com

Abstract

L'étude morphométrique de 200 individus de *P.caerulea*, peuplant deux étages différents (l'horizon supérieur du médiolittoral et l'horizon supérieur de l'infralittoral) du littoral rocheux des côtes de Korbous (golfe de Tunis), semble révéler l'existence d'une variation morphologique de la coquille associée à la distribution verticale. Les patelles du médiolittoral supérieur auraient probablement besoin de développer une coquille plus haute et une radula plus robuste leur permettant de s'adapter aux importantes fluctuations de facteurs environnementaux.

Keywords: Gastropods, Mediolittoral, Infralittoral, Mediterranean Ridge

Introduction

Patella caerulea est une espèce endémique de Méditerranée. Elle colonise, avec les autres espèces de patelles, le littoral rocheux. Comme toutes les autres espèces de ce genre, *P. caerulea* montre une grande plasticité morphométrique. Cette dernière représenterait une stratégie adaptative aux importantes fluctuations de facteurs environnementaux [1]. Dans cette étude, nous nous proposons d'analyser la diversité morphologique de *P. caerulea* peuplant deux étages différents du littoral rocheux des côtes de Korbous (golfe de Tunis), à savoir l'horizon supérieur du médiolittoral et l'horizon supérieur de l'infralittoral.

Matériel et Méthodes

Au total, 200 individus de *P. caerulea* ont été prélevés, à raison de 100 individus au niveau de chaque étage (horizon supérieur du médiolittoral, horizon supérieur de l'infralittoral) du site de Korbous (golfe de Tunis). Pour chaque spécimen de *P. caerulea*, cinq mensurations métriques ont été relevées à l'aide d'un pied à coulisse électronique au $1/100^{\rm ème}$ près : longueur (L), hauteur (H), distance entre le sommet et le bord antérieur (Apa), distance entre le sommet et le bord postérieur (App) et longueur de la radula (Lr). Les droites de régression ont été établies, à partir des valeurs de ces caractères transformés en log et en choisissant comme variable de référence la longueur de la coquille (L). L'évaluation des similitudes et des différences, pour un caractère donné chez les spécimens des deux étages, a été estimée par l'analyse de la variance globale ANOVA et le test de Fisher.

Résultats et discussion

Les résultats obtenus ont montré l'existence d'une étroite corrélation entre les différents paramètres étudiés (R > 0,9). L'analyse de la variance (ANOVA), appliquée aux rapports (In Lr) / (In L), (In H) / (In L), (In App) / (In L) et (In Apa) / (In L), a révélé des différences significatives entre les deux droites de régression relatives d'une part, aux échantillons du médiolittoral supérieur et, d'autre part, à ceux de l'infralittoral supérieur (p < 0,05). Ces résultats semblent indiquer que la hauteur de la coquille (H) et la longueur de la radula (Lr) des patelles habitant le médiolittoral supérieur (Fig.1), les premières ont, en outre, un sommet décalé ves l'arrière (Fig.2)

Fig. 1. Relation entre ln (Lr) et ln (L) et ln (H) et ln (L)

Fig. 2. Relation entre ln (App) et ln (L) et ln (Apa) et ln (L)

Ainsi, les patelles vivant au niveau du médiolittoral supérieur semblent développer une coquille plus haute afin de retenir une quantité d'eau plus importante. Ceci confirme les travaux de Balaparameswara Rao et Ganapati [2] qui ont signalé, chez l'espèce *Cellana radiata*, une différence morphométrique en relation avec la distribution verticale des individus et ont attribué cette plasticité morphométrique aux conditions de la dessiccation. Quant à la différence de la longueur de la radula, elle pourrait être en relation avec la nature différente du couvert algal des deux étages [3]. Les patelles du médiolittoral supérieur auraient probablement besoin de développer une radula plus robuste leur permettant de brouter les algues encroûtantes qui sont plus fréquentes à ce niveau.

RESEARCH TOOLS FOR TEACHING: A SCIENTIFIC PATH FOR 14 YEAR-OLDS TO UNDERSTAND MARINE ACIDIFICATION OCEAN ACIDIFICATION: BRING RESEARCH INTO CLASSROOMS

Fulvia Bradassi¹*, Francesco Cumani¹ and Guido Bressan¹

¹ University of Trieste - Life Sciences Department, 34100, Italy - FULVIA.BRADASSI@phd.units.it

Abstract

The fact that marine water is becoming more acidic because of the rising of atmospheric CO_2 partial pressure seems to be almost unknown to the public. A partnership with a middle school was established to fulfil the gap between research and the educational system. An experimental course on global climate change and ocean acidification was offered to 14 years-old pupils. The course, experimentally based on thallus of calcareous red algae grown under different acidic conditions, represents not only a way to spread knowledge on global climatic change among teenagers, but also a tool to measure how much new methods of teaching can improve scientific knowledge and skills at school. *Keywords: Algae, Global Change, Ph*

Ocean acidification seems to be one of the most likely consequences of the increase of atmospheric CO2 partial pressure, causing a remarkable change in the marine environment. [1]. Although ocean acidification might have great impacts, the phenomenon is still not well known and is almost unknown to the public. Our research team is focusing on the biological response of calcareous red algae (Corallinaceae) to ocean acidification [2]. The Corallinaceae play a fundamental ecological role in different marine ecosystems, from tropical reefs to high latitude cold waters. Different evidence, supported by vast and recent literature, suggest that, depositing mainly high-Mg calcite into their cell-walls, the Corallinaceae may be more susceptibile to ocean acidification than other calcifiers [3]. Since we believe that education can play a key role in changing habits of new generation, regarding anthropic CO2 emission and ocean acidification prevention, we decided to build a link between researchers and school. Thanks to specific skills in teaching that some members of our group developed for previous working experiences, and thanks to the support of C.I.R.D. (Interdipartimental Centre on Didactical Research - University of Trieste) we established a partnership with a middle school in town. We offered an experimental course on global climate change and ocean acidification to 14 years-old pupils. The experiment, based on thallus of Lithophyllum incrustans Philippi (1837) demonstrates that a lower pH than actual (7.8 versus 8.2) influences the growing rate and even the morphogenetic development of microscopical thalli. We randomly chose 21 students from all the 3rd classes of the schools and offered them to join the project, attending a course of 25 hours. Another 21 students, not taking part in lessons, represented the control group. The course was based on experimental observation of the growing of microscopical thallus, from spores released in the 1st day of culture until 14th day. The pupils learned to treat two 20-liter marine aquariums in which they grew the algae. In the first tank the pH value was the natural one (8.2), while in the second the pH value was mantained lower (7.8) through CO₂ insufflation. Pupils also learned to use instruments, to collect qualitative and numerical data, to represent the data, to elaborate them, and to take conclusion from the outcoming. The personal engagement of the students, achieved through self-motivation, plays a fundamental role into the learning process: it is supposed that the girls and boys, attending to this course should develop their scientifical knowledge and skills, including scientific language, more than control group [4]. All the students have been tested at the beginning of the school year, and will be at the end, to estimate previous skills and knowledge and homogeneity between the two tested groups. The scientific abilities and knowledge taken as terms of reference are those fixed by OCSE - PISA (Organizzazione per la Cooperazione e Sviluppo Economico - Programme International Student Assessment) for 14 years old students. The OCSE standard [5] is compared to the italian ministerial standard [6], recently revised and updated.

HIGH EFFICIENCY FEEDING STRATEGY OF *TURSIOPS TRUNCATUS* IN THE FISHING GEAR DEPREDATION.

G. Buffa¹, G. Buscaino^{1*}, A. Bellante¹, F. Filiciotto¹, C. Buscaino¹, A. Adamo¹, P. Labruzzo¹ and V. Di Stefano¹ ¹ IAMC/CNR U.O.S. di Capo Granitola - giusy.buscaino@cnr.it

Abstract

Some feeding strategies of Bottlenose dolphin appear to be associated to human activities, allowing dolphins to catch prey at a low energetic cost. A comparison study on three different artisanal fishing gears depredated by a *Tursiops truncatus* population was the objective of this work. Two monofilament nets named "Sgammerrara" (Sg1, Sg2) and one trammel net were used. An analysis of the collected data set suggests that the phenomenon of depredation is an example of *Tursiops truncatus* high behavioural plasticity and ability to discriminate between different opportunities, choosing those providing greater benefits. *Keywords: Fisheries, Coastal Systems, Competition, Diet, Behaviour*

Introduction

Some feeding strategies of Bottlenose dolphin appear to be associated to human activities allowing dolphins to catch preys at a low energetic cost. The bottlenose dolphin diet is varied and often includes many fishes that are the target species of small-scale fisheries [1]. The "Operational Interaction" with artisanal fisheries is a serious problem because of attacks to nets and the economic damages for fishermen [2]. A comparative study on three different artisanal fishing gears depredated by a Tursiops truncatus population is the objective of this work.

Materials and methods

The study was carried out on November 2005 inside the Ognina bay (South-East Sicily), where a family of fishermen claimed frequent depredation raids by Tursiops truncatus in their nets. Two 254 m long nets named "Sgammerrara" (Sg1, Sg2) and one 1,080 m long Trammel net were used. The Sgammerrara is a fixed monofilament net, divided into three continuous functional sectors: the first two sectors are named respectively "Coda" and "Petto", while the third is named "Campile" and has the same shape as a hook [Fig. 1]. Data comprising species, weight of the catch, as well as damages on the nets (number of holes/tears testifying the dolphin depredation) were collected daily. CPUE and damages were calculated in order to asses differences among the nets. Moreover, the visual monitoring of the Sg1 was performed in order to report dolphins presences, behaviours and photo-ID of the specimens near the nets.

Fig. 1. The Sgammerrara net

Results

11 sampling sessions on Sg1, 11 on Sg2 and 7 in the Trammel net were carried out. In relation to the damages on the nets, it can be assumed that dolphins depredated more the Sg1 (82% of hauls), less with the Sg2 (63% of hauls) and never the Trammel net (ANOVA p<0.001). Moreover, the CPUE was the highest for the most damaged gear (Sg1-CPUE=9 \pm 2 kgh-1m-1; Sg2-CPUE=1.09 \pm 0.07 kgh-1m-1; Trammel net-CPUE=1.04 \pm 0.09 kgh-1m-1; ANOVA p<0.001) [Fig. 2]. In addition, the composition of the catches was different between Sgammerrara and Trammel net. No by-catch event was registered during the experiments. Three different animals were identified (Foto-ID) twice and the observation indicated that specimens moved towards the Campile and stayed there (in total 3.5 hours) with a feeding behaviour.

Discussion

A careful analysis of the collected data set suggests that the dolphins differently depredated the nets in relation to nets fishing efficiency and to species composition. The behavioural observation allowed to make the hypothesis that

dolphins could use the Campile sector of Sgammerrara as a barrier against which they push fish. The experiment confirms the efficiency of Tursiops truncatus strategies as a result of its behavioural performances and its absence of by-catch events. The analysed phenomenon of depredation is an example of Tursiops truncatus high behavioural plasticity and ability to discriminate among different opportunities, choosing those providing greater benefits.

Abstract

Surface current measurements provided by a HF radar system allowed to identify typical patterns of the circulation of the Gulf of Naples (Tyrrhenian Sea), and to associate them with the prevailing forcing conditions. Circulation data were then used as input for a model simulating the transport of particles released in ocean basins (GNOME - General NOAA Oil Modeling Environment). The results of this study highlight peculiar characteristics of the surface dynamics and transport processes in the Gulf of Naples, allowing an estimate of the residence times and the identification of potential particle aggregation and retention areas. *Keywords: Circulation, Tyrrhenian Se, Water Transport, Pollution*

Historical reports on the circulation of the Gulf of Naples (GoN) highlight the occurrence of highly dynamic structures over the basin [1, 2]. As for other marginal and coastal basins, even in the GoN wind stress represents the most important local forcing, directly and indirectly affecting surface current fields [1, 2, 3, 4, 5]. Wind forcings display a typical seasonality [5] associated to the large-scale atmospheric circulation acting over the region; when such forcings are weak, as it often is the case in summer, a locally induced breeze regime can act as primary driver of sea surface circulation. The circulation of the GoN can also be remotely driven by the larger-scale circulation of Southern Tyrrhenian Sea [3], with which it is in direct communication. The resulting circulation structures allow the coexistence and mixing of different water masses [6], with characteristics ranging from those typical of oligotrophic environments [6] to that attributable to coastal systems [7]. In addition to its peculiar hydrographic and oceanographic features, the GoN holds a leading role among the marginal basins of Southern Tyrrhenian Sea for socio-economic reasons. A severe anthropic activity impinges on the system, ranging from urban settlements to tourism and maritime traffic, with potentially drastic consequences on ecosystem dynamics and water quality. The necessity of preserving and sustainably exploiting the environmental resources requires an accurate understanding and monitoring of the circulation and transport processes acting in the basin, by which forestalling or mitigating potentially hazardous events. In the last years, increasing awareness about the importance of operational oceanography systems has promoted the development of new techniques and instruments to investigate the real-time, multi-scale circulation patterns in a target area and their effects on transport and diffusion of pollutants, with a special emphasis to coastal zone management. The purpose of this work is to study the surface circulation patterns in the GoN as driven by typical local wind conditions and by Southern Tyrrhenian guidance, and to assess their effects on transport processes of passively buoyant particles. The synoptic, basin scale circulation of the GoN is reconstructed by means of a HF radar system (CODAR O. S. Ltd., USA) operating since October 2004. From the available dataset we selected four periods, each lasting 8 days, with typical forcing conditions for the investigated area. We first analysed the cross-correlation between wind stress and surface current components and directions, and afterwards we investigated the associated surface current velocity and vorticity fields. In addition we applied the GNOME (General NOAA Oil Modeling Environment, NOAA, USA) transport model to simulate the fate of passive conservative particles released in coastal sub-area (Bay of Naples). The results here presented indicate that each set of conditions determines peculiar, not easily foreseen circulation structures and transport processes, as the result of the superimposition of multiple cooccurring factors. Such an integrated approach, moreover, permits an evaluation of the renovation times of the water mass and the investigation of the exchange mechanisms between sub-basin areas.

COMPARAISON DES CARACTERISTIQUES ENVIRONNEMENTALES ET DE LA DISTRIBUTION DE LA MATIERE ORGANIQUE DANS DEUX LAGUNES MEDITERRANEENNES : BAGES-SIGEAN ET CANET

R. Buscail ^{1*}, F. Vouvé ², D. Aubert ¹, M. Desmousseaux ¹, C. Canal ² and G. Jeanty ¹ ¹ CEFREM -UMR 5110 CNRS- Université de Perpignan, 66860, France - buscail@univ-perp.fr ² IMAGES-EA, Université de Perpignan, 66860, France

Abstract

Les caractéristiques environnementales et la matière organique de l'eau et des sédiments superficiels de deux écosystèmes lagunaires du littoral du Languedoc-Roussillon (Golfe du Lion - Méditerranée NW) ont fait l'objet d'un suivi saisonnier (2009). Ces recherches ont été réalisées dans le cadre du programme ANR-CES et de son action CIEL «Contaminants et Interactions au sein d'Ecosystèmes Lagunaires». Ces résultas seront intégrés à l'interprétation de deux autres tâches, la tâche 2 «Caractéristiques du modèle biologique : *Anguilla anguilla*» et la tâche 3 «Impact des contaminants dans les milieux et les organismes». *Keywords: Lagoons, Sediments, Surface Waters, Organic Matter, Western Mediterranean*

Les lagunes de Canet et Bages-Sigean ont été choisies pour leurs contrastes en superficie, profondeur, communication avec la mer et apports en eau douce qui conditionnent leurs caractéristiques environnementales. La plus vaste, Bages-sigean avec une surface de 38 km² et un bassin versant 12 fois supérieur, a une profondeur moyenne de 1,5 m et maximale de 3 m. Le chenal portuaire de Port-La Nouvelle assure sa communication avec la mer à son extrémité sud. Elle est alimentée en eau douce par trois cours d'eau (Berre, Robine, Canelou). Canet est plus petite, avec seulement 6 km² mais un bassin versant très important (53 fois supérieur). Sa profondeur moyenne de 0,2 m est très réduite (maximum 0,7 m). La lagune de Canet possède un grau quasi fermé par des vannes non-fonctionnelles. Elle est alimentée en eau douce par deux canaux permanents (Agouille de la Mar, Fosseille) et une rivière temporaire (Réart).

Des mesures de T°, pH, salinité, O₂ dissous, réalisées à chaque prélèvement saisonnier d'eau aux 15 stations, renseignent sur la variabilité physicochimique de la tranche d'eau. Dans les deux lagunes, la température varie entre 5 et 25°C mais les minimums de salinité et d'O₂ dissous peuvent être plus bas à Canet où des épisodes d'eutrophisation sont classiques en été. La quantité de matière organique et la qualité des eaux sont évaluées par les paramètres suivants : MES, COP, NtP, Chla, COD, NtD, sels nutritifs (PO₄²⁻, NO₃²⁻, SiO₂). Les carottages des sédiments superficiels ont permis d'observer les variations spatiales et temporelles des caractéristiques de leur contenu en matière organique. Son abondance est décrite par les concentrations en Corg, Nt, lipides, carbohydrates et acides aminés et sa qualité par les rapports C/N, Chla/Pheo et le C-Bioassimilable.

Globalement les eaux de Canet sont 7 fois plus riche en MES (150mg/l contre 20mg/l), enrichies en matière organique (11% contre 4% COP et 1,1 contre 0,6% NtP). La variabilité spatiale est peu marquée dans Canet (excepté un enrichissement au droit de l'Agouille de la Mar), par contre dans Bages on observe une nette distinction entre le bassin Nord enrichi car soumis aux apports des effluents de la ville de Narbonne canalisés par la Robine et le Canelou. Le bassin sud est en communication avec la mer d'où l'effet de dilution par les eaux marines moins riches.

Les sédiments présentent des concentrations en Corg et Nt décroissantes de Canet à Bages N puis Bages S en relation avec une même tendance dans les eaux sus-jacentes. En terme de qualité, la matière organique des sédiments de Canet est nettement enrichie en C-Bioassimilable (6,2 mg/g contre 4,3 mg/g à Bages N et 3,1 mg/g à Bages S) principalement en raison de concentrations en lipides et carbohydrates supérieures lui conférant un caractère nutritionel important (48% du CO total).

Une comparaison sera établie avec une lagune voisine, celle de Salses-Leucate précédemment étudiée [1].

Abstract

As the current main source of continental fresh water discharge in the Mediterranean Sea, the Rhone river inputs are a key forcing for ecosystems of the Gulf of Lions in the northern part of the western basin. An oceanographic buoy has been installed at the Rhone river mouth in June 2009 for high frequency multi-parameter measurements with bottom, water column and air sensors. Data are sent in near real time towards an onshore data center.

Keywords: Rhone Delta, Coastal Systems, Gulf Of Lions, Instruments And Techniques, River Input

With an average flow of 1700 m³.s⁻¹, the Rhone river is currently the main source of fresh continental water inputs in the Mediterranean Sea. Draining an industrialized catchment, the Rhone river is therefore a major forcing for the western Mediterranean Sea and the Gulf of Lions ecosystems. Its contribution to riverine inputs in the Gulf of Lions is estimated to be more than 85% for water and 80% for suspended particulate matter (SPM) [1, 2]. Understanding and modeling the functioning of the coastal system in this area requires a good knowledge of the quantity of water, SPM, nutrients and pollutants brought to the sea by the Rhone river.

In order to complete the multi-parameter measurements acquired at the SORA^[a] monitoring station located in Arles 50 km upstream from the sea a new instrumented platform was installed at the Rhone river mouth. It will help studying the complex processes occurring in the fresh/saline water transition zone. In the Mediterranean area and especially in the Gulf of Lions, extreme events such as floods and storms are known to play a key role in the ecosystem dynamic. To observe these events, a high frequency observation system has been designed. Coupling high frequency measurement with near real time data transmission will allow detecting an event and triggering additional sampling. It will also provide the mean to periodically check the instrument functioning.

In June 2009, the East Roustan buoy $(43^{\circ} 19.2 \text{ N}, 4^{\circ} 52 \text{ E}, 20 \text{ meters water depth})$ which is one of the two marker buoys of the river prodelta has been replaced by a new platform equipped with oceanographic instrumentation. This new system consists of a buoyancy beacon (fig. 1) which is suitable for small range tide environment [3]. Compared to a chain mooring buoy, this beacon allows simple cable connections between the surface platform and the sea bottom instruments. Bottom sensors get energy from a solar panel unit and are connected to an electronic management and communication device installed in the top part of the buoy.

Initially, the buoy was equipped with two multi-parameter sensors (one below the subsurface and the other close to the sea bottom), a weather station, a photosynthetic active radiation sensor (PAR) and an acoustic current Doppler profiler (ADCP). The acquisition and transmission of periodic data to the Coriolis *in situ* data center (www.coriolis.eu.org) via the GSM network is operational and an interface for online consultation of the data is available. In a second phase, further instruments will be added, including a nutrient sensor, a high resolution altimeter and a benthic station equipped with oxygen microelectrodes for sediment remineralization studies.

This new observation system, Mesurho, is a part of the coastal operational oceanography *in situ* network to be developed in the north western Mediterranean. The collected data will be used among others by the Previmer forecasting and analysis system (www.previmer.org).

Mesurho project has received support from the Ifremer MEDICIS program and the French national research agency (ANR) through the EXTREMA and CHACCRA projects. It has received funding support from the Provence Alpes Côte d'Azur Region.

Abstract

This study was part of the Rough Cilicia Survey Project, which is an ongoing archaeological investigation of a 60 km coastal strip in southern Turkey In this paper palynological examination of surface samples and terrestrial sediments samples indicate a pattern of degraded vegetations from western Rough Cilicia is discussed. The previous results of palynological samples indicate a pattern of degraded vegetations. *Plantago* is obtained for areas with serious grazing experience; whereas, *Juniperus oxycedrus L., Q.coccifera L.* and *Chenopodiaceae, Plantago* characterize the effect of human impact on natural forests. *Keywords: Biogeography, Eastern Mediterranean, Lagoons*

Western Raugh Cilicia lies on the southern Mediterranean coast of modern Turkey and was administrated in Roman times as part of the Roman province of Cilicia (hence the term "Rough ", contrasting with "Flat Cilicia" to the east). The history of human settlement in southwest Turkey has been studied as a series of archaeological and historical field surveys and excavations. For this region, including western Rough Cilicia, the reconstruction of vegetation and human - induced landscape change is primarily based upon pollen analysis and other paleoecological methods. While archaeological data, including those from excavation and field survey, can sometimes be biased by differential site destruction and modern looting of burials, palaeoecological data tend to be continuous and do not suffer from the chance destruction of archaeological remains. During the 2001 and 2002 seasons of the Rough Cilicia Archaeological Survey Project, geophysical trenches were cut in river basins of the Gazipasa countryside in order to obtain pollen and macrobotanical samples to determine the history of regional vegetation patterns. Pollen was concentrated from 0.4 to 1.1 liter subsamples to which exotic Lycopodium spores (c. 12.000 grains per tablet) were added (1). The sediment samples for pollen analysis (~1 cm3 fresh material) were collected as samples and treated using standard palynological techniques ([2], [3]). This method includes HCl, HF, and KOH digestion, before staining with safranine and mounting with glycerine jelly. The pollen percentages are based on the pollen sum of arboreal (AP) and nonarboreal pollen (NAP), excluding spores. The localities of obtained surface samples are represented by three lagoonal areas in the Hacimusa, the Bickici and Delice River basins. Distribution of the pollen grains in Bickici and Delice Rivers differs from that which occurs in the Hacimusa River. Arboreal pollens are represented by Juniperus oxycedrus L. and Pinus in Hacimusa river as the highest value; whereas, Juglans reaches the highest values in Bickici and Delice Rivers. According to our preliminary evidence of surface samples, two different vegetation types are in the study area. Eu- Mediterranean vegetation contains xsrophytic shrubs and evergreen vegetation (Pinus brutia, Quercus and Erica, Artemisia) and Oro-Mediterranean vegetation includes decidious forest (Pinus brutia, Q. Cerris, Juniperus, Cedrus) The previous results of analysis from the terrestrial sediments samples indicate a pattern of degraded vegetations (Figure 1).

Fig. 1. Relative abundance of dominant pollen types in terrestrial sediments

Plantago is obtained for areas with serious grazing experience; whereas, *Juniperus oxycedrus L., Q. coccifera L.*and Chenopodiaceae, *Plantago* characterize the effect of human impact on natural forests and their replacement by secondary vegetation. They also reveal the existence of three different

Palynological zones related to the Last Glacial/Interglacial paleoclimatic conditions in the source area, as reflected by the increasing steppe types.

Гab.	1.	Types	of	vegetation	and	characteristic	assembleges	in	three	lagoonal

ANTIFOULANTS IN SEDIMENTS FROM THE FRENCH MEDITERRANEAN COAST

Roberto Cassi ¹, Imma Tolosa ¹ and Jae R. Oh ^{1*} ¹ IAEA - j.oh@iaea.org

Abstract

Organotins have been used most extensively as the main biocide in antifouling paints. Due to deleterious effects, the use of organotins on small boats has been widely prohibited since the mid-1980s. IMO's Antifouling System Convention entered into force on 17 Sept. 2008 [1]. As a result, other formulations have been used. The goal of this study is to assess the level of antifoulants in ports and marinas along the Southern France coastline. Simultaneous derivatisation and extraction were used for organotins sample preparation and a GC-FPD (610 nm filter) was used for determinations. Other antifoulants were extracted by a microwave and analysed with a GC-NPD. Every port and marina showed high levels of organotins (37-4000 ng Sn/g d.w.) [2]. The only non-organotin compound found was Irgarol 1051 (<1-689 ng/g d.w.). *Keywords: Sediments, Coastal Waters*

Organotin compounds have been used most extensively as the main biocide in marine antifouling paints. Organotin-based paints have seen service on boats of all sizes, from small yachts to supertankers, therby ensuring the global dispersion of tributyltin (TBT) throughout the marine environment. Due to deleterious effects on non-target organisms, the use of organotin compounds as antifouling agents on boat hulls of small vessels has been widely prohibited since the mid-1980s. IMO's Antifouling System Convention entered into force on 17 September 2008 [1]. As a result of restrictions on the use of organotin based paints, other antifouling formulations containing organic biocides have been utilised. Ports and marinas are recipients of a variety of toxic chemical inputs and can affect adjacent marine coastal ecosystems by, for example, dumping of dredge spoils. Thus, monitoring levels of contaminants in ports and marinas should be an important issue for local authorities. The goal of the present study is to assess the occurrence of organotin compounds and several other antifoulants in ports and marinas all along the Southern France coastline. Apart from organotin compounds, Irgarol 1051, Sea-nine, chlorothalonil, dichlofluanid and folpet were also measured in surface sediments collected in the major ports and marinas. Simultaneous derivatisation and extraction using sodium tetraethylborate were used for organotins sample preparation. An HP 5890 GC equipped with a FPD (610 nm filter) was used for all organotin determinations. A 30 x 0.25 mm x 0.25 um HP-5 capillary column was used with splitless injection.Other antifoulants were extracted by a microwave system and extracts were cleaned up using SPE florisil cartridges. An HP 6890 GC-NPD was used for all antifoulants determinations. A 30 x 0.25 mm x 0.25 um HP-5 capillary column was used with pulse splitless injection. Every port and marina exhibited high levels of organotin compounds, with concentrations ranging from 37 to 4000 ng Sn g-¹dry wt [2]. The only non-organotin compound found was Irgarol 1051. The concentrations ranged from <1 to almost 700 ng g-1dry wt and, not surprisingly, the highest levels were found near the ship chandlers. Despite the strict regulations introduced 20 years ago in France banning the application of TBT based antifouling paints on ships of <25 m and more recently on all other boats, TBT still appears to be the main active ingredient in marine antifouling currently used in Southern France.

COMPARAISON DU CYCLE SEXUEL DE *MONODONTA ARTICULATA* EN MILIEU D'ORIGINE (ILES KERKENNAH) ET APRES TRANSFERT SUR SITE POLLUE

Mohamed Karim Cheour¹ and Nejla Aloui Bejaoui¹*

¹ Institut National Agronomique de Tunisie, 1082, Tunisie - bejaoui.nejla@inat.agrinet.tn

Abstract

L'activité sexuelle de *Monodonta articulata* a été étudiée dans deux sites du Golfe de Gabès (Tunisie) dont l'un est fortement soumis aux rejets anthropiques. Durant la période d'échantillonnage, le même schéma général de déroulement des stades du développement gonadique est observé avec un repos sexuel hivernal (janvier - février) et une activité de reproduction (mars à juin) avec une petite variation selon le sexe. Le décalage, mis en évidence au niveau de la durée des différentes phases sexuelles entre les mâles et les femelles des deux sites, pourrait, à terme, avoir des conséquences sur le potentiel reproducteur de l'espèce. *Keywords: Mollusca, Gastropods, Reproduction, Gulf Of Gabes*

Introduction

Monodonta articulata est un mollusque prosobranche (Archeaogasteropode; Trochidae) très commun en Méditerranée. Cette étude porte sur la caractérisation des stades sexuels de *Monodonta articulata* dans son milieu d'origine (îles Kerkennah) et après transplantation dans un site pollué (port de Sfax). Cela nous permet d'évaluer l'influence des polluants sur le potentiel reproducteur de l'espèce.

Matériel et méthodes

L'étude a été réalisée durant la période allant de janvier à juin 2009. Un effectif total de 360 individus de *M. articulata* a été prélevé du site de référence (îles Kerkennah) et transféré en cages dans le port de Sfax. Une trentaine d'individus ont été récoltés mensuellement dans chaque site. Les observations macroscopiques ont été classées selon l'échelle de maturité d'Underwood [4] modifiée avec une précision complémentaire relative aux évolutions cytologiques. L'étude macroscopique a été complétée par une étude histologique des gonades en microscopie photonique.

Résultats et discussions

Dans le site de référence (îles Kerkennah), le repos sexuel (**Stade I**) s'étend, chez les deux sexes, sur les mois de janvier et février (Fig.1).

Fig. 1. Déroulement de la gamétogénèse chez les *M.articulata* (femelles et mâles) du site Kerkennah de janvier à juin 2009

Le début de la gamétogenèse (**Stade II**) chez les deux sexes commence dès février et s'achève en avril (femelles) et en mars (mâles). Le stade de développement des gamètes (**Stade III**) est précoce chez les mâles. La maturité sexuelle (**Stade IV**) est de même plus précoce dans la lignée mâle ; cette maturité étant atteinte un mois plus tôt que chez les femelles. L'émission gamétique (**Stade V et VI**) s'étend d'avril à juin chez les mâles et de mai à juin chez les femelles. *M. articulata* transférée dans le port de Sfax montre des variations dans la durée et la séquence des différentes phases sexuelles. On observe une prolongation de la période du repos sexuel chez les deux sexes et une précocité de la maturité sexuelle des gamètes femelles et mâles (Fig.2).

Toutefois un prolongement du stade de développement est enregistré chez les mâles et les femelles du site Kerkennah.

Fig. 2. Déroulement de la gamétogénèse chez les *M.articulata* (femelles et mâles) du site port de Sfax de janvier à juin 2009

Une comparaison du déroulement du cycle reproducteur entre les *M. articulata* des deux sexes d'un même site montre une absence de synchronisation entre les périodes de ponte des gamètes mâles et femelles, et cela aussi bien à Kerkennah qu'à Sfax. L'étude de l'activité sexuelle de *M.articulata* des sites, Kerkennah et port de Sfax, a montré en définitive que la gamétogenèse se déroule de mars à juin (avec une petite variation selon le sexe). Ces résultats concordent avec ceux de Garwood et Kendall [3] et Underwood [4]. L'inactivité sexuelle, observée en hiver (janvier- février), a été également mise en évidence par Underwood [4] et Williams [5].

Conclusion

Le décalage observé au niveau de la durée des différentes phases sexuelles entre les mâles et femelles des deux sites se traduit par des perturbations au niveau de la séquence des phénomènes sexuels. Cette étude doit être complétée par une analyse plus complète de la nature des polluants incriminés et par l'identification de leur effet au niveau cytologique.

IMPACT DU PROJET D'AMENAGEMENT DE LA VALLEE DU BOU REGREG SUR LA QUALITE DES EAUX DE BAIGNADE DE LA PLAGE DE SALE

Essediya Cherkaoui 1* and Aderrahman Nounah 1

¹ Laboratoire : Enegétique, Matériaux et Environnement (Ecole supérieure de Technologie Salé) - echerkaoui@yahoo.fr

Abstract

La plage de Salé fait partie de la zone atlantique du nord, et s'étend sur 1 500 m. Ces dernières années, cette plage a été classée nonconforme à la baignade. Cela est dû essentiellement, à la pression des estivants et au fait que les eaux de la ville sont rejetées directement, sans traitement, le long de la côte ou au niveau de l'oued Bou Regreg. *Keywords: Sewage Pollution, Coastal Waters*

Introduction

Le long de la côte marocaine, parmi les 170 plages identifiées comme des espaces de loisirs, seules 86 plages font l'objet d'une surveillance de la qualité de leur environnement. Ce travail consiste à évaluer la qualité actuelle des eaux de baignade de la plage de Salé, après la réalisation d'une grande partie des travaux du projet de dépollution de l'oued et du littoral. Ce projet s'inscrit dans le cadre du projet d'aménagement de la Vallée du Bouregreg.

Qualité des eaux de baignade de la plage de Salé

Salé est une ville côtière marocaine située sur la rive droite de l'Oued Bouregreg. Elle s'étend sur une superficie de 672 Km^2 et a une population d'environ 823 345 habitants [1]. La totalité des effluents d'eaux usées de la ville de Salé sont rejetés directement dans l'océan Atlantique et dans l'oued Bouregreg, sans prétraitement. Cela provoque la contamination de la plage par les eaux de l'oued polluées à basse mer, et par la remontée des eaux côtières trop chargées par les rejets existants à haute mer.

Pour participer à l'amélioration de la qualité des eaux de baignade de la plage de salé ainsi que celles de l'oued Bouregreg et de remédier aux problèmes de pollution, le projet de dépollution de la côte atlantique et l'Oued Bouregreg a été initié (dans le cadre de l'aménagement de l'ensemble de la vallée du Bou Regreg). Ce projet prévoit la construction de stations d'épuration des eaux usées avant leur rejet dans l'Atlantique, minimisant ainsi leur impact. Afin de caractériser la qualité des eaux de la plage de Salé, après trois années de travaux pour le projet de dépollution, nous avons utilisé des indicateurs de la pollution fécale : les coliformes fécaux (CF) et les streptocoques fécaux (SF) durant les deux marées, en 2009. L'eau a été prélevée dans trois stations (1, 2, 3) le long de la plage lors de chaque marée. Dans toutes les stations échantillonnées à basse mer et à haute mer, la concentration moyenne des indicateurs de pollution fécale (CF= 2,03 10⁸ ; 0,3 10⁸/100ml et SF= 10⁸ & 6,95 10⁵/100ml) dépassent de loin les valeurs minimales. L'eau de la plage de Salé est donc une plage de mauvaise qualité, de classe D, non conforme à la baignade [2]. La concentration des coliformes fécaux reste toujours supérieure à celui des streptocoques fécaux lors des deux marées. Le rapport des coliformes fécaux sur les streptocoques fécaux (CF/SF) est supérieur ou égal à 1, indiquant que la pollution fécale au niveau de la plage est d'origine humaine. Cela est justifié puisque la source de la pollution est presque totalement due aux déversements des rejets urbains de la ville de Salé, sans traitement préalable, le long de la côte ou bien dans l'oued Bouregreg.

Conclusion

Le resultat des analyses bactériologiques classe les eaux de la plage de salé non-conformes à la baignade. Cela rejoint, le résultat du rapport nationale de la surveillance de la qualité des eaux de baignade au Maroc, quiconsidérait la plage de Salé comme étant une plage non conforme à la baignade durant les 10 dernières années. Cependant, l'impact positif du projet de dépollution de l'Oued et de la côte atlantique -dans le cadre de l'aménagement de la vallée du Bouregreg - qui a permis la supression de quelques rejets (infrastructures, installations...) existant sur les berges de l'Oued, n'a pas encore été observé.

HYPOTHESES ON A MEDITERRANEAN SEA REGIME SHIFT IN THE LATE 1980S

A. Conversi ^{1*}, S. Fonda-Umani ², T. Peluso ³, J. Molinero ⁴ and A. Santojanni ³ CNR - ISMAR and University of Plymouth - a.conversi@ismar.cnr.it ² University of Trieste, Dept. of Life Sciences ³ CNR - ISMAR ⁴ Leibniz Institute of Marine Sciences

Abstract

A comparative study of biological and physical time series in the eastern and western Mediterranean Sea for the period 1960s to 2005, combined with a literature review, finds that all point out to an abrupt period of change in the late 1980s that involved circulation and pelagic systems. We show, using regime shift detection methods, evidence that the Mediterranean Sea underwent a climate shift in the late 1980s. An extension of this analysis to larger scale climate indexes (NHT and NAO), shows that they changed around that time. We hence hypothesize that the Mediterranean shift is part of a larger, hemispheric change, and is related to other shifts recorded during the same period in all other European seas.

Keywords: Global Change, Ligurian Sea, Adriatic Sea, Time Series, Zooplankton

Introduction

Abrupt shifts involving both the physical and the ecological systems, called regime shifts [1,2] have been the focus of recent attention. Marine regime shifts hold particular relevance, because they encompass a multitude of physical properties and ecosystem variables, and subsequently can have major impacts on all trophic levels of marine food webs and the associated biogeochemical cycles. Our initial work in the Gulf of Trieste, North Adriatic, eastern Mediterranean, identified two periods, based on winter SST patterns: 1970-1987 and 1988-2005 [3]. Our analyses of the 36-year copepod abundance time series in the Gulf of Trieste, showed that the second period was characterized by ecosystem-wide changes: the arrival of new species, the rise or decline of several taxa, and changes in the phenology in several species [3]. In this work we extend these analyses to the western Mediterranean, including biological and physical properties over different geographical scales, as well as climate indices, and find that all point out to a period of change in the late 1980s.

Methods

In this study we have utilized the following monthly times series over the 36 year period January 1970 - December 2005, unless otherwise stated: total copepod abundance Gulf of Trieste, Adriatic, Eastern Mediterranean; northern Adriatic mucilage events time series (episodes); northern Adriatic red tides time series (episodes); Adriatic anchovy stock biomass (yearly, 1976-2001); zooplankton abundance, Point B, Ligurian Sea, West Mediterranean (weekly, November 1966 - December 1993); SST, Gulf of Trieste; SLP, Gulf of Trieste; SST, Ligurian Sea; SLP, Ligurian Sea; SST, Mediterranean Sea; SLP, Mediterranean Sea; North Hemisphere Temperature (NHT) index; North Atlantic Oscillation (NAO) index. These data have been analyzed using two regime shift methods: the cumulative sums, and the sequential t-test analysis of regime shifts (STARS). The cumulative sum technique consists of plotting the cumulative sum of standardized values over time, to which is subtracted the mean of time series [4]. The STARS method calculates a Regime Shift Index (RSI), which represents a cumulative sum of normalized anomalies relative to a critical value and provides a probability level for the identified year of regime shift, based on the Student's t-test [7].

Results

All Adriatic biological series investigated in this work (copepods, anchovy biomass, and the mucilage-red tide alternance) over 36 years show a step-like period of change in the late 1980s. The 27 year mesozooplankton series in Villefranche Bay, western Mediterranean, shows a step-like change in the late 1980s as well. To support the hypothesis that these changes in the pelagic system are accompanied by changes in the physical environment, we analyse available hydrographic properties (SST e SLP) at different geographical scales: local/regional (northern Adriatic and NW Mediterranean), and basin (Mediterranean), and compare with climate indices (NHT, NAO - hemispheric scale). We find that they all show a main period of change in the late 1980s Although the time serie are on the order of a few decades, and thus a persistent state cannot yet be assessed with certainty, it is the synchronicity of the period of change, involving biological and physical properties, different trophic levels in both Mediterranean sub-basins, which indicates the presence of a major reorganization in this sea.

Conclusions

Our results suggest that the Mediterranean Sea underwent a major change at the end of the 1980s that encompassed atmospheric, hydrological, and ecological systems, for which it can be considered a regime shift. We provide evidence that links local, regional, and basin scale hydrological properties with two major

indicators of large scale climate, the North Atlantic Oscillation index and the North Hemisphere Temperature index, suggesting that the Mediterranean shift is part of a larger scale change in the northern hemisphere. We hypothesize that the shifts that affected the North, Baltic [5], Black [6], and Mediterranean (this work) seas at the end of the 1980s, so far only partly associated, are all linked as part of a northern hemisphere change.

Fig. 1. Interannual variability of zooplankton abundance off Villefranche, Ligurian Sea (diamonds), and of total copepod abundance in the Gulf of Trieste, Adriatic Sea (circles), standard units. The black horizontal lines represent the stepwise trend showing the regime shift in the mean detected by STARS method. T-test, cumulative sums, and the STARS methods, all identift a period of change circa year 1987 (vertical bar).

FISHERY DATA AND CLIMATE CHANGE: EVIDENCE OF A RELATIONSHIP FROM THE VENICE LAGOON?

Elisa Coraci¹, Piero Franzoi¹, Matteo Zucchetta¹ and Fabio Pranovi¹*

¹ Department of Environmental Sciences, University Ca' Foscari, Venice, 30122, Italy - fpranovi@unive.it

Abstract

By analysing regime shifts detected within landings time series from the Venice lagoon, a significant decrease of catches from the mid 80s was highlighted. In order to explore possible causes, the correlation with climatic parameters has been analysed. Results show a significant negative correlation between temperature anomalies and landings, but no correlations with the NAO time series have been found.

Keywords: Fisheries, Temperature, Time Series, Lagoons, Adriatic Sea

Introduction

Trends in annual mean temperature anomalies for the globe show relatively stable temperatures from the 1800 through about 1910, a rapid and steady warming through the early 1940s, followed by another period of relatively stable temperatures through the mid-1970s. A rapid rise similar to that in the earlier part of the century has been observed since [1]. The Lagoon of Venice, like most lagoons, is a sensitive and fragile ecosystem, liable to major and sudden variations and, consequently, very dynamic [2]. Furthemore the lagoon is subjected to different kinds of external pressures and has evolved under strong anthropogenic presence. This emphasizes the challenge of a dynamic management taking into account the ecosystem historical trend. In the context of the environmental management and analysis of possible effects of climate change, growing interest is devoted to time series analysis, since they allow to describe temporal trends and individuate possible points of shift. In this context, landing data could play a crucial role, since it is generally assumed a correspondence between relative abundance of a species in landings and in the ecosystem [3] and often they represent the only available historical data source about temporal variations of the system.

Material and methods

The time series (1945-2008) here presented were obtained from the Chioggia fish market. In order to minimize possible sources of bias, such as variation in the fishing effort and/or fishing grounds, changes in fishing gears and/or target species [4], we decided to use the total catch of commercial categories caught within the lagoon environment by fyke nets (eel, grass goby, shrimp, green crabs, brown shrimp, mullet, sand gobies, flounder, cuttlefish, sand smelt). To detect regime shifts within the time series, the STAR method, which analyses discontinuity or change points expressed by shifts in the variance and especially in the mean [5], has been applied.

Results and discussion

Of the six different phases (regimes) identified, most of them are in agreement with results reported by other authors [6]: 45-64 increasing of the fishing capacity due to the engine-powered boat introduction; 65-75 increase of the carring capacity due to nutrient enrichment (eutrophication); 76-83 decrease in landings due acute eutrophication and beginning of dystrophic crises; 95-08 decrease in landings due to mechanical clam harvesting (Fig.1).

Fig. 1. Regime shifts recorded within the time series of total catches from the Venice lagoon.

We focused mainly on the negative trend recorded between the period 1984-94. To explore possible causes of this phase, we attempted to correlate the landings trend with climatic parameters (temperature and North Atlantic Oscillation-NAO). Results highlight a significant negative correlation between temperature and landings anomalies (cross-correlation analysis), but no correlations with the NAO time series were detected. From 1962-1982 the temperature anomalies are

mainly negative, while since 1983 a transitional phase characterized by positive values has been started, specially from 1988. This trend lasted until 2008, showing a general warming that seems to have affected the landings. Climate change, via its oceanographic influence, can play an important role in Adriatic ecosystems due to the incoming Mediterranean warmer water leading to changes of nektonic communities [7]. The obtained results are probably not sufficiently robust to explain the entire time series, being impossible, at the moment, to disentangle the single contribution of all other drivers (such as environmental factors or anthropogenic pressures). It is quite interesting, however, to underpin the inversion (from positive to negative for landings and from negative to positive for temperature) recorded in 1983-1984 (Fig. 2).

