MODELLING CHANGES IN EASTERN MEDITERRANEAN OCEAN CLIMATE FOR THE EARLY HOLOCENE

Fanny Adloff^{1*} and Uwe Mikolajewicz¹

¹ Max-Planck-Insitut fuer Meteorologie, 20146, Hamburg, Germany - fanny.adloff@zmaw.de

Abstract

We use the ocean general circulation model MPIOM to simulate the changes in hydrography and circulation for the eastern Mediterranean Sea during the early Holocene 'climatic optimum'. *Keywords: Paleoceanography, Eastern Mediterranean, Circulation Models, Hydrography*

During the Holocene, a series of changes in the conditions of the Mediterranean hydrography occurred, essentially led by the orbitally-induced changes in the insolation. This study aims to investigate these changes. We focus on the Mediterranean because this semi-enclosed basin has largeamplitude reactions to external forcings. To understand the sensitivity of the Mediterranean Sea to high- and low-latitude climate forcings and to estimate the response to expected global change, we are modelling the Mediterranean Sea at different time slices of the Holocene. We set up a regional version of the general ocean circulation model MPIOM for the Mediterranean (26 km horizontal resolution, 29 levels). We forced the model with atmospheric data derived from equilibrium time slice simulations with the coupled atmosphereocean-dynamical vegetation model ECHAM5/MPIOM/LPJ. The experiments are performed for both time periods 6000 years and 9000 years before present as well as for the pre-industrial conditions (500 years of integration for each). Diverse proxy records available from the marine cores are used for the validation of our simulations. The effect of insolation and fresh water input changes on the Mediterranean ocean climate for the Holocene are analyzed. The amplitude of the SST seasonal cycle is stronger, leading to colder winters with a resulting cooling of the deeper layers. The enhanced summer warming is restricted to the very uppermost layers leading to a strong vertical temperature gradient. For 9000 years BP, the increased Nile runoff (due to the enhanced North-African monsoon) is overcompensated by the missing outflow from the Bosphorus and the location of Aegean deep water formation is shifted westward. For the 6000 years BP, the Nile runoff is enhanced as well and the outflow from the Black Sea is reduced due to drier climatic conditions in SE Europe. The model results are compared to available SST/SSS reconstructions derived from paleoproxy data.

RAPID CHANGES IN THE SEDIMENTARY REGIME FOLLOWING THE DAMMING OF THE NILE: INNER SHELF OF THE DISTAL PART OF THE NILE LITTORAL CELL, ISRAEL

Ahuva Almogi-Labin ¹*, Barak Herut ² and Amir Sandler ¹

¹ Geological Survey Of Israel, Jerusalem, 95501, Israel - almogi@gsi.gov.il

² Israel Oceanographic and Limnological Research, National Institute of Oceanography, Haifa 31080, Israel

Abstract

In the past the Nile floods transported large quantities of fine-grain sediments and nutrients at the end of each summer to the inner shelf of Israel which is part of the Nile littoral cell. In order to determine the influence of the damming of the Nile on the sea floor 9 short cores (~30cm) were taken at ~40m in a S-N transect. The sediments, dated by Lead-210, significantly coarsen in the post-Aswan High Dam period with 5-10 times increase in >63 μ m size fraction, ~50% increase in CaCO3, ~50% decrease in total organic carbon and ~2.5‰ decrease (-19.5 to -22) in δ^{13} Corg. These parameters indicate a rapid and large scale change in the sedimentary regime and increasing oligotrophy during the last ~40 years, with far reaching implications for the future of the southeastern Mediterranean.

Keywords: Continental Shelf, Nile Delta, Eastern Mediterranean, Sediment Transport

Introduction

The southern inner shelf of Israel is located in the distal part of the Nile littoral cell. Until recently most of the sediments in the 30-50m silt belt [1] were derived from the Nile floods that reached the Israeli coast at the end of each summer by the alongshore northward current [2]. During the last century a series of dams were built along the Nile and since the operation of the Aswan High Dam almost all the discharge to the southeastern (SE) Mediterranean stopped, including ~10⁷ tones/y of fine sediments [3]. This completely changed the hydrological and biological regime in the SE Mediterranean turning it into a hyper-oligotrophic sea. In this study we intend to characterize the consequences of the shut down of the Nile River discharge to the SE Mediterranean and examine the post-Aswan High Dam sedimentation pattern in the middle part of the inner shelf of Israel, an area which is considered to be highly affected by these recent man-made changes.

Material and Methods

Nine short cores were sampled along ~160 km of Israel inner shelf from off Ashqelon in the south to off Acre in the north. The sediments were taken from the silt belt at 35-40m water depth, an area most sensitive to changes in Nile River discharge [1]. The sediments were cut into 1 cm thick slices, lyophilized and then analyzed for granulometry, clay mineralogy, major and trace elements, CaCO₃ and total organic carbon (TOC) content and δ^{13} Corg. Chronology was determined in three cores using Lead-210.

Results and Discussion

The inner shelf of Israel is an integral part of the Nile littoral cell and is located on its distal part under the affect of the alongshore northward current [4]. In the past, this current transported Nile derived nutrients and fine sediments to the Israeli coast [2]. The sediment regime of the inner shelf is expected to directly record changes in Nile discharge resulting from its damming during the last century. The top ~10 cm, which accumulated during the last ~40 years are significantly coarser than the underlying pre-Aswan High Dam sediments. The sand content exceeds 60% in post-Aswan High Dam compared to <10% in the pre-Aswan High Dam sediments (Fig. 1). Grain size mode increased gradually from ~5µm in the pre-Aswan High Dam to ${\geqslant}85\mu m$ in the post-Aswan High Dam sediments. Silt fraction, comprising ~75% in the pre-Aswan High Dam sediments decreased to ~45% in the post-Aswan High Dam sediments and clay content decreased by ~50%, from ~20% to <10%. The coarsening in grain size is more abrupt and rapid in the southern shelf, closer to the Nile, than in the northern distal part. In the later, the coarsening starts earlier, is more gradual and increases in two steps apparently as a response to an earlier stage of damming of the Nile that was hardly recorded in the southern shelf.

Sediment coarsening is also accompanied by a distinct but moderate increase in CaCO₃, from less than 10% to 15-20% in the southern shelf and to ~80% in the most distal northern part. TOC content of 0.8-1wt.% with δ^{13} Corg of about - 19.5% in pre-Aswan High Dam sediments decreased to less than 0.5wt.% TOC and about -22‰ δ^{13} Corg in the overlying younger sediments. The decrease in these variables reflects a major change in the regional nutrient budget and a major decrease in primary production that coincides with the damming of the Nile [3]. The trend of increasing oligotrophy in the inner shelf of Israel differs from recent reports on a major anthropogenic contribution of nutrients that supports increasing fishery in the Mediterranean coastal waters off Egypt [5]. This increase in fertility seems to be of local scale restricted mainly to the delta area,

unlike the pre-Aswan High Dam summer floods that were of significant and large magnitude and affected annually the Israeli shelf.

The decrease in TOC and δ^{13} Corg, indicators of nutrient supply and primary production, predates the sharp sediment coarsening. This may indicate that earlier phases of Nile damming had already contributed to the increasing oligotrophy of the SE Mediterranean, which accelerated after the operation of the Aswan High Dam.

Fig. 1. Sediment dynamics in the last ~100 years at the distal part of the Nile littoral cell (southern shelf of Israel): (a) % >63µm size fraction (circle) and % Al (x); (b) Grain size mode (µm); (c) % CaCO3; (d) TOC (wt.%); (e) δ^{13} Corg (‰). Note that the major change in the sedimentation pattern coincides with the operation of Aswan High Dam at 1965

Abstract

Based on new multibeam bathymetric data and high and ultrahigh resolution seismic-reflection profiles, different types of massmovement deposits have been mapped in three geomorphological environments (seamounts, valley walls and open slope) of the Almeria margin and adjacent Alboran Trough. Different factors have been invoked to explain the triggering of theses massmovements.

Keywords: Alboran Sea, Stratigraphy, Western Mediterranean, Sedimentation, Acoustics

Introduction

Mass-movement deposits of various types and sizes have been described in different sectors of the NW Mediterranean Sea as for example in the Balearic Islands, Ebro margin, and Gulf of Lion (1). But few examples have been studied in the SW Mediterranean Sea (2, 3) in spite of mass-movements represent an important process in shaping its margins. The present study focuses on the Quaternary mass-movement deposits of the Almeria margin and adjacent Alboran Trough in the eastern Alboran Sea (SW Mediterranean) which is a tectonically active area characterised by a complex morphostructure with margins, basins, and seamounts. To analyse the morphologies and distribution of the mass-movements as well as to examine their relationship between sliding and the environment where they occur, a large data set including multibeam bathymetry, ultrahigh resolution seismic profiles (Topas system) and high resolution seismic profiles (Airguns) have been analysed.