Fig. 2. Time series (1962-2008) of landings (line) and temperature anomalies (box).

Abstract

Comparison between stacked flood-event deposits and discharge records represent a new method for interpreting delta stratigraphy and link the delta to active processes. This work demonstrates the potential of prodelta cores to complement and extend the record back in time from gauge stations.

Keywords: Adriatic Sea, Po Delta, Sedimentation

The Modern Age Po Delta is the result of a marked phase of river-dominated growth, where increased sediment flux derived from climatic change and by human impact both on the catchment (deforestation) and on the delta (diversions to the south accompanied by construction of artificial levees to maintain a fixed channel network) [1]. The modern Po delta has an area of 380 km² created during the last 500 years [1]. The present Po River has an annual discharge of 1489 m3/s as measured from 1918 to 2009 at Pontelagoscuro, 90 km from the coast and just before the apex of the delta. Annual floods occasionally reach 10,000 m³/s. The Po River has two flood periods, June (snow melt) and November (cold frontal rain). Downstream of Pontelagoscuro, the Po forms a delta consisting of five major distributaries: Maestra, Pila, Tolle, Gnocca and Goro. Average suspended sediment delivery is 11.5 MT yr⁻¹, with a range of 2.9 M/yr (1983) to 22.4 M/yr (1937). Bedload is not measured but is predicted to contribute ${\approx}2.5\%$ of the total sediment output of the Po River [2]. Two basic types of prodelta deposits occur in high-resolution seismic records: (i) shingled lobes characterized by laterally continuous seismic reflectors consistent with preserved flood layers and (ii) prodelta lobes accompanied by massive cut-and-fill features. The latter may represent past periods dominated by direct hyperpycnal discharge from the river, whereas the former appears more consistent with present-day transport processes, including perhaps wave-supported gravity flows [1]. The October 2000 flood was a 50-year return interval flood resulting in a thick flood deposit (up to 35 cm) close to Pila mouth of the Po River [3].

Fig. 1. October 2000 flood deposit recovered at 20m water depth off " Pila" distributary channel. The 35 cm thick flood deposit, observed in Xray image, shows a complex internal stratigraphy also recorded by physical parameters.

Event-response coring on the Po River prodelta coupled with shipboard digital X-radiography, resistivity profiling, and grain-size analyses permitted documentation of the initial distribution and physical properties of the 4 major flood deposits of the last 100 years. From 1994 to 2009 the delta front of the Po river has been sampled and 4 major flood events are recorded in the uppermost unit of the recent deposits occurred in November 1994, October 2000, December 2002 and May 2009. Fine-grained sediment from the Po River settles close to the mouth, leaving only a small amount of material in suspension in the plume for direct deposition onto the prodelta. The Po flood deposit has a complex internal stratigraphy, with multiple layers, laminations, ripple cross bedding, lenticular bedding, soft-sediment deformation structures, and dramatic changes in grain size that imply rapid deposition and fluctuations in energy during emplacement due to ocean weather conditions.

Using the Fall-2000 flood "anatomy" as an example, we demonstrate that it is possible to correlate the associations of benthic foraminifera, thecamoebians, organic carbon content, concentration (X, ARM, SIRM) and grain-size

(SIRM/ARM, SIRM X, ARM/X) related magnetic parameters, in prodelta environments to evaluate the discrete unit produced by each flood [4]. In addition a suite a major, minor, and trace elements has been performed on a split core using X-ray fluorescence (XRF) core scanner to provide the variability of bulk-sediment chemistry in each flood deposit. Furthermore the 2009 cores record the 2000 flood layers with the internal stratigraphy preserved.

Fig. 2. Magnetic susceptibility record in 5 cores collected, from 2002 to 2009, off "*Po della Pila*" distributary channel. The flood deposit, marked by a shaded area, is preserved after 9 years from the emplacement.

All together these parameters allow to reconstruct the impact of recent and ancient flood events even where sedimentary structures are not unequivocal. An increasing contribution of magnetic minerals with larger grain-size is correlate with minima in the flocculation observed in the sediments.

The recognition of sedimentary structures and textures is important for gaining an inproved understanding of the behaviour and mechanism of sediment deposition from catastrophic flood events. These observations provide insight into nature of large scale flood processes that cannot be measured directly. Moreover a correlation between flood deposit and sediment discharge could define a threshold discharge required to produce sedimentary deposits. To fully appreciate the natural behaviour of shallow-water depositional systems before and under major human impacts, it is necessary to extrapolate timeaveraged estimates of changes in sediment supply from indirect data, such as the volume of depositional units (delta lobes) measured from HR seismic profiles [5].

MARINE ACIDIFICATION EFFECTS ON REPRODUCTION AND GROWTH RATES OF CORALLINACEAE SPORES (RHODOPHYTA).

Francesco Cumani^{1*}, Fulvia Bradassi¹, Annarita Di Pascoli¹ and Guido Bressan¹ ¹ University of Trieste, Dept Life of Sciences - francescocumani@libero.it

Abstract

A study on the effect of marine acidification on the production and surface increase of Corallinales spores was realized in an artificial controlled culture. The increase of CO₂ concentration in the artificial culture inhibited Corallinaceae spore production and growth, and caused an increase in the mortality of germination disks. Keywords: Global Change, Algae, Adriatic Sea

During the last few years the effect of the increase of carbon dioxide has been studied on mature calcareous red algae [1], [2], [3]. But little is known on the effect of marine acidification on the reproduction rates and surface increase of the Corallinaceae. For this reason a study on the production and growth of Corallinales spores was realized in an artificial controlled culture (microcosm). The values of pH, salinity, temperature and Total Alkalinity of the seawater were recorded several time every day at random intervals.

The calcareous red algae were submitted to different concentrations of carbon dioxide in three different bathtubs (15 l each). We carried out three "monophase cultures" (May and October 2008, May 2009) during which the values of pCO2 and of pH (first "control" bathtub pCO₂ = 370 ppm and pH = 8,2; second "intermediate" bathtub $pCO_2 = 550$ ppm and pH = 8,0; third "acid" bathtub $pCO_2 = 760$ ppm and pH = 7,8) [4], were maintained constant in each bathtub during the entire period of insemination; we made a "triphase culture" (July 2008) during which the pCO2 was progressively fitted step by step in three phases from 370 to 760 ppm in third bathtub and fitted step by step in two phases from 370 to 550 ppm in second bathtub. The calcareous encrusting red alga Lithophyllum incrustans Philippi (Corallinaceae) was sampled in the gulf of Trieste (north Adriatic, Mediterranean Sea) to a depth of 3-4 m. The samples were subjected to thermic shock (temperature of about 24°C), to induce better sporulation (production and morphogenetic development of the spores). The spores were grown on specific supports slides for evaluation under the microscopy. A census of the growth disks was carried out within the first week from the beginning of the insemination, under the optic microscope. Subsequently some selected thalli were marked randomly and photographed weekly to study the surface growth rates (Image Pro Plus 6.0) [5].

In "monophase culture", even if developed in different seasons, a decrease in the presence of the thalli was observed as the CO2 concentration increased. In the July culture ("triphase culture" - progressive acidification), October 2008 and May 2009 ("monophase culture" - pCO2 and pH constant) after one month from the beginning of the culture a new census of the thalli was carried out. In all three cases an increase in the mortality of thalli was recorded with pCO2 increase (Fig. 1).

Fig. 1. Number (bars) and % mortality of coralline algae spores (circles and triangles) in "monophase" (May and Oct '08, May '09) and "triphase" (Jul '08) cultures

The rate of growth of the germinated disks was expressed as the difference between the surface of the thalli on their last day of culture and their measured surface after a week from the beginning of the insemination (ΔS). In

"monophase culture" the thalli show a smaller growth with an increase of seawater acidity (Fig. 2).

Fig. 2. Average spores growth (ΔS average) after 1 month in "monophase" and "triphase" culture

The results indicate that the increase of CO₂ concentration in the artificial culture inhibits the Corallinaceae spore production and growth, and an increase of the mortality of germination disks. This could have a negative influence on the colonization of calcareous algae not only at the species level, but at an ecosystem level since other authors have reported similar results [1], [2].

THE ROMANIAN BLACK SEA MACROALGAE UNDER CURRENT ENVIRONMENTAL QUALITY OF COASTAL WATERS

Sava Daciana ¹* and Bologa s Alexandru ²

¹ Faculty of Natural and Agricultural Sciences, "Ovidius" University - daciana.sava@gmail.com

² 2National Institute for Marine Research & Development "Grigore Antipa", Mamaia 300, RO-900581, Constanta 3, Romania

Abstract

The authors present an updated assessment of the present state of the macroalgal flora from the Romanian Black Sea waters, after a study that took place between 1999-2009. The research shows that the current algal communities consist of a small number of species, but with considerable biomass. The perennial associations mentioned have declined and the free substratum is now covered by opportunistic species with a short life cycle. Appropriate ways of conservation would be the improvement of physicochemical conditions of coastal waters and maintenance of the under water Marine Reserve "Vama –Veche" in the south part of our coast. *Keywords: Black Sea, Phytobenthos*

The Black Sea ecosystem, mainly in its northwestern sector, has changed under the influence of harmful factors which also affected the qualitative and quantitative state of macrophytobenthos [1, 2]. The present paper shows the data obtained after a 10 year survey, compared with previous data [3], in order to point out the changes of this major component of the Black Sea ecosystem. The algae were collected from various types of hard substratum. From each sample, algae were identified and representative individuals were kept for the herbarium collection. For biomass estimation three samples were randomly taken from a surface of 100 cm² at depths between 0.5 - 7 m, the algal material was than dried and weighed, in order to obtain the values of dried biomass. In the collected samples, 16 Chlorophyta, 5 Phaeophyta and 10 Rhodophyta were found. Compared with previously reported results, it is quite evident that the number of species from each phylum decreased over the years (Table 1).

Tab. 1. Evolution of macroalgal species between 1977-2002

Phyllum	Bavaru, 1977	Vasiliu, 1980-1995	Sava,1995-2002
Chlorophyta	31	22	16
Phaeophyta	14	9	-4
Rhodophyta	41	24	10
Total	86	55	30

The relatively high number of Chlorophyta, compared with other groups can be explained by the fact that eutrophication seems to favor the development of green algae. The quantitative data emphasized that green and red algae were dominant, with a significant decrease after 2004 that can be related to the amelioration of the state of the marine ecosystem along the Romanian shore in recent years, which could have beneficial consequences on the whole algal vegetation. Generally, our present observation confirms previous studies: qualitative decline, high biomass of *Enteromorpha, Cladophora* (Chlorophyta) and *Ceramium* (Rhodophyta), the almost disappearance of perennial species (brown alga *Cystoseira*) [4, 5]. The continuous observation of the evolution of physicochemical parameters of shallow waters, and the continuous biodiversity monitoring will allow us to estimate the trend in the near future, because anthropogenic factors are still present and are likely to disturb directly and indirectly the ecosystem and community structure in the Black Sea.

DISTRIBUTION AND BIOLOGY OF TWO SYMPATRIC *PHALERIA* SPECIES (COLEOPTERA: TENEBRIONIDAE) ON MALTESE SANDY BEACHES

Alan Deidun ¹*, Antonia Pawley ¹ and Patrick J Schembri ¹ ¹ Department of Biology, University of Malta - alan.deidun@um.edu.mt

Abstract

Differences in the zonation and habitat preferences of two sympatric *Phaleria* species on five Maltese sandy beaches were investigated. *P. bimaculata* has a more seaward zonation than *P. acuminata* and occurs at higher densities. Behavioural aspects of the two species were also investigated in the laboratory through the use of choice chambers. The two species have similar sand moisture content and grain-size preferences, and a similar phenology, but different sand organic content preferences *Keywords: Beach, Behaviour*

Introduction

Beetles of the genus *Phaleria* are one of the major consumers of debris on sandy beaches in the Mediterranean. The coexistence of different species of *Phaleria* on Mediterranean islands has been well documented [1, 2]. One such species-pair – *Phaleria acuminata* and *Phaleria bimaculata* - occurs in the Maltese Islands [3], with the two species being sympatric on some beaches and allopatric on others. Zonation along the shore, sand moisture content, sand organic content and sediment grain-size preferences, as well as seasonal variation in abundance, were investigated for the two species.

Materials and Methods

Five Maltese sandy beaches (Mgiebah, Golden Bay, and White Tower Bay on Malta, and Ramla l-Hamra and Xatt l-Ahmar on Gozo) were sampled during different seasons in 2001-2003 and in 2006-2007 by means of pitfall traps placed at regular intervals between the strandline and the vegetated margins of the beach. At each station, two plastic cups were buried flush with the sand surface and connected by wooden walkways that acted to deflect animals into the traps; traps were left overnight. For behavioural experiments, individuals of both species were tested separately in a series of choice chambers (glass troughs) presenting, in separate trials, choices between sand with different (i) moisture content, (ii) organic content, and (iii) grain size. At the end of each trial the number of *Phaleria* individuals in each compartment of the choice chamber was recorded by sieving out the sand and counting the number of individuals.

Results and Discussion

The Phaleria species occurred sympatrically on two beaches (Golden Bay, Mgiebah) and allopatrically on the other three (Phaleria acuminata - Ramla l-Hamra; Phaleria bimaculata - Xatt 1-Ahmar and White Tower Bay). On Mediterranean beaches with sympatric Phaleria, the two species normally occupy different zones (e.g. [2]). In the present study, sympatric P. bimaculata had a more seaward distribution than P. acuminata; peak densities of P. bimaculata and P. acuminata occurred at a mean distance of 9m and 41m away from mean sea-level (MSL), respectively. Additionally, P. bimaculata was consistently recorded in higher densities than P. acuminata on beaches where the two species were sympatric (mean capture frequency: P. bimaculata = 3.35±5.33SD inds/trap/hr; P. acuminata = 0.97±1.06SD inds/trap/hr). Whilst such interspecific differences in position on the shore have been attributed to differences in sand moisture preferences [3], no significant differences in sand moisture preferences for the two Phaleria species were found in the choice experiments made in the present study. Zonation of sympatric Phaleria species could be due to a preference for different sand grain sizes [4] but again, choice-chamber experiments made in the present study did not show significant differences between the grain-size preferences of the two species, while all the beaches sampled were characterized by 'medium sand' (Wentworth-Udden scale), except for the wet zone of White Tower Bay (medium/fine sand), where only P. bimaculata was recorded. A temporal variation in abundance of sympatric species-pairs of Phaleria has been suggested [3]; the results of the present study as well as of a previous one [5] do not support this since the sympatric Phaleria species showed similar seasonal patterns, with the highest abundances recorded in the spring and the lowest in autumn in both species. The present study did not identify any beach physical parameter that modulates the zonation and abundance of the two species, and in Malta at least, P. acuminata and P.bimaculata appear to have a high degree of niche overlap. However, in behavioural experiments, P. bimaculata exhibited a significantly (p=0.05) higher preference for organically enriched sand than P. acuminata, hinting at possible niche partitioning in terms of feeding preferences. It has been suggested that Phaleria species make good bio-indicators of the health of beach ecosystems [6], however, before they can be used as such, a good knowledge of their ecology and behaviour is necessary, especially when different species occur sympatrically. *P. bimaculata* was previously recorded from Ramla I-Hamra ([7], but was not found there in other studies (e.g. [5]), including the present one. This may either mean that the species has become extinct from this beach or else that the population here is so small and patchily distributed that it is not easily sampled; in either case, this underlines the precarious nature of populations of psammophilic species in localities such as the Maltese Islands where sandy beaches are few and small and under heavy anthropogenic pressure [8].

DISTRIBUTION OF TYLOS SPP. (CRUSTACEA, ISOPODA) ON MALTESE SANDY BEACHES AND OBSERVATIONS ON TYLOS EUROPAEUS.

Alan Deidun ¹*, Francesca Galea Bonavia ¹ and Patrick J Schembri ¹ ¹ Department of Biology, University of Malta - alan.deidun@um.edu.mt

Abstract

The occurrence of *Tylos europaeus* and *T. sardous* on 10 Maltese beaches was investigated. *T. europaeus* occurred on two beaches on Gozo and *T. sardous* on a single beach on Malta. The largest population was of *T. europaeus* at Ramla I-Hamra on Gozo, but even here the isopods occupied a limited zone close to sea-level. The diurnal and nocturnal distribution of this population as well as temporal changes in distribution pattern over two years were studied in order to provide baseline information for the conservation of this rare psammophile in the Maltese Islands.

Keywords: Beach, Conservation, Biodiversity, Coastal Systems

Introduction

Only 2.4% of the Maltese coastline is sandy [1]. This, and the intense human activity on beaches during the summer months, make most sand-associating species rare and potentially threatened, particularly if they are strictly psammophilic. Two species of the psammophilic isopod genus Tylos, T. *europaeus* and T. *sardous*, occur in the Maltese Islands [2], both of which appear to be rare not only because their habitat is limited, but also because even where they occur their populations are not large. To provide baseline information on these species in the Maltese Islands, their distribution on the larger beaches was studied by sampling surface-active animals at night and animals buried in the sand during the day. One beach had a relatively substantial population of *T. europaeus*, which allowed more detailed observations on the spatial and temporal distribution of this species to be made.

Material and Methods

Pitfall traps were deployed 1m apart along shore-normal transects extending from mean sea-level (MSL) landwards, on 10 sandy beaches in the Maltese Islands. Each trap was set flush with the sand surface and was separated from adjacent traps by a 1m wooden walkway to deflect wandering animals towards the traps. Traps were deployed for eight seasons over two successive years (2002-2003). The daytime distribution of *Tylos europaeus* buried in the sand was studied at Ramla I-Hamra, Gozo, where the largest population occurs [3]. A 30x30cm quadrat was deployed at 1m-intervals along a shore-normal transect in the wet zone of the beach and at 1m, 3m, 5m and 10m intervals from the strandline in the dry zone. Sand within the quadrat was removed and wet sieved through a 0.5 mm mesh; this procedure was carried out successively for the 0-10 cm, 10-20cm and 20-30cm depth strata of the sand within each quadrat.

Results and Discussion

Of the 10 beaches sampled, Tylos were only found on three: Ramla 1-Hamra and San Blas on Gozo, and Paradise Bay on Malta. The sand from all three beaches had a median particle diameter of 0.25mm, classifying it as fine sand on the Wentworth Scale. Although Tylos was previously recorded from Mistra Bay [2], no individuals were collected from this site in the present study. The specimens from Ramla 1-Hamra and San Blas were identified as Tylos europaeus on the basis of pleon morphology, while those from Paradise Bay were identified as Tylos sardous. The abundances of T. europaeus at San Blas and of T. sardous at Paradise Bay were very low (individual abundances of 0.05inds/trap/hr for T. europaeus at San Blas and 0.26inds/trap/hr for T. sardous at Paradise Bay) and these populations were not studied further. In summer, the daytime distribution of T. europaeus at Ramla l-Hamra was limited to a narrow zone 3-7m above mean sea level. Within this zone, adult population density ranged from 220 to 450 individuals/m³ but juveniles had densities of 450-3200 individuals/m³. Individuals were found at all three depth strata within the sand (0-10 cm, 10-20cm and 20-30cm), with most adults in the deepest stratum while juveniles were mainly restricted to the upper stratum. During winter, juveniles were again more abundant than adults at almost all the stations, but the isopods were recorded from the surface (0-10 cm) depth stratum only. Adults occurred in higher abundances than juveniles in the pitfall trap collections over all the eight sampling seasons except summer 2002 and summer 2003, and males outnumbered females at all times. Gravid females were found in the spring of both 2002 and 2003, implying that reproduction occurs once a year, as already noted by others (e.g. [4]), and that the preponderance of juveniles in summer was the result of recruitment.

Fig. 1. Distribution of juvenile, adult male and adult female *Tylos europaeus* in the upper 0-10cm layer of sand relative to mean sea-level at Ramla l-Hamra, Gozo.

At Ramla - 1 Hamra, T.europaeus showed a clear seasonal shift in distribution along the shore, with individuals being zoned further away from MSL during the autumn and winter, and shifting progressively seaward during the spring and summer months, as also observed for the species on a Tyrrhenian beach [5]. There was a high degree of inter-annual variation in abundance of surface-active animals; just four individuals were collected in the pitfall traps in winter 2003, as compared to 619 individuals in winter 2002; this is probably related to colder air temperatures during the winter of 2003 which may have resulted in more inactive individuals. It has been suggested [5] that adverse climatic conditions, especially low air temperatures, could become a limiting factor and depress surface activity in T. europaeus. Although common on Mediterranean shores, both species of Tylos are overall rare in the Maltese Islands, especially T. sardous, which appears to only occur on a single beach, and even where found, populations are restricted to a limited zone of the shore. Therefore, if such species are to continue to survive locally, some management of the populations is necessary and studies such as the present one provide basic information on the populations on which conservation management actions may be based.

WINTER TRENDS IN THE NORTHERN ADRIATIC

Tamara Djakovac¹, Romina Kraus^{1*}, Robert Precali¹ and Nastjenjka Supic¹ ¹ Rudjer Boskovic Institute, Centre for Marine Research - kraus@cim.irb.hr

Abstract

Winter (February) phytoplankton blooms characterise the northern Adriatic. A significant decrease of winter phytoplankton abundance in the western part and an increase in the eastern one during the 1990-2007 period was observed. Furthermore, salinity and nutrient winter trends in the western and eastern part of the northern Adriatic differ as well. An interpretation of the observed changes was required.

Keywords: Adriatic Sea, Nutrients, Phytoplankton, Po Delta, Salinity

Introduction

The northern Adriatic is one of the most productive regions of the Mediterranean Sea. A well defined eutrophication gradient decreases eastwards, mainly due to the Po River discharge [1], leading to a significantly higher phytoplankton abundance in the western part. Especially high phytoplankton blooms appear in winter (February). Blooms are especially intense when waters from the Po River spread over the large northern Adriatic area (in prep.). We are presenting western and eastern winter trends in phytoplankton abundances, salinity and nutrient concentrations for the 1990-2007 period.

Methods

Phytoplankton (20-200 μ m), salinity and nutrient (total inorganic nitrogen and orthophosphate) samples were collected in February at stations SJ108 and SJ107 at standard oceanographic depths along the along the Po River Delta - Rovinj transect for the 1990-2007 period (Figure 1). Parameters were determined by standard oceanographic methods.

Fig. 1. Northern Adriatic map with sampling stations

Results

In the western part (SJ108), surface phytoplankton abundances and nutrient concentrations decreased, while in the eastern one (SJ107) they increased over the last 20 years. Salinity of the surface layer showed an opposite trend (Figure 2). Phytoplankton abundances vs. nutrients and salinity showed a positive and negative correlation, respectively.

Conclusion

Winter trends in phytoplankton abundances in the western and the eastern part of the northern Adriatic in the 1990-2007 period significantly differ and correspond to trends in salinity and nutrient concentrations. Decreasing trends in the western (eutrophic) and increasing ones in the eastern (oligotrophic) part were observed. We suppose that the observed phytoplankton and nutrient decreasing trends in the western part of the northern Adriatic ecosystem were a direct consequence of the extreme change in the Po River freshwater inflow (in prep.). However, the eastern conditions could be probably assigned to circulation regime changes.

Fig. 2. Phytoplankton abundance (open square, bold-solid line), salinity – s (xsign, bold-dashed line), total inorganic nitrogen – TIN (grey circle, dot line) and orthophosphate concentration – P (solid triangle, dashed line) in the western part of the northern Adriatic – station SJ108 (a) and in the eastern – station SJ107 (b) during the period 1990-2007 with corresponding linear fit lines

SENSITIVITY MAPPING OF THE FRENCH MEDITERRANEAN COASTAL ENVIRONMENT

Céline Duffa¹, Carolyn Scheurle¹ and Hervé Thébault¹*

¹ Institut de Radioprotection et de Sûreté Nucléaire - herve.thebault@ifremer.fr

Abstract

In case of any accidental marine pollution, the vulnerability of coastal zone not only depends on the extent and type of pollution, but also on the environmental and socio-economic characteristics. Therefore, to allow decision makers and experts to assess their decisions on synthetic and operational information, an atlas of sensitivity for French Mediterranean coastal environments is produced. The estimated sensitivity, defined for each delimited section of the coast, is based on many physical, ecological and socio-economical criteria.

Keywords: Coastal Systems, Gis, Pollution, Economic valuation

Introduction

Today, about 30% of the international maritime traffic concern Mediterranean harbours or are on transit and estimated 50% of the transported merchandises are supposed to present a risk (Aprin et al. 2008). An accidental release of hydrocarbons or chemicals is rendering the marine and coastal zones vulnerable. In order to face such accidental marine pollutions and their consequences, specifically adapted coastal management strategies and decision making processes are needed. Within this context, the project CLARA II (Calculs Liés Aux Rejets Accidentels en Méditerranée; http://clara2.ema.fr) aims to provide a decision support tool focussing on the French Mediterranean. Among other things, this tool will provide a sensitivity atlas of the French Mediterranean coast. Produced sensitivity maps are used to support decision makers and experts to prepare the interventions and to first estimate the consequences in case of pollution.

Methodology

In order to establish the respective sensitivity maps, the French Mediterranean coast (including Corsica) has been divided in zones. Taking into account main environmental characteristics as well as requirements to management and decision making processes in case of an accident, 32 zones have been distinguished. Seawards they are limited by four miles and/or 50 meters depth. The collection embraces information and data on the various environmental (physical, dynamical and biological) and socio-economic characteristics. Face to any marine pollution, these stakes presence and importance will contribute to increase or decrease the vulnerability of a zone. Therefore, we consider them as sensitivity factors. Their individual values are evaluated on a sensitivity scale from 1 (less sensitive) to 5 (very sensitive), which translates their relative importance. For instance, south Corsica zones present a high sensitivity considering risk on protected areas (see Figure 1). While distinguishing the summer and winter season, this will be done fore each of the 32 zones and for each type of pollutant studied. On this basis, a "global" index (encompassing the environmental and economical indices) is calculated for each of the zones and the two seasons. This step of the study is accompanied by a multi-criteria study, based on different point of view to give a relative weight to each factor. In order to homogenise and treat the spatial data we use a Geographic Information System (Arc GIS9 ESRI).

Results and Conclusions

Sensitivity indices are attributed to all selected and collected data: Environmental factors (e.g. biodiversity, protected areas, cost morphology), and socioeconomical factors (e.g. fisheries and aquaculture as well as tourist and recreational activities). While distinguishing the summer and winter season, this is done fore each of the 32 zones and for each type of pollutant studied. The resulting sensitivity maps aim to geographically represent the sensitivity indices of one zone relative to another zone. A correspondence to so-called absolute values is not intended.

Fig. 1. French Mediterranean Sensitivity relative to existing protected areas

Firstly dedicated to the French Mediterranean coast, moreover, the concept aims to create standardized tools which make it possible to represent and compare the sensitivity of various coastal environments. Our preliminary results underline the potential to transfer the approach, and encourage the possibility for an application beyond the immediate objectives of the project CLARA II.

Abstract

L'objectif de ce travail consiste à suivre la répartition spatiale des éléments nutritifs (NH_4^+ , NO_2^- , NO_3^- , PO_4^{3-} , N-T, P-T et N/P) au niveau de 15 stations côtières du Golfe de Gabès. Les résultats montrent que le Golfe de Gabès représente une limitation en azote et que le statut trophique de la zone étudiée est oligotrophe. *Keywords: Gulf Of Gabes, Nutrients*

Introduction

Le Golfe de Gabès est caractérisé par un climat pré-saharien aride à semi aride, et par une faible pluviométrie dont la moyenne annuelle est de 200 mm an⁻¹. Le Golfe de Gabès est situé sur la façade Sud-est de la Tunisie. Il s'étend de "Ras Kapoudia" au niveau de la parallèle 35°N jusqu'à la frontière tuniso-lybienne. Il abrite les îles Kerkennah, Kneiss et Jerba et les lagunes de Bougrara et d'El Bibane [1]. Au cours de cette étude, nous avons souhaité évaluer le statut trophique des eaux côtières du Golfe de Gabès.

Matériel et méthodes

Les échantillons ont été collectés mensuellement dans le cadre du réseau de surveillance phytoplanctonique REPHY, entre mars 2006 et février 2007 au niveau de 15 stations peu profondes (< 1 m).

Les échantillons ont été collectés à l'aide d'une bouteille fermante de type Van Dorn entre 10 à 20 cm de profondeur et conservés à -20°C et à l'obscurité jusqu'au jour de l'analyse.

Le dosage des éléments nutritifs (nitrate (NO₃⁻), nitrite (NO₂⁻), l'azote ammoniacal (NH₄+), l'ion orthophosphate (PO₄³⁻), l'azote total (N-T) et le phosphore total (P-T)) (après minéralisation respectivement en ions NH₄⁺ et en ions PO₄³⁻ suite à une réaction avec le potassium persulfate à 120°C) a été réalisé en flux continu par un auto-analyseur (BRAN + LUEBBE) de type 3 selon le principe colorimétrique en utilisant un spectrophotomètre UV-visible (6400/6405) [2].

Résultats et discussions

Les teneurs en éléments nutritifs sont présentés au niveau du tableau 1.

Tab. 1. Les concentrations Moyenne \pm écart type des éléments nutritifs (µmol l⁻¹) et du rapport N/P. La dernière ligne donne les résultats d'analyse statistique (ANOVA). * Différence significative entre les stations échantillonnées (*p<0.05, **p<0.01, ***p<0.001)

	NH₄⁺	NO ₂ ⁻	NO ₂ ⁻	PO43-	N-T	P-T

Jabiat Haj Ali	3.9 ± 3.2	0.5 ± 0.5	2.2 ± 1.9	0.8 ± 0.7	20.4 ± 7.4	3.3 ± 1.8	8.4
Cannel de Cotusal	5.7 ± 5.4	0.5 ± 0.5	2.9 ± 2.1	0.5 ± 0.3	23.7 ± 7.9	3.0 ± 2.1	19.7
F	1.61	1.82*	1.41	2.93***	1.65	3.66***	

Les concentrations moyennes d'azote total (N-T) varient entre 19.1 ± 5,7 µmol l⁻¹ au niveau de la station El Grine et 25.6 ± 9.1 µmol l⁻¹ au niveau du port de Gabès. Les concentrations en nitrate (NO₃⁻) ne diffèrent pas entre les stations et elles représentent les concentrations les plus élevées 3.6 ± 2.8 µmol l⁻¹ au niveau de Hassi Jerbi. Les concentrations en NO₂⁻ sont très faibles (ANOVA, F=1.82, p<0.05) et ne dépassent pas 0.5 µmol l⁻¹ à l'exception des stations de Tarfelma, le Port de Gabès, Karboub, Hassi Jerbi et Cheikh Yahia où les concentrations en ions ammonium ne présentent pas de différence significative et sont élevées (> 2 µmol l⁻¹). Les concentrations en phosphore total et en ion orthophosphate montrent une différence significative entre les stations (ANOVA, F=3.66, p<0.001 et F=2.93, p<0.001 respectivement). Les valeurs les plus élevées en phosphore total sont enregistrées dans les stations Zarrat et

Port de Gabès (Tableau 1). Les concentrations en PO_4^{3-} sont élevées au niveau des stations Zarrat, Port de Gabès et Jaboussa (Tableau 1). Le rapport N/P: DIN (DIN= $NO_2^{-+} NO_3^{-} + NH_4^{+}$) sur DIP (DIP= PO_4^{3-}) varie de 3.5 au niveau de la station Jabousssa à 19.7 dans le canal de Cotusal. Dans la majorité des stations le rapport N/P est inférieur à celui de Redfield (16), à l'exception de Karboub, Hassi Jerbi et Cannel de cotusal où le rapport N/P représente 18.3, 19.3 et 19.7 respectivement, ce qui confirme une limitation en azote due à l'utilisation excessive des formes azotés par les bactéries et le phytoplancton. Cette observation est semblable aux résultats des eaux côtières du Golfe de Gabès [1], confirmant que le bassin méditerranéen oriental est un écosystème «oligotrophe» [1,3].

SPILLOVER EFFECTS OF A MARINE PROTECTED AREA ON A EXPLOITED LOBSTER PALINURUS ELEPHAS RESOURCE

Maria cristina Follesa ¹*, Danila Cuccu ¹ and Angelo Cau ¹

¹ Department of Animal Biology and Ecology, University of Cagliari, Italy - follesac@unica.it

Abstract

We investigated the effects of the Su Pallosu marine protected area (Central western Mediterranean) on the adjacent *Palinurus elephas* (Fabricius, 1787) fishery. After 11 years of no-take protection, a gradient of the lobster biomass (Catch Per Unit Effort) from the interior of the reserve up to a distance of about 20 km from its centre was found. CPUE showed non linear decline with distance from the centre of the reserve.

Keywords: Decapoda, Marine Parks, Western Mediterranean

Introduction

Fishing restrictions in a marine protected area (MPA) can promote an increase in biomass of species leading to a spillover to surrounding commercial areas and enhancing local fisheries [1,2,3]. After 11 years of absence of fishing activity, we investigate spillover from Su Pallosu MPA (CW Mediterranean) to commercial fishing zones based on the effects on artisanal local fisheries of lobster.

Materials and methods

The study was carried out in the Su Pallosu marine protected area of the centralwestern Sardinia (central-western Mediterranean) and its surrounding commercial zones. The area (4 km² area), identified in 1997, was closed to the fishing since 1998 (Regional Law No. 776 of 6-5-1998). Catch data were collected in 2008 during the annual lobster fishing season (May-September) onboard of artisanal commercial boats equipped with trammel net. Specifically, commercial data of 4 different local boats (Seleca, Monè, Marlin and Queen of sea) selected on the base of the main distance of their operative fishing zone from the centre of the protected area, were registered. Experimental fishing surveys inside the area by the same commercial boats were also performed. The geographic positions of the start and end of each fishing set were recorded. CPUE was calculated by the weight (kg) of lobsters caught per meter of trammel net per boats.

Results

The experimental main CPUE inside the reserve was 10.72 ± 7.27 kg/boat/meter net. An evident progressive declining gradient of commercial CPUE values increasing the distance from the centre of the protected area was observed (Fig. 1). Commercial fishing data in fact show the existence of a negative lobster abundance up to 5 km away the protected area. Over 10 km from the centre of the MPA the commercial CPUE values settled to about 0,2 kg/boat/meter net (Fig.1).

Fig. 1. Commercial mean CPUE (kg of lobster caught per boat per meter net) \pm sd versus the main distance of each boat's operative fishing zone from the centre of the protected area

Conclusions

Net emigration of animal across reserve boundaries should create a gradient of density as results of the movement behavior and catchability and exploitations rate of the species in the adjacent fishery (Russ et al. 2003). In our study the limited mobility of *Palinurus elephas* (60.4% of lobsters moved less than 2 km from the centre of the area, [4]) jointed to the reduced dimension of the

protected area (4 km²) and the high fishing pressure across the boundary seem to be the main factors that should have conducted to gradually reduce to the availability of lobsters as distance increased.

Abstract

Oceans are exposed to a combination of local and global pressures. Effective conservation measures are urgently needed. Several initiatives focused on Mediterranean seascapes by listing habitats and assemblages on the basis of their putative abundance and ecological importance. Our analyses reveal that these classification schemes are questionable in terms of taxa representativeness and basic ecological knowledge of the selected entries. Past efforts had the merit of creating a conservation framework for Mediterranean seascapes, but it is time to make some steps forward, to better account for the changes occurring at Mediterranean scale and to better fit the world wide accepted marine conservation criteria. *Keywords: Biodiversity, Coastal Management, Conservation*

Introduction

The Mediterranean Sea is a semi-closed basin exposed to interactions of local and global pressures driving rapid biodiversity changes in terms of species life cycles, trophic interactions, composition, abundance and distribution of assemblages (1, 2). The adoption of measures relying on criteria effectively facing the magnitude of these changes is urgently needed. The EU Habitat Directive is one of the main tools for biodiversity protection in Europe. Marine habitats, however, are treated sparingly in these classification schemes. The RAC-SPA at Tunis (3) tried to react to this superficial treatment of marine habitat diversity focusing on Mediterranean seascapes by listing habitats and assemblages on the basis of their putative abundance and ecological importance. This attempt, together with some others (4, 5), had the merit of creating a framework for Mediterranean seascapes, representing the baseline for the conservation and management of this basin. Here, we analyse this classification to highlight criticalities and propose adjustments to improve the available tools for biodiversity management and protection.

Materials and Methods

The RAC-SPA classification is featured by a hierarchical structure going from the topographic structure of the substrate to the presence of a series of species-assemblages potentially locally dominant (*i.e. facies* and/or *associations*). We used the ISI Web of Science (www.isiknowledge.com) to search published articles dealing with the species/taxa characterizing the *facies* and the *associations* included in the classification.

Results

The classification includes 162 entries (with a total of 128 species included in the list). Our analysis reveals that: 1- The classification scheme is mostly algal-oriented, the 63% of the species being algae (Fig. 1). The genus *Cystoseira* spp. is represented by 13 species, while bioconstructors such as vermetids or bryozoans are included only as general groups. 2. The algal bias, in many cases, allows analyses just in spring-summer, whereas the assemblages typical of winter (e.g. large hydroids) are treated insufficiently. 3-The 14% of the species considered in the list is not covered by ISI journals and the 16% is cited only once or twice. About half of the included species have been cited by less than ten papers (Fig. 2). 4- There is an important lack of proportion between the entries devoted to shallow assemblages in comparison to those devoted to the so-called circalittoral habitats, which are under represented.

Fig. 2. Number of publications for each species included in the list. Species with 0 publications (n=18) were not reported

Discussion & Conclusion

Our analyses reveal that these classification schemes are taxonomically biased in favour of algae, lack basic ecological knowledge of several selected entries, privilege shallow assemblages and disregard deeper ones and are applicable in some seasons and not in others. Thus, if the aim of the classification is an inventory of dominant habitats, assemblages and species of the Mediterranean Sea, it is awkward to justify the exclusion of a variety of benthic organisms largely represented in this basin. In case the aim is to focus on conservation and management efforts, the inclusion of entries in available lists should be updated, relying on ecological criteria clearly decided *a priori* for deciding which taxa should be "in" and should be "out", based on a general consensus in the scientific community.Past efforts had the merit of creating a conservation framework for Mediterranean seascapes, but it is time to make some steps forward, to better account for the changes occurring at Mediterranean scale.

EFFECT OF MULTIPLE DRIVERS ON THE RECOVERY OF MARINE BENTHIC ASSEMBLAGES

Simonetta Fraschetti 1*

¹ Università del Salento, CoNISMa, 73100, Lecce, Italy - simona.fraschetti@unisalento.it

Abstract

Human threats on the world ocean are multiple and escalating. Effects of multiple stressors can lead to the loss of resilience and an increased risk of regime shifts. The illegal fishery of the date mussel *Lithophaga lithophaga* (L.) is one of the most harmful human activities affecting subtidal rocky habitats in the Mediterranean Sea. I experimentally investigated the interactive effects of nutrient availability and sea urchin grazing on the recovery of subtidal benthic assemblages disturbed by date mussel fisheries. Results suggest that: 1) in enriched plots where grazers were removed, recolonization by macroalgae can be observed in 12 months; 2) the two factors have an antagonist effects; and 3) the presence of grazers imperils the restoration of disturbed assemblages. *Keywords: Biodiversity, Coastal Management, Conservation, Eutrophication, Coastal Processes*

Introduction

Multiple stressors act in synergies. Their combined effect can be accumulative, fully additive, multiplicative, mitigative, or under the dominance of one or more stressors. The effects of some anthropogenic stressors are well documented, but the combined effects of multiple stressors are poorly known. Stressors are usually considered in isolation, with simplistic interpretations of the effects of human activities on coastal environments [1, 2]. In the Mediterranean Sea, shallow rocky calcareous habitats are heavily threatened due to the destructive fishery of the European date mussel *Lithophaga lithophaga* (L.), which leads to the desertification of tens of kilometres of rocky coast each year [3, 4]. The effects of this disturbance are well-known but the information is still scarce on patterns of recovery and potential for restoration [5]. We explored, through a manipulative experiment, the interplay between nutrient supply and grazing pressure in shaping the recovery trajectories of benthic assemblages impacted by the date mussel fishery.

Material and Methods

The experiment was carried out for 1 year within 12 square plots of $25m^2$ (2 plots for each combination of factors, plus two control artefacts) at about 6m depth, in the no take zone of the MPA of Porto Cesareo (SE Italy). Plots were sampled 9 times (separated at least by 1 month) through photographic sampling method. 10 randomly replicates of 16x23cm were done for a total of 720 replicates units. The experimental plots were enriched by a slow-release fertilizer (Osmocote-pro 18N:9P:10K, Scotts Company) contained in small mesh bags fixed on the rocky substrates. Four bags were used for each plot selected for the application of this treatment. The presence of grazers was manipulated removing by hand all sea urchins at the beginning of the experiment and every time was necessary through a twice-weekly monitoring activity

Results

Univariate and multivariate analyses showed that grazing pressure significantly affects the resilience of disturbed assemblages, strongly decreasing benthic recovery rates of disturbed assemblages. When herbivores are removed, experimental nutrient enrichment enhances recolonization patterns, significantly increasing the number of macroalgal taxa. Recolonization by macroalgae (such as *Anadyomene stellata* and Dyctiotales) occurred only when grazing activity is removed. The combined effect of herbivores in presence of enriched conditions decreased benthic diversity and cover.

Discussion and Conclusion

Results suggest that 1) in enriched plots where grazers were also removed, recolonization by macroalgae can be observed in less than one year; 2) the two factors have an antagonist effects; and 3) the presence of grazers imperils any potential of restoration of disturbed assemblages. These findings stress that the two drivers could act as antagonistic stressors, so that the restoration of our system can be a difficult task. This experimental study is likely to provide useful indications for the management of disturbed assemblages to promote the recovery of assemblages under different trophic conditions.

THE RECREATIONAL VALUES OF EUROPEAN COASTAL ECOSYSTEMS AND THE IMPACT OF CLIMATE CHANGE UPON THEM

Andrea Ghermandi¹* And Paulo A.L.D. Nunes¹

¹ Fondazione Eni Enrico Mattei - Andrea.Ghermandi@Feem.It

Abstract

This study investigates the economic value of recreational activities in European coastal ecosystems and the potential impact of climate change thereupon. The current values are estimated based on a meta-analysis of 315 value observations from 79 independent studies. Values are found to be significantly affected by characteristics of the valuation study, site-specific characteristics and context characteristics such as biodiversity richness and geoclimatic variables. Benefit transfer techniques are used to scale up values and assess the recreational benefits of coastal ecosystems in 14 European countries. Both the highest individual and aggregated willingness to pay for coastal recreation is found in Mediterranean countries. The impact of climate change on such values under the conditions defined by the four IPCC scenarios is assessed.

Keywords: Biodiversity, Coastal Systems, Economic valuation, Ecosystem services

For the purpose of this study, a large data set of non-market valuations of recreational activities in coastal ecosystems was constructed. In total, 320 primary valuation studies were retrieved and investigated. Of all studies, 79 were found to contain sufficient information for the meta-analysis. The total number of observations in the data set is 315.

The average willingness to pay (WTP) per person per year for recreational activities in the valued sites is estimated by means of meta-analysis. The explanatory variables include valuation study characteristics (e.g., valuation method, welfare measure), site characteristics (e.g., ecosystem type, type of ecosystem service provided) and context characteristics (e.g., GPD per capita, population density, richness in biodiversity, and temperature). Values were standardised to 2003 US\$ per person per year.

The results of the meta-regression show that the coefficients of most explanatory variables are statistically significant and with the expected sign. Recreational fishing produces higher individual values than non-consumptive recreational activities. Income effects and population density effects are identified. Values are significantly affected by richness and threats to biodiversity and are positively correlated with temperature. The explanatory value of the model is reasonably high (adj. $R^2 = 0.47$).

Benefit transfer techniques are used to scale up the values estimated with the meta-regression and assess the average individual WTP and aggregated WTP for coastal recreational activities in 13 European countries during the baseline year 2003. Table 2 presents the mean baseline values of WTP per person per year and the aggregated values of coastal recreational activities in the 13 European countries investigated. The highest individual and aggregated values are found in Mediterranean countries such as Italy, Spain and Greece.

The effect of climate change on the recreational values of coastal ecosystems in Europe is investigated based on the storylines of the four IPCC scenario families A1, A2, B1 and B2. The effect of climate change is introduced in the meta-regression model through changes in the values of the context variables and in the total number of tourist arrivals per year. The analysis of the results shows that coastal recreational activities in Mediterranean and Scandinavian countries have the highest potential to benefit from economically oriented policies such as those described in IPCC scenarios A1 and A2. Central and Northern European countries would similarly benefit in terms of overall social welfare from coastal recreational activities from conditions as in scenario A1 and A2, though to a lesser extent. Figure 1 presents as example the comparison of the estimates for scenarios A1 and A2 across individual countries.

CLIMATE CHANGE IMPACTS ON CLAM DISTRIBUTION IN VENICE LAGOON: A MODELLING APPROACH.

Michol Ghezzo¹*, Silvia Silvestri², Michele Pellizzato³ and Georg Umgiesser¹

Abstract

Climate change impacts on growth and settlement of larvae of the clam *Tapes philippinarum* in Venice lagoon have been analyzed using a lagrangian larval growth and settlement model. The model has been coupled to a hydrodynamic-transport model, calibrated by the comparison with experimental data, and run according with different climate changes scenarios on 2030. The two scenarios were: i) increase of temperature, ii) increase of temperature combined with sea level rise. Our results show that an increase in temperature without an increase in sea level displays the worse impacts on the settlement of larval stages in the whole lagoon. Both scenarios implicate a considerable change in settlement distribution in different areas employed in fishing and seed harvesting activities. *Keywords: Fisheries, Global Change, Models, Larvae, Lagoons*

Introduction

The Venice lagoon is the biggest lagoon in the Mediterranean Sea, characterised by shallow water areas, complex bathymetries and morphological forms. One of the most profitable activities practised in Venice lagoon is clam fishing. Due to management issues, the activity, initially allowed on the whole basin, is now taking place in limited areas of the lagoon, assigned to fishermen by a local government body through 'concessions'. While 'concessions' are employed for the clam culture, other areas are used as source of seed. The goal of this study was to analyse the dynamics of growth and settlement of Tapes philippinarum clams at the juvenile planktonic and spat stage. The adult organisms may growth in an area far from the area where they have been generated, and this factor becomes important in order to predict the position of the 'concession' in the future. In particular, we analysed the dynamics of growth and settlement under two scenarios of climate change trough a lagrangian growth-settlement model coupled with a hydrodynamic-transport model in order to reproduce dispersion, growth and settlement of clam larvae.

Methods

SHYFEM is a hydrodynamic finite element model, which can simulate the circulation and the transport of the water masses and the spatial and temporal evolution of water temperature in the lagoon [1]. The model is able to represent both eulerian and lagrangian transport. This last has been used to calculate the trajectories of lagrangian particles that represent a pool of larval organisms. Each particle is characterised by length, weight, age, settlement state and larvae survival, assumed to be dependent on water temperature. The model has been applied on a bi-dimensional scale on the whole lagoon basin. In order to calibrate each module of the model and to define a reference situation, we have simulated the year 2005 under realistic forcing. Each larva has initial length of 60 micrometers. All particles are transported across the basin and increase their length in function of the local water temperature. When the larvae have a length of about 220 microm they settle on the sediment. When the lagrangian simulation starts the initial particle distribution reflects the distribution of the most productive areas in the lagoon [2]. We assume that a new emission of first stage larval organisms takes place every 90 days in the same initial areas (next generation) and inserts in the lagoon one million of new particles. Two climate change scenarios have been considered according with trends estimated for southern Europe: i) increase of temperature of 0.8°C (T08), ii) increase of temperature and sea level of 0.1 m (L10T08).

Results

The hydrodynamic model has been calibrated with several water level and water temperature measurements. A comparison between experimental data on larval length and weight and simulated data has been carried out in order to verify the functional form employed to simulate the growth and the temperature response from a larval organism.

The comparison between the spatial distribution of the modelled density of settled organisms and the distribution of the most productive areas used to the fishing activity or for the seed harvesting activity indicates that, from a qualitative point of view, the model is able to reproduce the main pattern of distribution. To give a quantitative estimate, three sampling stations have been considered in the inner central part of the lagoon in the year 2005. The comparison between measured and modelled density of individuals per square meter in the areas close to the sampling points indicates that in one case the model can reproduce the order of the measurements, in two cases the model

overestimates the data of one order of magnitude. The explanation of this difference is that the quality of sediments has an effect on the settled organisms survival. For this reason we applied 'a posteriori' a corrective factor calculated on the basis of the composition of the sediment in the lagoon. To evaluate the effect of the climate changes on settlement we compared the organisms (particles) successfully settled in the lagoon before the autumnal emission, in the reference simulation and in the scenario simulations. The comparison of the percentage of the successfully settled organisms calculated on the whole lagoon area indicates the T08 scenario as the worst combination, involving a decrease of 1.7% of the successfully settled organisms, whereas in the T08L10 the decrease is only 0.5 %. The number of organisms per square meter that colonises the "concessions" and the seed harvesting areas has been used to evaluate the changes in suitability of each area as consequence of climate changes. Three areas used for the 'concessions' are actually the most productive, but they reduce their suitability in both scenarios. At the same time an increase of the number of settled organisms can be found in a qualified area and other areas, not suitable at present. This effect is evident in the T08L10 scenario. With respect to the seed harvesting zone, the most important area shows a decrease of settled organisms in both scenarios in particular in T08.

Conclusions

We developed a tool that is able to reproduce the dynamics of growth, dispersion and settlement of clam in Venice lagoon. The results of our simulation show that climate changes should negatively affect clam settlement in the Venice lagoon, in particular, the actual level of the sea together with an increase in temperature may have the major negative effects. Furthermore, the impact will not be homogeneous across the lagoon. These results suggest that our numerical tool can be successfully employed in support to the decision regards the lagoon and the fishery management.

Abstract

Rapid global warming can affect an ecosystem's ability to adapt naturally. The potential impacts of climate changes on the clam fishery in the Venice lagoon have been analysed according to two different scenarios by 2030. Biological and socio-economic consequences of changes in population dynamics and species distribution have been evaluated. Both hypotheses of change of sea level rise and surface temperature have shown that the natural capital will be negatively affected and that the impact will not be homogeneous across the whole lagoon.

Keywords: Lagoons, Economic valuation, Coastal Management, Bivalves

With about 800 fishermen and a generated income of about 80 million euros, the Manila clam (*Tapes philippinarum*) fishery is one of the most profitable activities in the Venice lagoon [1].

Due to management issues, the activity, initially allowed on the whole basin, is now taking place in limited areas of the lagoon, assigned to fishermen from a local government body and called 'concessions'. While 'concessions' are employed for clam culture, other areas are specifically used as a source of seed. The process of identification and assignment of the concession and areas for seed harvesting is articulated and involves numerous management organisms [2].

According to the last Plan for the management of fish resources [2] 3000 ha of surface of the Venice lagoon are designated to clam fishing. This area has been estimated to guarantee the sustainability of the fishery, but only 2000 ha of this surface area are productive.

There is the need to identify the areas that can guarantee the socio-economic stability of the activity. This process is becoming challenging since the adult organisms may grow in an area far from the area where they have been generated.

The knowledge of the possible distribution of clam biomass on the lagoon basin in terms of density and dispersion can support local government and management bodies involved in decisions dealing with the choice of the extension and position of 'concessions' within the basin as well as the assignment of these areas to the fishermen.

Rapid global warming can affect can affect an ecosystems ability to adapt naturally. The lagoon ecosystems are particularly sensitive to change of climatic conditions due to the shallowness and the low volume of water in relation to the surface area [3].

An integrated bio-economic model has been developed according to the valuation framework showed in the figure 1, in order to assess the socio-economic consequences of climate change impacts on biodiversity loss with respect to the Manila clam (*Tapes philippinarum*).

In particular, we analysed the dynamics of growth and settlement under two scenarios of climate change: i) increase of temperature (T08), ii) increase of temperature combined with a sea level rise of 10cm (T08L10).

Fig. 1. Valuation framework

The impacts have been analysed through a 'biological model' that results from combining a lagrangian growth-settlement model with an hydrodynamic model (see fig. 1).

The value of each area has been determined by taking into account the outputs from the 'biological model' in terms of number of organisms per square meter that will reach the market size. Bivalves reach the market size, $L_{0}\,,$ when their weight is equal to 12.5 g.

By taking into account the final number of organisms per square meter, N_0 , their size, L_0 and a market price about 4 euros per kilogram, it is possible to estimate the revenue of the 'concessions'.

The revenue of each 'concession' in one year is equal to:

 $V_i (\Delta t, t_0, L_0, N_0) = \sum p \mathbf{x} \operatorname{Hi}$

Where i is the concession, p is the price per kilogram and H is the total biomass of a i 'concession'.

The net income is equal to the income that a 'concession' generates after subtracting costs and expenses from the total revenue.

Our results show that climate changes would negatively affect clam biomass in the Venice lagoon in both scenarios. The impact would not be homogeneous across the lagoon and taking into account different hypothesised sea level rise scenarios, we found that the actual sea level, combined with an increase in temperature, would have major implications. There are areas in which the settlement process would be particularly difficult and areas that would become more suitable for fisheries. By keeping the actual asset of areas in the lagoon, and maintaining the same level of income, equal to about 40.700 euros per year, the number of fishermen would have to decrease by about 200 in the T08L10 scenario and 300 in the T08. If we maintain the same number of people employed in this sector, it would no longer be possible to ensure the same level of income: the income would be reduced in scenario T08 by about 40% and in scenario T08L10 by about 30%. The loss of biodiversity will increase the current level of social tension. It becomes important to promote aquaculture, to protect the nursery areas and to experiment practice of culture with the support of tools as the bio-economic model we developed.

HEALING MUD FROM SECOVLJE SALTPANS

Neli Glavaš¹* and Nives Kovac¹

¹ National Institute of Biology, ljubljana, 1000, Slovenia - glavas@mbss.org

Abstract

The Secovlje saltpans are the northernmost in the Adriatic Sea. Salt is recovered from sea water by solar evaporation and during this process two side products are produced - salt pan mud and brine, both of which have healing effects. Due to its balneological features, healing mud (peloid) is used to threat various diseases and to improve general health and well-being. In order to determine the composition of the mud to be used for pelotherapy different chemical and mineralogical analysis were performed. *Keywords: Adriatic Sea, Coastal Systems, Chemical Analysis*

Introduction

The Secovlje saltpans are the northernmost in the Adriatic Sea and one of the few in the Mediterranean where salt is still produced in the traditional way. Salt is recovered from sea water by solar evaporation and during this process twoside products are produced - salt pan mud and brine, both of which have healing effects. Due to its balneological features, healing mud (peloid) is used to threat various diseases and to improve general health and well-being. The mechanisms responsible for these therapeutic features are generally considered to be associated with physical/chemical and thermal effects of the mud [1,2].

Materials and methods

Mud samples were taken on 8th January 2009 at five different sites (M1, B2, D1, L1, P2) in the area of the Secovlje saltpans. The samples were freeze-dried and grounded to a fine powder for analysis. FT-IR spectra were obtained on homogenized samples using a Perkin-Elmer Spectrum One spectrometer. The organic carbon (OC) and total nitrogen (TN) contents were determined with a Carlo Erba model 1108 elemental analyzer. The carbohydrate content was determined spectrophotometrically after Dubois [3], while the proteint content was determined bx X-ray powder diffraction (XRD).

Results and discussion

In order to determine the composition of the mud to be used for pelotherapy chemical and mineralogical analysis were performed on samples from five different sites in the area of the Secovlje Salina. Three samples were taken from the crystallizing salt basins (P2, L1, B2), where the mud is exposed to higher water salinity, while the samples D1 and M1 were collected on the river Drnica and channel Curto, which are used for water supply to the saltpans. Organic matter content (Table 1) was overall rather low (0,8-2,3 wt.%), with the highest value at site M1. The values of carbohydrate and protein content were more even, with higher values for samples from the crystallizing salt basins.

Tab. 1. Organic carbon (OC), total nitrogen (TN), carbohydrate (CHO) and proteins (PRT) content.of mud samples from sites M1, L1, D1, P2 and B2.

sample	OC	TN	CHO	PRT
	(%)	(%)	(mg/g)	(mg/g)
M1	2,3	0,1	6,2	3,5
P2	1,4	0,2	6,6	0,1
D1	0,8	0,1	3,4	-
L1	1,2	0,1	3,1	0,5
B2	1,0	0,1	6,5	0,1

The FT-IR spectra (Figure 1) of the mud from all five sites revealed carbonates (2513, 1795, 1420-1450, 876 and 713 cm⁻¹), silicates (1870, 1160, 1020, 799, 780, 695 and 530 cm⁻¹) and clay minerals (3625 cm⁻¹) as the major inorganic components. The organic carbon is confirmed by peaks at 3000-2800 cm⁻¹ (CH₂ and CH₃ groups), 1641 cm⁻¹ (Amide I) and 1150-1000 cm⁻¹ (carbohydrates). Mineralogical analysis confirmed calcite, quartz, halite, muscovite, manganium oxide and clay minerals as the major components.

The database from this study will provide essential data for establishment of normative regulations (standard criteria) and thermal mud production.

Abstract

The PREI (*Posidonia oceanica* Rapid Easy Index) is a method used to assess the ecological status of seawater along Mediterranean French coasts. It was drawn up according to the requirements of the Water Framework Directive (WFD 2000/60/EC) and was tested on 42 stations in PACA (Provence-Alpes-Côtes d'Azur) and Corsica. The PREI is based on five metrics: shoot density, shoot leaf surface area, E/L ratio (Epiphytic biomass/leaf biomass), depth of lower limit, and type of this lower limit. The 42 studied stations were classified in the first four levels of status: high, good, moderate and poor. The PREI values ranged between 0.280 and 0.847; this classification is in accordance with our field knowledge and with our knowledge of the literature. The PREI was validated regarding human pressure levels (r^2 = 0.74).

Keywords: Posidonia, Monitoring, Coastal Waters, Phanerogams, Biometrics

Introduction The European Union has launched a new strategy to conserve and recover the ecological quality of the marine environment. In order to attain this objective, the Water Framework Directive (WFD) has established the basis of policies for the monitoring, protection and enhancement of the status of aquatic systems in the Member States. The main goal of the WFD is to achieve (or maintain at least) a "good water status" for all the European waters by 2015. To this end, this directive defines the concept of ecological status as the quality of the structure and functioning of ecosystems associated with homogenous water bodies. The evaluation of the status of each water body is based on the use of some organisms or groups of organisms sensitive to anthropogenic pressures: biological quality elements (BQEs). Phytoplankton, macroalgae, angiosperms and benthic fauna are the BQEs to be considered. According to the WFD, biological variables indicative of the status of these BQEs should be used for evaluation and monitoring purposes. On the basis of previous work on the bioindicating of water global quality by Posidonia oceanica this species was chosen for the Mediterranean area as the angiosperm BQE [1]. As permitted by the WFD, each member state, involved in this BQE, can define its own method to evaluate the state of the Posidonia oceanica meadow. We describe the PREI (Posidonia oceanica Rapid Easy Index) method used in French coastal regions to evaluate the ecological status of water bodies in the Mediterranean Sea following WFD requirements.

Methodology We calculated the PREI with five metrics measured in P.oceanica meadows to define the ecological status of French Coastal Waters according to the WFD recommendations: shoot density, shoot surface, E/L (ratio between epiphytic biomass and leave biomass) measured on shoots sampled at the same depth; depth of the lower limit and type of this limit (regressive, progressive or stable). These metrics were selected because they provide pertinent information on the vitality of the meadow (at the individual and population level) for a wide spectrum of disturbance (water transparency, nutrient concentrations and eutrophization, sedimentary dynamics, grazing pressure...) regularly described in the Mediterranean Sea [2]. As such, they constitute unequivocal indicators of Posidonia oceanica. They are also easy to obtain with a good cost-efficiency ratio and low technological investment. According to the WFD, the classification of ecological status is based on the deviation of the status of the BQE from its potential status under pristine conditions (reference conditions: RC). This ecological status is expressed using a scale going from 1 (RC) to 0 (worst conditions where the BQE is badly affected or missing). The ratio between the status of a given BQE noted in a station and its status in the reference conditions is called the Ecological Quality Ratio (EQR). To calculate this EQR, a definition of RC has to be made. RC describe the characteristics in undisturbed conditions. On this basis, considering that no pristine conditions could be found in the studied area, we postulated RC as a "theoric optimal site", corresponding to the best values of each metric noted in the field. We defined EQR' as an index integrating the averaging of the chosen individual metrics: EQR'= (N density + N leaf surface area + N (E/L) +N lower limit)/3.5 with:- N density = value measured-0/reference value-0; - N leaf surface area = value measured-0/reference value-0; 0 being considered as the worst value for the density and for the leaf surface area. - N (E/L) = [1 - (E/L)] $\times 0.5$; - N lower limit = (value measured-17)/ (reference value -17), 17 m being considered as the worst lower limit for Posidonia meadows. N' = depth noted

on the field + λ , where $\lambda = 0$ (stable limit), $\lambda = 3$ (progressive limit) or $\lambda = -3$ (regressive limit). We arbitrarily assigned an EQR value of 0.100 for the "bad" status boundary; the other EQR boundaries were obtained by dividing the remaining scale (from 0.100 to 1) into four categories of equal amplitude: "High, Good, Moderate and Poor status" [3]. Therefore, where P. oceanica existed, the EQR was computed as follows: EQR = (EQR' + 0.11)/(1 + 0.10). Application of the method to the French Coast The sampling was performed at a 15 m depth in April (2007) to prevent the masking effects of depth and seasonal variability . At each station, shoot density, depth and type of lower limit were noted in situ by a scuba diver. Twenty shoots of P. oceanica were collected for the laboratory measurements (biometry and E/L). The 42 studied stations were classified in the first four levels of status: high, good, moderate and poor. The PREI values ranged between 0.280 and 0.847. Two meadows (8%) received the status of poor in PACA (Corbière and Villefranches); 16% and 22% were qualified as moderate, 62% and 67% as good, 13% and 11% as high both in the PACA area and along the coast of Corsica. The mean PREI EQR in PACA was slightly lower than along the coast of Corsica (0.609 and 0.635 respectively).

In order to verify the robustness of our PREI, we calculated an anthropization index. The anthropization index was defined as the sum of 7 impact factors affecting the seawater quality and /or biotope quality: fish farming, industrial development, agriculture, tourism, fishing, commercial ports and urbanization. Each impact factor was classified from 0 (no impact) to 5 (dramatic effect on the meadow). The quality of seawater expressed by our anthropization index was negatively correlated with the PREI (r^2 =0.74). Our index is a destructive technique, requiring scuba divers, using shoot density, the most adopted standardized descriptor (Montefalcone, 2009). All stations were sampled during a short period (10 days), which avoided seasonality effects. The PREI is both cost effective and easily applied. It requires scuba divers working on random punctual stations (15 m depth) and on positioned stations (depth limit). It is a reliable approach for estimating the state of *P.oceanica* meadows and the ecological status of seawater.

DISTRIBUTION ET ABONDANCE DU ZOOPLANCTON DE LA COTE NORD DE LA VILLE DE SFAX (TUNISIE): COMPARAISON DE DEUX METHODES D ECHANTILLONNAGE

W. Guermazi^{1*}, A. Rekik¹, Z. Drira¹, J. Elloumi¹, A. Bouaïn¹ and H. Ayadi¹

¹ Université de Sfax, Faculté des sciences de Sfax. Département des sciences de la vie, 3000, Tunisie - wassim016@yahoo.fr

Abstract

La modalité d'échantillonnage agit sur l'abondance relative des différentes classes et espèces de copépodes (P<0,001). Les espèces de copépodes qui échappent à l'échantillonnage par la bouteille fermante sont plus élevées que celles qui ne sont pas récoltées par le filet à plancton. Par contre, les deux techniques d'échantillonnage ne semblent pas affecter la densité du zooplancton total (P>0,05). *Keywords: Coastal Systems, Zooplankton , Sampling Methods, Gulf Of Gabes*

Introduction

Les méthodes de collecte de données sont, depuis longtemps, considérées comme un facteur important pour élucider la dynamique des écosystèmes marins [1]. L'estimation de la densité et de la diversité du zooplancton a été réalisée par diverses techniques d'échantillonnage [2]. Dans cette étude, deux techniques d'échantillonnage du zooplancton, par le filet à plancton et la bouteille fermante, ont été testées au niveau de 18 stations réparties sur 6 transects le long de la côte nord de la ville de Sfax. L'échantillonnage du zooplancton a été effectué au niveau de 3 stations dans chaque transect pendant le mois de juillet 2007.

Résultats et discussions

14 classes ont été répertoriées au niveau de 18 stations avec une nette dominance des copépodes qui est de l'ordre de 61,40 % pour les échantillons récoltés par le filet à plancton (Figure 1). Par contre, les copépodes contribuent seulement à 43,36 % dans les échantillons récoltés par la bouteille fermante. Les résultats d'ANOVA complété par le test post-hoc Duncan sur les densités des copépodes montrent une différence hautement significative entre les deux méthodes employées (F= 4,01; d.d.1 = 89; P< 0,001). Les abondances relatives des nauplii, des copépodites et des adultes, obtenues par les deux techniques d'échantillonnage, sont similaires, de l'ordre de 60, 23 et 17 %, respectivement. Toutefois, l'analyse statistique montre des différences hautement significatives (ANOVA-Duncan, P<0,001). Les cyclopoïdes dominent largement avec une abondance relative significative (F = 25,32 ; d.d.1 = 35 ; p<0,0001) de l'ordre de 75,78 et 87,73 % enregistrées respectivement pour les échantillons récoltés par le filet et la bouteille fermante. L'abondance des harpacticoïdes estimés par le filet et la bouteille diffère significativement (p>0,001) et est environ de 12,63 et 6,55 %, respectivement. Les calanoïdes sont moins abondants que les cyclopoïdes et les harpacticoïdes. L'abondance est de l'ordre de 11,38 et 5,64 %, enregistré respectivement pour les échantillons récoltés par filet et bouteille fermante. Les poecilostomatoïdes sont présents accidentellement au niveau de la zone d'étude (< 0.21%) (Figure 1). Pour les échantillons prélevés par le filet, un total de 15 espèces réparties en 12 familles a été répertorié au niveau de la zone prospectée (Tableau 1). La contribution des Oithonidae dans le nombre total des copépodes varie entre 54,89 et 80,46 %.

Fig. 1. Abondances relatives des copépodes et des différentes classes enregistrées par le filet à plancton (A) et la bouteille fermante (B)

La contribution des autres familles apparaît faible par rapport à la famille des Oithonidae. En effet, la famille des Tachydiidae contribue à 10,05 %, la famille des Acartiidae représente 6,89 %, la famille des Stephidae 4,12 %, la famille des Tisbidae 1,64 % et les autres familles (Ectinosomidae, Paracalanidae, Centropagidae, Temoridae, Clytemnestridae, Corycaeidae et Oncaeidae) sont présentes en faible abondance. Un total de 11 espèces réparties en 8 familles ont été répertoriés au niveau de la zone prospectée quand l'échantillonnage est

fait par la bouteille fermante (Tableau 1). L'abondance des Oithonidae, au niveau des différentes stations étudiées de la côte nord de Sfax, domine largement, entre 64,28 et 99,62 %. Cependant, les familles des Clytemnestridae, Acartiidae, Tachydiidae et Stephidae présentent respectivement 3,96, 3,23, 2,59 et 2,28 %. L'abondance des autres familles (Ectinosomidae, Temoridae et Oncaeidae) est peu importante.

Tab. 1. Les espèces de copépodes inventoriées dans la zone d'étude par les deux méthodes d'échantillonnage

Classes de copépodes	Filet à plancton	bouteille fermante

Oncaea conifera	×	×							
Oncaea mediterranea	×	0							

× : présents ; 0 : absents

Cette étude montre une nette dominance de l'espèce *Oithona nana* avec 72,84 % au niveau des échantillons prélevés par le filet. Toutefois, l'espèce *Oithona similis* domine les échantillons récoltés par la bouteille fermante avec 66.17 %. Les autres zooplanctons (Larves de cirrhipède, Larves véligères de gastéropode, Ostracodes, Bivalves, Annélides polychètes, Méduses, Tintinnides, Euphausiacés, Zoés, Amphipodes, Cladocères, Nématodes et Appendiculaires) ont été répertoriés au niveau de toutes les stations, mais avec une abondance plus importante pour les échantillons prélevés par la bouteille fermante (56,64 % du zooplancton total) (Figure 1). L'ANOVA n'a pas révélé de différence significative de densité entre les deux techniques d'échantillonnage (p>0,05). Cette étude montre que la technique d'échantillonnage affecte l'estimation de l'abondance et la distribution des copépodes, ce qui corrobore les résultats de Youngbluth [3].

CARBONIC ANHYDRASE IN MUSSEL MYTILUS GALLOPROVINCIALIS: A PRELIMINARY STUDY

Dijana pavicic Hamer¹* and Bojan Hamer¹

¹ "Ruder Boškovic" Institute - pavicic@cim.irb.hr

Abstract

We investigated the esterase activity of carbonic anhydrase (CA) on total esterase activity level in mussels sampled from 19 locations along the Croatian coast of Adriatic Sea. The results of total esterase activities in winter were lower than in summer at almost all investigated locations. CA activities determined in gills of mussel sampled in winter ranged from 1.75% to 24.65% of total esterase activity. CA activities in summer samples were practically not detectable. Despite *in vitro* research showed potential application of CA activity in bioassay and biomarker studies for application of CA as a biomarkers of environmental pollution further research are needed.

Keywords: Adriatic Sea, Ecotoxicology, Enzymes, Mollusca, Pollution

INTRODUCTION

Carbonic anhydrase (CA), a ubiquitous enzyme in the bacteria, plant, and animal kingdoms catalyses the reversible hydration of CO_2 to produce H⁺ and HCO₂ using zinc as a cofactor. To date 15 CAs or CA-like proteins have been identified in mammals. In humans, for CAII isozyme, turnover number for CO2 hydration is the highest known for any enzyme, while for the other isozymes activities are lower in the order CAII > CAIV > CAI > CAIII. There are several CAs which have shown esteraze activity, enzymes known to hydrolyse endogenous substrates, and the majority hydrolyse lipid ester substrates. In in vitro conditions, the esterase activity of CA was determined, both in physiological and pathological conditions. Additionally, besides Na,K-ATPase, CA represents a key enzyme involved in the adaptation of marine organisms to environmental conditions [1]. Experimental studies performed on Crustacea gills have shown two main isozymes of CA located in membrane-bound and in cytosolic fractions, functionally similar to mammalian CAIV and CAII [2]. So far no report has dealt with the esterase activity of CA on total esterase activity level in mussel.

MATERIAL AND METHODS

In this study the esterase activity of CA on total esterase activity level was investigated in mussels sampled from 19 locations along the Croatian coast. The gills were the target tissue because the respiratory, ionic transport and pH regulatory enzyme function of CA and it's potential usage as a biomarker of environmental pollution was the main topic. Previously it was suggested the possible application of CA activity inhibition as an *in vitro* bioassay for the detection of heavy metals in pollution monitoring using the mussel *Mytilus galloprovincialis* Lamarck, 1819 [3,4]. Total esterase activity was measured in the cytosolic fraction of gills homogenates by colorimetric end point reaction using p-nitrophenyl acetate as enzyme substrate, and CA activity was estimated by the same enzymatic reaction using acetazolamide as a specific CA inhibitor.

Fig. 1. Total esterase activity in cytosolic fraction of mussel gills: (-AZM) without specific CA inhibitor and (+AZM) with acetazoamide inhibition.

RESULTS

The results of total esterase activities in winter (March; average value 0.137 ± 0.057) were lower then determined for the summer season (August; 0.153 ± 0.036) at almost all investigated locations (Fig. 1). CA activities determined in gills of mussels sampled in winter ranged from 1.75% to 24.65% of total esterase activity. CA activities in summer samples were practically not detectable. This is preliminary research; it is difficult to assume a direct relationship between pollution at investigated sites with determined CA activities, especially in the summer period.

INSTEAD OF CONCLUSIONS

Inspite *in vitro* studies showing clear inhibition of CA activity with heavy metals, for the application of CA as a biomarker of pollution further detailed research on the effects of environmental and physiological factors and different CA isozymes activity using different inhibitors, protein characterization and sequencing are needed. With this paper we report a partial CAII sequence of *M. galloprovincialis* (Fig. 2) which is, according to the NCBI database the first normal one for Mollusca, Bivalvia, besides nacrein, nacrein-like proteins and the novel CA from *Tridacna gigas* with two CA domains.

Fig. 2. Alignment of our partial *M. galloprovincialis* cDNA sequence with similar human and fish CAs after NCBI blast.

Abstract

The purpose of this study is to include expert knowledge as one part of the modelling system and thereby offer the chance to create a productive interactive system between expert, mathematical model, ASM ([1]), and artificial neural networks (ANNs). An attempt to determine outflow-influencing parameters in order to simulate spring flow is presented. *Keywords: Models, Behaviour, Algerian Basin*

The Bouteldja dune aquifer (NE of Algeria) is fed by rains and streaming water on the sandy argillaceous relieves in the Est. The lateral passage to the gravel of the Bouteldja Plain is marked by numerous bogs that correspond to the piezometric level. These bogs have long been an environment for migratory birds and a natural reserve for many species. However, the continued exploitation of about 30 wells has negatively influenced the hydrodynamic equilibrium of the aquifer and has brought a diminution of spring's capacity ([2], [3]). In this study, we tried by using a hydrodynamic model and the neural network to ascertain the state of the resources and to identify the factors responsible for the decreasing flows of the three principal springs of the area (Bougles, Bourdim and Titteri) by using neural networks. The calibration in the non-steady state allowed for the depletion of the layer storage, related essentially to an overexploitation, and a weak recharge to be taken into account. This hydraulic deficit was represented by a drop of the piezometric surface (Figure 1) that can amount to 30 m, and by a closely corresponding reduction of the areal extent through which groundwater emerges into the surface. This situation had a direct consequence on the surface, on the hydrologic regime of the wet areas, and on the degradation of the water quality of rivers and lakes. The ANNs show that the decrease in flows of the springs is not only due to the unfavourable climatic conditions, but also to the intensive exploitation of the aquifer. These results show that the groundwater reserves are decreasing over time, thus highlighting the need to take some urgent measures to stop this phenomenon.

Abstract

The spatial distribution of ciliates was studied in the Gulf of Tunis (NE Tunisia) in August 2006. 17 species belonging to 3 groups were identified. Spirotrichea was the dominant group in the inner (92%) and the outer (94%) shelf. The ciliate density decreased from the coast (mean \pm s.d = 108.33 \pm 80.10 cells l⁻¹) to the open sea (mean \pm s.d = 56.25 \pm 47.87 cells l⁻¹) areas. In terms of a vertical occurrence, the ciliate community showed a decrease from the surface to the bottom. *Keywords: Coastal Waters, Open Sea, Deep Waters, Surface Waters, Plankton*

Introduction

Studies on marine protozoans have been carried out in the Mediterranean for many years, and their importance in the trophic organization and community structure of pelagic ecosystems has been emphasized [1]. However, studies addressing the distribution of ciliate assemblages in the Gulf of Tunis (NE Tunisia) are totally missing. Therefore, it seems very interesting to study the protozoa community in this area. The present study gives, for the first time, the structure and the spatial distribution of the ciliate community in the Gulf of Tunis.

Material and methods

Sampling was performed in 4 coast-to-offshore stations during a cruise on board the R/V Hannibal in August 2006. Samples were taken at 3 depths (surface, middle of water column and bottom) for stations <100 m deep and at 5 depths (surface, -10 m, -20 m, thermocline and bottom) for stations >100 m deep. In each station, profiles of temperature, salinity, dissolved oxygen and water density were collected with a CTD: SBE 9 equipped with a 12 Niskin bottle rosette sampler. Samples for nutrients were stored at -20°C before analysis with a BRAN and LUE BBE type 3 analyzer. Sub-samples (1L) for ciliates were fixed with acid Lugol solution (2% final concentration) and stored in the dark at low temperature (4°C) until analysis. The different species were quantified with an inverted microscope using 20 ml Utermöhl chambers. The entire surface of the chamber was examined at 40 x magnification.

Results and discussions

Water column profiles showing the range of physico-chemical in the different stations of the two gulfs are summarized in Table 1. During this study, a strong thermocline was detected at the mean depth of 30 m. No significant difference (P>0.05) was detected between the coast and the open sea area, in terms of physico-chemical parameters (Table 1).

Tab. 1. Min, max and Mean \pm S.D. of physico-chemical parameters in the Gulf of Tunis

	Min	Max	Mean ± s.d
Physical parameters			
Temperature (℃)	13.58	27.34	18.19 ± 5.16
Salinity (p.s.u)	37.17	38.68	37.77 ± 0.44
Sigma-t (Kg m ⁻³)	24.46	29.06	27.24 ± 1.63
Dissolved oxygen (mg l ⁻¹)	4.48	5.74	5.29 ± 0.47
Chemical parameters			
N-NO3 ⁻ (µmol I ⁻¹)	0.1	1.21	0.66 ± 0.35
N-NO2 ⁻ (µmol I ⁻¹)	0.02	0.63	0.25 ± 0.15
N-NH₄⁺ (µmol l⁻¹)	0.04	0.99	0.45 ± 0.36
Si(OH) ₄ (µmol I ⁻¹)	0.02	1.23	0.32 ± 0.4
P-PO4 ³⁻ (µmol l ⁻¹)	0.01	0.87	0.28 ± 0.24
T-N (μmol l ⁻¹)	5.61	10.56	7.18 ± 1.16
T-P (μmol l ⁻¹)	0.32	1.95	1.02 ± 0.33
N/P ratio	0.92	84.29	14.63 ± 20.98

The N/P ratio (mean \pm s.d = 14.63 \pm 20.98) was lower than the Redfield ratio (16) suggesting a potential N limitation. During this summer study, 17 different

species belonging to 3 groups: Spirotrichea, Oligohymenophorea and Colpodea were identified. In the coastal and the open sea stations, Spirotrichea dominated the ciliate community with 92% and 94%, respectively. In fact, this group was the most abundant in the Gulf of Gabes [1]. Although tintinnids were characterized by a small contribution to the ciliates community [2], in this present study, they contributed 40% of the total ciliates. Among this class, Choreotrichia contributed 80%. The loricates ciliates constitute an important group in the Choreotrichia (91%) and in the total of the ciliates community (40%). The protozoa community marked a decrease from the inshore (mean \pm s.d = 108.3 \pm 80.1 cells 1⁻¹) to the offshore (56.2 \pm 47.9 cells 1⁻¹). In terms of the vertical distribution, ciliate density showed a maximum in the middle of the water column (150 \pm 141.42 cells 1⁻¹). However, in stations where the bottom was above 100m, ciliate density showed a decrease from the upper (125 \pm 35.35 cells 1⁻¹) to the deeper (75 \pm 106.1 cells 1⁻¹) layer (Fig. 1).

Fig. 1. Vertical distribution of ciliate density in both inshore and offshore stations

This differed from the gulf of Gabes, where ciliate density increased from the surface to the bottom [1]. However, no significant correlation (P>0.05) was detected between the physico-chemical parameters and the spatial distribution of the ciliate community.

FLUVIAL INPUTS AND ISOTOPIC SIGNAL OF ORGANIC MATTER DISCHARGED TO THE NW MEDITERRANEAN

M. Higueras ¹, P. Kerhervé ²*, A. Sanchez vidal ¹, C. Liquete ¹, A. Calafat ¹, M. Canals ¹, W. Ludwig ² and S. Heussner ² ¹ CEFREM UMR CNRS 5110 - Université de Perpignan, 66860, France - kerherve@univ-perp.fr ² GRC Geociències Marines, Univ. Barcelona, 08071, Spain

Abstract

Nine rivers discharging to the NW Mediterranean (Gulf of Lions and Catalan Sea) are currently biweekly/monthly studied to understand their role in the transport of organic matter from the continent to the ocean. Water discharge, total suspended sediment, particulate organic carbon and nitrogen contents and their isotopic ratios will be used to answer to major questions regarding the amount and quality (as a measure of source) of organic matter which is effectively transported from land to sea. *Keywords: Western Mediterranean, River Input, Organic Matter*

River systems represent the primary pathway for carbon transport from the terrestrial to the marine environment, and are thus critical in determining the quantity and composition of carbon reaching the continental shelf. In addition, physical processes occurring at the shelf edge are capable of transferring this accumulated organic carbon to the deep sea. Thus, identifying sources and fluxes of carbon and nitrogen to the continental margin is essential to understanding carbon and nitrogen cycling in the overall marine environment. We have analyzed the temporal variations of water discharge, total suspended sediment, particulate organic carbon (C_{org}) and nitrogen (N) contents and their isotopic ratios (∂^{13} C and ∂^{15} N) from three Catalan rivers (Fluvià, Ter and Tordera) and six French rivers (Têt, Agly, Aude, Orb, Hérault, Rhône) flowing into the Catalan margin and the Gulf of Lion, respectively, in the Western Mediterranean [1].

First results from the 2008-09 period show that the origin of the organic matter carried by the Catalan rivers is mostly waterweeds in the Fluvià River and soil with terrestrial vegetation in the Ter and Tordera rivers. In addition, ∂^{15} N results show that Ter and Tordera rivers undergo anthropogenic inputs of inorganic nitrogen, while the Fluvià River is the less human-impacted. Moreover, alteration of the solid load by artificial dams has been observed to be a significant factor influencing the total suspended sediment in the Ter River.

The French rivers have high Corg and N contents (up to 20% and 5%, respectively). The main feature of this survey concerns the high seasonal variation in the quality of the riverine particulate organic matter excepted for the Rhone River. In summer, the biological production (mainly freshwater phytoplankton) is enhanced in sunlit and calm waters, whereas higher water flows floods discharging material mainly originated from soil erosion characterize winter and spring. The Têt River exhibited atypical ∂^{13} C and ∂^{15} N values that may reflect the large influence of the sewage treatment plant of Perpignan.

Overall, particulate matter samples from these nine rivers are used to characterize the riverine input to the adjacent coastal system and provide information about the fate of the land-sea transported particles and their potential impact on the marine ecosystems.

THE IMPACT OF THE CONSTRUCTION AND OPERATION OF LIQUEFIED NATURAL GAS (NLG) TERMINALS ON MERCURY MOBILITY AND REACTIVITY FROM POLLUTED COASTAL SEDIMENTS

M. Horvat ¹*, R. Rajar ², M. Cetina ², N. Ogrinc ¹ and D. Kocman ¹

¹ Jozef Stefan Institute - milena.horvat@ijs.si

² University of Ljubljana, Faculty of Civil and Geodetic Engineering

Abstract

The sediment of the Gulf of Trieste is heavily polluted by mercury (Hg) originating from Hg mining activities in the past. The construction of two gas terminals for LNG is planned in this heavily contaminated site. A simulation based on previously developed models and measurements indicated that due to the enhanced mobility and reactivity of Hg from the sediment, elevated mercury concentrations in fish are expected in the future.

Keywords: Coastal Management, Mercury

Mercury in the Gulf of Trieste is mainly present due to the discharge of the Soca river, which drains the area of the second largest mercury mine in the world, Idrija in Slovenia [1-5]. In 500 years of its operation, the mining activity discharged over 35.000 tons of mercury into the environment. A large quantity of this mercury is buried in the sediment of the Gulf of Trieste. Concentrations of Hg in sediment frequently exceed the limit value of 2 mg/kg. Due to the presence of methylating bacteria, mercury is transformed from inorganic form to monomethylmercury (MeHg) which is the most toxic compound of mercury [3]. Bioaccumulation and biomagnifications of MeHg in biota results in high concentrations of this toxic compounds in edible fish. Therefore, the reduction of MeHg in the environment is one of the primary objectives in remediation of mercury contaminated sites [4].

Based on the state of the art knowledge of mercury cycling the Gulf of Trieste, simulations of resuspension of the bottom sediments during construction and operation of the terminals were made by the 3D numerical model PCFLOW3D[6-9]. The PCFLOW3D is a non-steady state three-dimensional non-linear baroclinic z- coordinate model with hydrostatic approximation. The model was developed at the Faculty of Civil and Geodetic Engineering of the University of Ljubljana and consists of four modules: a hydrodynamic (HD) module, a transport-dispersion (TD) module, a sediment-transport (ST) module and a biogeochemical (BGC) module, in order to simulate the transport and transformations of mercury.

Besides the simulations of hydrodynamics and some basic pollutants, special care was given to the development of the module for the simulation of transport and fate of mercury. Initially, the seasonal (four seasons) hydodynamic of water was simulated based on measurement data of the temperature and salinity (3 D fields), the average seasonal wind directions and velocity, as well as water discharge of Isonco river. Taking the exact geographical position of planned NLGs, mercury concentrations in sediments, seasonal production of MeHg in sediments, the flux of inorganic Hg and MeHg into the water column was calculated. Specifics of seasonal variations in hydrodynamics and in particular biogeochemical cycling of mercury was taken into account. The calculations were mainly concentrated on the changes of MeHg release, which tends to bioaccumulate and biomagnify in food webs. MeHg production vary from season to season. The following relative intensity of MeHg production was taken into account: 2.5 for autumn, 1.5 for winter, 2.5 spring and 6 for summer. This ratios were experimentally determined in previous studies [3,4].

The model simulations showed that the construction of the two terminals would cause a resuspension of 75.000 tons of bottom sediment, and the ships transporting LNG would cause a resuspension of 175.000 tons of sediment per year. Based on the partitioning of mercury between sediment and water during different seasons and rates of mercury transformation from inorganic to organic mercury it was calculated that the highly toxic MeHg in the Gulf water would increase from the present 0.05 ng/L to about 0.09 ng/L and the concentration of MeHg in fish from the present 0.3 to 0.6 mg/kg. This raises a question of safe consumption of fish in the Gulf of Trieste.

Based on the methodology developed simulations of various scenarios were also proposed that would significantly reduce the production of MeHg during installation and operation of NLGs.

CIRCULATION, HYDROGRAPHY AND PRIMARY PRODUCTION CHARACTERISTICS OF THE SYRIAN MARINE WATERS, NORTHEASTERN MEDITERRANEAN SEA.

Mohammad Hussein ¹*

¹ University of Perpignan - mohammad.hussein@voila.fr

Abstract

This work describes the oceanographical properties of the Syrian marine water on the basis of two cruises performed during Dec.2006 and Mar.2009 using a 19plus CTD. Analysis of hydrological data from the study area reveals the presence of three water masses in each cruise: Land Water of lower salinity on water depths up to 20m during Dec and Mar, Levantine Surface Water with higher salinity only during Dec, Modified Atlantic Water of lower salinity in the bottom layer during Dec and in the surface layer during Mar, and finally Levantine Intermediate Water at the bottom during Mar. Chlorophyll-a concentration measured varied markedly with depth and season, being 0.05±0.01mg.m-3 during Dec and 0.08±0.01mg.m-3 during Mar. The deep Chl-a maxima, of 0.08mg.m-3 during Dec and 0.1mg.m-3 during Mar, were observed between 50-100m. *Keywords: Hydrology, Chlorophyll-a, Levantine Basin*

The Syrian marine water is one of the least-known areas of the Eastern Mediterranean sea and much work is needed to cover the gaps. This work describes the oceanographical properties of the Syrian marine water (northeastern part of the Levantine Sea) on the basis of two hydrographical cruises performed during Dec.2006 and Mar.2009 using a Seabird model 19plus CTD probe. Analysis of hydrological data from the study area reveals the presence of three water masses in each cruise; Land Water of lower salinity on water depths up to 20 m during Dec.2006 and Mar.2009, Levantine Surface Water with higher salinity (39.50-39.75) only during Dec.2006, Modified Atlantic Water of lower salinity (38.89) in the bottom layer during Dec.2006 and in the surface layer during Mar.2009, and finally Levantine Intermediate Water at the bottom during Mar.2009. Stratification was clearer in December compared to March, and cyclones and anticyclones were observed in specific times and locations. Geostrophic velocities, which were found to be directed northward with a maximum of 17 cm/s, revealed that cyclonic eddy (max. 7 cm/s southward at 150 m depth) in the northern area and anticyclonic one (max. 13 cm/s southward at 50 m depth) in the southern area were present. Dissolved oxygen was higher in Mar.2006 (214±4.8 µM) than in Dec.2009 (202±11.5 µM), with the whole water column (down to 300 m depth) being homogenous during Mar.2009, but only the top 125 m, which represent the Levantine Surface Water, were homogenous during Dec.2006 and decreases afterward due to the presence of the Modified Atlantic Water. Chlorophyll-a concentration measured varied markedly with depth and season, being 0.05±0.01 mg.m-3 during Dec.2006 and 0.08±0.01 mg.m-3 during Mar.2009. The deep Chl-a maxima, of 0.08 mg.m-3 during Dec.2006 and 0.1 mg.m-3 during Mar.2009, were observed between 50-100 m water depth. These Chl-a maxima were associated with the cyclonic and anticyclone eddies at 40-75 m and at 80-105 m water depth, respectively. Sea-viewing Wide Field of view Sensor (SeaWiFS) was used to validate the spatial and temporal distribution of chlorophyll-a (Chl-a) concentrations around Latakia (main city of the Syrian coast) during Dec.2006. A significant correlation was found between SeaWiFS and in situ data (r2=0.82). At low Chl-a concentrations (<0.1 mg-3), SeaWiFS estimates were approximately 70% of in situ values, but only 30% at high Chl-a concentrations (>0.1 mg-3). Keywords: Hydrography; Chlorophylls; Dissolved Oxygen; Geostrophic flow.