Results and discussion

Mass-movements have been identified in three geomorphological environments, seamounts, open slopes, and valley walls in the Almeria margin and adjacent Alboran Trough (Figs.1 and 2).

Fig. 1. Topas seismic profiles illustrating the mass movements in (A) the Sabinar Seamount and (B) the open slope environment.

The mass-movement deposits affecting to the seamounts (i) comprise slides scars and slides on the walls $(10^{\circ}-27^{\circ})$ that evolve downslope to mass-flow deposits resting on the slope break. These mass-flow deposits show a lobate shape in plan view and a lenticular geometry in cross-section and acoustically are characterized by semitransparent facies. Within the Quaternary sequence, the lobes of massflow deposits are vertically stacked and their size decrease progressively upward suggesting the occurrence of successive episodes of failure and their decrease in importance with time. These mass-movement deposits can be divided into two groups based on their size: small-scale (few km in length) and medium-scale (tens of km in length). The smaller deposits are identified in the Pollux, Sabinar, Gata, Maimonides, El Monsour, Yusuf, and Adra seamounts. With respect to the largescale mass-movement deposits they have been mapped in the south flanks of the Sabinar and Pollux seamounts (Fig.1A).

In the open slope environment (ii) a buried isolated body of mass-flow deposits has been identified at 800 m water depth, where the slope gradient is about 3°. It is located close to NE-SW La Serrata fault and to WNW-ESE anticline structures, both with surficial expression. This body displays a lenticular shape and seismically is defined by chaotic facies with reflections of high reflectivity that interrupt the lateral continuity of the stratified surrounding open slope deposits (Fig.1B).

In the Almeria canyon-channel mass movement deposits (iii) include mostly slides scars, and mass flow deposits and that are identified on their walls. Here, the occurrence of mass-movement processes is also evidenced by the canyon/channel fill deposits whose seismofacies reveal ancient cut and fills features, and mass-flow deposits (Fig.2).

Fig. 2. Topas seismic profile illustrating the mass-movement deposits identified in the walls of the Almeria Canvon.

Different factors have been invoked to explain the triggering of mapped massmovements. Those deposits in the seamounts and open slope environments result from the interplay of earthquake activity associated to fault activity and/or slope overstepping. While in the canyon-channel environment, the massmovement deposits are mainly related to the erosion activity and/or the slope overstepping. The different size of the mass- movement deposits in the seamount environment is conditioned by the available run-out distances and their topography profile morphology and slope gradients.

FORAMINIFERAL DISTRIBUTION IN THE KARSTIC ZRMANJA RIVER ESTUARY (EASTERN ADRIATIC

SEA)

D. Bogner ¹*, S. Živkovic ², N. Bojanic ¹, A. Smoljan ³ and O. Vidjak ¹

¹ University Centre for Marine Studies

Abstract

The foraminiferal taxonomic composition and density, granulometric composition, carbonate and organic matter contents were determined in recent surface sediments of the Zrmanja river estuary in June 2008. The results indicate that foraminiferal distribution strongly depends on location in the estuary and organic matter and carbonate contents, and granulometric composition of the sediments.

Keywords: Adriatic Sea, Estuaries, Foraminifera, Sediments

INTRODUCTION

This study was conducted at twelve stations in the Zrmanja river estuary, which is located in the north part of Dalmatia (eastern Adriatic coast). The Zrmanja river is approximately 69 km long and discharges into the Adriatic Sea, forming a highly stratified estuary [1]. The estuary can be divided in the upper (river Zrmanja from Jankovic buk to Novigrad Sea), middle (Novigrad and Karin Sea) and lower part (Velebit channel and the strati between Novigrad and coastal Adriatic Sea) [2]. The correlation between foraminiferal assemblages and sedimentary facies has been determined in estuarine and continental shelf areas [3,4], therefore we aimed to determine the relationships between foraminiferal distribution and chemical and granulometric composition of the sediments in the Zrmanja estuary.