CONTENTS OF HEAVY METALS IN COASTAL SURFACE SEDIMENTS FROM MONTENEGRIAN COAST

Danijela Joksimovic¹* and Slavka Stankovic¹

¹ Institute of marine biology, P.Box 69, 85330 Kotor, Montenegro, e-mail - djoksimovic@ibmk.org

Abstract

The aim of the present work was to determine the levels of lead, cadmium, arsenic and mercury in coastal surface sediments at three stations located in the "inner shore" waters Boka Kotor Bay, and at one station located "off shore" Montenegrian coast, considered as a reference station. The comparison of the results obtained for the "inner shore" stations with reference station showed that the content of this metals in some station are considerable increased in ratio to reference station. *Keywords: Sediments, Metals*

Introduction

Also as other areas on Montenegrin coast, this system (Boka Kotor Bay) is also under a great impact of anthropogenic factors and the activities on the shore. The river weighted by sewage, canalization and industrial waters brings large quantities of pollutants into the sea [1]. The material washed from the shore by large quantities of precipitation in Boka Kotor Bay, together with the stationed industrial objects and hospitals on the very shoreline of the Bay, contribute to the pronounced negative anthropogenic impact on this area [2].

Material and Methods

Samples of bottom sediments were taken from a depht of 15-20 cm using a internal diameter plastic gravity corer. Bottom sediments were characterized by amorphous form, brown-green colours, high hydration and significant organic matter content. The sampling was done in autumn of 2005 and 2006 at 4 stations in the Montenegrian coast (Kotor, Tivat and Herceg Novi in Boka Kotor Bay and Mamula, location at the open sea), Fig.1. Dry sample (abaut 0.3 g) is dissolved with HNO_3+HCLO_4+HF (4+1+6). All the samples were examined in laboratory using atomic absorption spectrometer equipped with a deuterium-are background corrector and Perkin Elmer MHS-10 hydride generator were used. Standard holow cathode lamps were used for all elements exept arsenic, for which a Electrodes Discharge (EDLs) lamp was used. Each samples was analyzed in triplicated.

Fig. 1. Map of investigated position (Boka Kotor Bay)

Result and Discussion

The Boka Kotor Bay, as a direct recipient of pollutants of anthropogenic origin from the area, showed the higher contents of Cd, Pb, As and Hg in bottom sediments in 2005 compared to 2006 when values for those heavy metals on every examined locations was much lower [3]. Comparing values of heavy metals on each location in the Bay with referent point (location at the open sea) much higher values of every heavy metal are detected [4]. Content of Cd in the Bay was 0.541-0.869 mg/kg and on the referent point it was 0.4146 mg/kg., Pb (3.722-9.561 mg/kg), As (3.77-5.21 mg/kg) and Hg (0.029-0.098 mg/kg). At the same period of 2006 detected values are much lower and the concentrations was for Cd (0.05-0.074 mg/kg), Pb (0.028-4.79 mg/kg), As (1.75-4.45 mg/kg) and Hg (0.014-0.093 mg/kg). Average contents of heavy metals diminish in series Pb>As>Cd>Hg in 2005, while in 2006 it was in As>Pb>Cd>Hg series. The

increase of lead, cadmium, arsenic and mercury on one station in Bokakotor bay can be explained as a area which is under great impact of industry and huge medical complex. Therefore there are numerous scientific studies being performed recently, directed at researching, improving and protecting the natural environment, especially water, as a limited and sensitive natural resource.

HOLOCENE GEOMORPHOLOGICAL EVOLUTION OF THE KALAMAS RIVER DELTA (EPIRUS, GREECE)

⁴ University of Paris 10, Nanterre, Rouen, France

Abstract

High resolution seismic profiling acquired by a boomer and a 3.5 kHz device has revealed the configuration and internal structure of the Kalamas River prodeltaic deposits. The acoustic survey shows that during the Holocene the Kalamas River mouth moved frequently as a result of the relative sea-level rise, constructing a delta with a complicated structure. In addition, the use of aerial photographs and topographic maps demonstrates that human forcing on the fluvial system during the last 50 years has modified considerably the natural evolution of the delta resulting in the retreat of the shoreline.

Keywords: Shoreline Evolution, Seismics, Deltas

Regional setting The Kalamas River discharges into the Ionian Sea, near the Greek-Albanian borders, and creates one of the most important hydrographic networks in Greece, in terms of freshwater and sediment influxes $(1.8 \times 10^9 \text{ m}^3/\text{y} \text{ and } 1.5 \times 10^6 \text{ t/y}$, respectively), and associated wetlands (designated as a Natura 2000 site). It is 115 km long forming numerous tributaries and drains a basin of about 1830 km². The river plays a fundamental role in the social and economic life within the region of Epirus (NW Greece).

Results and Discussion The deltaic plain of the Kalamas River covers a surface area of about 80 km². Within the plain, there are some topographic irregularities with the most significant of them being the mountains Mavro (509 m) and Maskilinitsa (142 m) [1]. At an early stage of the delta evolution (from the Last Glacial Maximum to the Early Holocene), these mountains were possibly islets, whilst the river mouth was located eastwards near the village Ragio. During the Holocene, river-born deposits were settled in front the prograding Kalamas River mouth shifting the shoreline to the west and constructing, finally, the present-day deltaic plain. Since 1958, an extended reclamation project of the deltaic plain has been realized. The alignment and diversion to the north of the river lower course, the construction of a dam near Ragio and a well developed irrigation network on the deltaic plain have provided about 3200 ha for cultivation. Presently, cut off meanders and abandoned channels are still visible by the detection of aerial photographs and represent the imprints of old pathways of the river route before the human interference.

Data from seismic profiling, in the vicinity of the active northwestern river mouth, show that the subaqueous delta of the Kalamas River is extended seawards some 5-6 km, at water depths up to 30-40 m. Within the first 2-3 km away from the shoreline, the water depths are very low and do not exceed 5 m. Farther and until water depths reach 30-40 m, the seafloor slope increases abruptly and attains a value of ~4%. The prodeltaic clinoforms present an oblique tangential progradational configuration pattern, consisting probably of mud and sandy mud. In depths greater than 30 m the distal ends of these clinoforms become thinner exhibiting an apparent onlap (Fig. 1). The above lithoseismic features are similar with those appeared in the nearby Arachthos River deltaic system [2].

Fig. 1. High resolution seismic profile exhibiting the clinoforms pattern in front of the active Kalamas River mouth.

Seismic profiling of the area near the inactive southern river mouth (Fig. 2)

indicates a high bottom gradient (>10%) and a subaqueous delta not sufficiently developed. This evidence may imply inadequate riverine sediment influx or a strong coastal hydrodynamic regime, which causes dispersion of the fluvial material into the open sea.

Fig. 2. Prograding directions of the Kalamas River delta. Contours (in m) indicate the thickness of the prodeltaic deposits.

In contrast, in front of the sand spit at the Drepano site (in the south part of the deltaic plain), the seismic survey displays the existence of a well built prodeltaic prism. The occurrence of this submarine lobate formation seems not to be connected with the old estuary (south) of the Kalamas River and, probably, is related to a third mouth at the Gulf of Igoumenitsa. This river mouth maybe functioned at the past as a secondary outlet without, however, ignoring the possibility to have acted as well as a primary estuary for some period of time.

Abstract

Data derived from historical charts, seismic profiling and sediment core analysis have indicated three migration phases for the Arachthos River mouth since 17th century and up to 1930s. Thereafter, three evolutionary stages in the geomorphology of the modern estuary occurred: rapid development of an extended deltaic lobe in front of the river mouth until 1960; deceleration of the subaerial progradation of the deltaic lobe during 1960-1987; and domination of significant erosion of the deltaic deposits from 1987 to 2000, causing shoreline retreat.

Keywords: Shoreline Evolution, Deltas, Seismics

Study area The Arachthos River discharges into the Amvrakikos Gulf (NW Greece) which is the biggest semi-closed coastal biotope (protected by the RAMSAR convention) in the Greek territory. The river is 110 km long and the cathement basin covers an area of about 1900 km². The average annual freshwater and suspended sediment inputs into the Amvrakikos Gulf are about $2.2x10^9$ m³ and $7x10^6$ tonnes, respectively [1].

Results and Discussion Reliable historical charts, published in the 17^{th} Century, indicate that the mouth of the Arachthos River was located about 6 km to the west from its present position, at the Paleobouka site. At the end of the 19^{th} or the beginning of the 20^{th} Century, the mouth moved naturally to the east, approximately 1 km from its present position. During the end of the 1930's, the lowest course of the river was aligned by the construction of artificial levees and diverted more to the east, at its present position (Fig. 1).

Fig. 1. Migration positions (a, b, c) of the Arachthos River mouth.

The above migration phases have been detected from high resolution seismic profiling as three equitant acoustic units within the recent prodeltaic deposits [2]. The lowest Unit C consists of almost *transparent* internal reflectors

indicating distal prodeltaic deposits; it is very likely for these sediments to have come from the Paleobouka site when the river mouth was initially located there. The intermediate Unit B shows a prograding sigmoid configuration pattern, presumably, made when the river mouth was located about 1 km westwards to its present position. The uppermost Unit A is characterized by wavy reflectors representing modern foreset deposits (Fig. 2).

Fig. 2. High resolution seismic profile located near the present Arachthos River mouth, showing the succession of the prodeltaic deposits.

The geomorphological evolution and shoreline displacement of the Arachthos River delta during the last 70 years was identified through a Geographical Information System (GIS) manipulation and analysis of: (a) three sets of aerial photographs taken in 1945, 1960 and 1985; (b) a satellite photograph taken in 2000; and (c) topographic diagrams of a scale 1:5000 published in 1981. The interpretation and comparison of the above data demonstrate the following: After the alignment and diversion of the Arachthos River in the end of 1930's and until 1960, an extended deltaic lobe in front of the new mouth had been rapidly developed, whilst the deposits near the older mouth were being subjected to erosion. The subaerial progradation of the new deltaic lobe decelerated during the period 1960-1987, with the older river mouth suffering a further retreat. Finally, since the construction of the hydroelectric dams at the Pournari site (located 20 km upstream the river mouth) in 1981 and 1996 and the development of an extended irrigation network, the sediment fluxes into the sea have become limited and the erosion processes have already dominated the estuarine area. This will inevitably lead to a significant reduction of the currently existing wetlands with a subsequent biodiversity loss, aquifer salinization, and rapid coastal subsidence.

Abstract

A three year (2006 -2008) Modis satellite data time series has been used to document the seasonal variability of the Evros river plume in the NE Aegean Sea. Satellite data were coupled with field measurements, providing the river plume distributional pattern, which leads subsequently to the quantitative estimation of plume concentrations. Winter plume is dispersed seawards towards south-west, in contrast to the summer plume, which is constrained primarily along the nearshore zone. *Keywords: Aegean Sea, River Input, Coastal Waters*

Introduction - The transboundary Evros river drains a catchment of 52.000 Km2, being the largest river debouching in the North Aegean Sea. It discharges annually about 3,26 10^9 m³ of freshwater and some 1,7 10^5 tones of sediment, mostly in suspension (Pehlivanoglou, 1989). During the last decade many studies have been referred to the Evros river plume using satellite data (Georgopoulos, 2002, Kanellopoulos, 2009) and discussed its influence on the sedimentation of the inner continental shelf of the NE Aegean Sea (e.g. Pehlivanoglou, 2000, Kanellopoulos, 2008). In general, Evros river plume follows the Samothraki anticyclonic circulation, either responding to the Coriolis Effect and/or to the local wind forcing, depending on its strength. The aim of this study is to identify the seasonal distribution pattern and the strength of the Evros River plume via the examination of inter-annual data set of MODIS images.

Data collection and methodology - All the available MODIS (Level 1A) swaths intersecting the region 40°28'-40°54'N and 25°31'-26° 12'E for the period of January 2006-December 2008 were downloaded from the Goddard Distributed Active Archive Center. These data were processed to Level 2 TSM product using default NASA coefficients and TSM Clark standard algorithm, as implemented by SeaDAS. Monthly averages were calculated from available products and composited further into seasonal means, considering October-March and April-September, as winter and summer periods, respectively. Data were re-mapped to WGS'84 (Zone 35ºN) Mercator projection. The algorithm product was calibrated comparing filtered surface water samples, obtained from 12 stations, on the $8^{\hat{t}\hat{h}}$ and 11^{th} of September of 2008 to the corresponding pixel value of the Level 2 TSM products for the same dates. Field data were filtered through pre-weighed 0.7µm (FG/G-Wattman, 47mm diameter)) glass-fibber filter and after dried, reweighed again for the determination of the Total Suspended Matter (TSM) concentration. A least-squares application provided the equation (1), which describes nearly the 89% of the variability. TSM= 0.1065 *pv+0.2423 (1) where, pv= L2 TSM product pixel value. Finally, in order to trace plume characteristics, a Natural Breaks classification method, with the use of a GIS tool, was applied to the output seasonal product, classifying four different TSM concentration classes.

Fig. 1. Winter Evros River plume classification

Results

The spatial distribution of the winter plume had mainly a south-west orientation. On the basis of the spatial distribution of four water spectral classes the following water types were identified (Figure 1): (1) the immediate plume core; (2) the plume edges and nearshore waters; (3) the peripheral plume and the inner shelf water; and, (4) the offshore water. The first class refers to the main plume core, with values greater than 0.25mg/lt, functioning during the whole winter period. The second category (0.10-0.25mg/lt) depicts the intermediate region of the plume and the nearshore waters being turbid due to resuspension induced by the wave activity. The third type is the peripheral region of the plume (0.05-0.10 mg/lt) whilst the forth class regards to the common TSM offshore water values (<0.05 mg/lt).

The summer plume, being associated with low riverine water/sediment fluxes was mainly constrained close to the coast, coinciding with the nearshore zone.

Fig. 2. Summer Evros River plume classification

Conclusions - The systematic analysis of the satellite imagery data coupled by seasonal in-situ data show that the interannual plume pattern during winter extends seawards to the south-west; this is attributed to the high river discharge and the influence of the offshore anticyclonic circulation. During summer period, the weak riverine influxes restrict plume distribution within the nearshore zone at either side of the mouth area controlled by the coriolis effect and the directions of prevailing winds (mostly N/NE during summer).

A COMPARISON OF BIOTIC INDICES IN ASSESSING ECOLOGICAL QUALITY AT THE NE AEGEAN SEA (MYTILENE STRAIT, LESVOS ISLAND)

N. Katsiaras ¹*, A. Evagelopoulos ¹, A. Atsalaki ¹, D. Koutsoubas ¹ and N. Simboura ² ¹ Hellenic Centre for Marine Research, Institute of Oceanography ² Department of Marine Sciences, University of the Aegean - mar01042@mar.aegean.gr

Abstract

The performance of three biotic indices (AMBI, Bentix, M-AMBI) has been compared in communities of soft sediment habitats (mostly covered by *Posidonia oceanica* meadows) at a coastal area of the NE Aegean Sea. AMBI and Bentix had similar trends, but M-AMBI's dependence to Shannon diversity rendered a more degraded state, possibly due to the dominance of species related to HP communities.

Keywords: Zoobenthos, Coastal Systems, Bio-Indicators, Aegean Sea

Introduction

The implementation of the Water Framework Directive (2000/60/EC) requires the development of new biotic indices that would be capable of (a) responding to anthropogenic disturbance, (b) distinguishing different levels of ecological quality and (c) being applicable in any geographical area. The past years, a number of such biotic indices have been developed and tested. Although robustness seems to be a common merit in these indices, this study aims to evaluate their suitability in the ecological attributes at a particular regional scale. In order to accomplish sufficient index performance comparisons, the influence of local and regional natural variability and the nature of the habitat and ecosystem element on index accuracy and stability must be investigated [1].

Study Area and Methods

The coastal area of Mytilene Strait (NE Aegean Sea) is considered to have low urban development; however tourism and population seem to have increased over the last decade. In a baseline study during 2007, the local human pressures and the suitability of indices (classifying the ecological status) were investigated. The first sampling station was located in an area where no significant human activity was identified and the rest four stations were selected according to possible sources of environmental degradation (waste treatment plant-Station 2, port-Station 3, aquaculture units- Station 4 and 5). Quantitative samples were collected, by a Van Veen grab, from soft sediments mostly covered by *Posidonia oceanica* meadows. Species Richness (S) and the Index of Shannon Diversity (H') were calculated. Bray-Curtis similarity analysis was also applied. The biotic indices Bentix [2], AMBI [3] and M-AMBI [4] were used to classify the ecological status. For the application of M-AMBI, the reference conditions of mixed sediments (H'=6, S=120, AMBI=0) were used, as suggested by Simboura and Reizopoulou [5].

Results

A total of 6574 individuals belonging to 247 taxa were identified. The gastropods Bittium reticulatum, Jujubinus striatus, Alvania geryonia and Pusillina marginata were the most abundant in the first three sampling stations. It is noteworthy that the individuals of Bittium reticulatum represented 35.85% of the total abundance. Species Richness (S) had the highest value in Station 4 (102 species), comparatively high in the previous three stations and the lowest value in Station 5 (42 species). The highest values of Shannon diversity (H') were recorded in Station 4 and 5 (4.71 and 4.48), whereas the values of Stations 1 to 3 were 3.65, 3.58 and 3.91 respectively. Through Bray-Curtis similarity analysis, three main clusters were identified; the group formed by Stations 1 to 3, Station 4 and Station 5. The application of Bentix and AMBI classified all stations to High status, except of Station 5 which was classified to Good status. M-AMBI designated only Station 4 to High status and rendered a more degraded state at the first three Stations (Good status) and at Station 5 (Moderate status). According to Bentix classification, the group of sensitive species has a percentage over 93% at all Stations apart from Station 5. Among the ecological groups of AMBI/M-AMBI classification, only Group I and II seemed to be significant at the same Stations, while Group I had a much higher percentage than Group II (between 71% and 86.1%).

Discussion

All three biotic indices seemed to be sufficiently sensitive to the level of anthropogenic disturbance caused by the aquaculture units at Station 5. The Good status is similar to what it has been found in previous research effort regarding the effects of local aquacultures to the benthic communities [6]. A large convergence of the assessment is noted for station 4 among all indices and for Stations 1 to 3 among AMBI and BENTIX, while M-AMBI seems to underestimate condition in relation to the other indices. Because of the high percentage of Group I and the ecological status shown by AMBI, the M-

AMBI difference could be attributed to the apparent influence of this index by Shannon Diversity and its dependence to methodological and ecological factors rather than to anthropogenic disturbance. It is known that the dominance of certain species produces low diversity estimations, although those species are usually related to non-polluted environments [7]. In certain stations, the dominance of *Bittium reticulatum* seems to be associated to the presence of *P. oceanica* meadows [8] and therefore it could not be related to anthropogenic pressures, but to the ecological attributes of the local habitats. The nonmultivariate classification to ecological groups (as applied by Bentix and AMBI), seems to capture the ecological status sufficiently and it is also validated by the analysis of other abiotic/biotic measurements in the study area [9]. However, this conclusion could not be directly linked to the health status of *P. oceanica* meadows in the study area and it is pointed out that the successful estimation of ecological status based on macrophytes and their associated assemblages remains a priority issue.

Tab. 1. The values of Species Richness (S), Shannon Diversity (H'), EQR and the classes of ecological quality for AMBI, Bentix and M-AMBI in the 5 sampling stations

Stations	s	H"	AMBI (EQR)	Bentix (EQR)	M-AMBI (EQR)
1	89 72	3,65	High (0,96) High (0,96)	High (0,97) High (0,97)	Good (0,76) Good (0,72)
3	95	3,91	High (0,96)	High (0,97)	Good (0,79)
4	102	4,71	High (0,94)	High (0,95)	High (0,83)
5	42	4,48	Good (0,78)	Good (0,68)	Moderate (0,60)

DISTRIBUTION AND FATE OF THE ORGANIC MATERIAL DISCHARGED BY THE RHONE RIVER

P. Kerhervé^{1*}, R. Buscail¹, N. Bossard¹, G. Jeanty¹, J. Carbonne¹ and C. Rabouille² ¹ CEFREM UMR CNRS 5110 - Université de Perpignan, 66860, France - kerherve@univ-perp.fr ² LSCE-IPSL, 91191, Gif sur Yvette Cedex, France

Abstract

Within the framework of the ANR-CHACCRA program, a monthly sampling of suspended particles (SP) on the downstream part of the Rhone River (Arles station) has been performed during 4 years (2006-2009), combined with seasonal cruises on the Rhone prodelta for collecting sediments. Carbon and nitrogen content, stable isotope ratios ($d^{13}C$ and $d^{15}N$) and biochemical analyses have been performed on these materials in order to understand the role of Rhone River in the distribution of the particle organic material and its fate within a coastal environment (prodelta area).

Keywords: Gulf Of Lions, Rhone Delta, River Input, Sediments, Organic Matter

Continental shelves are dynamic sedimentary environments that receive, store and export high amounts of organic carbon (OC) and nitrogen (N) introduced by a variety of terrestrial and marine sources. Rivers provide the major pathways for the input of terrestrial organic matter to marine sediments. The Gulf of Lions is a key area of the Mediterranean Sea since it receives the Rhone River discharge, the largest river input into the Mediterranean Sea in terms of liquid and solid fluxes [1].

The purpose of our study is to compare the variations in term of flux and quality of the riverine particulate organic material (RPOM) from the Rhone River with the distribution and the quality of the sedimentary organic material (SOM) from the Rhone prodelta. The strategy developed within the framework of the ANR-CHACCRA program is based on a monthly sampling of Rhone RPOM at Arles started in January 2006 and on coastal cruises (April 2007, September 2007 and May 2008) for collecting sediments off the Rhone mouth. Carbon and nitrogen contents (OC%, N%) and stable isotope ratios (d13C and d¹⁵N) were performed to assess the Rhone inputs and to follow this material once settled off the mouth. Further analyses on the three main organic classes (protids, lipids, sugars) were achieved also on sediments and some river samples to characterize the OM, investigate its spatial and temporal distributions. Our results exhibited a relation between the quality of the SOM with seasons and regimes of the Rhone River. Moreover, taking into account the large size of the Rhone watershed, our survey showed that floods can discharge two kind of RPOM that should follow different fate in coastal sediments. We knew that the RPOM fluxes change markedly according to seasons and floods and now, we have to integrate the temporal heterogeneity in the nature of RPOM in further studies. What are the responses of the prodelta benthic fauna to this heterogeneity? As extreme hydro-climatic conditions on the shelf of the Gulf of Lions may induce large transfer (e.g. cascading event) of this RPOM to the deep basin [2], does this RPOM heterogeneity in term of nature influence the deep ecosystems?

CONTAMINATION PAR LES MÉTAUX LOURDS DE LA FRANGE CÔTIERE DE TETOUAN: KABILA À L'EMBOUCHURE D'OUED LAOU

Soumaya Khannous ¹*, Hassan Er-Raioui ¹ and S Bouzid ¹

¹ Faculté de Sciences et Techniques de Tanger, 90000, Maroc - khsoumaya@yahoo.fr

Abstract

La contamination de l'écosystème littoral par les métaux lourds constitue l'un des problèmes majeurs en toxicologie environnementale. À la différence des polluants organiques, les métaux lourds ne font pratiquement pas l'objet de biodégradation. Ils peuvent alors s'accumuler dans les chaînes alimentaires pour atteindre des seuils toxiques [1]. Cette étude, réalisée en 2006 – 2007 sur des organismes bivalves (*Castilla Chione*) et ayant pour objectif de caractériser l'état de la contamination de la frange côtière de Tétouan (Kabila - Embouchure d'Oued Laou) par les métaux lourds a révélé la contamination de ce littoral par certains métaux. *Keywords: Mollusca, Metals, Mediolittoral*

Introduction

Parallèlement au développement industriel et de l'urbanisme, la contamination générale des côtes par des produits organiques et chimiques est devenue une véritable préoccupation. Ces polluants considérés comme dangereux provoquent des effets néfastes sur l'écosystème marin, en l'occurrence les ressources halieutiques. Des études antérieures [2] portant sur le suivi chimique des coquillages décrivent des teneurs caractéristiques des zones salubres. Bien qu'inférieures aux normes admises, les concentrations en Pb enregistrées sont plus élevées que celles du Cd et du Hg au niveau de l'ensemble des sites étudiés. Les résultats montrent également que les variations annuelles sont irrégulières, rendant difficile l'interprétation des tendances.

Matériels et Méthodes. Des échantillons de vernis ont été récoltés au niveau de six stations. Les prélèvements ont été étalés sur un cycle annuel de juillet 2006 à juin 2007 avec une périodicité saisonnière. Les échantillons d'organismes bivalves (*Castilla Chione*), considérés comme des accumulateurs potentiels de polluants et largement utilisés dans la bio-surveillance des eaux de mer, ont été décortiqués, broyés et lyophilisés. La minéralisation a été effectuée par l'acide nitrique et à l'acide sulfurique. Après minéralisation, les métaux lourds (Cd, Cu, Zn, Cr, Pb et Ni) ont été analysés par spectrométrie d'émission optique (ICP).

Résultats et discussions

Les teneurs en métaux enregistrées dans les différents sites analysés sont exprimées en mg/kg du poids sec varient de 54 à 66,50 pour le zinc, de 7,45 à 13,13 pour le nickel, de 0,25 à 4,8 pour le plomb, de 4,70 à 6,9 pour le cuivre, de 1,25 à 3,67 pour le chrome et de 0,1 à 0,35 pour le cadmium. Les concentrations ne sont pas négligeables bien que les activités industrielles et portuaires soient moins développées que dans les pays industrialisés. Les concentrations en métaux chez les organismes étudiés montrent des fluctuations importantes et laissent penser à une bioaccumulation sélective par rapport à certains métaux (Figure. 1). Ceci peut refléter le processus de compétition pour les sites d'adsorption.

Fig. 1. Concentrations moyennes annuelle des métaux lourds (Cd, Cr, Cu, Ni, Pb, Zn) en mg/kg de poids sec dans les différents sites étudiés (kab : Kabila, M'dq : M'diq, OM : Oued Mellah, CN : Cabo Negro, OL : Oued Laou, Emb : Embouchure d'oued

Les concentrations en Zn montrent les valeurs les plus élevées, suivies de celles relatives au Ni et au Cu, et enfin celles correspondant au Pb. Cette même distribution a été également enregistrée par certains auteurs pour différentes

espèces de gastéropodes de l'étang de Berre (France) [3]. L'ordre d'importance des teneurs métalliques dans l'étang de Berre est le suivant : Zn > Cu > Pb > Hg. L'analyse des concentrations des moyennes annuelles des métaux étudiés chez *Castilla chione* ne marque qu'une légère variation spatiale.

Dans la figure 2, représentant les variations saisonnières des concentrations moyennes des métaux enregistrées chez *Castilla Chione*, il apparaît que les concentrations relatives aux différents métaux Zn, Ni, Cu, Pb, Cr et Cd varient de la même façon dans le temps. Ces métaux montrent une légère variation temporelle.

Fig. 2. Les variations saisonnières des concentrations moyennes des métaux (Zn, Ni, Cu, Pb, Cr, Cd) enregistrées chez *Castilla Chione*.

Par ailleurs, il convent de souligner que les concentrations enregistrées le long de la frange étudiée restent faibles comparées aux concentrations relevées chez des espèces voisines prélevées dans des sites pollués ou non faisant partie de la Méditerranée française, des côtes algériennes ou du littoral atlantique marocain au niveau de Rabat, Salé et Mohammédia [4], [5].

LITTER COMPOSITION AND SOURCE IDENTIFICATION FOR 80 BEACHES IN GREECE

S. Kordella¹, G. Papatheodorou¹*, M. Geraga¹, E. Fakiris¹ and A. Mitropoulou²

¹ LABORATORY OF MARINE GEOLOGY AND PHYSICAL OCEANOGRAPHY, DEPARTMENT OF GEOLOGY,

UNIVERSITY OF PATRAS - gpapathe@upatras.gr

² Mediterranean S.O.S Network

Abstract

Composition of beach litter was assessed for 80 beaches in Greece, with the participation of the volunteers of the international campaign "Clean up the Med 2006 & 2007", coordinated in Greece by the N.G.O Mediterranean S.O.S. This study showed that plastic is the dominant litter material, followed by paper and aluminium. Furthermore, public participation in beach litter surveys is proposed as an appropriate method to promote environmental awareness. *Keywords: Pollution, Beach, Coastal Management, Eastern Mediterranean*

Introduction

Although numerous studies have been carried out on marine debris globally, in Greece marine litter research is very limited [1]. The aim of this study is to (i) evaluate beach litter composition, for the first time in Greece for a significant amount of coasts (80), with the participation of volunteers [2] and (ii) explore the relations between the different litter materials and marine and land – based beach litter sources.

Methods

For the purposes of the present study, data were collected with the collaboration of volunteers who participated in the "Clean Up The Med 2006 & 2007" Mediterranean campaign of voluntary beach clean - ups, that is coordinated by the Italian N.G.O. Legambiente and for Greece by the environmental N.G.O. Mediterranean S.O.S. In Greece, thousands of volunteers (2006: 10,938, 2007: 15,748) participate each year in the Clean up the Med campaign that not only aims at physical removal of beach debris, but also at raising public awareness and education on marine pollution issues, through dissemination of informational material as well as a questionnaire, the "Beach Observation Questionnaire" (B.O.Q). The B.O.Qs, which were filled in from the volunteers during the clean - up, acquire qualitative information regarding the probable beach litter sources, as well as litter composition data. The volunteers counted and classified the items of litter found in the beaches according to their composition, in eight categories: glass, plastic, paper, aluminium, other metals, rope, building materials and other materials (Table 1). The "other materials" category was excluded from the data processing for reasons of results interpretation. B.O.Qs from 49 beaches were processed in 2006 and from 31 beaches in 2007 (Fig.1).

Fig. 1. Map showing the 80 beaches (dots) studied in Greece.

The qualitative information includes the litter sources that affect each beach. Litter sources were distinguished in two major groups: land - based and

marine – based. Land – based litter sources, were separated in two minor groups: a) sources that are involved with recreational activities that usually take place on the beach (e.g. bathing) and b) sources that do not interfere directly with recreational activities, such as rivers, municipal drainage systems, ephemeral streams and sewage inputs, refuse dumps. Marine – based litter sources were separated in: a) sources referring to commercial and recreational fishery and b) sources concerning with navigation (merchant ships, ferries and recreational boats).

Results and Discussion

Plastic was the dominant litter material (Table 1) in the majority (69 beaches) of the beaches that were surveyed, in accordance with the global tendencies [1, 3]. Plastic dominance was followed in both periods by paper and aluminium. However, in 11 out of 80 beaches paper was the most abundant material indicating recent pollution [3]. In two beaches the dominant litter material was aluminium and in one beach building materials suggesting local influence. The qualitative information in combination with the litter composition data, showed that the majority of beaches (56) were polluted by recreational activities while the most dominant marine based litter source was navigation (46 beaches). Moreover, land based sources that do not relate with recreation; seem to pollute the beaches with building material; while fishery appears to be responsible for metallic (apart aluminium) items of litter on the Greek surveyed beaches. The present large scale study would not have been achieved without the participation of volunteers whose involvement in coastal management issues can lead to environmental awareness [2].

Tab. 1. Mean values of the litter material categories. "Other metals": litter made of any metal but aluminium; "Building materials": material used for construction; "Other materials": litter that cannot be classified in any of the other categories.

Litter Material	2006	2007
Categories	Mean (%)	Mean (%)
Glass	5	6
Plastic	43	51
Paper	13	18
Aluminium	12	7
Other Metals	4	3
Rope	8	6
Building Materials	5	2
Other Materials	10	7

THE NOWADAYS STATE OF THE SEA OF AZOV RUSSIAN COAST

Ruben Kosyan¹ and Marina Krylenko^{1*}

¹ Southern branch of the P.P.Shirshov Institute of oceanology, RAS - krylenko@mail.ru

Abstract

When elaborating and implementing coast protection measures it is necessary to take into consideration the existence of lithodynamical systems including sources of nourishment, transit and accumulation of sediments. The Sea of Azov coast protection systems, which take into account geological, hydro-lithological and economical peculiarities of the coast, well combine the efficiency of coastal protection with the possibility to use the shore for recreation and economic purposes. *Keywords: Coastal Management, Coastal Systems, Sea Of Azov*

The Sea of Azov coast has a large economic potential. Today a rate of its opening up is considerably increased. Old industrial and transport objects on a shore are reconstructed and new ones are built. Stability of inter-political situation, comfort climatic conditions, richness of the area with natural, cultural and historical places, ease to access the area and development of the transport net make the Kuban-Near-Azov region a very attractive for a recreation field of economy. Complex study of modern coastal processes affords to single out three main types of coasts: abrasion (abrasionlandsliding), accumulative and stable ones. A length of eroding coasts within this section is 240 km, that of accumulative one - 230 km. A length of relatively stable coast is about 120 km. Spits Chushka, Achuevskaya, Yasenskaya, Kamyshevskaya, Dolgaya may be considered as accumulative forms, which are fed due to bottom sediments from bars of Khanka Lake, Beisugsky and Akhtanizovsky firths are widely spread. Today a part of accumulative coast undergoes erosion. Especially intensive is erosion of Dolgaya spit. In 2008 in some places a rate of the eastern coast retreat was 4-6 m. Abrasion coast can be observed near Primorsko-Akhtarsk and Yeisk towns, near Cape Kameny, to the north of Glafirovskaya spit and in other places. A rate of retreat of the coast cliffs is 1.8-2 m per year, and in some places it is 5-7 m/yr. Every year tens of hectares of lands are lost, during the last 100 years a belt of land, 500-600 m wide, was cut by sea [1]. Such a high rate of abrasion may be explained both by the influence of natural (geological structure of coasts, rising of the water level by the effect of wind) and anthropogenic factors. Erosion of coasts composed of loess loams practically does not give a material for a beach formation. During the period of water level rising under wind storm waves influence directly upon coast cliff coast retreat can reach several tens of centimeters during one storm. Stable coasts where abrasion and accumulative processes are not well defined today are observed in firths and between mouths of the rivers Protoka and Kuban. It should be noted that a term "Stable" can be used only in a sense of relatively weak influence of waves directly upon the shore. At the same time a coastline retreats in many places, especially between rivers the Kuban and the Protoka and this can be explained by a relative rise of a sea level and by the other processes. A human activity in the Sea of Azov basin has resulted in a great transformation of its ecosystem and this has affected on the structure of alongshore sedimentary flows. River solid run-off, abrasion products and products of biogenic origin are the main sources of material supply into the coastal zone. Construction of water storage basins results in the decrease of solid run-off in several times as compared with natural regime [2]. Decrease of natural reproduction of mollusks and uncontrolled shell withdrawals are important reasons of erosion of unique shell spits [3]. Retreat of a coastline results in destruction of arable lands and industrial objects situated on shore. To prevent this, local coast protection complexes are created within inhabited localities, as a rule. A total length of protected sections of the Sea of Azov coast within the Krasnodar region is about 30 km. When the whole length of the coast is 572 km. Coast protection has realized with the help of bank retaining walls, baffle plates, artificial beaches, rip-rap berms, fills of figure blocks, groins, breakwaters and other erections. Today a majority of existing constructions are insufficiently effective ones; many of them are damaged or destroyed. A large mobility of sediments, landsliding and sagging, oscillations of sea level under effect of wind create additional troubles for coast protection [4]. Walls of different design were built in Morozovsky and Tamarinsky settlements, on the southern coast of Yeisky firth, in Dolzanskaya Stanitsa. Some of them need a reconstruction, the other is damaged, and neighbor coast sections undergo intensive erosion. The state of the coast protected by ripraps or artificial beaches is considerably better one. Man-made beaches are a part of the coast protection complex in Prtimorsko-Akhtarsk town near lighthouse, in Alexandrovka settlement. They are 10-20 m wide and they protect coast from erosion well enough. Building of complex coast protection constructions including artificial beaches in combination with different kinds

of sediment holding erections can be recommended for protection of the southeastern coast of the Sea of Azov. It's better to make berms, groins and heels in riprap variation. Such constructions keep sediments better owing to a high roughness of side planes and cavities; they better scatter wave energy and do not break a compositional integrity of a natural landscape. Correctly designed anthropogenic elements increase diversity of landscape and promote its attractiveness. Since a near shore zone is a shallow one, the use of interrupted breakwaters which suppress wave energy behind the breakwater can give good results. And then a wave shadow is created between the shore and an erection, accumulation of sediments occurs. Building of wave suppressing erections of large stones or figure blocks is possible outside the recreation zones.

FISH ASSEMBLAGES OF TWO ADJACENT COASTAL LAGOONS IN RIVER NESTOS DELTA (NE GREECE)

M. Koutrakis ^{1*}, A. Sapounidis ¹, D. Lachouvaris ¹, D. Chariskos ¹ and A. Mirli ¹ ¹ NAGREF - Fisheries Research Institute - manosk@inale.gr

Abstract

The fish fauna diversity of two adjacent coastal lagoons in northern Greece, after 12 months sampling (Vassova 25 species and Erateino 27 species), is used as an indicator of the water quality in these lagoons. *Keywords: Lagoons, Aegean Sea, Fishes*

Management, 16: 171-196.

Introduction

The fish fauna can be used as an indicator of the environmental quality of the lagoons. Vassova and Erateino lagoons are situated in the northern Aegean Sea, at the western bank of Nestos River delta (Northern Greece). Vassova lagoon is approximately 270 ha in surface area with a mean depth of 0.8 m. Erateino lagoon is larger in surface area (350 ha) with a mean depth of 1.1 m.

Materials & Methods

Fish were collected monthly from August 2007 to July 2008, using a nylon centre-bag seine net (2 mm bar mesh size) of 12 m length and 1.2 m height. The bag seine was hauled for 30–50 m to cover an area of 250 m², approximately. The relative abundance was estimated by the Catch per Unit Effort method (CPUE: specimens/100 m²) [1]. Sampling was conducted in two stations; one close to the entrance one inside the lagoons.

Results & Discussion

Overall, 36 species representing 19 families were identified in both lagoons (Table 1). 25 of them were identified in Vassova (24 in the entrance and 11 in the inside) and 27 in Erateino lagoon (22 of which were found in the entrance and 20 in the inside). From the above species the residents are almost the same in all stations (7 to 9). The migrant species are 10 and 11 in Erateino entrance and inside respectively but 13 in the Vassova entrance and only 4 in the inside. The low number of migrant species found inside the Vassova lagoon can be linked to the low water quality in the lagoon, which is also indicated by the low DO concentration [2]. Probably this is the reason that the species prefer to remain in the entrance of the lagoon where due to the tidal water movement the environmental conditions are better. The fact that almost the same number of species was found in the entrance and in the inside of the Erateino lagoon indicates a possibly higher water quality in contrast to the Vassova lagoon. The dominant species in the lagoon is the Pomatoschistus sp., with an abundance of 537 to 1495 individuals/100 m². It is followed by Atherina boyeri, showing higher abundance in the inside of the Erateino lagoon (246 ind./100 m² Aphanius fasciatus again in the same station (230 ind./100 m²), and by all species of the Mugilidae family.

Abstract

Two indicators of the trophic state, TRIX index and Fp ratio, for the first time were used to assess trophic conditions in the Boka Kotorska Bay. The TRIX value in this area ranged from 3.02 to 5.58 (4.11 ± 0.66) while the values of the Fp ratio varied between 0.05 and 0.33 (0.17 ± 0.08). The results indicated that the study area corresponds to a "good" trophic state, with moderately productive waters.

Keywords: Adriatic Sea, Eutrophication

Introduction

The inner part of Boka Kotorska Bay, where our research took place, is a relatively shallow, semi-enclosed Bay strongly influenced by freshwater discharge. This input, together with sewage discharge and agriculture runoff, causes nutrient enrichment and eutrophication which can lead to highly undesirable changes in ecosystem structure and function. One of the principal effects of the enhanced nutrient concentration is a massive increase in primary productivity. Vollenweider [1] has defined a trophic index (TRIX) based on chlorophyll *a*, oxygen saturation, dissolved inorganic nitrogen and total phosphorus to characterize the trophic state of coastal waters. Claustre [2] has defined the Fp ratio which indicates the variability of the phytoplankton community i.e. the influence of environmental conditions on the phytoplankton community. The aim of this study was to apply trophic index TRIX and Fp ratio for assessment of the trophic state of the Boka Kotorska Bay.

Material and methods

Seawater samples were taken seasonally from April 2008 to March 2009 at three stations in the inner part of the Boka Kotorska Bay. Temperature, salinity and oxygen concentrations were measured *in situ* by multi Line P4-Universal Meter. Concentrations of nutrients were measured on unfiltered water samples using standard colorimetric methods [3]. The qualitative and quantitative analyses of pigments in the water samples were determined using HPLC method [4]. The Fp ratio was calculated as described by Claustre [2] using pigment concentrations while the trophic index TRIX was calculated according Vollenweider et al. [1].

Results and discussion

Temperature followed changes in seasonal insolation, with minimum value measured in winter (10.70 °C) and maximum in summer (27.90 °C), both in the surface layer. Salinity was lower in spring because of rain and run-off with minimum value of 5.2 PSU in the surface layer, while maximum value was established in the bottom layer during winter (37.0 PSU). Oxygen ranged from minimum saturation in winter (61%, 2m below the surface) to its maximum in summer (114%) in the 5m below surface layer where also high phytoplankton production has been established.

Fig. 1. Box & Whisker representation of seasonal TRIX and Fp index in inner part of the Boka Kotorska Bay

Chlorophyll *a* concentrations were found often enhanced after rainfall, which indicates to the importance of diffusive nutrient inputs for the ecosystem in the Bay. The highest N:P ratio (199) was detected in the same period on surface that can indicate to P limitation common in the Mediterranean [6] and the Adriatic sea [7].

According to chlorophyll *a* concentration and the criteria of Håkanson the area could be described as oligo-mesotrophic. The TRIX values (Figure 1.) in this area ranged from 3.02 to 5.58 (4.11 ± 0.66) while the values of the Fp ratio varied between 0.05 and 0.33 (0.17 ± 0.08). According to TRIX classification criteria, the mean seasonal value between 4 and 5, investigation area corresponds to good trophic state, moderately productive waters with occasional water turbidity, anomalous water colors and bottom water hypoxia episodes. Values of TRIX and Fp were similar as in Gulf of Trieste [5] and northern Adriatic [8] and indicated slight eutrophic conditions. Its seems that this two indicators are complementary, and we agree with Flander-Purtle and Malev suggestion [9] that in new TRIX tropic index it is necessary to include also Chl *a* degradation products as an indication of the physiological status of the phytoplankton community.

THE CLIMATIC OPTIMA ASSESSED USING SEDIMENTS OF THE BLACK SEA

Eliso Kvavadze¹* and Kakhaber Bilashvili²

¹ Iv. Javakhishvili Tbilisi State University, 0128 Tbilisi, Georgia

² Institute of Paleobiology, National Museum of Georgia, Tbilisi 380007, Georgia - e.kvavadze@yahoo.com

Abstract

The database for palynological studies of marine, lagoon, alluvial and bog sediments of the Black Sea coastline on the territory of Georgia includes 26 profiles of Holocene sediments. The analysis and synthesis of the plotted pollen diagrams allowed us to make a stratigraphic subdivision of Holocene sediments and to reveal climatic fluctuations for the last 10000 years. Most informative appeared to be pollen spectra of marine formations where there are no intervals and sediment accumulation. *Keywords: Black Sea, Sea Level, Paleoceanography, Sediments*

Introduction

The palynological and sedimentological analysis showed, that the lowest level of the Black Sea occurred 18-17 thousand years ago. During this regression corresponding to the last phase of the Würm Ice Age the sea level was located 120m lower than at present. The cooling was replaced by the intensive warming, glaciers began to melt and a New Black Sea transgression began. By the onset of the Holocene (10 thousand years ago) the sea level increased nearly by 70 m [1]. According to the palynological data, the combination of vast number of pollen of heat-loving arboreal species which grow in lower mountain belts and low values of redeposited pollen are markers to reveal the Black Sea transgressive phases. On the contrary, during the Black Sea regression, the role of heat-loving elements decreases and there is a sharp increase in the quantity of secondary redeposited pollen caused by enhancement of erosion processes due to lowering of the general erosion basis. During the Holocene, transgressive phases with warm climatic conditions lasted longer than the regressive phases. The most significant warming and, accordingly, the sea transgression took place in the Atlantic period when during nearly three millennia (8000 - 5500 BP) the climatic trend was directed towards the increase both in precipitation and temperatures. This process reached its peak 6000 - 5500 years ago and the sea in Colchis for the first time for the whole post-glacial period exceeded by several meters the present-day level [2]. At the beginning of the Atlantic period, with establishment of humid and warm conditions, there appeared the first Neolithic agricultural settlements on the alluvial plains of Southern Kartli, where, besides grain-growing, gardening, viticulture, beekeeping and even weaving was developed. In the Eneolithic the warming process continued and mild climatic conditions facilitated the occurrence of new cultures and penetration of agriculture into the high mountains. The second significant ingression of the Black Sea waters took place at the end of the Subboreal period (3800 - 2400 years ago), which was also due to climate warming. The sea level again was higher than nowadays. Broad-leaved forests with participation of chestnut, lime, wing nut and dzelkva are expanding their areas. In high mountains stock-breeding is being replaced by agriculture where, besides grain-growing, viticulture and horticulture were developed. Trade might also have successfully developed, since in the archaeological monuments dated to the 15th - 14th cents. B.C., besides other imported inventory, cotton fabric and its numerous fibers were found. It is known that at that time cotton was manufactured only in India. The last 2000 geological years are characterized by more frequent transgressions and climatic fluctuations among which rather a long climatic optimum of the Middle Ages which lasted nearly for five centuries (7th - 11th cents.) is distinguished. The last warming and significant transgression of the Black Sea lasted for 200 years and took place in the 15th - 16th centuries. The influence of human activity on development of the landscapes had been observed since the Subboreal time when deforestation took place not only on the Colchis lowland, but also in the mountains of Western and Southern Georgia.

Conclusions

The comparison of the suggested scheme of climatic changes with similar schemes of mountain territories of the southern part of Europe and the Near East perfectly demonstrates the global character of climatic fluctuations resulting afterwards in oscillations of the level of the southern seas in Europe, including the Black Sea [3].

SPATIAL AND TEMPORAL ANALYSIS OF BACTERIAL DIVERSITY ASSOCIATED WITH THE MEDITERRANEAN GORGONIAN PARAMURICEA CLAVATA

Marie La Rivière ¹*, Joaquim Garrabou ² and Marc Bally ¹

Abstract

We combined terminal-restriction fragment length polymorphism (T-RFLP) and clone library analyses to investigate the diversity and the spatio-temporal changes of bacterial assemblages associated with the gorgonian *Paramuricea clavata*. We found a clear difference between the bacterial communities during winter and summer while T-RFLP profiles were highly similar between *P. clavata* populations separated by hundreds of kilometres. Sequencing data from 16S rDNA clone libraries demonstrated the presence of distinct phylogenetic taxa during summer and winter, with an increased diversity in the warm season. In the context of recurrent gorgonian diseases and mortalities, this picture of the structure of bacterial communities will be helpful to monitor the effects of thermal anomalies on the resident microbial flora.

Keywords: Bacteria, Cnidaria, Mortality, Western Mediterranean, Global Change

Introduction

Mass mortality outbreaks in coastal ecosystems have considerably increased during the past few decades affecting in particular marine invertebrates [1]. In the Northwestern (NW) Mediterranean, recurrent mass mortalities have affected benthic macroinvertebrate species such as gorgonians, sponges and bryozoans. The environmental driver of these large-scale events was an increase in seawater temperature during temperature anomalies in summer [2]. From diseased P. clavata colonies, we previously isolated a Vibrio coralliilyticus strain that showed thermodependent virulence during controlled infection experiments in aquaria, supporting the involvement of bacterial pathogens in gorgonian die-offs [3]. We hypothesized that variations in specific composition of bacteria associated to P. clavata at elevated temperature could be used to detect potential pathogens prior to apparition of disease signs, and might help identify causal agents. However, composition and dynamics of the natural microbial communities living in association with temperate gorgonians are unknown. The main aim of this study was to establish a baseline for diversity and abundance of the bacterial community of *P* clavata

Material and methods

Three sampling sites were chosen along the NW Mediterranean coast: Riou Island (gulf of Marseilles), Medes Island (Catalan coast) and Scandola (NW Corsica). For each site, apical branch tips of 3 *P. clavata* colonies were collected at a depth of 20 m, in march 2007, july 2007 and february 2008. Three liters of seawater were also collected and filtered for analysis of planktonic bacteria. For T-RFLP analysis, bacterial 16S rDNA was amplified from total genomic DNA by PCR using fluorescent-labeled universal primers. PCR products were digested by restriction endonucleases *CfoI* and *MspI* and separated on an ABI 3130 Genetic Analyzer (Applied Biosystems). The terminal restriction fragments (T-RFs) data collection for each sample was converted into a binary matrix which was used for metric multidimensional scaling (MDS) analyses. Clone libraries were generated by amplification of 16S rDNA using unlabeled primers and subsequent cloning in pGEM-T vector (Promega). Sequences were compared to 16S GenBank database using the Blast program.

Results and discussions

The T-RFLP profiles of bacterial 16S rDNA obtained from three independent P. clavata colonies sampled at the same site were highly similar, suggesting that gorgonians maintain a conserved microbial population. Comparison of profiles obtained from Riou, Medes and Scandola further indicated that bacterial communities were very similar between geographically remote P. clavata populations. In agreement with a bacterial-gorgonian interaction, no overlap was found between T-RFLP profiles of bacterial communities of P. clavata and those of the surrounding seawater. Seasonality in bacterial diversity was investigated by the analysis of P. clavata colonies sampled at the three study sites in the winter and the summer of 2007. T-RFLP data showed that species composition differed greatly between the two seasons. Furthermore, no significant differences in bacterial communities were found between samples from winter 2007 and winter 2008. Ordination by MDS supported clustering of bacterial assemblages by seasons, and confirmed that P. clavata colonies from different areas of the NW Mediterranean harbor closely related microbial flora (Fig. 1).

Bacterial 16S rDNA clone libraries were derived from *P. clavata* colonies sampled in winter and summer at the Riou site. The winter library was dominated by sequences of a unique bacterium (100% of the 88 clone sequences) affiliated with gamma-proteobacteria. The highest identity scores were obtained with *Spongiobacter*-related sequences (92%), previously

Fig. 1. MDS representation plot of the distances between T-RFLP profiles of Riou (square, diamond), Medes (triangle) and Scandola (circle) samples collected in summer (white) or winter (black)

retrieved from marine sponges. In summer, a larger diversity of bacteria was detected and clone sequences were dominated by members of the Firmicutes (*Paenicillus sp.* and *Propionibacterium sp.*, accounting for 86% of the 92 clone sequences). Although the role of associations between bacteria and *P. clavata* is unknown, understanding how they change through time may represent a potential indicator of the gorgonian health status. Studies on tropical species of corals and gorgonians have demonstrated shifts in the microbial populations of affected colonies prior to visual signs of disease [4]. Thus, changes in the normal microbial community could serve as an early signal of stressful environmental conditions. We are currently looking for bacterial associations in different sympatric gorgonians (*Eunicella singularis, Eunicella cavolinii* and *Corallium rubrum*) to evaluate if related bacteria appear in different hosts. A similar pattern of host-microbe associations might reveal common mechanisms through which bacterial communities and gorgonian health are interlinked.

Abstract

The stability in the number of artisanal fishing boats and fishers, the relatively high yield (catch per unit effort ranging between 1.8 and 3.6 kg/100 m net) and the high commercial value of the targeted species, suggest that local fisheries are sustainable in the marine protected area of Scandola and adjacent areas.

Keywords: Fisheries, Marine Parks, Western Mediterranean

Introduction

The Scandola Marine Protected Area (MPA) was set up in 1975 (west coast of Corsica, western Mediterranean Sea). It includes a no-take area (72 ha) and a partially protected area (928 ha, mean depth 45 m) where professional fishing is allowed, but where recreational fishing (angling and spear fishing) and diving are forbidden. A survey of the fishing effort and catches within the MPA and in adjacent areas (Gulf of Ghjirulata southwards, Gulf of Focolara and Punta Scuglietti northwards) was started in 2000.

Material and Methods

Fishing gear was plotted on maps, on the basis of their GPS (Global Positioning System) position, at key periods of the fishing season (spring, summer and autumn). The catches were measured, weighed and identified on board by scientists embarked thanks to the cooperation of the fishers.

Table 1. Fishing effort and catches in the MPA of Scandola and adjacent areas. Gear = 100-500 m net. Spring = April-May, summer = July, autumn = September-October. ww = wet weight. n = number of sampled gear. md = missing data. n = number of data, SD=standard deviation.

Results and discussion

At the study site, artisanal fisheries are characterized by seasonality (April to November) and small boats (11 m maximum) with only one fisherman onboard, using trammel nets and gill nets, targeting demersal and benthic fishes in spring and autumn, and spiny lobsters in summer. Catches are multispecific (61 species). The no-take area harbours relatively dense populations of protected species such as the teleost Epinephelus marginatus (grouper) and species of high commercial value such as the spiny lobster Palinurus elephas. Over the whole year, no increased fishing effort could be evidenced close to the limits of the no-take area. The fishing effort is higher near the shore, especially within the partially protected area in autumn when fishers are targeting Mullus surmuletus while spiny lobster fishing is banned, and in spring when they are targeting Sparids (e.g. Dentex dentex, Spondyliosoma cantharus and Diplodus spp.). The high commercial value of the spiny lobster was responsible for the summer seawards drift of the nets (near the 100 m depth line). In contrast with the general decline of the number of fishermen in Corsica and in other Mediterranean areas, the number of fishers and fishing boats has been stable in the study area over the past decades, in spite of increasing fishing effort (motor power and boat equipment). Overall, the yield (catch par unit effort: 100 m net) was relatively high (Table 1) in comparison with other Mediterranean areas (e.g. 0.8-1.5 kg/100 m net/outing, Strait of Messina [1]). In addition, most fished species are of high commercial value [2].These results suggest that local fisheries are sustainable.

The way in which the presence of the MPA and its management contribute to this sustainability, if they in fact do so, remains to be investigated. An increasing amount of data suggests that a positive role of the MPA constitutes a realistic hypothesis. In addition to contributing to our knowledge of artisanal fishery, the survey has encouraged co-operation between fishers and the MPA authority. Managers, as well as fishers, have become more aware that conservation objectives need not necessarily conflict with those of commercial exploitation, and may contribute to the sustainability of the fishery [2, 3].

FISH FAUNA COMPOSITION AND ABUNDANCE IN TWO DIFFERENT ESTUARINE HABITATS IN THE IONIAN SEA

V. Liousia ¹*, S. Batziakas ¹, I. Daouti ¹, C. Genas ¹, A. Oikonomou ¹ and I. D Leonardos ¹

Abstract

Monthly changes of the estuarine fish fauna composition and abundance were investigated in two different habitats in the Ionian Sea. For each month, species richness was measured by the total number of species caught in each station, and the Shannon–Wiener diversity index was calculated. An ordination method (CA) was applied in order to examine the temporal presence of fishes in the studied ecosystems. Eutrophic conditions and type of vegetation influence the settlement and retention of fish in both stations. *Keywords: Ionian Sea, Biodiversity, Coastal Systems, Population Dynamics*

Estuaries show high levels of habitat heterogeneity and support a large fish production due to the high nutrient levels in the bottom sediments and water column [1]. Estuarine ichthyofaunal assemblages have been extensively studied in many parts of the world [1,2], but the temporal distribution, abundance, seasonal diversity and the diversity indices of fish in Mediterranean estuarine systems is poorly known [3,4]. The aim of this study is to explore the monthly changes of the fish fauna composition and abundance in two different estuarine habitats in the Ionian Sea (Station I: Drepano in the Port of Igoumenitsa, Station II: Neohori in the Amvrakikos Gulf). Drepano is near the port of Igoumenitsa and has an open fetch in the sea. It is a part of Kalamas River estuarine ecosystem. The sea grass habitat of Drepano habitats compromises predominatly of Zostera sp providing a landscape of patchy seagrass amongst areas of bare sand. Amvrakikos Gulf is a shallow semi-enclosed embayment in the Ionian Sea. It is connected with the Ionian Sea through a narrow channel (width 800 m, depth 12 m). The seagrass habitat of Amvrakikos gulf comprises predominantly of dense Posidonia oceanica vegetation. Amvrakikos is one of the most eutrophic gulfs in Greece in contrast to Drepano which has very high water inflow. Fish species were collected in each habitat (station) on a monthly basis from July of 2008 to June of 2009 using a beach seine. Fish samples were preserved in 4% neutralized formalin solution and later identified to species level. For each month, species richness was measured by the total number of species caught in each station, and the Shannon-Wiener diversity index was calculated. In each station, the pattern of temporal changes in the structure of the overall fish community was explored by Correspondence Analysis (SPSS, Ver 17). In station I a total of 23.430 individuals were sampled, representing 39 species from 17 families. In Station II a total of 15.278 individuals were sampled, representing 26 species from 15 families. Species richness and diversity index varied significantly amongst habitats. Correspondence Analysis revealed a certain interaction between fish assemblage and seasonal changes in each station (Fig 1). In Station I in winter and spring the most dominant species belong to the families of Mugilidae, Sparidae and Labridae, in Summer the species of the Mulidae, Clupeidae, Atherinidae and Blenidae family dominate the ecosystem while in Autumn the species of the families Gobididae and Engraulidae are highly present. In Station II in Winter and Autumn the dominant species belong to the families of Gobididae and Atherinidae, in Spring in the families of Mugilidae and Atherinidae while in summer the species of the families of Syngnathidae, Blennidae, Sparidae and Cyptinodontidae are highly present. The highly eutrophic conditions and the dense foliage of the Amvrakikos Gulf are a limiting factor for the settlement and retention of fish in contrast to the oligotrophic conditions of Drepano.

FUTURE SCENARIOS OF RIVER DISCHARGES OF WATER AND NUTRIENTS TO THE MEDITERRANEAN AND BLACK SEA

Abstract

The purpose of this paper is the development of future scenarios on the riverine inputs of water and nutrients to the Mediterranean and Black Sea. Based on detailed reconstructions of the river fluxes during the last 40-50 years, we identified their major controlling factors which were then used to project the budgets from the recent past into the near future. The modelling framework is given by the IMAGE model and its spatially explicit parameterisations of potential drivers, such as population growth, socio -economic development, land use changes and climatic boundary conditions. The future scenarios are based on the four scenarios for the years 2030 and 2050 developed within the Millenium Ecosystem Assessment. *Keywords: River Input, Global Change, Nutrients*

Anticipation of future environmental changes is one of the major scientific challenges in Earth sciences. Two major drivers, commonly regrouped under the term of global change, are crucial for future ecosystem changes. The first is climate change, strongly acting through modification of the water cycle on Earth and its temporal variability. The second driver is demographic and socio-economic development, frequently accompanied by negative feedback on ecosystems services, e.g. through the massive release of pollutants and/ or the reduction of biodiversity. River discharges of water and associated elements are highly sensitive to both drivers, making them good indicators for global change in general. Moreover, as the fluxes represent a major link between the terrestrial and marine domains, they can be considered active players in the future evolution of the coastal ecosystems that closely depend upon river inputs.

The Mediterranean is one of the regions on Earth where global change is expected to cause considerable environmental impacts. The region has been identified as a "hot spot" for climate change. Many observation and modelling studies indicate that there is an ongoing trend towards warmer and dryer conditions, which is likely to continue in the future. On the other hand, the Mediterranean lies on the border of three continents, with different cultural, economical and political characteristics. This contrast is further enhanced when including the drainage basin of the Black Sea, because of the abrupt economical changes on the former USSR countries in the early 1990s. As a consequence, future demographic and economic development is expected to occur heterogeneously in this region, which may alter the spatial distribution of the actual environmental conditions. Exploitation of the coastal resources represents a major income for local populations, traditionally through fisheries and agriculture, and, as the Mediterranean has become the greatest tourist destination in the world, increasingly also via tourism. Therefore regional scenarios on the future evolution of river discharges to the sea are important to assess the potential impact of global change in the Mediterranean region, both in coastal waters and within the surrounding drainage basins.

The development of these scenarios is the purpose of our paper. Based on detailed reconstructions of the river fluxes during the last 40-50 years, we identified their major controlling factors which were then used to project the budgets from the recent past into the near future ([1], [2]). The quantitative framework of both the hindcasting and forecasting modelling scenarios is given by the IMAGE model and its spatially explicit parameterisations of potential drivers for the river fluxes, such as population growth, socio-economic development, land use changes and climatic boundary conditions. The future scenarios are consequently based on the four scenarios for the years 2030 and 2050 that were developed within the Millenium Ecosystem Assessment (MEA), and for which IMAGE produced the corresponding data layers.

We focussed on two contrasting parameters or parameter groups within the river fluxes. These are the fluxes of freshwater and the fluxes of nutrients, represented by nitrate and phosphate. Our results predict a significant trend of decreasing freshwater fluxes for the future, which already started in the past. Regional hot spots for this decrease are the drainage basins of the Alboran Sea and, when including the demographic evolutions, also the drainage basins of the Alboran Sea and North-Levantine seas (Fig. 1). The predicted total nutrient fluxes to the Mediterranean and Black Sea remain in the envelope of the observed variability during the last 40 years. At regional scales, however, the budgets may considerably change. In the Mediterranean drainage basins of the North, such as

the North-Western Basin and the Adriatic Sea, they uniformly tend to decrease. But in the basins of the South- and North-Levantine seas, where populations will grow rapidly, they may strongly increase. In the past, nutrient inputs from these two drainage basins were almost negligible in the total budgets, but they might become major components in the future.

Fig. 1. Evolution of the population specific water resources in the drainage basin of Mediterranean and Black Sea. Standard deviation corresponds to the differences between the four future scenarios. The distinguished sub-basins are the Alboran (ALB), North-Western (NWE), South-Western (SWE), Tyrrhenian (TYR), Adriatic (ADR), Ionian (ION), Central (CEN), Aegean (AEG), North-Levantine (NLE), and South-Levantine (SLE) seas. WMED, EMED, MED corresponds to the Western, Eastern and entire Mediterranean Sea, and BLS represents the entire Black Sea

ARTISANAL FISHING IN THE PROXIMITY TO A ROCKY LITTORAL MARINE RESERVE IN THE NORTHWESTERN MEDITERRANEAN: MEDES ISLANDS

Paloma Martin^{1*}, Miquel Sacanell¹, Vanessa Stelzenmuller² and Francesc Maynou¹

¹ CSIC-ICM - paloma@icm.csic.es ² CEEAS

CEFAS

Abstract

The fishing effort applied is low. Catches consist of most valued species and large- sized individuals. The creation of the reserve shifted the economic activity from fishing and agriculture to tourism. Keywords: Marine Parks, Fisheries, Western Mediterranean

Introduction

The small archinelago of the Medes Islands consists of seven islets and a number of reefs situated scarcely a mile from the coast. The primary purpose of the marine reserve, created in 1983, is conservation, scientific research and ecotourism. Before 1983, trammel net, longline and spare fishing where common in the reserve. In addition, trawlers used to operate very close to the rocky grounds. The tourism-related activities, non- extractive uses, are by far the main economic activity in L'Estartit, the port whose fishermen traditionally used to fish in Medes Islands.

Methods

The Marine Reserve represents a total surface of 511 ha (emerged zone not included). It comprises an integral reserve (93 ha) and a buffer area (418 ha), where artisanal fishing can be practised. The geographical situation (center of Meda Gran Island is 42° 02' 55" N, 3° 13'30" E). Only fishermen from the very close fishing port of L'Estartit are allowed to go fishing into Medes Islands. On board sampling (2003- 2005; 157 days at sea; 7 different vessels; 223 sets sampled; total weight sampled: 2600 kg; 107 species) allowed the identification of the fishing grounds, the characterization of the métiers (fishing gear, target species, seasonality) and corresponding catches (number and weight, by species); all fishes were measured (total length, mantle length, cm). Sampling allowed also the estimation of the discarded catch. Data for the winter months, when the fishing activity is at its lowest during the year because of weather conditions, were scarce, and thus, the characteristics of the métiers used in this season are not presented.

Results

Fishing can be practised 5 days a week, all year round, by the fishing boats based in L'Estartit. It is estimated that weather conditions allow go fishing around 120 days a year. In practice, the fishing effort applied is much lower. The fishing fleet is made up of 29 boats and the number of professional fishing licences is 15 (Generalitat de Catalunva, fleet census 2005). Of these, no more than ten go fishing all the year, and only three-four fishermen go routinely into the buffer zone. Trammel net and longline are the fishing gears allowed in the buffer area. A fisherman uses different métiers, thus, the characteristics of the vessels, by métier, are similar (lengh: 6 m; horsepower: 40 hp; age: 25 years). Most fishing activity concentrates in an area of around 4 km from the reserve border, mainly within 2 km from the reserve border. The seasonality regarding the target species and use of fishing gears is typically Mediterranean. Daily catches (total, landings and dicards) by fishing gear are given in Table 1. The specific composition by métier, expressed as percentage of the total catch (species representing >5% of the total catch; winter data not included) was as follows: trammel net targeting Mullus surmuletus (M. surmuletus (27%), M. cephalus (23%), P. acarne (16%), Diplodus sargus (5%)); longline targeting Sparus aurata (S. aurata (80%), Dicentrarchus labrax (16%)); gillnet targeting Pagellus erythrinus (P. erythrinus (35%), Merluccius merluccius (11%), Pagellus bogarayeo (10%). Scomber japonicus (8%). Myliobatis aquila (6%)): gillnet targeting M. merluccius (P. erythrinus (29%), M. merluccius (22%), Lophius piscatorius (9%), S. japonicus (8%)); traps targeting Octopus vulgaris (O. vulgaris (58%), Conger conger (34%)). The two gillnet métiers were differentiated taking into account the fishing grounds. The size distributions of the target species correspond to fishes significantly larger than those caught by similar fishing gears in areas not affected by protection regulations (Fig. 1). The most discarded species was Mugil cephalus.

Discussion

Catches displaying the positive effects on fishing ([1], [2], [3]; this study) derived from the existence of the reserve (most valued species, large sizes), tourism-related activities drive the economic activity (for example, more than 60.000 scuba dives and around 200.000 tourists in cruises around Medes Islands per year).

The information collected on board on the fishing activity and resources exploited in the area around Medes Islands marine reserve can be taken as reference point to assess the evolution of these resources.

A SCALE FOR MEASURING PEOPLE S OPINION ON THE VALUE OF WATER RESOURCES

Steriani Matsiori ¹*, Z. Stamkopoulos ¹ and Ch. Neofitou ¹

¹ The Department of Ichthyology and Aquatic Environment University of Thessaly - steriani@uth.gr

Abstract

The opinion of visitors on the environmental values of the river Penaeus (central Greece) was investigated. All types of environmental values were studied. The methodology that was employed for the development of measurement scales, was a combination of applied methodological research techniques in marketing research. More specifically, evaluation of a-Cronbach, Principal Component Analysis with Varimax rotation were used in order to assess the internal consistency and construct validity of the used scale.

Keywords: Economic valuation, Ecosystem services, Intermediate Waters

Introduction

The expression of total economic value (TEV) is an attempt to express the motivations behind people's preferences for environmental assets and the services these resources provide. The TEV provides a framework, to comprehensively evaluate natural and environmental resources [6]. The TEV is used in environmental economics to divide an environment into different components of value [6]. The mechanisms that link resources to individual and community well being, are the direct use of natural resources (for example, commercial and non-commercial recreation), the indirect use of a resource (i.e. ecosystem function values such as protection of biodiversity) and the non-use (such as the preservation of natural ecosystems, species or special areas) [7]. Economists divide use values into three main categories: direct, indirect and option values [4]. A type of option value is quasi-option value that has been described as the value of preserving options for future use given same expectation of the growth of knowledge [2]. On the contrary non-use values can be divided further into existence, bequest, and option values [5]. For many economists the option value may be classified as use value because is clearly connected to potential use (direct or indirect) and it is considered as unnecessary with the argument that it derives from the real use [9]. The existence value and the bequest value have not functional significance, for [8] existence value should not be used in cost-benefit analysis. The main objective of this paper is to investigate the existence of all type of environmental values and to examine who people perceive or recognize them in practice.

Materials and methods

The present research was carried out in the Penaeus River (central Greece), one of the most important aquatic ecosystem of Greece. Target population was visitors of the region. The socio-economic profile of survey sample (246 valid questionnaires) is given in Table 1.

Tab.	1.	Socioed	conomic	profile	of	survey	sample
rao.	1.	DOCIOCO	ononne	prome	O1	Survey	sample

Sex	53.3 % (Men)
Age	29-30 (33.75%)
Education level	Higher education (18.7%)
Occupation	Office Employee (21.1%)
Monthly income	900-1200 (17.1%)

The lack and the weakness of creating a sampling frame before the beginning of the study had led to the selection of the cluster sampling method [1]. A questionnaire was developed to determine all the types of environmental values. For this purpose every type of environmental value was described by a number of motives according to [7] and 47-attribute scale was derived to measure the value of the destination area. A five point Likert scale was used to measure visitor's opinions [3]. Evaluation of a-Cronbach and Principal Component Analysis with Varimax rotation were used in order to assess the internal consistency, construct validity of the used scales, classify types of values and investigate the motives that influence people to value a water resource. The identification of factors that describe the involved variables was performed by the orthogonal rotation method or the Varimax method. For determining the factors that were drawn it was used the eigenvalue or the characteristic root criterion (eigenvalue ≥ 1) [1].

Results and Discussion

The principal components analysis gave 6 factors that explain the 72.37% of total of the total variability (Table 2). Only 4 of them can be explaining people's opinions for river value. The Bartlett's test of sphericity has shown that there is high statistical significance (x^2 =8.293,97, p=0.000 and d.f.=990) and shows that the factor analysis model is suitable for our data. Kaiser – Mayer – Olkin (KMO) value shows that the measure of sampling was suitable

(0.94). Reliability analysis of the scale revealed that a-Cronbach was 0.98. Examining corrected item-to-total correlation and value of coefficient alpha if item deleted, no items were found that would increase coefficient alpha significantly (>0.01), so all items retained. It is very From the results, the people do not distinguish the deference between direct and option value. The use value (direct and option), was the most important type (50.34%) and follows by the existence value (10.75%). This is in accordance to many economist's opinions which suggests that it is value of assuring future direct or indirect use [9]. According to survey results people has an anthropocentric consideration of the environment and their attribute and give more significance to instrumental value of them. The results of our research shows that people recognize most of the different types of environmental values but classification high use values. Types of values like quasi-option value can not be noticeable. The results confirm the opinion of many environmental and natural resources.

Tab. 2. Principal components analysis results

Factors	ldentificatio n	Mean score per Factor	Explanatory Dispersion %	a- Cronbach
F1	Use value (Direct and option value)	3.3293	50.345	0.964
F2	Existance value	2.8690	10.748	0.934
F3	Indirect use value	3.0348	3.426	0.935
F4	Bequest value	3.0263	2.969	0.8484

EUTROPHICATION INDICATORS IN THE NORTHWEST COAST OF THE ALBORAN SEA: A MULTISCALAR TIME ANALYSIS

Jesús m. Mercado ¹*, Dolores Cortés ¹, Teodoro Ramírez ¹ and Esperanza Liger ²

¹ Instituto Español de Oceanografía, Centro Oceanográfico de Málaga - jesus.mercado@ma.ieo.es ² University of Málaga

Abstract

A time series of hydrology, nutrients and chlorophyll a during 1992-2007 was analysed to study the influence of the hydrological dynamics and nutrient pollution on the trophic state of a coastal station located at the bay of Málaga. The results indicate that water quality has improved during the last decade.

Keywords: Alboran Sea, Eutrophication, Phytoplankton, Nutrients, Time Series

Introduction

The link between anthropogenic sources of nutrients and eutrophication symptoms in coastal areas is generally accepted. However, the analysis of time series reveals that the coastal systems respond in various different ways to nutrient enrichment. This variety of responses is due to physical and/or biological attributes that together act as a filter to modulate the response to the signal of change in nutrient loading. Furthermore, the simultaneous operation of other stress factors (including the climate system) influences all the signals and the filters. The availability of nutrients in the northwest sector of the Alboran sea is strongly influenced by quasi-permanent upwelling of enriched deep water associated to the hydrological structures generated by the Atlantic jet that penetrates through the Strait of Gibraltar. Additionally, the wind regime regulates the intensity of the upwelling. The objective of this work is to study how these hydrological constrains may contribute to modulate the response to nutrient enrichment of the coastal ecosystem in the bay of Malaga .

Methods

One station located close to the bay of Málaga was sampled each three months from october-1992 to february-2007. During each visit, the Secchi disc depth was determined and vertical profiles of temperature and salinity were obtained. Additionally, water samples for nutrients and chorophyll a (chl a) analysis were collected at 0, 10 and 20 m depth. Nitrate and phosphates and chl a concentrations were analysed according to the methods detailed in [1]. TRIX index was calculated according to [2]. The seasonal variability patterns were tested by determining the statistical significance of the differences among seasonal means. An exponential smoothing of the seasonally adjusted series was performed in order to remove high-frequency component of variability (residuals series). Inter-annual change patterns and linear trends over time were examined by analysing the smoothed series. The significance of the monotonous trends over time was tested by fitting the smoothed series to a linear model.

Fig. 1. Seasonally adjusted and smoothed time series of different measured variables. The dotted line indicates the linear trend calculated by least square fit of the trend component time series.

Results

The annual maxima of temperature were obtained in summer, and salinity and nitrate peaked in spring. Nitrate concentration averaged for summer-period was reduced 5-fold with respect to the spring period. In contrast, phosphate concentration did not follow a defined seasonal cycle. The temperature described a linear monotonous increase trend over time (Fig. 1). The linear time trends for the salinity, nitrate and phosphate were also significant although negative. The residuals series of temperature and salinity were significantly correlated (r = -0.55, p < 0.05). However, there was not correlation between residuals series of salinity and nitrate or phosphate. Chl a concentration and Secchi disc depth did not describe any clear seasonal variation pattern, although normally higher chl a values were obtained in spring. Both variables experienced a monotonous decrease trend over the study period. Residuals of chl a were positively correlated with nitrate concentration (r=0.35 p < 0.05), however the correlation with phosphate was non-significant statistically. As obtained for nutrient concentrations and Chl a, TRIX index decreased over time.

Discussion

The study area is characterised by the presence of surface Atlantic water (AW) that is more or less modified depending on the degree of upwelling of deep Mediterranean water (MW). Therefore, the salinity decrease trend over time denotes a progressively lesser influence of the MW, as previously showed by [2] in other locations of the Alboran sea for the period 1992-2002. Atlantic water is usually depleted in nutrients. Consequently, the increasing influence of the AW produced a reduction of the nutrient concentration. Coincidently, chl a trended to decrease over time, indicating that the stock standing of phytoplankton at decadal scale was mainly controlled by the availability of nitrate. The high-frequency variability of chll a appears to be also controlled by the nitrate availability, as residuals series of both variables were significantly correlated. However, residuals series of nutrients were not correlated with salinity, probably indicating that the local peaks of nitrate and phosphate (which were especially conspicuous in 1992, 1994 and 2002) were not related with hydrological dynamics. It could be hypothesized that this high-frequency variability is due to nutrient discharge from terrestrial sources. The decrease trend over time of the TRIX index is a consequence of both the reduction of the nutrient and chl a concentrations (oxygen concentration did not experience any decadal variation pattern).

COMPARATIVE ANALYSIS OF GENETIC DIVERSITY OF BENTHIC SPECIES ACROSS THE NORTH-WESTERN MEDITERRANEAN SEA: A PILOT STUDY FOR MANAGEMENT PERSPECTIVES

B. Mérigot ¹*, E. Boissin ¹, E. Egea ¹, J. B. Ledoux ¹, K. Mokhtar-jamaï ¹, G. Penant ¹, D. Aurelle ¹, J. P. Féral ¹ and A. Chenuil ¹ ¹ Université Aix-Marseille II, Centre d'Océanologie de Marseille – UMR CNRS 6540 DIMAR; Station Marine d'Endoume, 13007 Marseille, France - bastien.merigot@univmed.fr

Abstract

Relative genetic diversity patterns of six marine benthic species are compared in a common set of areas in the north-western Mediterranean Sea. Genetic diversity of populations of two ophiuroids, two echinoids and two gorgonians is analysed in areas with contrasted environmental and anthropogenic conditions, ranging from Catalonia to the French Riviera. This study may provide a first step toward a broader multi-species analysis at larger scale in the Mediterranean Sea with implications for biodiversity management and protection.

Keywords: Biodiversity, Genetics, Coastal Systems, Western Mediterranean

The assessment of biodiversity within and among sites is central to identifying and prioritizing area for monitoring, management and protection. Genetic variation is widely recognized as one of several currencies for biodiversity evaluation ([1]), and protection of genetic diversity is incorporated into many national and international conventions. While previous works were mainly dedicated to study genetic diversity of populations of single marine species ([2], [3], [4]), no study until now compared relative genetic diversity patterns of distinct species in a common set of Mediterranean sites.

In this pilot study, the relative genetic diversity patterns of 6 benthic species are compared across areas ranging from Catalonia to the French Riviera in the north-western Mediterranean Sea (Fig. 1). The species studied are Amphipholis squamata, Ophioderma longicauda, Echinocardium cordatum, Paracentrotus lividus, Corallium rubrum and Paramuricea clavata. Some of these species are exploited by humans and threatened by the current regional warming of the Mediterranean Sea ([5]). These species have different dispersal abilities (eg. Amphipholis squamata does not dispose of a free larval phase in contrast to Paracentrotus lividus) and movement abilities (mobile versus fixed). As a result, distinct studies showed that some of them could be strongly structured at both local and regional scales (eg. Corallium rubrum [4]), while other species were structured only at large scale (eg. Paracentrotus lividus [2]). In this context, the selected areas (Catalonia, Blue Coast near Marseilles, Marseilles bay, Marseilles Calanques, French Riviera (Porquerolles island, Villefranche sur Mer, Monaco), Corsica island) allow to consider contrasted distance, environmental and anthropogenic influences on the studied species.

Fig. 1. Map of the commun areas for which relative genetic diversity patterns of distinct species are compared in the north-western Mediterranean Sea.

According to the species considered, sequences of two kinds of markers are analysed to investigate genetic diversity: mitochondrial DNA (ie. mitochondrial 16S rDNA and fragments of the mitochondrial gene coding for the subunit one of the cytochrome oxydase (mtCOI)), and nuclear DNA (ie. microsatellite loci). Genetic variability across populations in Mitochondrial DNA sequences and microsatellite loci, according to the species considered, are characterised by means of complementary diversity descriptors ([6], [7]). Such an approach will allow to assess differences and/or similarities in genetic diversity patterns that hold across species and areas studied, and to discuss management perspectives.

ETUDE BIOMETRIQUE DE CAULERPA RACEMOSA VAR. CYLINDRACEA (BRYOPSIDALES, CHLOROPHYTA) SE DEVELOPPANT SUR DIFFERENTS TYPES DE SUBSTRATS

Yosr Mezgui ¹*, Aslam Sami Djellouli ¹, Amel Zerzeri ¹ and Oum kalthoum Ben Hassine ¹ ¹ Faculté des Sciences de Tunis, 2092, Tunisie - mezgui_yosr@yahoo.fr

Abstract

Dans la région de Cap Zebib (Nord de la Tunisie), *C racemosa* var. *cylindracea* se développe à la fois sur un substrat dur (roches) et sur un substrat meuble (sable). Des relevés mensuels des paramètres biométriques, réalisés selon un cycle de 13 mois, révèlent une variation cyclique marquée par une période de croissance optimale, située en automne, et par une période de disparition macroscopique totale des thalles, observée en hiver. D'autre part, les résultats montrent que le développement de l'espèce ne varie pas en fonction du substrat.

Keywords: Algae, Biometrics

Le complexe C. racemosa (Forsskål) J. Agardh n'est signalé que depuis peu en Méditerranée [1]. A partir des années 90, on note une extension rapide de l'espèce [2]. Verlaque [3] reconnaît en méditerranée 3 variétés de C. racemosa : (1) la variété turbinata-uvifera, (2) la variété lamourouxii et (3) la variété cylindracea. La variété cylindracea est considérée comme envahissante [3] et [4]. Elle est décrite, par ailleurs, comme colonisant différents substrats à différentes profondeurs et comme tolérant les températures hivernales, relativement basses, du Nord de la Méditerranée. Dans la perspective de contribuer à la connaissance du développement de la variété invasive, nous avons effectué une étude biométrique comparative, de deux peuplements de C. racemosa var. cylindracea, se développant sur deux types de substrats différents. Cette étude est réalisée dans la région de Cap Zebib (Nord Est de la Tunisie) où les peuplements de C. racemosa var. cylindracea se développent à la fois sur un substrat dur : roches (noté SI) et sur un substrat meuble : sable (noté SII). Ces deux stations sont situées à une profondeur moyenne de 0.3 m. Des prélèvements mensuels ont été effectués au niveau de chaque station durant une période de 13 mois, allant de juillet 2005 à juillet 2006. Les estimations mensuelles de la biomasse révèlent une période de disparition macroscopique totale des thalles de l'espèce en hiver. Puis, à partir du mois d'août, on assiste à une croissance de la biomasse des thalles qui atteint un maximum en automne, soit une valeur de 25 g/m² de poids sec au niveau de la station SI et 19,25 g/m² dans la station SII. Toutefois, le test de Kruskal-Wallis ne révèle aucune différence significative entre les deux stations (H = 90.75, p = 0.907).

Fig. 1. Variations mensuelles du poids sec des populations à *Caulerpa racemos*a var cylindracea.

On note également que le diamètre des stolons reste constant et présente une moyenne égale à 1 mm (test ANOVA, F = 0.460, p = 0.501), au niveau des deux stations (SI et SII) et durant toute la période où un développement de l'algue est observé. En revanche, la longueur totale cumulée des stolons, nulle au mois de juillet, atteint son maximum (233,25 m/m² en SI et 120 m/m² en SII) en septembre. La longueur cumulée des stolons diminue progressivement par la suite pour aboutir à une disparition des thalles au mois de janvier. La longueur totale cumulée des stolons différence significative entre SI et SII durant les 13 mois d'échantillonnage (Kruskal-Wallis test: H = 90.75, p = 0.907). Le nombre total moyen de frondes par m² atteint un maximum de 10 212

frondes/m² au niveau de SI et de 5 187.5 frondes/m² au niveau de SII. Le nombre de frondes ne présente aucune différence significative entre SI et SII (Kruskal-Wallis test: H = 84.3, p = 0.844). En conclusion, la croissance de *C. racemosa* var. *cylindracea* semble ne pas être influencée par la nature du substrat.

Abstract

Remote sensing is a powerful tool in monitoring seagrasses, especially for managing the ecosystem. Along the coast, seagrass meadows are often subject to increased turbidity and may exhibit negative physiological responses to stress, or can tolerate it through photo-adaptation. Physiological changes are also evident in the genetic structure of meadows. This research aims at implementing a methodology for suitably monitoring mediterranean coastal ecosystem and, in particular, seagrasses, using an integrated and synergic approach. This consists of a more advanced remote sensing techniques and GIS technologies coupled with innovative methods for *in situ* measurements devoted to calibration of aero-spatial remotely sensed data. We investigated two sites: Central Tyrrhenian Sea (Italy) and the Aegean Sea (Greece).

Keywords: Posidonia, Remote Sensing, Physiology, Monitoring, Biogeography

Fig. 1. Map of seagrasses distribution at S. Marinella site derived from Landsat-TM data of 1991.

INTRODUCTION

SIMS (*Seagrasses Integrated Monitoring System*) project is aimed at monitoring and mapping seagrass distribution and estimating the related biophysical parameters in two European areas. The goal of our project is to support different activities concerning customers' duties in terms of shallow water ecosystem management by means of Earth Observation data processing. Instead of using only laborious field collection methodology in a sometimes difficult environment, the project intends to provide customers with improved information, in line with other new technologies (i.e. GIS).

In this research we used satellite imagery as a tool for monitoring *Posidonia oceanica* meadows comparing two sites in the Mediterranean: the central Tyrrhenian Sea (Italy) and the Aegean Sea (Greece).

Tyrrhenian Sea.

The Tyrrhenian site is located off the central coast of Lazio region, close to the S. Marinella site. In this site some years ago research activities were started to monitor bio-physical parameters of *P. oceanica* meadows. Rhyzomes from the near zone of Civitavecchia were transplanted *in situ* to remediate seagrass lost.

Results of these multi-yearly ENEA's activities include the monitoring of meadows evolution in terms of phenological parameters and genetic trends [1, 2].

Maps of main seagrass beds at this test site were first developed by diving activity. Geo-referencing was done with careful measurements taken by means of cartography and bathimetry. This meadow presents a patchy distribution of *P. oceanica* plants in the entire coastal area, which extends for several

kilometres. As can be seen in figure 1, the preliminary map obtained from Landsat-TM data of 1991 (even with some artefacts arising from the sensor low radiometric resolution) shows the distribution of the seagrasses in the area.

Aegean Sea

The second site is situated in the Aegean Sea, in East Greece, in the area around Arkoi island. Monitoring the Aegean sea by satellite images (IKONOS, LANDSAT, MERIS) allowed to track large areas of *P. oceanica* and seagrass beds in this part of the Mediterranean.

The framework of this project is satellite imagery used in combination with visual census data. This will lead to the development of a tool to quantify the size and the density of the seagrass meadows. Simultaneously seagrass biodiversity, both in Tyrrhenian and Aegean populations, will be evaluated by the RAPD molecular marker technique [1, 2].

The expected results are:

-to assess the role of environmental processes in shaping genetic diversity of seagrasses to identify molecular populations-specific RAPD patterns, from the combined studies of genetic variability and bio-chemical tests;

-to relate such patterns to environmental conditions and morphological and physiological features of the aquatic plants and to detect early process genetic erosion in stress conditions;

-to specify Remote Sensing and GIS procedures and bio-physical parameters/indicators thematic maps, designed to support sustainable management policies of Mediterranean ecosystems.

This research is financed by ESA: Project ITT No: AO/1-5828/09/I-EC

THE CHANGING WATER BUDGET OF QUINTO BASIN (RAVENNA, ITALY), A COASTAL WATERSHED UNDER CLIMATE CHANGE.

A. Minchio^{1*}, M. Antonellini¹, G. Gabbianelli¹, M. Laghi¹, V. Marconi¹ and P. Mollema¹

¹ University of Bologna (IGRG) - a.minchio@gmail.com

Abstract

The seasonal water budget of the Quinto Basin, a coastal watershed along the Adriatic sea in Italy, is calculated based on land use, under current and future climate conditions. Estimates of the future hydrologic surplus or deficit helps among others to understand whether salt water intrusion will be even a larger problem in the future than it is today, threatening both agricultural and natural ecosystems. *Keywords: Adriatic Sea, Coastal Processes, Global Change, Hydrology, Salinity*

Introduction and study methods

We present the water budget of a small coastal watershed (The Quinto Basin, Ravenna, Italy) by calculating the seasonal evapotranspiration based on land use. For the farmland, wetlands, natural areas, pine forest and bare soil we use CROPWAT [1] with different crop factors to calculate the evapotranspiration (Etc). To reduce the number of calculations we selected the most common soils and crops (wheat, maize, alfalfa, peaches and grapes). Reed represents the vegetation in the wetlands. Open water evaporation on lakes and old quarries is also calculated [2]. The climate data used in this study is based on measurements from four local weather stations. For an estimate of future climate, the averaged output of fifteen GCM models, in two scenarios (A1b and A2) for the period 2079 - 2099 (IPCC, 2007) is used. In comparison with today, the minimum temperature will be higher whereas the maximum temperature is higher mostly in winter but will not increase considerably in summer. The total annual precipitation is thought to decrease from 635 mm to 619 mm (scenario A1b) or 596 mm (scenario A2) and relatively more rain will fall in winter. The humidity is predicted to be higher, the winds less strong in the future.

Results

The annual ETc values decrease under the future climate scenarios used for this study. However, since relatively more rain falls in winter (up to 64% for A2), the summer (April-September) water deficits increase considerably. Whether or not this results in an increase of irrigation requirement depends also on the soil type and planting date. All the crops on all types of soil will need more irrigation under A2 except Peaches and Wheat. Evaporation of open waters, wetlands and bare soil is decreasing since the futures higher humidity compensates for the higher temperatures.

Fig. 1. The difference in annual net irrigation requirement between today and the future (scenario A2) for agricultural land, and the difference between current and future deficit (precipitation minus evapotranspiration) for the other areas.

Fig. 2. Summer water deficit (mm) for present and for scenarios A1b and A2.

Discussion and conclusions

This study shows that air humidity and wind velocity has a large influence on (crop) evapotranspiration and evaporation of open water in the Quinto Basin. It is a parameter that is not often discussed in future climate studies but needs more attention. Summer water deficits will increase and therefore agricultural practices including planting dates should be reconsidered. Although we have an estimate of Pine tree transpiration, not much is known about current or future evapotranspiration of natural areas.

TENEURS EN HYDROCARBURES DANS DIFFERENTS PORTS DU GOLFE DE TUNIS, TUNISIE

N. Mzoughi¹, L. Chouba^{1*}, Z. Souli¹, L. Hamdi¹ and R. M'rabet¹

¹ Institut National des Sciences et Technologies de la Mer, La Goulette, 2060, Tunisie - lassaad.chouba@instm.rnrt.tn

Abstract

Dans le cadre d'un projet de recherche de l'INSTM, une étude sur l'état des lieux de la contamination par les hydrocarbures - sous ses différentes formes aliphatiques et aromatiques polycycliques (HAP) - dans différents ports selon leurs activités (passager, commerce, pêche et plaisance) a été réalisée. La collecte de trois échantillons d'eau de mer et de sédiments de chaque port a été réalisée au mois de mai 2008 et ce, dans différents ports du golfe de Tunis. Les concentrations les plus élevées en hydrocarbures dans les sédiments et dans l'eau sont enregistrées dans les ports de Radès et de Sidi Bou Saïd qui ont une activité maritime importante. *Keywords: Ph, Sediments, Pah*

Les résultats des analyses effectuées ont révélé que les concentrations sont variables, entre 4,1 et 37,5 µg/g pour les hydrocarbures aliphatiques et entre 0,3 et 7 µg/g pour la somme des HAP dans les sédiments. Les teneurs trouvées dans les échantillons d'eau varient entre 0,25 et 5 µg/L pour les hydrocarbures aliphatiques et 0,15 et 7,1 µg/L pour les HAP. Les concentrations les plus élevées en hydrocarbures dans les sédiments et dans l'eau de mer sont enregistrées dans le port de Radès qui présente une activité commerciale importante et celui de Sidi Bou Saïd qui est caractérisé par ces activités de plaisances maritimes. L'analyse des données a montré une prépondérance des composés à 4 et à 5 noyaux par rapport à ceux à 2 et à 3 noyaux dans les trois ports. Cette différence peut être expliquée par la volatilité des composés à faibles noyaux aromatiques dans la zone d'étude, par l'évolution de la matière organique dans les sédiments et également par la courte durée de dégradation des précurseurs biogéniques. De manière générale, la présence ou non des hydrocarbures dépend de la géochimie du milieu et des structures chimiques (réactivités, volatilité, poids moléculaires, etc.) des composés.

Fig. 1. Somme des hydrocarbures aliphatiques (HA) et aromatiques polycycliques (HAP) en µg/L dans des échantillons d'eau prélevés des trois ports de la Goulette (G et P), Radès (Rd) et Sidi Bou Said (Sb)

La figure 1 montre des concentrations variables en hydrocarbures, les teneurs les plus élevées sont observées dans la station G3 de la Goulette et les trois stations de Radès. La concentration des hydrocarbures aliphatiques est la plus prépondérante dans les sédiments des trois ports étudiés (figure 2). Cette prépondérance ainsi que la présence des complexes non résolus (UCM) obtenus dans les chromatogrammes des différents échantillons montre l'origine pétrolière de ces hydrocarbures [4].

Fig. 2. Somme des hydrocarbures aliphatiques (HA) et aromatiques polycycliques (HAP) en $\mu g/g$ dans des échantillons de sédiments prélevés des trois ports de la Goulette (G et P), Radès (Rd) et Sidi Bou Said (Sb).

D'une manière générale, l'augmentation de la concentration des hydrocarbures aliphatiques peut être expliquée par la production de ces composés (Digenèse) dans un milieu dépourvu d'oxygène.

ETUDE DU RYTHME LOCOMOTEUR D'ORCHESTIA MONTAGUI, ISSU DE LA LAGUNE DE BIZERTE (NORD TUNISIEN) EN CONDITIONS D'ENTRAINEMENT ET EN LIBRE COURS

Karima Nasri-Ammar¹* and Raja Djelassi¹

¹ Unité de recherche Biologie animale et systématique évolutive, Faculté des Sciences de Tunis, 2092 Tunisie - knasri@planet.tn

Abstract

Le rythme de l'activité locomotrice de l'Amphipode supra littoral Orchestia montagui a été enregistré au niveau de la population de Bizerte (Nord de la Tunisie). L'étude de la variation saisonnière des caractéristiques du rythme locomoteur a montré une période circadienne et un temps d'activité plus longue et plus étendu en été qu'en hiver. Par ailleurs, l'étude du rythme de l'activité locomotrice des animaux expérimentés a révélé l'existence d'une composante ultradienne de période égale à 12h et ceci quelle que soit la saison.

Keywords: Crustacea, Behaviour, Lagoons

Introduction

Les rythmes biologiques constituent une réponse adaptative permettant aux organismes vivants de maximiser leur gain d'énergie et d'optimiser leur chance de survie, d'où l'importance de la synchronisation de l'activité locomotrice par les facteurs environnementaux, considérés comme des entraîneurs. En effet, plusieurs recherches ont montré que la photopériode constitue un puissant synchroniseur de ce comportement [1], [2] et [3]. Le but de ce travail est d'analyser et d'étudier la variation saisonnière des caractéristiques du rythme de l'activité locomotrice d'*Orchestia montagui*, Amphipode vivant en sympatrie avec sept autres espèces d'Amphipodes dans l'étage supra littoral.

Matériel et Méthodes

L'activité locomotrice d'*Orchestia montagui* a été enregistrée dans une population issue des berges de la lagune de Bizerte (Nord de la Tunisie), au mois de juin (photophase naturelle = 14h37) et au mois de décembre (photophase naturelle = 9h39). Les individus adultes, collectés manuellement ont été transférés, au laboratoire, individuellement, dans des actographes placés dans une enceinte climatique permettant de contrôler aussi bien la température que la photopériode. Les spécimens d'*Orchestia montagui*, maintenus sous une température constante de 18 \pm 0.5°C, ont été soumis, durant la première semaine à la photopériode naturelle du jour de la collecte puis ont été maintenus durant la deuxième semaine, en libre cours (obscurité continue).

Résultats et discussion

L'analyse des actogrammes en double plot, ainsi que les courbes d'activité locomotrice moyenne par heure et par jour ont permis de mettre en évidence une sensibilité plus importante des individus testés vis-à-vis de l'aube expérimentale et ceci quelle que soit la saison considérée (Figure 1).

L'étude des caractéristiques du rythme de l'activité locomotrice (période circadienne sous cycle nLD ; période circadienne en libre cours; stabilité du rythme [SNR] ; pourcentage de rythmicité, rapport temps d'activité/temps de repos) a montré que quelle que soit la saison, été ou hiver, le taux de rythmicité circadienne d'*Orchestia montagui* est beaucoup plus important en présence de synchroniseur (alternance lumière / obscurité) qu'en obscurité continue (DD). De même, ce taux de rythmicité est plus important durant la saison estivale qu'hivernale. Cette rythmicité, bien marquée en été, permet aux animaux d'éviter la déshydratation pendant les heures où la température est élevée. D'autre part, l'analyse statistique montre que le rythme locomoteur d'*Orchestia montagui* est statistiquement plus stable en été qu'en hiver et ceci en présence de synchroniseur. Enfin, quel que soit le régime photopériodique imposé (LD ou

DD), les animaux sont plus actifs en été qu'en hiver (Tableau1).

abnounah@yahoo.fr

Abstract

L'estuaire de Bou Regreg a été progressivement délaissé, n'offrant que quelques rares activités de loisirs. Le développement des deux villes riveraines, Rabat et Salé, s'est accompagné d'une multiplication et d'une intensification des impacts anthropiques, surtout après l'installation du barrage Sidi Mohammed Ben Abdellah en 1974 à 23 km de son embouchure. Cette étude compare l'état environnemental de la vallée du Bou Regreg avant les travaux d'aménagement et trois ans après. Keywords: Coastal Management, Sewage Pollution

Introduction

Le projet de dépollution de l'estuaire et du littoral, considéré comme prioritaire, entre dans le cadre du projet d'aménagement de la vallée du Bou Regreg [1]. Cette vallée constitue un élément d'union entre les deux villes historiques et s'étale sur une superficie de 6 000 ha, allant de l'embouchure de Bou Regreg jusqu'au barrage Sidi Mohammed Ben Abdellah.

Projet de dépollution de l'estuaire et du littoral

Ce projet a accordé un intérêt particulier à l'environnement et à la préservation de l'écosystème [2]. La dépollution de la vallée et du fleuve, la réhabilitation et le reboisement des carrières, la sauvegarde du site naturel dans son ensemble étaient les premières démarches entamées. Ainsi, plusieurs actions visant la généralisation de la haute qualité environnementale ont été progressivement entreprises notamment dans les domaines suivants :

- Assainissement solide, avec l'ouverture de la décharge d'Oum Azza en remplacement de la décharge de l'Oulja réhabilitée et définitivement fermée en 2006 et de celle d'Akreuch, en cours de réhabilitation, permettant ainsi de mettre fin à toute forme de pollution qu'elles engendraient y compris les rejets de lixiviats dans l'estuaire.

- Assainissement liquide, qui consiste en l'installation d'un réseau d'assainissement liquide couvrant toute la région de la wilaya de Rabat - Salé. Il doit conduire, à terme, les effluents vers deux stations de prétraitement à Rabat (station de Youssoufia bas) et à Salé. Durant ces trois années de travaux, en plus de l'élimination de plusieurs rejets des eaux usées localisés le long de l'estuaire (Figure 1) - surtout dans la partie aval du pont My El Hassan qui correspond à la première séquence de ce projet - il y a eu : - réhabilitation du site par la fermeture de la décharge d'Oulja, - transformation de la décharge d'Akreuch en centre de transfert, - réhabilitation des carrières et reboisement d'un tunnel sous la colline des Oudayas, - réalisation du projet de tramway de Rabat Salé.

Etat de l'estuaire avant et après le lancement des travaux d'aménagement :

Avant le commencement du projet d'aménagement de la vallée du Bou Regreg et en absence d'un système de dépollution, l'estuaire du Bou Regreg et le littoral recevaient une pollution essentiellement organique estimée à 200 000 m³/j d'eaux usées. En comparant avec les normes des eaux de baignade marocaines du point de vue qualité, les eaux de l'estuaire sont très polluées et généralement impropres à la baignade [3], [4]. Dans la partie située en aval du pont My El Hassan, les eaux de l'estuaire restent très polluées avec des fortes concentrations de coliformes fécaux (CF) bien qu'ils aient subit une diminution de 4×10^6 CF/100ml en 1999 [4] à 2,1 $\times 10^6$ CF/100ml en 2008. Leurs concentrations restent toujours supérieures à celles des streptocoques fécaux (SF). Le rapport CF/SF est supérieur à 4 ce qui nous permet de conclure que la pollution est d'origine fécale humaine.

Conclusion

Après trois ans de travaux d'aménagement, seule la partie située en aval du pont Moulay El Hassan a connu une dépollution presque totale, mais le problème persiste toujours parce que cette partie subit l'influence des eaux polluées de l'oued à basse mer et des eaux du littoral à haute mer.

RISK OF INUNDATION CAUSED BY SEA LEVEL RISE ALONG THE BULGARIAN BLACK SEA COAST

Atanas Palazov^{1*} and Hristo Stanchev¹

¹ Institute of Oceanology, Bulgarian Academy of Sciences - palazov@io-bas.bg

Abstract

Over recent decades the increased frequency of natural hazards resulting from global climate change has become one of the most severe problems affecting the sustainability of the coastal zone. In particular, low-lying areas which are strongly affected by flooding pose the most serious consequences for the functions of coastal systems and public safety. Such areas are also most attractive and productive environments both for settlements and human activities because they offer great variety of possibilities for better livelihoods, easy access to the sea, and wide and vast beaches. These settings make even more important the efforts to identify coastal areas with high priority of risks to sea flooding.

Keywords: Black Sea, Coastal Processes, Sea Level

Introduction

The Bulgarian Black Sea coast has a length of 412 km, as 58% of it is exposed to progressive coastal erosion and landslide processes [1,2]. Such natural hazards have been aggravated by increasing anthropogenic impacts associated with accelerated urbanisation and human influence along the coast. There are 14 Bulgarian Black Sea coastal municipalities which embrace about 5.21 %from the entire territory of the country and hosted about 8.85 % of the national population. Coastal units potentially vulnerable to sea level rise along the Bulgarian coast are firths, lagoons, sandy beaches and dunes often being also under subsidence processes. Firths and lagoons are typical of the Bulgarian coastal zone. Firth configuration almost repeats the contours of old river valleys drowned during the Holocene. The number of firths and lagoons are 26 and 5 respectively [3]. Long-term sea level changes along the Bulgarian Black Sea coast have been traced for more than 100-year period. Based on the records of two sea level gauges, located at towns of Varna and Burgas, a continuous sea level increase has been found, particularly over the last few decades. Natural and anthropogenic factors are pointed out as the main causes for accelerated sea-level rise. The natural factors involved include changing river discharge into the Black Sea, rainfall-evaporation balance and water exchange through the straights linking the Black Sea to the Mediterranean [3]. The mean values of average sea level rise for the Western part of the Black Sea vary between 1.5 mm/y and 3 mm/y [4]. Although such rates are not dramatic for the Bulgarian coast there would be a case of sudden sea level rise under certain meteorological conditions. In contrast to climate change-induced sea level rise, which can be predicted over a middle-time scale, the extreme sea level increase associated with storm surges, tsunamis and rain-storms could have a short, but particular devastating impact on coastal areas. Significant coastal changes typically occur during such extreme events. As a consequence, functions and values of the coastal systems could be degraded, and public safety and economy could be affected [5]. Coastal storms are extreme meteorological events that mainly occur along the Bulgarian Black Sea coast in winter with the strongest N and NE winds. There are some examples of extreme events along the Bulgarian coast: the storm happened in February 1979 accompanied by sea level increase; and the storm in June 2006, also combined with pour rains. Extreme wind waves are the main cause of flooding in low-lying coastal territories.

Analysis

To indicate low-laying territories potentially vulnerable to flooding due to extreme sea level rise along the Bulgarian coast, medium scale 1:50 000 topographic maps were used [6]. Maps processing includes a series of steps: scanning, geo-referencing and digitizing with help of Geographic Information System (GIS) ArcInfo 9.2. The following approach was accepted: sea level rise scenarios from 1 to 5 m with interval of 1 m were assumed on the basis of historical background and data collected over a 100-year period (Fig. 1). The performed analysis shows that 14 towns, 17 villages, 13 sea resorts and 7 small campsites would be potentially flooded by extreme sea level rise of 5 m. Number of affected coastal population counts almost 100 000 from all 549 765 residents at these sites, according to last Census data [7]. Low-laying areas around Varna Bay, Kamchia River resort, Burgas town, Sunny beach resort. Pomorie town and coastal section between Albena resort and Kranevo village were identified as most vulnerable to inundation (Table 1). The risk to flooding is higher in summer presumably due to greater numbers of tourists having their rest at the sea coast. In summary, about 20% (83 km) of the entire 412 km long Bulgarian coast are indicated as flood-prone territories or these are coastal units most vulnerable to inundation due to extreme sea level rise of 5 m. Total number of local coastal residents at these sites constitutes 6.93% of country's population.

Conclusions

Sea level rise along the Bulgarian Black Sea coast up to 1 m could cause damages on 7% of the territory and population of the coastal settlements. Sea level rise up to 5 m could cause damages on 21% of the territory and 16% of the population of the coastal settlements. Expected damages in residential area caused by inundation of 1 m would amount to 33% of territory and 42% of population from those affected by inundation of 5 m. As the most risks zones are defined the territories around of the towns of Varna, Burgas, Balchik, Pomorie and Nessebar, Kamchia river region, Sunny beach and Albena resorts. Totally, between 40 and 97 thousand local residence could be affected and between 9 and 27 square km of settlements inundated in case of different scenarios. Although the probability of casualties due to extreme storms is quite high, in actual fact the economic losses in terms of hotel, transport and other infrastructure damages are predominant. As a result of such events the economy of a small municipality like Nessebar will be greatly affected due to its high dependence on the tourist industry. Therefore, many potential users and institutions interested in sustainable development, including local government, civil protection authorities, stakeholders, coastal decision makers and community would benefit from the results obtained for coastal hazards to elaborate appropriate mitigation measures and adaptation policies.

TROPHIC STATE AND NUTRIENT RATIOS IN A HELLENIC COASTAL MARINE ECOSYSTEM AFFECTED BY AGRICULTURAL ACTIVITIES

Alexandra Pavlidou ¹* And Roza Psyllidou-Giouranovits ¹ ¹ HELLENIC CENTER FOR MARINE RESEARCH (HCMR) - Aleka@Ath.Hcmr.Gr

Abstract

Nutrient concentrations and their ratios in the north Lakonikos Gulf, a coastal marine environment affected mainly by agricultural activities, were used in order to describe the ecosystem and to characterize it as an oligotrophic area. The agricultural activity in the adjacent plain, the Evrotas River discharges as well as the small streams inputs in the area seems to have insignificant impact in the marine environment. Nitrogen limitation was observed in the study area. *Keywords: Coastal Systems, Nutrients*

INTRODUCTION

Measuring nutrient concentrations is a topical concern in many coastal systems, since the anthropogenic nutrient enrichment may result in a change of the trophic state of an ecosystem [1]. Excess nutrients (N and P) discharged from anthropogenic activities have been identified as one of the major pollution point sources leading to eutrophication in the coastal waters.

The coastal area of Lakonikos Gulf ($36^{\circ}44.06'$ N and $22^{\circ}34.96'$ E) (Fig. 1) is mainly used for agricultural purposes, with a few small towns and tourist sites located along the coastline. Fishing activity is also developed in the area. The industrial activities in Lakonikos Gulf are very few, thus in terms of pollution sources, the aforementioned agricultural activities and untreated domestic effluents are the most important. Nutrient samples were collected from a grid of 29 sampling stations in the northern sector of the Lakonikos Gulf during June 2008, in order to present the nutrient concentrations and their ratios in Lakonikos gulf and to determine the trophic state in the area.

Fig. 1. Study area location and sampling stations grid

RESULTS AND DISCUSSION

Low nutrient concentrations were measured in the study area (0.100 µM for phosphate; 0.207 µM for nitrate; 1.274 µM for silicate; 0.051 for nitrite; 0.258 for ammonium). To determine the trophic state in the area, a concentration scale proposed by Karydis [2] was used, dividing the area into 4 different trophic levels: oligotrophic (<0.07 µM, phosphate; <0.62 µM, nitrate; <0.55 µM, ammonium), lower mesotrophic (0.07-0.14 µM, phosphate; 0.62-0.65 µM, nitrate; 0.55-1.05 µM, ammonium), upper mesotrophic (0.14-0.68 µM, phosphate; 0.65-1.19 µM, nitrate; 1.05-2.20 µM, ammonium) and eutrophic (>0.68 µM, phosphate; >1.19 µM, nitrate; >2.20 µM, ammonium). Inorganic phosphorus at stations L04, L05, L07 and L17 corresponded to an oligotrophic state according to the Karydis concentration scale, whereas at all the other stations inorganic phosphorus corresponded to a lower mesotrophic state. The nitrate concentrations measured in the study area showed higher mesotrophic waters only for the deeper layers of stations L12 and L13 and oligotrophic for all the other sampling stations. In general, higher nitrate concentrations were observed in deeper water layers. Ammonium concentrations showed lower mesotrophic water type for station L23 and oligotrophic water type for all the other stations. The mean N:P ratio ranged between 1.49 and 11.8 with a mean N:P ratio of 5.27. The mean Si:P ratio calculated 12.7 and the mean Si:N ratio calculated 3.26. It is noteworthy, that the N:P ratio is significantly declined due to very low nitrate concentrations at the upper layer of the water column. According to Justic et al. [3], three criteria have been applied for P-limitation, N-limitation and Si-limitation as follows: a) P-limitation, if Si:P>22 and N:P>22; b) N-limitation, if N:P<10 and Si:N>1; c) Si limitation, if Si:P<10 and Si:N<10. 83% of our data indicated N-limitation whereas, 27% indicated Si-limitation. Plimitation was not found. According to these results, nitrogen controls the functioning of Lakonikos marine ecosystem. In general, the study area was characterized as an oligotrophic area indicating that the agricultural activity in the adjacent plain, the Evrotas River discharges as well as the small streams

inputs in the area seems to have insignificant impact in the marine environment.

SESAME PROGRAM : RECENT EVOLUTION OF PHYTOPLANKTON COMMUNITIES IN NORTH-WESTERN MEDITERRANEAN COASTAL WATERS

Bernard Queguiner ¹*, Mathias Girault ¹ and Beatriz Beker ²

¹ Laboratoire d'Oceanographie Physique et Chimique / Centre d'Oceanologie de Marseille, 13288, France -

bernard.queguiner@univmed.fr

² Service d'observation, Centre d'Oceanologie de Marseille, 13288, France

Abstract

Results obtained during the SESAME program emphasize major changes in phytoplankton communities. The nutrient limitation is characterized by an increased duration of limitation by phosphate which has gradually extended from January to all the first 6 months of the year between 1996 and 2007. Taxonomic data collected since 1994 shows a high variability of phytoplankton developments. Bloom seasonality is slightly marked although it tends to occur during winter and spring when the environment is replenished with nutrients. A long-term of biodiversity loss is observed as well as a disruption marked by decreasing cell concentrations around 1996-1997. The evolution of a few phytoplankton species of diatoms and dinoflagellates indicates another change around 1998-1999. Results are interpreted with reference to the North Atlantic Oscillation.

Keywords: Phytoplankton, Biodiversity, Coastal Systems, Nutrients, Gulf Of Lions

We have analyzed datafrom the CNRS-INSU SOMLIT observation program at three stations of the French Mediterranean coast, from Banvuls/mer to Villefanche/mer. The 3 stations show different trends. With regard to nutrient limitation, the time-series of Banyuls/mer and Marseille both show a gradual change that results in an increased period of limitation by phosphate which has gradually extended from January to the first 6 months of the year between 1996 and 2007. The situation appears more stable in the bay of Villefranche/mer. This contrast partly reflects changes in river flows during the last decade in the Gulf of Lions. Recently, Ludwig et al. (2009) documented a drastic increase of the NO3/PO4 ratio of Rhône River freshwater from ~20 to ~80 in between 1990 and 2000. This trend is a general feature of the Mediterranean Sea and appears related to mitigation strategies for urban pollution treatment targeting the reduction of phosphorus emissions. Ludwig et al. (2009) also highlight the increase of potential limitation of marine primary production by both phosphate and silicic acid, the latter being more a problem for coastal phytoplankton community changes (shift from diatoms to flagellates). An examination of taxonomic data collected since 1994 on a fortnightly basis shows a high variability of phytoplankton developments in coastal waters. Seasonality of blooms is only slightly marked although they tend to occur during winter and spring when the environment is replenished with nutrients after strong wind (mistral) events. The data set shows a disruption marked by decreasing cell concentrations of microphytoplankton around the years 1996-1997.

Fig. 1. Evolution of 4 sentinel species of the Bay of Marseille in parallel to that of the monthly NAO (North Atlantic Oscillation) index (the green curve represents 12 months central moving average of the monthly NAO index).

Of the 228 taxa of diatoms and of dinoflagellates that were observed in the Bay of Marseille, only a few show an interesting development that is manifested by their appearance or disappearance from the ecosystem. The dinoflagellate *Prorocentrum minimum* decreased sharply after 1999, while the genus *Gymnodinium* seemed to find more favourable conditions for its development. For diatoms, from the same period, *Chaetoceros curvisetum* became very common while *Thalassionema frauenfeldii* almost disappeared in the records. These species can be considered sentinel species whose presence or absence is a reflection of changes in environmental conditions. It is interesting to note that the period shift corresponds well to a persisting maximum in the monthly NAO (North Atlantic OScillation) index temporal evolution.

Changes in diversity showed a surprising contrast with changes in the NAO index. The period 1999-2000, characterized by a positive NAO index, corresponds to a large decrease in the Shannon index and the Pielou evenness concomitant with evolution of the sentinel species mentioned above. The decrease of diversity also matched the seasonal extension of potentially limiting conditions for phosphate although available nutrient data do not offer a sufficient background to describe accurately the evolution of the nutritional environment of phytoplankton for the period prior to 1996. It is therefore possible that anthropogenic changes have directly influenced the microphytoplankton community structure, including the dissolved Si/P ratio known to control the seasonal succession. However, the system does not appear to have suffered from severe disturbance, as no proliferation of flagellates has so far been observed over the study period. A second sharp decrease of diversity was observed in 2004, particularly marked for the H index, and occurring in parallel with an increase in phytoplankton bloom intensity (in terms of biomass) in the Bay of Marseille. The accumulation of phytoplankton biomass reflects the imbalance between the production processes and the consumption processes including grazing by zooplankton and the shift in phytoplankton species and biodiversity could be linked to changes in the community of grazers (Katechakis et al., 2002). It is therefore possible that the trend observed at the end of the series is a reflection of profound changes in the pelagic ecosystem.

Fig. 2. Long-term evolution of the Shannon (1948) index (H) and of the Pielou (1966) evenness (E) of microphytoplankton in the Bay of Marseille. The grey curves show the variations of the 6 months central moving average of daily interpolated data normalized against the average of each data set. The dotted lines represent the trends of declining diversity for the 1994–2006 period.

Abstract

As a step towards operational management of marine ecosystems SPECiMed will develop a predictive understanding of how marine biogeochemical cycles and ecosystems respond to changing forcings, including how large-scale climatic variations impact regional ecosystem functioning through the changing physical dynamics and the alteration of biogeochemical cycles. SPECiMed relies on the joint expertise of oceanographers from the fields of physics, chemistry and biology to comprehend the ecosystem response to forcing. The 3-yearproject relies on the existing SOMLIT coastal stations of Marseille (SOFCOM) and Banyuls/mer (SOLA) and will implement the two shelf stations JULIO (SE entrance of the GoL) and MOLA (SW exit). *Keywords: Phytoplankton, Zooplankton, Nutrients, Mesoscale Phenomena, Monitoring*

SPECiMed was designed as a component of the INSU-CNRS "Chantier Méditerranée" under the framework of the MERMEX project in its mediumterm strategy of Enhanced Observing Periods (EOPs). In comparison with Long Observation Periods (LOPs) implemented in the framework of MOOSE (Mediterranean Ocean Observation multi-Sites on Environment), SPECiMed positions itself as an EOP designed to meet its specific scientific goals. Within MERMEX, SPECiMed will be more focused on the studies of ecological processes (biogeochemistry and food-web interactions).

Fig. 1. SPECiMed will combine the classical methodologies and the new investigation tools for exploring the pelagic ecosystem of the Gulf of Lions.

The rapid development of the Mediterranean basin had significant positive impacts on living standards of people but it was largely achieved at the expense of environmental balances essential to human well-being. With increasing anthropogenic pressure, the Mediterranean basin has now become an endangered environment both in terms of its ecological balance and exploitable resources and of the water systems that sustain human activities. Regarding the marine environment, despite the intensive research efforts undertaken in the Mediterranean Sea for over a century, an integrated vision of how its ecosystems function is still lacking. Yet this knowledge is indispensable to meet the expectations of the Mediterranean basin development and sustainable management issues it raises.

In the northwestern Mediterranean (NWM), studies on the impact of climate on plankton communities are limited by the small number of long-term series. Nevertheless, few studies have addressed the question of the long-term drift in composition and dynamics of plankton. A long-term evolution of phytoplankton communities has been at least detected in several places of the French NWM coast, e.g. at DYFAMED station and especially in the Gulf of Lions (GoL), during the research projects EC2CO/GolPhyZ and the ongoing EU/SESAME partly devoted to plankton series data mining. The decadal variability of coastal phytoplankton in the Bay of Marseille from 1994 to 2006 suggests a close link to the North Atlantic Oscillation (via processes that still need to be assessed at the mechanistic level), a possible regime shift in the years around 1999, as well as signs of biodiversity loss.

The Mediterranean Sea is often compared to the world ocean given its thermohaline anti-estuarine circulation. It is also characterized by an eastward gradient of oligotrophy associated with a succession of different plankton communities. Therefore it is difficult to observe the evolution of the Mediterranean as a whole. Even if trends can be predicted using numerical models, these must be validated continuously in view of ongoing climate change. Therefore, the regional level appears appropriate. At first glance, the NWM basin is a mosaic of nested ecosystems offering similarities with the general situation of the World Ocean: An estuary at the mouth of a great river, the Rhône River, which brings locally large nutrient loads on a continental shelf, the GoL, and a coastal current, the Northern Current (NC), which separates the land-to-ocean aquatic continuum from an oligotrophic gyre. SPECiMed aims at establishing a three-year observation platform of plankton communities incl. bacteria, phyto-, microzoo- and mesozooplankton, associated biogeochemical cycles of major elements (C, N, P, and Si), as well as monitoring the physical environment impacting the pelagic communities.

Planktonic organisms generally are classified on the basis of size, nutritional, and physiological characteristics or phylogeny. Regardless of the criterion used, broad diversity is revealed, as illustrated in Figure 2. Thus, the planktonic organisms include several size-classes, from < 1 μ m to several cm, so that sampling as well as quantitative observation of SPECiMED will take advantage of the use of several complementary means of investigation, each appropriate to one part of the size spectrum. SPECiMED will also develop the parallel use of *in situ* sensors like Lase Optical Plankton Counter (LOPC), Laser In Situ Scaterrometer and Transmissiometer (LISST) mounted on tracted Moving Vessel Profilers (MVP) in conjunction with hull-mounted ADCP to explore the mesoscale field of phyto- and zooplankton. While continuous measurements of currents will be performed by bottom ADCP moorings, integration between biology, geochemistry and physics will be provided by the coupled physical-biogeochemical multi-element multi-species model *Eco3M*.

Fig. 2. Representative classification of planktonic organisms by size showing the diversity of various autotrophic and heterotrophic groups (modified from Karl, 1999). The dark area corresponds to the compartments for which historical time-series data are available in the Gulf of Lions, the light grey area corresponds to the compartments for which detailed information is lacking.

Abstract

Le Maroc constitue l'une des régions du pourtour méditerranéen où l'érosion est la plus importante. Dans cette étude nous avons dressé, à partir de la cartographie des paramètres et facteurs de l'érosion (lithologie, géomorphologie, relief, occupation du sol), une carte de sensibilité à l'érosion dans le bassin versant de l'oued Laou. Le résultat montre une forte érodabilité des terres dans les secteurs Sud-est et Nord-ouest du bassin qui sont des terrains à fortes pentes. *Keywords: Erosion, Sediment Transport*

Le Maroc constitue l'une des régions du pourtour méditerranéen où l'érosion est la plus importante. Ce fléau touche plus particulièrement la région du Rif constitué essentiellement de formations friables, où les précipitations sont de type torrentielles et dont la couverture végétale a connu une forte dégradation ces dernières décennies. Dans cette étude, nous nous sommes intéressés au bassin versant de l'oued Laou qui se situe dans des provinces de Tétouan et de Chefchaouen entre 35°29'22" N et 35°00'54" N, et 05°04'16" W et 05° 26'05" (NW du Maroc). Il couvre une superficie de 939,242 Km² et un périmètre de 168,335 km. L'objectif de ce travail est d'évaluer la sensibilité des sols au niveau du bassin versant de l'oued Laou. La méthodologie consiste à cartographier les paramètres les plus significatifs intervenant directement dans l'érosion : la topographie, la lithologie, la géomorphologie et l'occupation du sol. Une base de données a été constituée pour chaque facteur et intégrée dans un système d'information géographique.

Paramètres d'évaluation

Lithologie : La lithologie du bassin étudié présente une forte résistance au niveau de la dorsale calcaire et les dépôts paléozoïques et une très forte érodabilité pour les dépôts du Quaternaire et les alluvions. *Relief* : À l'exception de la plaine côtière, la zone étudiée montre un relief accidenté avec des pentes abruptes. L'utilisation du Modèle Numérique de Terrain (MNT) au pas de 10 m, généré à partir de la numérisation des courbes de niveau, nous a permis d'extraire la carte des classes de pentes. *Occupation du sol* : le couvert végétal du bassin de l'oued Laou induit une forte érodabilité au niveau des terrains non boisés et une diminution au niveau des forêts de feuillus qui sont plus résistants à l'érosion. *Géomorphologie* : présence de zones de glissements de terrain et d'éboulis surtout dans les bords de l'oued, du barrage, et dans les zones à fortes pentes.

Superposition cartographique

La couche d'information est d'abord rastérisée selon la maille de base du MNT pour homogénéiser les échelles des sources de données et pouvoir ainsi les croiser spatialement. La superposition numérique des différents paramètres de l'érosion nous a permis de dresser une carte d'érosion potentielle au niveau du bassin versant de l'oued Laou. La carte obtenue (figure 1) est une information qualitative de 5 classes (très faible, faible, moyenne, élevée et très élevée), qui renseigne sur le degré de sensibilité des sols à être mobilisé par les facteurs de l'érosion hydrique [1]. La carte montre une forte érosion dans les secteurs Sud-est et Nord-ouest du bassin qui sont des zones à relief très accidenté et à pente élevée, expliquant leur grande sensibilité à l'érosion malgré des terrains des plus résistants. Cela peut également être expliqué par l'exposition de ces versants aux précipitations, aux vents dominants et à une plus longue durée de l'ensoleillement. Dans les autres zones du bassin, malgré une couverture végétale peu importante et des terrains peu résistants, la sensibilité à l'érosion reste de faible à movenne. Ceci montre que la pente constitue, en plus du facteur climatique, est le facteur principal de l'érosion dans cette région.

Fig. 1. Carte de sensibilité

CONCLUSION

L'approche multisource, combinant le relief, la lithologie, la géomorphologie et l'occupation du sol dans un SIG nous a permis d'identifier et de cartographier les surfaces de terres arables nécessitant la plus grande priorité d'interventions pour la protection du patrimoine sol et pour réduire les apports solides au niveau des retenues des barrages.

EVALUATION OF BIOMARKERS RESPONSE AT THE SE GULF OF TRIESTE (SLOVENIA) AND BOKA KOTORSKA (MONTENEGRO)

Andreja Ramšak ¹*, Bojana Tkalcic ² and Zoran Kljajic ³ ¹ Marine biology station, National institute of biology - ramsak@mbss.org ² 2Predstruge 66, 1312 Videm-Dobrepolje, Slovenia ³ 3Institut za biologiju mora, Dobrota bb., p.fah 69, 85330 Kotor, Montenegro

Abstract

In order to assess spatial distribution and temporal trends of pollution, response of different biomarkers of exposure were measured at three stations in Slovenian coastal waters included in long term biomonitoring MED POL programme and at two stations in Montenegro. Biomarkers response showed no differences between stations with different ecological status. Keywords: biomonitoring, Adriatic Sea, *Mytillus galloprovincialis Keywords: Adriatic Sea, Mollusca, Monitoring*

Introduction

A suite of biomarkers were used to measure effects of pollutants at northern and southern Adriatic, two regions with different pollution loadings and ecological characteristics. Both examined areas are still under high anthropogenic pressures with emphasizing urban and industrial wastewaters, tourism and agriculture. Both examined coastal area is highly pressured by building and reconstruction, small shipyards and maritime transportation. The coastal sea is intensively exploited by fishery and aquaculture. Chemical monitoring of sediments and sea water was mostly focused to persistent aromatic hydrocarbons and heavy metals. Distribution of certain heavy metals showed most pronounced difference between areas; stations in northern Adriatic being more loaded with mercury (1) and southern stations are more loaded with lead. The stations received different pollution loadings mostly from point sources. Ecological status of sampling stations was yearly evaluated in northern stations according to guidelines WFD (2).

Results and discussion

Biomarkers responses were measured in mussels (*Mytillus galloprovincialis*) collected from their natural beds at three sites along Slovenian coast and at two sites at Boka Kotorska Bay. Reference sites were Bay of Strunjan (SLO) and Bay of Kotor (MNE). Metallothionein concentration (MT) and micronuclei frequency (MN) was analysed and evaluated according to the recommended methodology (3), acetylcholinesterase activity (AChE) was determined using Ellman colorimetric method (4) using the whole viscera in crude homogenate and acetycholin as substrate. The statistical differences among samples from different sites were tested by the analysis of variance (ANOVA Tukey-post-hock HSD test).

Table 1. Response of biomarkers from sampling sites at northern and southern Adriatic Sea.

	Slovenia			Monteneg	gro

(µg/g w.w.)					
Acetylcholin	8,34±1	10,7±3,2	9,46±1,4	9,45±5	12,63±1,2
esterase activity					
(nmol/min mg)					

Differences in circulation regime and ecological characteristics between sampling stations at northern part (SE Gulf of Trieste) with stations at southern Adriatic (closed Bay of Kotor and Bay of Tivat) make comparison and analysis of biomarkers very valuable and interesting in terms of pollutants distribution and their effect to mussels. Adoption of pollutans such as heavy metals in caged mussels at northern and southern stations revealed almost equal concentrations of Hg, Pb, Ni, but twice higher amount of Cr in Bay of Koper comparing with other stations (project Mytiad 2008). Slightly higher amount of PAH were determined in mussels from Bay of Kotor during the same experiment comparing with northern reference site Bay of Strunjan. Ten times higher content of organochlorine pesticides was found in mussels from reference site in Bay of Kotor comparing with reference site at Bay of Strunjan. Frequencies of MN were followed in the period of one year at northern stations. Higher frequency was detected during the May at the same station in Bay of Koper and in caged mussels exposed in Slovenian marinas with poor circulation and higher level of pollutants. Station in Bay of Tivat (Bijela) was exposed to higher concentrations of Cu, Pb, Zn; especially Cu can act as genotoxic agents. Condition index should be used in biomonitoring to adjust the metal concentration in mussels and to eliminate the effect of trophic differences between stations. Spatial distribution was evident in condition index among stations which corresponds the trophic conditions at sampling sites. Most pronounced difference between northern and southern stations was in MT concentrations. Three times higher MT concentration was found at northern stations comparing with southern stations in wild mussels collected and analysed at the same time. The level of MT concentration at northern stations was in the same range through ten years period (5). The level of Cd in mussels is up to 1,0 mg kg⁻¹ and Hg 0,3 mg kg⁻¹ with trend to decreased in last years as established through monitoring programme (6). Substantial difference in heavy metals pollution among northern and southern stations was in concentration of some metals. Station Bijela (Bay of Tivat) have higher levels of some heavy metals (arsenic and lead) with low binding capacity to MT. On the other side, the concentration of total Hg was determined to be ten times higher in northern Adriatic than in other parts (1). The higher level of MT in northern stations could be a consequence of high binding affinity of Hg to MT, even though its low induction ability. The MT concentration showed decrease from northern to southern Adriatic. Results on MT concentrations obtained in mussels from eastern coast of Istria and Kvarner (Croatia) were between 50- 100 µg/g w.w. (7). Activity of AChE was measured in whole mussel tissue and was in the same range at northern and southern stations as measured in September 2009. Lower activity of AChE was found in May at stations in Bay of Strunjan and Bay of Piran.

EFFECTS OF OCEAN ACIDIFICATION ON JUVENILE CLAMS RUDITAPES DECUSSATUS

P. Range ¹*, L. Chícharo ¹, M. A. Chícharo ¹, R. Ben-hamadou ¹, D. Piló ¹, D. Matias ², S. Joaquim ² and A. P. Oliveira ² ¹ Centro de Ciências do Mar, Universidade do Algarve, 8005-139 Faro, Portugal - prange@ualg.pt ² Instituto Nacional de Recursos Biológicos (INRB-IPIMAR)

Abstract

We report the preliminary findings of a 3 month-long experiment aimed at investigating the effects of elevated pCO_2 and reduced pH on the juvenile stages of the clam *Ruditapes decussatus*. The concentration of CO2 in seawater was manipulated by diffusing pure CO₂, to attain two reduced pH treatments (-0.4 and -0.7 pH units), which were compared to seawater with natural pH levels. We found no differences among treatments in the size or weight of the clams. The natural pH treatment showed significantly larger mortality than the acidified treatments. The peak of mortality coincided with the occurrence of sporadic spawning events, which were not observed in the most extreme acidification treatment. This suggests that the increased survival under acidified conditions may be associated with a delay in the reproductive cycle of the clams. *Keywords: Carbon, Bivalves, Coastal Waters, Physiology, Ph*

Introduction. Anthropogenic emissions of carbon dioxide (CO₂) are changing the carbonate chemistry of seawater, causing decreases in pH and in the saturation state of carbonate minerals, which are major components for biological calcification. Whether and how this process of "ocean acidification" will affect marine organisms is currently a topic of great concern. The detrimental effects of acidic waters on bivalves have long been identified (1) and a critical pH value (<7.0) has even been proposed in relation to marine bivalves (2). More recent studies indicate that future CO₂ concentrations, predicted by the IPCC scenarios, can significant reduce calcification (3) and growth (4,5) of bivalves. Other aspects of bivalve physiology previously shown to be affected by reduced pH include acid-base regulation (4), respiration (4) and reproductive output (6). Here we report the preliminary findings of a 3 month-long experiment aimed at investigating the effects of elevated pCO₂ and reduced pH on the juvenile stages of the clam *Ruditapes decussatus*.

Methods. The experiment started on 09/06/2009 and ended on 23/10/2009. The rearing system was open, supplied with a continuous flow of filtered natural seawater to minimize the interference from the metabolic wasteproducts of the organisms. Seawater chemistry was manipulated by diffusing pure CO2, to attain two reduced pH treatments (-0.4 and -0.7 pH units), which were compared to seawater with natural pH levels. Each level of pH had 3 replicate tanks with clams, each stocked with 100 juvenile clams. Temperature and salinity were not controlled, but were continuously monitored, along with pH. Combined with measurements of total alkalinity and dissolved oxygen, taken at regular intervals, these variables allowed the estimation of the amount of carbonates in the seawater. The bivalves were fed in continuous flow with an adequate mixture of microalgae. The response of the juvenile clams was measured in terms of mortality, growth, biochemical composition, calcification and microstructure of the shell. The physiological response was also evaluated, in terms of feeding behaviour and metabolic rates.

Results and Discussion. Values of pH recorded during the experiment were maintained within the planned intervals (Mean \pm SD): pH -0.7 (7.50 \pm 0.12); pH -0.4 (7.81 \pm 0.06); pH CT (8.14 \pm 0.09). During the first 75 days the clams grew from 10.2 \pm 2.29 mm to 12.4 \pm 2.51 mm (shell-length, mean \pm SD). We found no differences among treatments in terms of the average size or weight of the clams. After 75 days there was a significant difference in survival between the natural pH and the two acidified treatments: pH - 0.4 = pH - 0.7 > pH CT (Figure 1). In contrast, the RNA/DNA condition index revealed an opposite pattern: pH -0.4 > pH -0.7.

Considering the reported effects of acidic seawater on bivalves, the decreased mortality of R. decussatusjuveniles under reduced pH conditions was an unexpected result. Some earlier studies (1,7) did not specifically addressed increasing CO2 concentrations and other methods of acidification were used, so their results should be interpreted with caution. The peak mortality in our experiment occurred in the same tanks where a spawning event was observed. just a few days before. No spawning was observed in the pH -0.7 treatment, which suggests the increased survival in that treatment may be associated with a delay in the reproductive development of the clams. The pattern of reduced growth under experimental conditions of reduced pH, previously reported for other species of bivalves (4,5), was also not apparent in our study. It is important to note, however, that the pH reductions imposed in our experiment, although within the range of values projected by IPCC, were not as severe as in those previous studies. Further clarification and interpretation of the preliminary findings reported here is expected when the full dataset is available.

Fig. 1. Mean (+ SD; n=3) survival after 95 days for each of the 3 pH levels considered; letters identify groups of means that are significantly different (SNK tests, p<0.05)

Abstract

Sediment remobilization induced by the passing of commercial tankers and cargo vessels in the Venice Lagoon, Italy was investigated during two sampling campaigns in March and July, 2009. A suite of instruments was utilized to measure suspended sediment concentration (SSC), water depth, and water velocity on the shoals alongside the shipping canal. SSC concentrations above 500 mg L⁻¹, much higher than the background concentration of 7 mg L⁻¹, were recorded at 50 cm above the sediment surface for several minutes after the passage of large ships. A threshold based on the Froude number and the size of the ship was calculated below which large waves directly linked to large SSC events do not form, thereby preventing previously isolated contaminated sediments to be reintroduced into the marine environment.

Keywords: Estuaries, Coastal Management, Sediment Transport, Waves

Introduction/Methods

Given their geographical orientation as a natural barrier to the open seas, coastal lagoons provide prime locations for shipping ports. Although the shipping industry is beneficial to the world's economy, it is important to discuss the possible negative impacts shipping can have on local ports, such as pollution from ship ballast water, introduction of invasive species and sediment resuspension and redistribution [1]. Herein, we investigate how shallow water waves produced by ships influence suspended sediments upon extended shoals in the Venice Lagoon, Italy. The sediments in the vicinity of the shipping channel are contaminated and therefore we aim to ascertain which parameters (i.e. vessel velocity, draft, width, tidal level etc.) influence the formation of powerful waves from shipping vessels outside the channel in the Venice Lagoon, and how much resuspension these waves, only vessel velocity and the timing of transit in relation to tidal levels can be controlled.

As the vessel velocity increases and as the size of the vessel increases the amplitude of the wave increases and therefore the probability for the formation of a shallow-water wave increases. When the shallow water wave breaks it generates high near-bottom current velocities (U_{max} ; m s⁻¹) along the sediment surface leading to re-suspension events [2].

$$U_{max} = \frac{\pi H}{T * \sinh \frac{2\pi h}{\lambda}}$$

Fig. 1. Equation 1

(1) where H is the wave height (m), T the wave period (s), h the water depth (m) and λ the wavelength (m). The larger the U_{max} , the greater the amount of resuspension will occur. Therefore, as expected, larger resuspension events will develop in the presence of high waves. An acoustic Doppler current profiler (ADCP) was utilized to measure SSC in the canal while two optical backscatter sensor (OBS) arrays were placed 50 m onto the shoals alongside the canal at a mean depth of 1.5 m. An S4 electromagnetic current meter with an internal OBS was also placed alongside one of the OBS arrays to measure water depth and velocity. Meanwhile a canal-normal transect of pressure sensors was spaced at 100 m intervals away from the canal to reproduce the propagation length and shape of the shallow water waves. An automated identification system (AIS) was used to collect vessel size, velocity and heading data.

Results

More than 100 ships generated waves associated with SSC change as recorded by the OBS arrays, however only 10 waves were sufficiently large and steep to cause extensive resuspension events. An extensive SSC event was considered to be one in which the change in SSC was over 300 mg L⁻¹ and in which the sediment remained in suspension longer than 6 minutes. Schoellhamer relates the product of the Froude number and the size of the ship to wave height [3]. Using a modified version of the Schoellhamer relationship including the water level on the shoals, we are able to determine a critical threshold of these parameters below which the shallow water waves will not attain the height or steepness necessary to create large SSC events (Figure 1). The knowledge of this threshold can help in the management practice of the lagoon.

Fig. 2. SSC event magnitude versus the modified Schoellhamer parameter. Large resuspension events do not occur below the threshold of 0.75.

Pressure sensor data shows the length of wave propagation along the shoals. Though there was significant dissipation of energy with distance from the channel, large waves are still recorded at least 1000 m onto the shoal, and are likely to be the one of the primary cause of extensive subsurface erosion seen in the central lagoon over the last 30 years [4].

SPATIAL DISTRIBUTION OF ZOOPLANKTON DURING SUMMER IN THE NORTH COAST OF SFAX (EASTERN MEDITERRANEAN SEA, TUNISIA)

A. Rekik¹, Z. Drira¹*, W. Guermazi¹, J. Elloumi¹, S. Maalej¹ and H. Ayadi¹

¹ Université de Sfax, Faculté des sciences de Sfax. Département des sciences de la vie. Unité de recherche UR/05ES05. Biodiversité

et Ecosystèmes Aquatiques. - zaherdrira@yahoo.fr

Abstract

Copepods were the most abundant zooplankton on the North coast of Sfax, contributing to 61.29% of the total zooplankton. A total of 12 copepods families were identified in all stations, with an overwhelming abundance of Oithonidae (76.70% of copepod abundance), which were characterized by neritic r-strategy-type species dominated by *Oithona nana* (55.85% of the total copepod abundance). *Keywords: Zooplankton , Coastal Management, Copepoda*

Introduction

The North Coast of Sfax is one of the main ports in the Gulf of Gabes. The coast has rich aquatic resources contributing about 65% of the national fish production in Tunisia [1]. Several findings have provided evidence that zooplankton such as copepods make a major contribution to optimal growth and fish survival. The distribution of copepod assemblages in Tunisian coastal waters has been studied in the Bay of Tunis [2], in the Tunis North Lagoon [3] and in the Gulf of Gabes [4].

Materials and methods

2.1. Sampling

Sampling was carried out in July 2007. Samples were collected from forty five stations located between 0.5 and 4.5 m along the North Coast of Sfax.

2.2. Biological parameters

Zooplankton was sampled by a cylindro-conical net. Zooplankton samples were preserved in 4% borax buffered formaldehyde solution. They were stored with pink Bengal to improve their identification and also to facilitate dissection of copepods. The enumeration was performed under a vertically mounted deepfocus dissecting microscope (Olympus TL 2).

2.3. Statistical analysis

The potential relationships between variables were tested by Pearson's correlation coefficient.

Results and discussion

Zooplankton assemblages in the North Coast of Sfax were dominated by copepods with a total of 21 species, accounting for 61.29% of the total zooplankton abundance (Fig. 1A). The spatial distribution of total zooplankton illustrates a high copepod density (61.39×10^4 individuals m⁻³) in station 13 associated with Oithonidae aggregations. We observed great numbers of nauplir ranged between 0 and 38.86 x 10^4 individuals m⁻³. Copepodid stage ranged from 0 to 15.89×10^4 individuals m⁻³ and adult stage varied between 0 and 10^5 individuals m⁻³. Cyclopoids contributed the largest fraction (76.70%) followed by harpacticoids (11.91%) calanoids (11.10%) and Poecilostomatoids (0.29%) (Fig. 1C).

Fig. 1. Relative contribution of zooplankton abundance (A), copepods demographic class abundance (B) and copepods groups' abundance (C) in sampled stations.

A total of 12 copepod families were found in all stations, Oithonidae dominating the total abundance of copepods (76.70%), among which *Oithona nana* was the most abundant species representing 55.85% of the total copepod abundance. Species translated into a highly significant correlation between copepod and *Oithona nana* abundances (r = 0.712, n = 45, p < 0.05) and between total zooplankton and *Oithona nana* abundances (r = 0.604, n = 45, p < 0.05). The

other zooplankton contributed only a small proportion of the total zooplankton (38.71%).

⁶ Stazione Zoologica "Anton Dohrn", Napoli, Italy

Abstract

Hypoxic/anoxic events affect quite frequently the northern Adriatic Sea during the warm season, especially the Po delta and the Emilia-Romagna coastal areas of south of it. Such events derive from a combination of physical, chemical and biological processes. A hydrodynamic model with a biogeochemical flux module has been producing daily 72-hour forecasts of the northern Adriatic area since June 2007. Available data have been compared to model forecasts. Computed statistics demonstrated a good model skill in forecasting hydrodynamics of the area, while skill in forecasting dissolved oxygen resulted much lower; the latter has been improved by correcting the forecast for the mean bias computed using buoy measurements of the previous 7 days. Keywords: Adriatic Sea, Coastal Models, Anoxia, Oxygen, Coastal Waters

Anoxic and hypoxic events are observed quite frequently in the northern Adriatic Sea during the period from late spring until autumn, especially in the Po delta and the Emilia-Romagna coastal areas south of it [1]. Anoxic events are observed also in the Gulf of Trieste and, rarely, in the much wider area between the Po delta and the Istrian Peninsula. Such events negatively affect environmental conditions, fisheries, tourism of the area. In the northern Adriatic Sea, some key factors for development of hypoxic conditions are related to river runoff (influencing phytoplankton bloom, stratification of the water column, light penetration) and coastal inputs, hydrodynamics, atmospheric conditions, reactivity of the seafloor.

Fig. 1. Map of the study area with the E1 buoy position and the main bathymetric lines; the insert show the wider northern Adriatic area.

The European LIFE project EMMA (contract LIFE04/ENV/IT 000479) was devoted to define an observing-forecasting system, plus a Decision Supporting System relying on the information provided by the latter, in order to help local authorities in the management of such events. The project focused on the Rimini area (fig. 1), where the meteo-oceanographic buoy E1 has been deployed and it is being transmitting near real time data since August 2006 (data are showed online at http://e1.bo.ismar.cnr.it). The observing system was complemented by regular monitoring of "Daphne II" vessel of ARPA SO Daphne along the Emilia-Romagna coastal area. Additional, non-periodic cruises were being held with R/V Dallaporta and R/V Urania in order to assure the buoy maintenance and to provide in-situ data in a wider area (also for model initialization).

The forecasting system is based on a 3-D hydrodynamic model, the Regional Ocean Modeling System (ROMS; [2]) integrated with the Fennel (a Fashamlike) biogeochemical fluxes module (which includes dissolved oxygen and carbon dynamics). The model grid covers the whole Adriatic Sea with an horizontal resolution of 2 km and 20 s-levels [2] in vertical. The fluxes of heat, water and momentum through the air-sea interface are interactively computed (using the ROMS SST) from the COSMO-I7 operational atmospheric model forecasts, managed by the Hydro-Meteo-Clima Service of the Emilia-Romagna Region (ARPA-SIMC) in the framework of the Limited Area Model Italy (LAMI) agreement. Real time Po river runoff is considered by the model as a source of both freshwater and nutrients, while climatologic values are used for other rivers (as real time data are presently not available). Nutrient inputs from Emilia-Romagna coast, particularly relevant during the summer season, are simulated with 13 additional point sources. From June 2007 the system is being producing every day the forecast for the next 72 hours (according to the present time span of COSMO-I7 forecast); the current ROMS forecast is initialized by a restart file produced by the ROMS run of the day before.

Forecasts produced by the model are compared to several kind of data: temperature, salinity, dissolved oxygen time series measured by moored buoys (E1 in particular); sea level time series measured by coastal tide gauges; vertical profiles of temperature, salinity and dissolved oxygen acquired during oceanographic surveys and regular monitoring; sea surface temperature and chlorophyll measured by satellite. Statistics have been computed in order to assess the forecasting skill. It results that temperature and salinity forecast are being maintaining for over two years of integration a good correlation with measured data and a quite low Root Mean Square Error (rmse), with any data assimilation or insertion in the model. Performance of dissolved oxygen forecast is worst, with a lower correlation and a higher rmse, but most of the rmse derives from a mean bias. This should be mostly due to processes unresolved by the biogeochemical module, like benthic respiration. Work is in progress aiming to improve the system, also by including in the model simplified benthic processes; meanwhile dissolved oxygen forecasts in the Rimini area show a good performance by removing the mean bias computed from the data measured by E1 buoy during the 7 days preceding the new forecast.

To our knowledge, this is the first operational system able to produce shortterm forecast of hypoxic/anoxic events in a Mediterranean Sea area.

SELECTION OF THE PRIORITY AREAS ON THE WEST COASTS OF MERSIN USING GIS TO ASSESS A MARINE CONSERVATION PLANNING

Serdar Sakinan¹* and Ali cemal Gucu¹

¹ METU- Institute of Marine Sciences - serdar.sakinan@gmail.com

Abstract

The subject of this study is selection of priority areas for marine conservation planning along western coasts of Mersin, by incorporating biological and socioeconomic data through geographical information system (GIS). The geographical borders of the study area were determined by the data availability from previous surveys, which were designed to investigate Mediterranean Monk seal habitats and populations. Consequently a reserve system composed of three segments were found to be the best selection where the patches were located at west of Anamur (Mellec), surroundings of Kizilliman and Between Akkuyu and Ovacik. Along with the recommendation of priority areas for conservation, the methodology used in this study was recommended for further studies in selection of areas for protection.

Keywords: Conservation, Coastal Waters, Levantine Basin

As the important fish stocks continue to decline the need of improving protection and management of marine areas is becoming more evident and marine protected areas are viewed as important tools (Côté and Finney, 2006). The coast of Turkey holds considerable marine biodiversity and marine resources. On all along the Turkish coasts many critical habitats are sheltering endangered species and commercially important species. Despite the more noticeable efforts for the protection of the marine environment within last years. increasing exploitation of coastal regions and degradation of marine resources are emerging as important environmental threats in Turkey. Nevertheless there is still important difficulties in creating the MPAs due to the interference of different institutions in decision making and enforcement of the regulations (Okumus,2002) and lack of methodology for assessment of the coastal areas for producing conservation plans and zonation. The core issue of this study is to generate a methodology on measuring, mapping and analyzing of available marine biodiversity data and surrogates in the study area including the perturbation sources and socioeconomic conflicts, for selection of new priority areas and optimization of the borders of the present protected area. Incorporating all the available information through GIS and prioritization of the sites is the main objectives of this research.

The base data used for this study were derived from field surveys carried out on the coastal area, between Bozyazi and Ovacik. Taking into consideration of the supplementary data, the study was extended the area between Mellec and Bogsak which constitutes a 181km coastline at west of Mersin. The offshore extent of the study area was defined by the trawl data availability, which is limited within 2 nautical mile distance from coastline.

The fish assemblage of shallow coastal area within depth of 0-10m was assessed by visual census survey, covering the whole area where the stations distributed in near equal longitudinal distance. Assemblage of the demersal species of deeper waters (10-100m) was assessed by trawl sampling. Considering the difficulty of measuring whole biodiversity of the area, surrogates were used to represent biodiversity. Surrogates were coastal habitat types, endangered species habitats and some certain fish species data derived from trawl and visual census data sets. Socioeconomic information was also collected during the surveys which were combined with the information extracted from Google Earth satellite images later on. All the obtained data was combined under a geo-database and mapped using GIS. After creation of the data layers Marxan was employed for site selection. Marxan is software designed for selection of the areas for creating marine reserves. With Marxan, it is possible to include socioeconomic information and optimize borders of the reserve system to provide compactness. The strength of the software is the simulated annealing algorithm by which Marxan finds optimal solutions. Several different tests were applied to find suitable values for settings of the software. Afterwards 8 different scenarios were created by changing the representation targets for each conservation feature. Finally a set of different sized but similarly located reserve systems were defined.

Consideration of multiple factors including cost, socioeconomic environment of the area is required along with the ecological factors. The biggest problem is to find an optimal solution that provides the best balance of biodiversity and socioeconomic concerns. The Kizilliman Marine Protected Area is designated to restore the marine ecosystem deteriorated by excess fishing pressure. Since the ultimate goal of this work is to optimize the conservation measures in the MPA analysis have basically focused on the fish communities and use it as a tool for supporting conservation site prioritization. Moreover considering the insufficiency of fish data for site prioritization, supplementary information such as critical habitats and coastline structure were used. As being one of the basic components of the decision making process the socioeconomic structure of the area was also assessed and incorporated in the analysis.

The framework was constructed to place two predefined critical zones at core of reserve system, which are most effective whelping sites of the Mediterranean monk seals in Turkish seas. With the aid of GIS and Marxan this aim was achieved by including the rest of the available biologic and socioeconomic information where the size and borders were optimized. Additionally a new zone located at neighborhoods of Akkuyu and Ovacik was identified as priority area. Finally two kinds of results were generated: best solution and irreplaceability. While decision of locating the protected areas was accomplished by best solutions, the irreplaceability values were essential for classifying the importance of the zonation and identifying the hotspots.

Fig. 1. Best scenario with irrepleacebility values

Consequently a reserve system was selected consisting of three regions. The regions were located at Anamur, Bozyazi and Ovacik. Moreover Akkuyu region where the nuclear power plant construction is on focus, found to be located in one of the core area of the reserve system assessed by this study. This result shows that a need for reassessment for the location of power plant need to be done, considering the possible negative effects of the nuclear power plants, over ecosystems.

REPARTITION DES POLYPLACOPHORES DANS LE LAC NORD DE TUNIS ET CARACTERISATION MORPHOMETRIQUE DE L'ESPECE DOMINANTE *LEPIDOCHITONA CAPREARUM* (SCACCHI, 1836)

Hedi Salah¹ and Nejla Aloui Bejaoui¹*

¹ Institut National Agronomique de Tunisie, Sfax, 3050, Tunisie - bejaoui.nejla@inat.agrinet.tn

Abstract

Cette première étude écobiologique sur les Polyplacophores de Tunisie met en évidence la présence de trois espèces sur le substrat rocheux de la digue centrale du lac Nord de Tunis après son aménagement en 1988. L'analyse en composantes principales des paramètres métriques de l'espèce dominante *L.caprearum* révèle l'existence de deux groupes d'individus. Cette ségrégation reflète l'influence des paramètres abiotiques, en particulier des teneurs en sels nutritifs, sur la morphologie de ces Mollusques. *Keywords: Mollusca, Rocky Shores, Lagoons, Growth*

Introduction

Les Polyplacophores présentent une large répartition en Méditerranée [1] mais n'ont pas fait l'objet d'études en Tunisie. Ce travail est une contribution à la connaissance de leur écologie en particulier au niveau de la digue centrale du lac où leur abondance a augmenté après l'amélioration des conditions hydrodynamiques de ce milieu lagunaire.

Matériel et méthodes

L'étude a été réalisée entre octobre 2007 et juillet 2008. Six aires, d'une profondeur maximale de 50 cm, ont été sélectionnées sur la digue. Les aires A1, A2, A3 sont situées sur la frange côtière Nord et sont soumises aux apports d'eau de mer alors que A4, A5, A6 sont situées au sud et sont représentatives d'un milieu lagunaire dont les eaux, sortantes vers la mer, sont chargées en sels nutritifs. Des prélèvements mensuels, dans chacune des aires, de l'espèce dominante *L. caprearum* ont permis de réaliser une étude morphométrique dont le but est d'identifier l'influence des paramètres du milieu sur la distribution et les caractéristiques morphologiques de l'espèce.

Résultats et discussion

Sur les trois espèces identifiées *Lepidochitona caprearum, Lepidochitona cinerea* et *Chiton olivaceus, L. caprearum* est la plus représentée en terme d'abondance à l'intérieur de chacune des aires. La répartition de ces espèces sur la digue centrale du lac montre que *L. caprearum* est présente dans l'ensemble des sites prospectés à l'exception de la 4^e aire (Fig. 1).

Fig. 1. Répartition des espèces recensées dans les différentes aires d'études sur les deux premiers axes de l'analyse en composantes principales (ACP)

En effet, au niveau de l'aire 4, les valeurs moyennes de la matière en suspension $(30,3 \pm 9,81 \text{ mg/l})$ et du phosphore total $(35, 65 \pm 7,87 \mu g/l)$ sont les plus élevées et celle de l'O₂ $(8,54 \pm 5,5 \text{ mg/l})$ est la plus faible. Ces résultats confirment l'influence de la turbidité sur la répartition des Polyplacophores, mise en évidence par Zavodnik *et al.* [2]. *L. cinerea* est l'espèce la mieux repartie sur l'ensemble des aires étudiées. *Chiton olivaceus* est au contraire une espèce à affinité marine, présente seulement dans l'aire 1. La répartition de ces espèces, obéit, comme toute espèce lagunaire [3], à l'influence de la salinité, de la profondeur et du degré de confinement. L'ACP des données relatives à la longueur antéro-postérieure, à la largeur et à l'épaisseur et, portant sur un effectif total de 652 individus de *L.caprearum*,

montre deux nuages de points (Fig. 2).

Fig. 2. Représentation graphique des différents échantillons de *Lepidochitona caprearum* sur les deux premiers axes de l'ACP des paramètres métriques

Le premier super groupe met en évidence une forte agrégation entre les différents spécimens des aires 1, 2, 3 et 6. Le nuage de points de la 5^e aire est indépendant de ces échantillons. La largeur et l'épaisseur sont les variables les plus discriminantes dans la séparation de ces deux groupes. L'aire 5 est caractérisée par une charge trophique supplémentaire liée à la présence de pêcheries d'anguilles. Baxter et Jones [4] ont souligné le rôle de la charge trophique, en particulier sur les Polyplacophores. D'autres facteurs physico-chimiques peuvent expliquer par ailleurs les variations observées et confirment cette influence déjà bien mise en évidence par Boolootain [5]. Les individus présentent en effet une croissance optimale dans l'aire 5.

Conclusion

L'étude des Polyplacophores dans le lac Nord a mis en évidence les limites de tolérance de ces espèces vis-à-vis des conditions abiotiques ainsi que l'influence des facteurs trophiques dans la croissance morphométrique de *L. caprearum* de l'aire 5.

JUVENILE FEEDING HABITS OF MUGILIDAE SPECIES FROM ESTUARINE SYSTEMS IN NORTH AEGEAN

SEA

Ioanna Salvarina¹, Manos Koutrakis¹* and Ioannis Leonardos² ¹ NAGREF - Fisheries Research Institute - manosk@inale.gr ² Biological Applications & Technology Dep., Univ. of Ioannina, 45110 Greece

Abstract

The feeding preferences of 823 juvenile fishes belonging to five species of the Mugilidae family from Strymonikos Gulf estuarine systems were analyzed. A similar feeding strategy pattern was found for all species, except *M. cephalus*, which had one dominant food category.

Keywords: Diet, Estuaries, Fishes

Strymonikos Gulf is one of the richest fishing grounds in North Aegean Sea. The fish biodiversity observed in Strymonikos estuaries is among the highest recorded in the Mediterranean Sea [1]. Many studies have been conducted concerning fish fauna [1] and other aspects of the area [e.g. 2]. This is the first study of feeding habits of Mugilidae species in the Greek area.

Materials & Methods

Samplings were carried out, using a bag seine net (12 m length, 3 mm bar mesh size), on a monthly basis from September 1997 to May 1999, in two sampling stations in each estuarine system of Strymonikos Gulf (Rihios and Strymon). Stomach content was analyzed using the percentage volumetric composition and the percentage of frequency of occurrence of each food category [3]. The vacuity index was also estimated for each species as VI% = (number of empty stomachs) / (total number of stomachs examined) *100. To determine the feeding strategy of the species the modified Costello graphical method [4] was used. Analysis of covariance (ANCOVA) was performed to compare the volume of gut content among sampling sites and seasons.

Results & Discussion

A total of 823 specimens (Total Length: 14–130 mm) belonging to species *Chelon labrosus, Liza aurata, L. ramada, L. saliens* and *Mugil cephalus* were examined for their diet composition. The total vacuity index was 28.19%. *L. aurata* had the lowest vacuity index (18.15%) and *M. cephalus* the greatest (41.21%). The main food categories that were found in volume contribution of individual species diet included: phytoplankton (33%), amphipods (26%) and detritus (19%) for *C. labrosus*, mysids (40%), copepods (17%) and amphipods (16%) for *L. aurata*, phytoplankton (28%) and aquatic vegetation (20%) for *L. ramada*, phytoplankton (39%) and amphipods (31%) for *L.saliens* and phytoplankton (88%) for *M. cephalus*. A similar feeding strategy pattern, with varying degree of specialization, was followed by all species, except *M. cephalus*, which had one dominant food category (phytoplankton) (Fig. 1).

Fig. 1. Relationship among prey specific abundance (Pi%) and frequency of occurrence (FO) of food categories of Mugilidae species. Plots based on the modified Costello method [4]. (amp: amphipoda, cop: copepods, mys: mysids, anim: other animals, ins: unidentified insects, clad: cladocerans, det: detritus, chir: chironomids, phyt: phytoplankton, veg: aquatic vegetation, pol: polychaets, worm: other worms, dec: decapods, chaob: chaobors, cir: cirripedia).

RUN-UP ALONG EMBAYED BEACHES DURING STORMS (BARCELONA, NW MEDITERRANEAN)

Amanda Sancho garcía 1* and Jorge Guillén 1

¹ INSTITUTO DE CIENCIAS DEL MAR (CSIC) - asancho@icm.csic.es

Abstract

In this study, we analyze the displacement of the waterline associated to the run-up produced during storms at three beaches of Barcelona city. Video images measurements of the run-up were carried out during the most energetic storms between 2001 and 2008. Wave run-up observations are then compared with a run-up related parameter, which takes into account wave characteristics and beach foreshore slope, in order to obtain an equation that can be used to predict the run-up along these beaches. Keywords: Beach, Shoreline Evolution

A significant portion of the population lives in coastal areas that are exposed to different hazards such as flooding and coastal erosion. Flooding at the emerged beach during storm conditions is very common in Mediterranean coasts. In Barcelona beaches (NW Mediterranean) these events produce important damages in the coastal structures (i.e. promenade, showers, etc). In this study, three Barcelona beaches have been studied: La Barceloneta, Somorrostro and Nova Icaria (Fig. 1). These are artificial embayed beaches with steep slopes, and are protected with coastal structures. In order to quantify the run-up, the effect of the most energetic storms on theses beaches was evaluated from 2001 to 2008. In total, fifteen storm events were analyzed, all with Hs higher than 3 m during the peak of the storm.

Fig. 1. Localization of Somorrostro, La Barcelona and Nova Icaria beaches(NW Mediterranean)

For each storm event, the hourly waterline position of each beach was obtained from the 10-minute time exposure images by means of an Argus video system [1]. The video system is located atop a building close to the Olympic Marina at a height of around 142 m, and it is composed of five cameras pointing at the beaches and offering a 180° view of the coast (images available at: http://elb.cmima.csic.es). A reference waterline was defined for each beach and storm as the result of the averaged position from all available waterlines of each storm event. The horizontal component of the run-up was obtained using lines perpendicular to this reference waterline. The results show values of the maximum about 50 m in emerged beach area of La Barceloneta (Fig. 2), 30 m in Somorrostro and 40 m in Nova Icaria are flooded during storms. However flooding is not homogeneous along the beach.

In order to obtain a predictive tool for the run-up in Barcelona beaches, the observed displacement of the waterline at each profile along the beach during the storm (D), was related with a runup-related parameter (F), which includes wave characteristics (significant wave height, Hs, and wave length, Lo), mean sea level (MSL) and beach foreshore slope $(tan\beta)$ and represents the horizontal $F = \sqrt{H_s L_o} + \frac{MSL}{\tan\beta}$

component of the run-up as:

In general, a significant correlation was found between both parameters. The fit is better in Somorrostro (best fit, $R^2 = 0.50$), than in La Barceloneta (best fit, R^2 = 0.40) and Nova Icaria (best fit, $R^2 = 0.27$).

Fig. 2. Picture of La Barceloneta beach on 25th December 2008. The line shows the waterline position at the peak of the storm (27/12/2008). Coordinates are given in metres measured from a local zero

In conclusion, video-monitoring provides detailed information of run-up during storm events. This data can be used to improve the predictive character of the general run-up equations and give useful information for coastal management.

MEDITERRANEAN MARINE AND COASTAL ECOSYSTEMS: AN ECONOMIC VALUATION

Didier Sauzade ²*, Anaï Mangos ² and Jean-pascal Bassino ¹ ¹ University Montpellier III

² Plan Bleu - dsauzade@planbleu.org

Abstract

This study proposes a first exploration at the scale of the 22 Mediterranean countries of the economic value of sustainable benefits to society provided yearly by marine and coastal ecosystems. The methodology is adapted from the System for Environmental and Economic Accounting of the United Nations. Using available data at national and regional level, total benefits for all the riparian countries are estimated at 29.4 billion € i.e. 15% of Greek Gross National Income (GNI), or 130 % of Tunisian GNI. Keywords: Coastal Management, Economic valuation, Ecosystem services, Eastern Mediterranean, Western Mediterranean

Blue Plan (UNEP/MAP), whose mission is to inform stakeholders for sustainable development in the 22 Mediterranean countries, has been entrusted to assess the economic value of benefits provided by Mediterranean marine and coastal ecosystems. The objectives are to enhance awareness of these benefits to society and offer policy makers a common metric for better management [1].

Materiel and methods

Benefits provided by ecosystems to people are obtained from ecological services (Tab. 1), following a widely accepted classification. The economic valuation method used is adapted from SEEA [3] and is restricted to sustainable and direct benefits (e.g. fishing excluding over fishing and seafood processing). Estimation of benefits is based on computable substitutes, or proxy values (see Tab. 2) computed for the reference year 2005 using available ecosystem characteristics and national or regional level data extracted from various public databases (Fishstat, Labor-stat, UNdata, AQUASTAT, Eurostat...) such as fish catches, value added (VA), labor force... Various value transfer methods had been used when necessary. All calculations are available.

Tab.	1.	List	of the	e estimated	benefits,	adapted	from	[2]
------	----	------	--------	-------------	-----------	---------	------	-----

Category	Ecological services	Estimated benefits	
Production	Food production	Resource rent of fisheries & aquaculture	
services	Raw materials	Resource rent of marine sand extraction	
		Global climate regulation (value of CO ₂ sequestration)	
Regulation services	Gas & climate regulation	Regional climate regulation (value of rainfall d to sea evaporation)	
	Disturbance prevention	Coastal protection due to Posidonia meadows	
	Bioremediation of waste	Storage, burial & recycling of waste water	
	Leisure and recreation	Resource rent of tourism, hotels & restaurants and real estate in coastal areas	
Cultural services	Cognitive benefits Cultural heritage & identity Future unknown & speculative benefits	Not counted	
Support services	Various supports to other ecological services	Not counted to avoid double counting	

In short, the resource rent of fisheries and aquaculture was estimated on the sector VA, overfishing and other non sustainable practices being expressed by an overall coefficient valued to 80% derived from [4]. Resource rent for tourism, hotels, restaurants and real estate was evaluated at 5% of their VA in coastal areas through a multiple regression analysis of the coastal attractive effect computed on NUTS-3 Eurostat data. Erosion protection was appraised on the basis of the avoided coastal protection expenditures for approximately 1000 km of coast length, this figure being derived from available data on coastal erosion, protections in place, and presence of Posidonia meadows. Global climate regulation was estimated from recent data on the amount of anthropogenic CO2 sequestrated by the Mediterranean sea [5] and the average value of the carbon market. Value of the rainfall water evaporated from the Mediterranean Sea was estimated on the basis of quantities derived from [6], [7] and a shadow price for the agricultural water in Morocco given by [8]. Sustainability constraint was specially constraining for the estimation of the waste treatment, the benefit of which was valued considering the consumption of domestic water and the amount of a pollution compensation fee deducted in a real French situation considered as sustainable.

Results

Main results are summarized in table 2, giving a total amount of 29,4 billion €

i.e. 15% of Greek GNI or 130% of Tunisian GNI. A focus has been made on two countries, Greece and Tunisia, giving respectively 3,2 and 0,6 billion €or 2% and 3% of their GNI.

Discussion and conclusion

Results of this exploratory study show that the restriction to sustainable uses of ecosystem services leads to underestimation of benefits. Full application of the SEEA framework to marine and coastal ecosystems would require an extensive data base not presently available. Future extension of the work may concern coverage to additional sectors such as marine transportation or sand extraction. Benefits provided by remarkable ecosystems like Posidonia meadows could be also investigated, beyond the coastal protection service.

Tab. 2.	Estimated values of the benef	its provided by Mediterranear	n marine and
coastal	ecosystems		

Benefits	Proxy values	Values (M€)	
Fisheries and aquaculture	VA x Sustainability coefficient (=0.8)	2 869	
Hotels and restaurants	5% VA in coastal areas	4 1 3 3	
International tourism	5% VA in coastal areas	3 804	
Real estate in coastal areas	5% housing expenditure	11 198	
Erosion protection	Coastal protection expenditures avoided	530	
Global climate regulation	Sequestrated anthropogenic CO ₂ by value of CO ₂ ton	2 220	
Regional climate regulation	Rainfall agricultural water by water shadow price	2 490	
Waste treatment	Domestic water by pollution compensation fee	2 570	
Total benefits (year 2005) :	•	29 814

Abstract

In the frame of Italia-Malta community initiative program (the 'MonItaMal' project), the active mussel watch was used to evaluate the chemical contamination of Malta, Lampedusa and Linosa coastal waters. This study was carried out during 2006-2007 together with analysis of sediments. The concentration of heavy metals, TBT, PHs, DDTs, PCBs, and pesticides was assessed, providing a snapshot of the contamination levels in the Sicily channel.

Keywords: Bivalves, Chemical Analysis, Monitoring

Introduction

The mussel watch methodology is a widely used technique to monitor the levels of a large array of contaminants and biochemical parameters in marine coastal waters [1]. It is based on the ability of the mussels to concentrate chemical contaminants in their tissues in relation to their presence in the environment. Monitoring the quality of the coastal marine environment is an action recommended by the European Union, together with the preservation of habitats and their biodiversity. Malta and Lampedusa belong to different countries, but these two islands are located in the same geographical sector, the Sicily channel, and the adoption of common methodologies for environmental control is strongly advised by the UE.

Materials and methods

During 2006-2007, according with a standardized mussel watch protocol, a total of 43 mussel cages were deployed in 11 locations subjected to a different anthropogenic impact. In Malta, the mussel locations were in proximity of the marine protected area of Gnejna, close to sewage outfalls of Cumnija and Xghajra; in Lampedusa, locations were in proximity of the main harbor and within the protected area (A zone); in Linosa, an island characterized by a minimum anthropogenic pressure, 2 locations were considered (Fig.1).

Sediments and water samples were analyzed in order to fully characterize the study areas. Analyses of PAHs (16 EPA), PCBs (10 congeners), OC pesticides (pp'-DDT and its metabolites, HCHs, HCB, Aldrin, Dieldrin), heavy metals (Hg, Cd, Pb, Cu, Zn), TBT on mussel and sediment were realized by means of standardized laboratory methods.

Results and Discussion

Mussel cages recovery was of 70%. Results of heavy metals analysis were generally comparable between the three island, with no significant differences between Lampedusa Malta and Linosa. However, high levels of contaminants were found in correspondence of Xghajra (Malta), were metals, especially Hg, Pb e CU, had higher concentrations (up to ten times higher) with respect to background levels [1].

Mean TBT levels resulted of 2.53ng Sn/g w.w. In Malta, 0.43ng Sn/g w.w. at Lampedusa whilst in Linosa these compounds were not detected. Their degradation products (DBT e MBT) resulted to be significantly higher in Malta than in Lampedusa and Linosa.

PCB and pesticide contamination appeared to be low in both islands with levels comparable to the ones of Linosa. The maximum concentration of PCBs was of 30 ng/g d.w..

As for DDTs, the metabolites DDD and DDE were the main components. On the whole, the mean DDTs levels of Malta and Lampedusa (the maximum value was of 13-14 ng/g d.w. on both islands) confirmed those obtained from other mussel watch projects that used the same methodology in the same study area [1]. Nevertheless in correspondence of Xghajra, concentrations of 8 ng/g d.w. were detected. Similar levels of DDTs are known for highly polluted areas such as Naples, Barcelona and Marseille (Scarpato, unpublished data). Sediment analyses confirmed the mussel watch results, with the area of Xghajra presenting the highest values for metals (especially Hg and Cu), TBT and related degradation products (DBT and MBT).

Abstract

Arborescent benthic species, both algal and animal, define the architecture and functional ecology of certain "forest" structures. Such ecosystem engineers (foundation) species are declining throughout the world due to anthropic activities and/or global warming, leading to introductions and outbreaks of pests and pathogens. The case study of *Paramuricea clavata* here reported shows how the loss of the biggest foundation species of coralligenous assemblages may compromise the accretion processes of coralligenous reducing the presence of some calcifying species such as coralline algae and bryozoans. *Keywords: Biodiversity, Global Change, Mortality*

Introduction

During recent years climate warming and thermal anomalies are negatively affecting the survivor of marine benthic species, resulting in diseases and pathogens spreading, whose effects, always sudden and dramatic, lead to reductions in biomass of several filter feeders, sponges and gorgonians ([1], [2]). Considering gorgonians as engineering species able to shape the architecture and increase the complexity or influence the biogeochemistry of habitats, it is evident that a decrease in the population negatively affects habitat heterogeneity and biodiversity [3]. Here we investigate the effects of the loss of *P. clavata* colonies on coralline algae and bryozoans.

Method

Six plastic panels $15x10 \text{ cm}^2$ size were positioned inside and outside a gorgonian forest on the Portofino Promontory cliff (Ligurian Sea, Italy) to evidence possible effects of sea fans on the dynamics of colonization of a substratum. After the collection of the panels, four months after positioning (from May to September 2009), they were dry preserved and analysed at the stereomicroscope by a grid with a mesh of 1 cm^2 . Data were arc-sin transformed and analysed with Cochran's Test, ANOVA and SNK Test.

Results

Regarding coralline algae, four different morphotypes of newly settled Corallina *species* and three of *Peyssonelia* have been separated (Fig.1). Algae showed different frequencies in panels inside and outside gorgonians populations (20.3 \pm 2.8 and 18.2 \pm 2.4 inside and outside respectively) (ANOVA, P=0.0041) and the unique morphotype that presented differences in frequencies between inside and outside is the one we call *Corallina* sp. 2 (SNK, P<0.01), more abundant inside (15.1 \pm 5.3 and 1.6 \pm 0.9 respectivaly), while the other species showed similar frequencies. Regarding Bryozoa, inside gorgonian forest seven species of Bryozoa have been found, three of them exclusively inside (Fig.2). The Shannon diversity index underlines a major diversity in species inside the gorgonian forests (2.9 \pm 0.1 and 2.7 \pm 0.04 inside and outside respectively) (One-way ANOVA, P=0.02).

Fig. 1. Different *Corallina* and *Peyssonelia* unidentified species inside and outside the gorgonian forest

Fig. 2. Different species of bryozoans observed inside and outside of the Gorgonian forest

Discussion

The loss of foundation species changes the local abiotic and biotic environment on which a variety of other species depend [3]. One of the most dramatic example in the Mediterranean Sea is the rapid loss of sponge gardens and gorgonian forests [1]. The decrease of *P. clavata* colonies from coralligenous accretions will lead to a shift from a dim-light environment (optimal for some Corallinales) to a light exposed one. The negative effect we noticed towards some bryozoans may be also due to the reduction of a sort of physical protection played by sea-fans on rigid colonies. The studied area host high touristic fluxes of scuba divers, whose activities can have an impact on some sessile species.

These dynamics are rapidly changing shallow (0-40 m) coastal habitats seascapes, with unpredictable effects on marine trophic webs.

Abstract

Nous avons réalisé des prospections durant la période s'étendant de mois de juillet à novembre 2009 au niveau de la lagune de Bizerte visant les crabes présents. Ainsi, ces compagnes ont révélé la présence d'*Eucrate crenata* et son installation définitive dans cette lagune. Ces mêmes prospections révèle la présence des espèces *Parthenope angulifrons* et *Xantho poressa*, au coté la persistance des quatre autres espèces classiques de ce milieu à savoir; *Carcinus aestuarii, Pilumnus hirtellus, Maja squinado* et *Ilia nucleus*. Enfin, on signale la présence du crabe de roche *Pachygrapsus marmoratus* au niveau du canal de Bizerte et de son goulet, sa présence lagunaire reste très probable.

Keywords: Decapoda, Crustacea, Lagoons, Zoobenthos, Gulf Of Gabes

Introduction

La lagune de Bizerte est directement reliée à la mer méditerranéenne via le canal de Bizerte, ce qui lui doit ses caractéristiques biotiques et abiotiques plus proche du milieu marin que le milieu lacustre ; Elle est constamment soumise aux différents flux hydro-biologiques. Ainsi, ce milieu connaît depuis longtemps des flux d'échanges d'espèces animales et végétales, qui sont accélérés par les bouleversements hydrologiques (mise en place de plusieurs ouvres et barrages sur les affluents de la lagune) et surtout par le trafic maritime caractérisant le canal de Bizerte, son port commercial ainsi que la lagune où séjourne à longueur de l'année les navires de toutes les provenances attendant leur tour pour des travaux de carénage et de réparation, au niveau de la rive Sud-Ouest de la lagune.

Matériel et méthode

Au cours de cette étude, nous avons pu capturé les différentes espèces de crabes, au moyen de filets trémails conventionnelles, dont les mailles sont de 26mm/80mm/26mm. Les filets ont été mises à l'eau pendant 24h00, avant de les tirer à bord de l'embarcation et de repêchés les différentes espèces de crabes. Ainsi, nous avons réalisé des points de pêche de façon à couvrir le maximum de la superficie de la lagune et durant la période s'étendant de juillet à novembre 2009. Enfin, nous avons été aidés par les témoignages des pêcheurs locaux, en ce qui concerne 'existence l et l'apparition des espèces de décapodes recensées. Résultats des prospections Cette investigation ciblant la communauté de crabes dans la lagune de Bizerte nous a permis de confirmer la présence des espèces suivantes; Carcinus aestuarii (Nardo, 1847); C'est l'une des espèces littorale et sublittorale de crabes les plus caractéristiques de la méditerranée et en particulier les lagunes saumâtres tel la lagune de Bizerte. L'abondance de ce crabe dans les eaux littorales peu profondes peut être considérée comme indicatrice de pollution [3]. Ainsi, cette espèce se révèle la plus abondante au niveau de la lagune de Bizerte, ce qui confirme l'état de anthropisation et d'eutrophisation de ce milieu, en particulier au niveau de zones de balancement des marées et les zones à forte urbanisation. Pilumnus hirtellus (Linnaeus, 1761); Cette espèce remarquable par sa pilosité été capturée dans nos filets, mais en très faible nombre. En effet, c'est le crabe le plus commun de tout le littoral Tunisien (Com.per, 2009). Son caractère de refuge sous les pierres et entre les algues [3], explique peut être sa timide apparition et sa faible abondance.

Eucrate crenata (De Haan, 1835); Ce crabe de mer Rouge est présent dans les eaux tunisiennes depuis près d'une quinzaine d'années. Observé en premier dans le golfe de Gab ès (Zaouali, 1992), il est aujourd'hui, présent sur l'ensemble des côtes tunisiennes. Sa présence et son abondance mettent bien en évidence l'influence du réchauffement climatique global sur les eaux côtières de cette partie sud de la Méditerranée [1]. Après l'avoir observé au niveau de la lagune de Tunis, le voila aujourd'hui présent au plus au nord des côtes tunisiennes, au niveau de la lagune de Bizerte. Cependant, et après une vérification de nos données sur les décapodes de la lagune de Bizerte, nous pouvant dire que cette espèce est présente dans la lagune de Bizerte, au moins depuis 2005 (Com.pers, 2009). Ainsi, son ré-observation en 2009 et (en Avril 2010) confirme son installation définitive dans la lagune de Bizerte et la persistance des conditions abiotique et biotiques au niveau de ce milieu lagunaire favorablesà son existence.

Xantho poressa (Olivii, 1792); Cette espèce de roche est très souvent confondue avec sa cousine *Xantho incisus* (Leach, 1814), espèce atlantique présente en méditerranée [3], recensée déjà en Tunisie, au niveau du golfe de Gabès (d'après Zaouali, anonyme).

Cependant, et d'après les témoignages des pêcheurs locaux, cette espèce ne leur pas habituelle et malgré que ses effectifs demeurent très inférieurs à ceux de Carcinus aestuarii ou d'Ilia nucleus, elle se manifeste régulièrement dans leurs filets.

Parthenope angulifrons (Latreille, 1825); Cette espèce méditerranéenne [3] n'a pas été mentionnée précédemment au niveau de la lagune de Bizerte (Com.pers, 2009). Ainsi, et d'après les témoignages des pêcheurs recueillis, les effectifs de cette espèce seraient considérables, si on se réfère à la manifestation de cette espèce dans leurs filets. D'autre part, l'année 2008 serait marquée par l'observation de cette espèce de crabe dans la lagune. Actuellement, il serait toujours présent, mais avec des abondances nettement moins inférieures qu'en 2008.

Ilia nucleus (Linnaeus, 1758); Ce petit crabe, à la forme de noix et aux pattes longues et fragiles, est connu dans la lagune de Bizerte de depuis une dizaine d'années. Cependant et d'après le témoignage des pêcheurs et des observations personnelles, ces effectifs ont pris de l'importance depuis le début des années 90e. Ainsi, on peut considéré que cette espèce de crabe, vient dans la deuxième position après *Carcinus aestuarii*, en terme d'abondance. Cependant, cette espèce se trouve à des profondeurs plus importantes (généralement au delà de 5-6m) que celles caractérisent le crabe vert.

Maja squinado (Herbst, 1788); Cette espèce est l'une des espèces caractéristiques de la lagune de Bizerte et sa présence date depuis longtemps, malgré ces effectifs limités par rapports aux autres espèces ; En effet, l'espèce *Maja squinado* a une ex igence via à vis de son milieu puisqu'elle se trouve préférentiellement au niveau des substrats rocheux et difficiles d'accès, avec un net comportement de camouflage (couverture d'algues) [3], à la différence des autres espèces moins exigeants vis -à-vis du substrats et se trouvant dans la majorité des biotopes qu'offre cette lagune. La possibilité de présence de *Maja crispata* (Risso,1827) n 'est pas exclue (Com.pers, 2009).

Pachygrapsus marmoratus (Fabricius, 1787); Cette espèce a été péchée au niveau du canal de Bizerte, ainsi que le goule t qui connecte le canal à la lagune. Cependant, et malgré qu'aucun spécimen n'a été pêché au niveau de la lagune, sa présence lagunaire reste très possible. En effet, ce crabe de roche de la famille des Grapdidae se caractérise es par manifestations s nocturnes et son absence pendant le jour. Ainsi, quelques pêcheurs visant ce crabe l'appâtent et l'attirent durant la nuit moyennant une source de lumière (torche, lampe à pétrole, etc...). D'autre part, le confinement de cette espèce dans les zones rocheuses explique peut être son absence durant nos compagnes de prospection.

HYDROCHEMICAL SPECIFICS OF THE KAMCHIA RIVER MOUTH AND THE ADJACENT BLACK SEA COASTAL AREA

Galina Shtereva^{1*}, Anton Krastev¹, Boryana Dzhurova¹ and Ognyana Hristova¹ ¹ Institute of Oceanology - BAS, Varna, Bulgaria - g.shtereva@io-bas.bg

Abstract

The aim of the study is assessment of water quality (WQ) of the biggest Black Sea River (Kamchia River) and coastal waters on the base of chemical parameters. The results reveal that the nutrients content in river and mixing zone do not correspond to the Bulgarian WQ Standards. The transformed river waters are characterized with high nutrients concentrations and low salinity, pH and transparency.

Keywords: Black Sea, River Input, Nutrients, Metals, Oxygen

According to conceptual framework DPSIR (Driving forces –Pressure –State – Impact -Response) the main drivers (industry, agriculture and urbanization) in Kamchia River region (catchment and coastal zone) cause a significant pressure on the aquatic systems. The river collects urban effluents of many settlements in the catchment area, including untreated sewage discharges. The state of the river environment under long-term pressure/impact was already presented [1, 2]. The aim of the study is assessment of water quality of Kamchia River and coastal waters on the base of chemical parameters.

The study is based on monthly monitoring in Kamchia River during the 2006-2007 period of following parameters: pH, dissolved oxygen (DO), biochemical oxygen demand (BOD₅), nutrients as dissolved phosphorus (P), nitrogen (N), silica (Si) and metals. The investigation of water column in the coastal zone in front of the river mouth was carried out on the same parameters including salinity, transparency and metals in addition during the high flow period.

Long-term data of NIMH reveals monthly river discharge variability from 10.5 % to 17 % of annual discharge during the high flow period from January to May. In contrast to the historical data the recent period is characterized with similar mean monthly values of water quantity of discharge. An increase of the river discharge in autumn was established in relation to increased precipitation totals in Kamchia watershed. Average nutrients concentrations in the river for the investigated period are presented in Fig. 1.

Fig. 1. Average nutrients concentrations in Kamchia River

The interannual distribution of hydrochemical parameters is characterized with maximums of nutrients content in Autumn-Winter period corresponding to high values of precipitations and high value of water quantity of the river discharge. Sometimes our results reveal "poor" and "bad" status relative to National classification system for WQ. It means that there is a distinct pollution by nitrogen compounds largely due to agricultural activities and runoff from soil pollution. Deviation from normal distribution of nutrients content during some periods was established in consequence of anthropogenic pressure domination along the river stream. The factors, which influenced the nutrients content in the river at the downstream locality, is more numerous and complex. The results for the river WQ show that the nutrient content exceeds the permissible concentration (PC) maximum determined by the Bulgarian WQ Standards.

The river discharge directly influences the coastal waters near the mouth [3, 4]. Dissolved oxygen (saturation) is very important quality parameter indicating "health" of water environment. The data for coastal zone influenced by the river discharge reveal decrease of DO and OS, especially in bottom layer. The mixing zone of coastal area is characterized by salinity<7.9‰, pH<8.22 and very low transparency (Table 1).

Tab. 1	1. R	Range	of c	chemical	paramete	ers in	coastal	area	in	front	of	Kamchia	River
mouth	1 I												

Parameters	Mixing zone	Sea
Transparency, m	0.5-1.0	2.0-3.0
Salinity, ‰	0.9-7.9	10.4–14.3
рН	7.89-8.22	8.35-8.41
Dissolved oxygen (DO),µM/I	246-283	306-323
Oxygen saturation (OS), %	84.2-102.7	109.6-117.8
BOD ₅	2.04-3.31	2.50-2.88
Nitite N, µM/I	2.2-5.7	0.6-1.2

Ca ²⁺ , mg/l	84.7-144.6	204-219
Mg ²⁺ , mg/l	33.4-208.7	340-510
Fe, µg/l	190-413	43-92

Nutrients distribution in mixing zone reveals high nitrates and nitrites content exceeding PC [5]. The average concentration of DIN for all sampled area is $64.2 \,\mu$ M/l with maximum reached in coastal waters -165 μ M/l. Relatively higher content of metals Fe and Mn are found in samples collected in and near river mouth. Heavy metals concentrations in waters of coastal zone correspond to WQ standards according Regulation 8 [5].

The sediments with dominated coarse-grained fraction are characterized with low organic carbon content and low concentrations of metals. They are located near the river mouth, where the sedimentation is more active due to the sudden changes in hydrological conditions. The concentrations of metals in surface sediments are characterized by the following order of spreading: Fe>Mn>Zn>Pb,Cu>Ni>Cd.

The Kamchia River discharge impacts the coastal zone in an area located less 1 mile eastward and southward from the river mouth. Most significant influence is found in the upper surface layer which is characterized by higher nutrients and particulate material content and lower transparency, pH and salinity.

EFFECTS OF THE RECENT CLIMATE CHANGES TO THE WATER BUDGET OF A SEMI-ENCLOSED GULF IN EASTERN MEDITERRANEAN

Alexandra Spyropoulou¹ and George Tsirtsis²*

¹ Dept. of Marine Sciences, Univ. of the Aegean, Greece, spyropoulou@marine.aegean.gr

² Dept. of Marine Sciences, Univ. of the Aegean, Greece - gtsir@aegean.gr

Abstract

An analysis of available rainfall data for the period 1955-2008 was performed to assess changes in rainfall frequency and intensity in an Aegean island, Eastern Mediterranean. A statistically significant decrease was observed for the annual rainfall height and the number of wet days, whereas no trend was observed for the occurrence of extreme events. The effects of the changes in precipitation for the functioning of a semi-enclosed gulf were then assessed using a watershed model and a water budget analysis. *Keywords: Aegean Sea, Coastal Systems, Global Change, Eastern Mediterranean*

The recent climate changes probably constitute the main environmental concern facing mankind in the twenty first century [1]. The effects of changes in precipitation on the functioning of coastal systems, are probably more pronounced for small Eastern Mediterranean watersheds and the receiving water bodies that undergo rapid hydrological cycles characterized by a rather short rainfall period during winter and a dry summer.

In the present work, a time series of rainfall data (provided by the Hellenic National Meteorological Service, HNMS) were analyzed covering the period from 1955 to 2008 for the island of Lesvos, in the North-eastern Aegean and a large number of climatological indices was calculated [2] to assess local trends in precipitation. The effects of possible changes on the functioning of the Gulf of Kalloni, a semi-enclosed shallow water body surrounded by a watershed of about 413 Km² [3], were then analyzed using a watershed model and applying water budget analysis.

A statistically significant decrease (R^2 =0.1022, p=0.018) was observed for annual rainfall height (Figure 1) and the number of wet days (R^2 =0.1384, p=0.006) from 1955 to 2008, whereas the frequency and intensity of extreme events has shown no trend. Overall a significant trend towards dry conditions was sought for the study site, especially during the winter period.

Fig. 1. Trend of annual rainfall height from 1955 to 2008.

Typical years of wet (year 1961) and dry (year 2005) conditions were used as an input to a watershed model calculating the amount of runoff on a daily basis [4]. The model output and available data were then used to analyse the water budget of the receiving reservoir. A threefold decrease in the amount of runoff was predicted by the model (Figure 2) influencing remarkably the water budget of the gulf, although it is still functions as a dilution (during winter) and concentration (during summer) basin. However the excess of the sum of precipitation and river input over evaporation during winter has almost halved during the last decade since the decade of 1960, resulting to a remarkable decrease in the water renewal time in winter being 86 days for 1961 and 50 days for 2005.

Fig. 2. Annual runoff for a typical wet (1961) and a dry (2005) year.

In conclusion a trend towards dry conditions is observed in the islands of Northern Aegean in Eastern Mediterranean affecting the water budgets of both the river basins and the receiving water bodies. These changes need to be always taken into account by policy makers in the framework of integrated coastal zone management.

THE EFFECTS OF A WASTEWATER TREATMENT PLANT ON NUTRIENT AND CHLOROPHYLL A VARIATIONS IN IZMIR BAY (EASTERN AEGEAN SEA)

Fatma Sanem Sunlu¹*, Ugur Sunlu¹, Baha Buyukisik¹ and Serkan Kukrer¹

¹ Ege University Faculty of Fisheries Dept. of Hydrobiology - f.sanem.sunlu@ege.edu.tr

Abstract

The aim of this study was to determine the effects of the Izmir Big Channel Waste Water treatment plant oninorganic nutrients, physico-chemical parameters, (such as pH, dissolved oxygen, water temperature, salinity) and chlorophyll a levels of Izmir Bay. The variation of inorganic nutrients and chlorophyll a were investigated weekly during one year (2003-2004) in Izmir Bay. *Keywords: Aegean Sea, Nutrients, Chlorophyll-a, Coastal Waters, Pollution*

Introduction

The Bay of Izmir is located in the Western part of Turkey and surrounded by a densely populated community (Fig. 1). The Bay is divided into inner, middle and outer bays from the standpoint of topographical and hydrographical characteristics. The inner bay is considerably small in area (57 km2) and shallow in depth (max. 15 m). It received the majority of domestic and industrial wastewaters before the construction of wastewater treatment plants. This part of the bay still receives some inflow of freshwater from several creeks which are mostly polluted by industrial wastewaters. Because of limited water exchange with the outer bay and the Aegean Sea, pollution of the inner bay reached unacceptable levels. For this reason, the Izmir Municipality decided to construct the Izmir Big Channel Wastewater Project in 1969. Unfortunately, the construction of the plant could not be completed until the end of 2002. At the end of the plant construction in 2002, the pollutant levels of the inner bay water decreased gradually and the recovery period began. The aim of this study is to determine the effects of Izmir Big Channel Waste Water treatment Plant to the inorganic nutrients and chlorophyll a levels of Izmir Bay.

Fig. 1. Locations of the stations

Materials AND Methods

In this study, three stations were chosen for sampling, two in the inner and one in the middle part of the Izmir Bay (Figure 1). Physico-chemical parameters, nutrients, and some biological parameters were measured weekly during a one-year period. The samples, collected from three different stations and water depths, and nutrients were analyzed by standard methods ([1], [2], [3]). Chlorophyll a analyses, were carried using a UVD spectrophotometer (Bosch-Lomb Spectronic 21) following the method by [1]. Seawater temperature was recorded by an electronic thermometer with a sensitivity of ± 0.1 °C. The pH of the samples was also measured on-site using a pH-meter (Hanna Ins.). The dissolved oxygen (DO) was measured with a DO-meter (YSI, Model 55). The salinity of seawater was determined by the Harvey method.

Results and Discussion

The minimum, maximum and average values of the physico-chemical parameters belonging to the water samples from Izmir Bay are given in Table 1.The fact that the processes affecting Reactive Phosphate (RP) and TIN occur at different times indicates important differentiations in the temporal distribution of these two nutrients in the Inner Bay. From the distribution of the nutrients and their percentages, important evidence regarding the process have been gathered: a) Inflow with the creeks is especially evident during rainfall and there is a big increase in Si, Nitrogen forms; and b) the winds, although increasing fresh water inflow and water columns, frequently carry the ground water to the surface. This shows that the Inner Bay is often subject to a ground-water-based nutrient enrichment. c) The phytoplankton blooms caused by the inflow of nutrients to the Inner Bay in turn result in the uptake of nutrients by the phytoplankton (especially diatoms) which are then exported to the bottom waters and constitute the source for future phytoplankton blooms.

Thus, the horizontal export of the nutrients out of the Inner Bay remains limited. It is only due to the winds that the wastewaters flow outwards from time to time. Silicate, coming with the rainfall from the shore in non-point sources (i.e. creek, river) and point sources, is of great importance for the Inner Bay. Silicate is essential for the diatoms to compete effectively with dinoflagellates and it plays an important role in the increase in species diversity in the bay. We believe that unless the nutrient levels in the rivers are decreased, the Bay will continue its current state for a long time. Although a decrease in nitrogen has been observed after the start of the wastewater treatment plant, former studies showed that phosphate concentrations have not changed and that the plant has been ineffective regarding this subject.([4], [5],[6],[7]). The effective removal of phosphate will be an important precaution against the new strategy that the phytoplankton might take up against the decreasing TIN. A study of the N/P relations shows that for the biggest part of the year the ratio is below 16 and that nitrogen is the limiting nutrient. As a result, with the start of the wastewater treatment plant a decrease in the nitrogen and chlorophyll-a levels has been found, however there is no such evidence regarding the phosphate levels.

A PRELIMINARY STUDY ON MARINE LITTER IN THE AEGEAN SEA

Eda N. Topcu¹*, Arda M. Tonay¹ and Bayram Öztürk¹

¹ Istanbul University Fisheries Faculty Ordu cad. No 200 Laleli-Istanbul, Turkey / Turkish Marine Research Foundation (TUDAV) P.O.Box: 10 Beykoz-Istanbul, Turkey - edatopcu@istanbul.edu.tr

Abstract

Solid Marine Wastes present on the seabed and floating on the sea surface were investigated in the Aegean Sea. Compared to other locations in the Mediterranean, litter concentration on Northern to Mid Aegean Seabed is moderate even in populated gulfs, whereas floating marine debris concentrations are low and dominated by recreational items, probably restricted to summer season. *Keywords: Aegean Sea, Plastics, Pollution*

Solid waste materials (SMW) in the marine environment have become an important pollution issue with impacts on marine life and negative economic impacts. Only one study on litter has been conducted in the Aegean Sea [1]. The Aegean has, isince 1st May 2009, the status of "Special Area" under Regulation 5 of Annex V (MARPOL) which prohibits any discharges of garbage in sea. Regarding land-based pollution, the Barcelona Convention and its relevant protocol is the most effective international instrument.

SMW present on Northern to Mid Aegean Seabed were investigated in August, October and December 2008 (Fig. 1). Litter items were collected by trawling in depths ranging from 65 m to 880 m. Litter items caught in nets were collected, dried, separated, counted and weighted. The swept area method was applied for the calculation of the amount of litter on seabed. Floating Marine Debris (FMD) sightings were also recorded during August 2008 cruise by an observer with a handheld GPS and binoculars. The strip transect method (width=60m; length= distance of legs in km) was used in order to determine the abundance of FMD.

Fig. 1. Map of the study area. Small circles = FMD observations (n= 140). Triangles = trawling stations (1-6). Large circles = FMD tufts.

FMD were observed mainly in areas close to land (1,75–3,52 items/km²) whereas offshore areas were generally clean of litter (0–0,18 items/km²). However we should specify that one of the offshore transects was run under poor weather conditions. There is a significant correlation between the number of items and distance from land (r_s =-0,86). FMD were widespread in gulfs and some places seemed particularly concentrating litter items causing tufts of litter (Fig. 1). The highest abundances were found in the Dikili Strait located between Lesbos (Midilli) Island and Madra Stream-Altinova.

Accordingly bottom ML were mainly abundant in gulf areas (299,98-211,75 items/km²; 27,6-2,85 kg/km²) whereas the abundance of SMW was very low (48 items/km² and 2,26 kg/km²) in the open sea location between Lesbos and Chios (Sakiz) Islands. Litter pollution in gulfs is significant and similar to other sites in the world but lower than other locations in the Aegean Sea [1] and Black Sea [2]. SMW pollution is not very high compared to the value of 1935 ± 633 Items/km² which is estimated for the NW Mediterranean [3].

The highest values of FMD reported in this study are considerably low compared to other locations in the Mediterranean (2000 items/km², [4]; 1,5-25 items/km², [5]) and in the world (1-250 items/km², [6]). It is interesting to find such low values for the Aegean Sea which is an enclosed sea within the Mediterranean and an area of recreation and fisheries. ML tufts observed in gulfs make 1/3 of all litter items and could be the result of convergence zones of wind induced Langmuir cells. This natural collection system could facilitate the removal of ML in high season when FMD values arise.

Plastics were the dominant material type among both bottom (84,13%) and surface (75%) SMW. Most of litter items on seabed were nylon bags and wrappings whereas FMDs consisted of recreational items such as plastic sea beds and sea balls, followed by plastic bags, PET bottles and food wrappings. The recreational origin of most FMD items indicates a probable restriction to the summer season. Litter items seem to have mainly land-based origin considering their types and usage categories. Other litter sources could be fish farms (items such as fish feed bags and sacks were found) and pleasure boats. Only 5 items had labels readable on and 2 of them were overseas garbage.

This study reports low to moderate levels of bottom and floating ML pollution for some locations in the Aegean Sea. Although this result is promising, the limited number of stations and transects of this preliminary study does not allow to make a general conclusion on Aegean Sea ML pollution. More studies and monitoring programs are necessary in order to estimate pollution levels and develop appropriate mitigating solutions in the Aegean Sea.

ARE HIGHER TAXA ADEQUATE SURROGATES FOR SPECIES LEVEL RICHNESS IN MARINE BENTHIC MOLLUSC COMMUNITIES?

Irini Tsikopoulou ¹*, Chryssanthi Antoniadou ¹, Eleni Voultsiadou ¹ and Chariton Chintiroglou ¹ ¹ Department of Zoology, School of Biology, Aristotle University of Thessaloniki - etsikopo@bio.auth.gr

Abstract

The higher-taxa richness as a surrogate of species richness in macrobenthic mollusc communities was explored in Thermaikos Gulf, north Aegean. Statistical analysis showed significant correlation between richness at the species level and richness at the genus as well as the family level. In addition, an increase in correlation values over the years of study was observed, implying an increase of anthropogenic impact in the area.

Keywords: Aegean Sea, Biodiversity, Bivalves, Gastropods, Mollusca

Introduction

Species richness is considered as the most appropriate measure to assess biodiversity in a specific area [1]. However, in many cases the use of higher-taxa levels as surrogates for the species level can produce a reliable faunal distribution pattern provided that there is a strong correlation between species richness and genus and/or family richness [2]. Such an approach has the advantages of being expense-reducing and time saving for biomonitoring studies ([3], [4]). The present study examines the genera and families levels of gastropod and bivalve molluscs for their suitability as surrogates of species level in abundance and species richness assessment of macrobenthic molluscan communities, in Thermaikos Gulf, north Aegean.

Materials and methods

Sampling was carried out for three successive years (summer 2001 - winter 2004). Three vertical transects along the NE coasts of Thermaikos Gulf were selected in the area around the construction site of the new air corridor of Thessaloniki Airport. Six stations - two on each transect were sampled for benthic macrofauna with corer samplers at depths between 3 and 10 m. The Spearman rank correlation coefficient was used to determine whether there was a statistically significant correlation (r_s values) between richness at different taxonomic levels.

Results and discussion

In total, 6931 gastropods were collected belonging to 62 species and 920 bivalves belonging to 39 species. Genus and family levels provided adequate surrogates, for gastropod and bivalve species richness, in the three annual samplings (Figure 1). The correlation between species and family richness was lower (r_s =0.81) in the first sampling period (2001) than in the other two periods (2002, 2003). These results are in accordance with those of Chintiroglou et al. ([5]) for the same area concerning the mollusc fauna as a whole. In areas where anthropogenic impact is extensive, higher taxa are represented by a small number of species and their use as surrogates of species richness is more reliable than in non-disturbed areas ([1],[6]). In the study area an increased anthropogenic perturbation has been recorded over the years ([7]).

Fig. 1. Degree of correlation between richness for the species level and richness for higher taxonomic levels of molluscs as well as for gastropods and bivalves separately in the three sampling periods

MERCURY LEVELS IN SEDIMENTS FROM GREEK COASTAL AREAS

Eleni Tzempelikou ¹*, Fotini Botsou ¹, Manos Dassenakis ¹ and Michael Scoullos ¹ ¹ NATIONAL AND KAPODISTRIAN UNIVERSITY OF ATHENS - etzempelikou@gmail.com

Abstract

This study examines total mercury levels in coastal and lagoon surface sediments (n=55) from the Aegean and Ionian Sea. The results obtained were compared to bibliographic data from the Greek marine environment and spatial and temporal trends were evaluated.

Keywords: Mercury, Sediments, Aegean Sea, Ionian Sea

Introduction

Mercury is one the most toxic pollutants in the environment and in the last years several policies for the limitation of the use of this metal are coming into force. Thus, continuing monitoring studies can prove a useful tool in order to evaluate such initiatives. The aim of this study was to: a) determine Hg levels in sediments from 5 regions in the Aegean and Ionian Sea, b) compare these data to previously reported ones and obtain an overview of mercury distribution along the Greek coasts and c) identify main sources of pollution.

Study areas

The study areas of our research were the coastal areas of Western Saronikos Gulf (area 1a), Larymna Bay (area 2) and Maliakos Gulf (area 3) at the central Aegean Sea and two lagoons of the Corfu Island, Antinioti (area 17) and Korission lagoon (area 18) at the northern Ionian Sea (Fig. 1).

Results and discussion

Total Hg in sediments was determined with microwave assisted-extraction with HNO₃ followed by CVAAS analysis [1]. In the Aegean Sea, the concentrations determined ranged from 0.06 to 0.32 µg/g in the Western Saronikos Gulf, 0.14 - 0.54 µg/g in Larymna Bay and 0.12 - 0.34 µg/g in Maliakos Gulf. The higher concentrations were found at areas impacted from industrial activities, and more specifically in the vicinity of a crude oil refinery (Saronikos Gulf) and a ferro-nickel smelting plant (Larymna Bay). Higher levels (0.48 - 3.89 µg/g) were determined in lagoon sediments from the Ionian Sea. We believe that mercury in the two lagoons of the Corfu Island may have a natural origin, since no intense sources of pollution are recognized in these areas. Currently, additional research is conducted by our team, in order to determine sources and forms of mercury in surface and subsurface sediments.

The results of our study were compared with previously published data from other Greek coastal areas [2] - [6]. Some of these data are presented in Table 1; Figure 1 shows the locations of the areas. Elevated mercury levels were found in sediments of the Gulf of Thessaloniki (area 5) and Gulf of Kavala (area 9) in the northern Aegean Sea. These levels were attributed to industrial and municipal wastewaters. Sediments from Elefsis Gulf (area 1b) in Saronikos Gulf, Patraikos Gulf (area 19) in central Greece and Stratoni (area 8) in the northern Greece were moderately enriched in Hg and were comparable to the estuarine sediments of the transboundary Rivers of Strymonikos (area 7), Nestos (area 10), Axios (area 6) and Evros (area 11) in the northern Aegean Sea. The lower levels were found in the coasts of Crete Island (area 15),

Korinthiakos (area 13), Argolikos (area 14) and Pagasitikos Gulf (area 4). As far as it concerns temporal trends, in two occasions, Western Saronikos Gulf and Larymna Bay, an increase over time has been observed.

Fig. 1. Locations of the examined areas.

Summarizing the above results, the higher levels of mercury were found close to industrial sites and harbors, while urban runoff was recognized as a secondary source. Thus, we can conclude that mercury contamination in Greek coastal areas is mostly related to fossil fuel combustion and crude oil leakages from ships and washing from the urbanized sites.

Abstract

The Global Warming strongly affects coastal areas and can deeply change the status of transitional areas like lagoons. Numerical modeling is presented as a tool to characterize lagoons and to quantify their rate of change. The SHYFEM model has been applied to six Mediterranean lagoons and a comparison study between the lagoons has been carried out. The lagoons are the Venice lagoon and the Marano-Grado lagoons in the Adriatic Sea, the Taranto basin in the Ionean Sea, The Cabras lagoon in Sardinia, the Mar Menor in Spain and the Nador lagoon in Morocco, giving a representative picture of the lagoons situated around the Mediterranean basin. The numerical study of each lagoon is the baseline from where the different responses to climate changes, in terms of temperature and salinity variation, are studied.

Keywords: Lagoons, Models, Coastal Systems, Global Change

Introduction

Lagoons are fragile systems in an unstable equilibrium due to their characteristics, in transition between land and sea. Abrupt changes in terms of increasing temperature and major water supply due to global warming and sea level rise, can strongly modify these environments, particularly for those around the Mediterranean Sea. Monitoring permits to study the variation of the lagoon characteristics from measurements. Numerical Modeling allows the investigation also of future scenarios. The application of a model in a number of lagoons around the Mediterranean Sea and the inter-comparison of the responses of the lagoons to different forcings, in terms of temperature and salinity variation, can help both for the general characterization of lagoons and for the future scenarios of global warming on the areas of transition.

Description of Sites

The lagoons we chose are located all around the Mediterranean, and are part of very different environments, interacting both with shallow coastal areas, like the Venice [1] and the Marano-Grado [2] lagoons in the North Adriatic, or deep seas, like Mar Menor [3] and the Nador lagoon [4]. The lagoons range from a leaky type of lagoons (Venice) to a choked type (as for the case of the Cabras lagoon [5]). The number of inlets ranges from just one in the Nador lagoon [4] to 6 in the case of the Marano-Grado lagoons. Lagoons normally communicate directly with the sea, but, in the case of Taranto, a semi-enclosed basin between the sea and the lagoon is present [6]. Tidal range is from micro-tidal to mesotidal. The depth ranges from an average depth of 1 m to up to 6 meters.

Fig. 1. Location of the six Mediterranean lagoons studied.

All lagoons show strong impact of wind forcing. In most lagoons fresh water input is small, but it is relatively strong in the Marano-Grado case [2]. Wind and tidal stirring normally prevent the lagoons from developing stratification but less dynamic lagoons could show different vertical configurations. The exchange rate depends mainly on the inlet configuration, but also on the wind regimes in the case of multi-inlet lagoons. The exchange rate is also an important factor that can determine the residence time distribution inside the lagoons.

Methods

The model (SHYFEM) is a finite element model, especially suited to shallow water basins with complicated geometric and morphologic variations [1]. It solves the well known hydrodynamic equations with the semi-implicit algorithm on a flexible grid made of triangular elements. It has been applied in its 3D version in order to study the dynamics of lagoons introducing vertical variability and to properly describe the precipitation, evaporation and the river runoff effects in these areas. The model can compute the basic hydrodynamics, dispersion of tracers, temperature and salinity evolution, sediment transport and ecological parameters.

Results and Discussion

Temperature and salinity mean values and variability have been computed for the six lagoons, serving as the reference simulations. The A1B global change scenario has been applied to the lagoons, in terms of air temperature and evaporation increase, precipitation decrease, sea level rise and river runoff variation. In all lagoons higher residence times are registered, compared to the reference simulation, also caused by the major lagoon water volume, due to sea level rise. Lagoons become more saline partially due to the negative value of precipitation-evaporation. The 6 Mediterranean Lagoons have been classified using the division in choked, restricted and leaky. Leaky lagoons, as Marano-Grado Lagoons, are mainly governed by the exchange with the open sea and response to climate change is comparable with the open sea. On the other hand, chocked lagoons (Mar Menor) show more severe variations and experience the highest changes in temperature and salinity fields. Restricted lagoons show intermediate behaviour. These results are important also for other disciplines, like biology and ecology, to handle the global warming effects in transition areas.

UNDERSTANDING FLOWS OF ECOSYSTEM SERVICES: THE INTERCONNECTEDNESS OF TERRESTRIAL, COASTAL, AND MARINE SYSTEMS

Abstract

ARIES is a new methodology and web application meant to assess ecosystem services and illuminate their values to humans in order to make environmental decisions easier and more effective. In this contribution, we discuss the use of ARIES to understand how marine, coastal, and terrestrial ecosystems are linked in the provision of ecosystem services. We illustrate perspectives for integration of such thinking into coastal management and decision-making.

Keywords: Coastal Processes, Ecosystem services, Coastal Management

The benefits that our societies receive from ecosystems in the form of services such as water purification have a dynamic nature in that they are carried from source of origin to areas where they are used. Matter, energy or information serves as carriers that transmit the benefits through space and promote its transfer to humans. For example CO2 is the vehicle for carbon sequestration and storage, floodwater for disturbance regulation, and scenic views for aesthetic value. Tracking the spatial flow of benefits can be help highlight the interconnectedness between terrestrial, coastal, and marine ecosystems, providing decision-makers and managers a way to assess the propagation of potential impacts and the opportunity of protecting or enhancing existing functions. ARIES (ARtificial Intelligence for Ecosystem Services) is a new methodology and web application (Villa et al., 2009) meant to assess ecosystem services (ES) and illuminate their values to humans in order to make environmental decisions easier and more effective. By creating ad-hoc, probabilistic models of provision, use and flows of ecosystem services in a region of interest, ARIES helps discover, understand, and quantify environmental assets, their likely beneficiaries, and what factors influence their value according to specified needs and priorities. Thanks to a grant from UNEP, the coverage of ARIES is being extended to include coastal and marine systems, which are the focus of this contribution. Ecosystem services dynamics can be seen as a generalized source-sink problem, where ecosystems are the source of benefits that meet the needs of specific human beneficiaries. Modeling ES in a given spatial and temporal context requires: (1) determining the currencies of these benefits, such as water, CO2 etc; (2) determining likely surfaces of both provision and usage relative to the area and time of interest; (3) quantifying the rates of flow of the correspondent benefits. It is the rate of flow (current or potential) that can be directly related to the value of the ES. both in abstract and in economic terms. Most of the many difficulties of modelling ES depend on the high heterogeneity of behavior exhibited by the benefits they produce. Among these: 1. Provision and usage happen at entirely independent scales in space and time. Therefore, a scale-explicit approach needs to be taken, and theoretical instruments that can tackle multiscale systems are lacking. Recognizing the spatial and temporal decoupling between source and use, between benefits and their carriers has important implications for management, mitigation efforts, and policy actions. 2. The "currency" of benefit provision is rarely an easily modelled biophysical quantity. Easier cases include, e.g., CO2: quantification of its exchange from vegetation to atmosphere may be all that's needed to assess benefits of carbon sequestration. Things are much more complex with currencies like sense of identity or avoided risk of flooding. 3. Little clarity exists in the literature about quantifiable definition of ES, their benefits, and the modalities of their propagation from ecosystem to human beneficiary. The ARIES methodology is based on explicit conceptualizations that lay out first of all a novel vision of ES, based on the breakdown into individual benefits, each of which is modeled independently, then linked to the others. Domain ontologies in ARIES result from a large-scale expert consensus. Artificial intelligence techniques (machine reasoning, pattern recognition) examine source data and extract from the ontologies models that best represent the situation at hand. ARIES builds adhoc, probabilistic Bayesian Network models that inform the users of the full probability distribution of the outcomes of their decisions (Villa, 2009). The result of an ARIES user session is a set of GIS maps that describes in depth the spatial distribution of benefits produced the area, their potential and realized values, and the causal relationships that link the values to each other, to their likely beneficiaries, and to actual or potential policies. Users can enter a scenario explorer module to explore the likely changes in ecosystem service provision and usage engendered by changed environmental conditions, consequent to either natural change or their own actions. We will discuss the ARIES methodology and demonstrate the software toolkit to highlight its

potential in informing ES-centric decision-making in coastal and marine decision-making.

Abstract

This paper presents geo-scientific characteristics of a beachrock-type calcarenitic tsunamite from the Bay of Aghios Andreas (Peloponnese, Greece). Geomorphological, sedimentological, micromorphological, geochemical and geochronological studies were conducted to clarify the depositional processes and the post-sedimentary evolution. We found sedimentary structures such as basal unconformities, rip-up and intra-clasts, evidence of fining upward, thinning landward and upward increase in sorting as well as bi-to multimodal deposits all of which are described as features typical of recent or historic tsunami deposits. It is concluded that in the Bay of Aghios Andreas, Olympia's ancient harbour site was destroyed by tsunami impact. Keywords: Beach, Coastal Processes, Eastern Mediterranean, Geomorphology, Sea Level

Tsunami hazard in the eastern Mediterranean is among the highest worldwide. This is mostly due to the high seismic activity along the Hellenic Arc where the African Plate is being subducted under the Eurasian Plate inducing numerous strong tsunamigenic earthquakes. In addition, the Arabian Plate, moving northward at fast rates, is a serious source of seismically-related hazards. Paleotsunami research in the eastern Mediterranean has been strongly intensified during the past decades, in order to improve our understanding of the dimension and the dynamics of tsunami landfalls, and to gain reliable background information for future risk assessment. In addition to archival studies based on ancient accounts and historical data, an increasing number of geo-scientific field studies have been carried out to detect palaeotsunami deposits.

A new type of event deposit, beachrock-type calcarenitic tsunamites, has been described for the first time, based on three case studies from western Greece ([1], [2]). Here, we present details from beachrock studies at ancient Pheia, the harbour site of Olympia, which is located in the Bay of Aghios Andreas in the western Peloponnese. The archaeological remains of Pheia are almost completely submerged and lie in water depths down to 5 m below present sea level. The harbor is said to have been destroyed by earthquakes in the 6th century AD, most probably in 521 AD and/or 551 AD ([3]). The modern beach of Aghios Andreas is characterized by thick beachrock layers. In former studies, this beachrock was used as sea level indicator thus explaining the submergence of ancient Pheia by a complex sequence of gradual subsidence (6.5 m) and following minor uplift (1.5 m, [4]).

We carried out geomorphological, sedimentological, geoarchaeological and geochronological studies. The basal section of the beachrock, up to 3 m thick, is lying on top of an erosional discordance and consists of abundant coarse gravel. The mid-section of the beachrock is clearly laminated and shows several fining upward sequences out of fine sand from the littoral zone. Further sedimentary structures found are convolute bedding and load casting, both untypical of littoral environments. Such characteristics rather indicate gravity-induced flow dynamics in a water-saturated suspension-like matrix. In some areas, large ashlars were found incorporated into the calcarenite. These man-made blocks, still angular, do not show any signs of being moved or altered in the littoral zone; one block is even coated with original white plaster. Moreover, vibracoring revealed clear thinning land- and sideward of the beachrock, and the beachrock was discovered up to 40 m distant from the coast and up to 2.60 m above present sea level. It is, however, known from previous studies that during the Holocene, the relative sea level in the area has never been higher than at present ([3], [5], [6]).

Based on our results, the beachrock sequence at Aghios Andreas does not reflect at all sedimentary characteristics typical of a (lithified) beach but rather represents high-energy event deposits. Convolute bedding and load cast structures are assumed to document intermittent backflow shortly after highenergy deposition of thick allochthonous sand deposits onshore. We thus suggest that Olympia's harbor site was hit by tsunami associated to strong earthquakes. Submergence of Pheia's archaeological remains seems to be of coseismic nature such as observed during the southeast Asia tsunami in 2004.

CAUSES OF INFRALITTORAL BARRENS IN THE TURKISH MEDITERRANEAN AND POTENTIAL FOR ECOSYSTEM RESTORATION

Zeynep derya Yildirim², Zafer ali Kizilkaya²*, Enric Sala³ and Atakan Sukatar¹ ¹ Ege University

² Underwater Research Society - anemon@imagesandstories.com
³ Centre d'Estudis Avançats de Blanes (CSIC), Spain

Abstract

The goal of the study was to understand rapid change of benthic communities in the Turkish Mediterranean infralittoral, from dense algal forests to barrens. We conducted caging experiments in three sites and observed that macroalgae grew rapidly inside the cages but not outside. Juvenile rabbitfish invaded the cages at the end of the experiment and removed all algae within. These results suggest that the large abundance of Lessepsian herbivorous fishes may be a major cause for the desertification of the Turkish Mediterranean infralittoral. The restoration of the ecosystem may require the removal of Lessepsian fish species. *Keywords: Algae, Biodiversity, Eastern Mediterranean, Monitoring, Lessepsian migration*

Introduction

The Turkish Mediterranean infralittoral was dominated by abundant algal forests, dominated by the genus *Cystoseira* and Dictyotales, only a decade ago (pers. obs.). Current observations along the Turkish coast revealed that macroalgae have disappeared from many locales, and been replaced by extensive barrens with virtually no macroalgae. Sea urchins, which are the main cause of barrens elsewhere in the Mediterranean [1], were also absent in these barrens; but the alien herbivore from the Red Sea, the rabbitfish (*Siganus luridus* and *S. rivulatus*), was very abundant. In contrast, on Greek islands of the Dodecanese, where environmental conditions are very similar but rabbitfish were much less abundant, *Cystoseira* forests dominated infralittoral communinities. We thus hypothesized that the desertification of the Turkish Mediterranean infralittoral is due to the grazing activity of the abundant Lessepsian rabbitfish. To test this hypothesis, we conducted visual censuses of fish and benthos, and a caging experiment, in several locales of the Turkish coast.

Materials and Methods

To determine the extent of barrens and the structure of the herbivore community, we conducted underwater visual belt transects using scuba at a depth of 10m in five sites of the Turkish Mediterranean. We counted, identified, and estimated the size of all fishes within 15 replicate 25x5m transects per site, and calculated the biomass of algae by scrapping 20 25x25cm quadrats per site. We counted sea urchins using 150 50x50cm quadrats per site. In three sites with extensive barrens (Kas, Fethiye, and Bodrum) we conducted caging experiments to test wheter the absence of algae was due to the grazing by fish. We installed 12 60x40x25cm cages with plastic mesh on each site. Once a month, cages were lifted, and cages and nearby control quadrats were photographed. Algal cover of each taxa was estimated using Photogrid. A subsample of algae were collected to calculate the relationship between cover and biomass. In addition, pH, salinity, oxygen and turbidity were measured, and fish surveys were conducted around the cages.

Fig. 1. Monitoring the algal growth within a cage at Kas during three months in 2009: 1) April, 2) May, 3) June

Results and Discussion

Macroalgae grew very rapidly inside the cages (Fig. 1) - in some cases from 0 to 200 g m⁻² in four months - but not outside the cages (Table 1). Sea urchins were very rare in the study areas, and were not observed grazing around the cages. The native herbivorous fish *Sarpa salpa* was rare, but rabbitfish were very abundant throughout the study period. In September and October, rabbitfish recruitment was very high, and rabbitfish juveniles entered the cages and consumed every alga within.

Tab. 1. Algal biomass inside and outside the cages during the experimental period (g $\mathrm{m}^{-2})$

Bourum	outside	0.0	0.5	0.0	0.0	0.0	0.0	0.0	0.0

In contrast, *Cystoseira* spp and Dictyotales were observed in the mediolittoral, near the surge zone, where fish grazing activity is more limited.

These results suggest that herbivorous fishes, not sea urchins or environmental factors, are responsible for the creation of infralittoral barrens in the Turkish Mediterranean coast. This is the first documented case in the Mediterranean sea where herbivorous fishes create barrens, and where Lessepsian fishes have dramatically transformed the ecosystem, from one dominated by lush and diverse brown algal forests to another dominated by bare rock.

Restoration of algal assemblages ocurred at first successional stages and within small enclosures. The question is whether restoration efforts could be conducted at large scales. Based on our results, such restoration efforts may have to be based on overfishing of the introduced rabbitfishes *Siganus* spp.

ECO-HYDRODYNAMIC MODELLING OF EUTROPHICATION AND NUTRIENT CYCLES USING DELFT3D MODEL FOR THE CILICIAN BASIN

V. çaglar Yumruktepe ¹*, Baris Salihoglu ¹, Temel Oguz ¹ and Süleyman Tugrul ¹ ¹ Middle East Technical University Institute of Marine Sciences - caglar@ims.metu.edu.tr

Abstract

Major rivers and domestic wastewater discharges from the cities of Mersin and Iskenderun exert a severe stress on the Cilician Basin ecosystem. Recent studies show that the coastal regions of the basin show eutrophic characteristics, where on the contrary, the offshore waters of the Eastern Mediterranean Sea show oligotrophic characteristics[1-2]. This study aims to model the hydrodynamics coupled with the ecosystem of the Northeastern Mediterranean Sea. The coupled model used for the study is DELFT3D of Delft Hydraulics Labs. Europhication is being observed in the hot spots of the region, and using these data specific limiting nutrients and their cycles are modelled including the life cycles of several phytoplankton and zooplankton species. *Keywords: Models, Nutrients, River Input, Primary Production, Phytoplankton*

Physical, chemical, and biological properties of the basin is observed by six field surveys conducted by R/V Bilim of Middle East Technical University, Institute of Marine Sciences, within the framework of TARAL (TÜBITAK) project during September 2008 - August 2009. These cruises were conducted to observe the seasonal variations in the region, so there are winter, spring and summer data available for every field. We also collected chemical data from the related rivers. In order to analyse the eutrophication processes, a coupled physical-biological model was used. Observations were used to set the models initial and forcing fields. Two open water boundaries were included in the domain of the model being the south and west part of the basin, where the discharge of the major rivers, Seyhan and Ceyhan, and also a local river of Mersin Bay, Berdan are included. To show the effects of the domestic discharges, the discharge from the city wastewater plant of Mersin was included as inflow to the model. The studies show that the Northeastern Mediterranean Sea is phosphate limiting, but the effect of discharges show a shift in N/P ratio, especially in spring seasons.

Fig. 1. Spring 2009 N/P Ratio of Mersin Bay, representing the impact of discharges

This result is clearly seen by the model as major impacts of the river discharges. At certain times of the year, the Mediterranean is under high level deposition of nutrients from the Sahara Desert, and for that reason, atmospheric calculations are included in the model. As physical forcing functions, varying heat fluxes and wind data are used in the model to force circulation and stratification and mixing of the water column in varying seasons.

Fig. 2. Circulation model result of Mersin Bay showing the open water circulations and their effect on coastal regions

Regarding the eutrophication, four nutrients are taken as sources, NH_4 , NO_3 , PO_4 and Si. Three phytoplankton species are parameterized with respect to these nutrients being, flagellates, diatoms and dinoflagellates, and also general zooplankton species. Dissolved oxygen is modelled in conjunction with the eutrophication process, and biochemical oxygen demands results are observed respectively.

ANTHROPISATION ET ÉROSION BIOLOGIQUE : CAS DU GOLFE DE TUNIS

Jeanne Zaouali 1*

¹ Institut National Agronomique de Tunisie, 2025, Tunis, Tunisie - jeanne.zaouali@planet.tn

Abstract

La comparaison faite entre l'état environnemental du golfe de Tunis dans les années 70 et l'état actuel met en évidence une «dévégétalisation» sur quelques 150 km2 et une profonde déstructuration de tout l'écosystème du golfe. *Keywords: Algae, Posidonia*

Le golfe de Tunis, situé à la jonction entre les bassins occidental et oriental, occupe une position clé en Méditerranée méridionale. Avec la concentration sur ses rives de près du cinquième de la population nationale (2 millions d'habitants), de l'essentiel du tissu industriel national (85 %) et l'essentiel de l'activité portuaire aussi bien touristique que commerciale, ce milieu subit de très fortes contraintes. Le poids grandissant des stress environnementaux au niveau du golfe a suscité l'attention des autorités qui ont mis en route un vaste programme de surveillance environnementale devant aboutir à des mesures de réhabilitation. Les observations faites dans les années 70 sur l'état des phytocénoses benthiques de l'ensemble du golfe (1) nous ont permis de caler un point « zéro écologique ». A des fins de comparaison, une campagne de surveillance environnementale a été faite en juin 2008. Elle a concerné 43 stations réparties sur l'ensemble du golfe (eau, sédiments et macro benthos). L'ensemble des résultats obtenus, a permis de connaître les principales réponses de l'écosystème aux stress, à savoir :

- la remontée générale de la frange basse de la végétation (fig1), celle-ci étant nettement plus forte dans toute le secteur ouest du golfe sous influence du seul fleuve tunisien pérenne, à savoir la Mejerdah, et moindre dans le secteur est où la pression anthropique directe, en dehors de celle exercée par les arts traînants, est très faible.

 l'importante diminution des surfaces occupées par les herbiers de posidonies et, dans de nombreux cas, leur disparition, notamment dans la portion ouest de la baie de Tunis - sous influence directe des contraintes liées au voisinage de la capitale-.

- engendrée par la progressive opacification des eaux chargées de particules en suspension, l'éradication sur près de 150 km2 des prairies de *Caulerpa prolifera* qui, dans les années 70 succédaient aux herbiers. Pour la même raison, la remontée des éléments de la biocénose coralligène, très importante, est passée de 50 à 10 m.

Fig. 1. Golfe de Tunis-profondeur (en mètres) de la frange basse de la phytocénose infralittorale en 1972 (trait plein) et 2008 (pointillés).

Cette déstructuration de l'écosystème littoral, sous les contraintes accrues liées au réchauffement climatique global, a laissé place à une large colonisation par des espèces exotiques tropicales et plus spécialement par *Caulerpa racemosa* qui, à l'heure actuelle, est présente tout au long du littoral du golfe.