MATERIALS AND METHODS

Surface sediment samples (0-2 cm) were collected using Van Ween grab in June 2008. The sediment was immediately frozen, stored at -20 °C and freezedried in the laboratory. Foraminifera were counted in the fraction larger than 125 μ m, in the aliquots containing about 300 foraminiferal specimens. The granulometric composition, carbonate and organic matter contents in the sediment were analysed as described in the reference [5;

RESULTS AND DISCUSSION

Based on the statistical analysis of foraminiferal composition and abundances and sediment properties at the investigated stations, the results are as follows: 1) The differences between the five stations in the upper estuary sediments were considerable. Sand content decreased from Jankovic buk (97.5%) to Zrmanja mouth (10.6%). The same trend was noticed for carbonate content (34.2 and 72.3%, respectively), while portion of organic matter increased (1.13 and 6.87%, respectively). Foraminiferal density at these stations ranged from 2 to 971 specimens per 1 gram of dry sediment, and was dominated by the cosmopolitan species Ammonia tepida (40.8-80.2%). The other abundant taxa were Aubignyna perlucida (0-16.9%), Cribroelphidium decipiens (0-14.1%), Elphidium spp. (1.7-42.1%) and Quinqueloculina spp. (0-10.5%). Species Ammonia tepida and Aubignyna perlucida are found in other areas with lower salinity [6,7]. The station in the strait between Novigrad and coastal Adriatic Sea had the highest gravel (37.9%) and carbonate contents (72.3%). Connemarella rudis (26.5%) and Triloculina tricarinata (14.3%) were dominant species. Presence of Connemarella rudis is in accordance with its preference for sandy sediment [4], while Triloculina tricarinatais usually found in areas with intensive circulation [8]. The six marine stations in the Novigrad Sea, Karin and coastal Adriatic Sea were characterized by the foraminiferal density between 104 and 475 specimens per 1 g of dry sediment, the highest organic matter (6.55-10.68%) and lower carbonate contents (15.8-45.9%). At these stations Cribroelphidium decipiens (11.1-16.5%), Ammonia tepida (1.6-20.8%), Bulimina aculeata (0.3-15.2%), Protelphidium granosum (0.5-10.7%) and Asterigerinata mamilla (0-11.8%) were dominant. Those species are associated with fine-grained sediments [4,9], and at these stations fine-grained clay particles contents were the highest (39.0-53.5%). These results indicate that in the river Zrmanja estuary foraminiferal distribution is strongly affected by the locations in the estuary, as well as by organic matter, carbonate contents, and granulometric composition of the sediment.

Abstract

Observation of coastal areas may address to different aspects of the environment such as parameters and processes of water quality, hydrodynamics, geomorphology, meteorology and ecology. Satellite and airborne remote sensing can provide an important contribute for assessing and monitoring the status of water quality. Selected case studies, which describe data acquisition and processing, outline improvements in the advanced methodologies and provide examples of gaps and barriers to produce useful applications in coastal areas, are presented.

Keywords: Coastal Waters, Remote Sensing, Adriatic Sea

Introduction

Coastal areas are characterized by small-scale processes, high spatial and temporal variability of the main physical and biogeochemical properties of the water, hazards and unpredictable events. These areas are very sensitive to the impact of human activities and land use in watersheds, along the coast and further inland, of fluvial discharges, and of marine processes.

Local and national authorities require innovative methods and technologies for managing coastal risks and monitoring water quality, in order to satisfy operational, spatial and qualitative requirements with a good cost-benefit ratio. In the recent decades, a helpful contribution has been obtained by the Remote Sensing data, which can significantly enhance the information available from traditional data sources providing synoptic views of large portions of Earth with a relatively high revisiting frequency and therefore early detection of anomalies and degradation of the ecological status.

Remote sensing of the bio-optical parameters can be an important way for monitoring the coastal environment. Whereas the optical properties of open ocean (Case 1 water) are primarily a function of phytoplankton concentration, coastal waters (Case 2 water) represent a more complex optical environment [1]. The optical properties in these areas are due to a mix of phytoplankton, suspended sediments, and CDOM that can vary independently from each other. Besides the water colour can be influenced by bottom reflectance and we must take account of the natural variability in the types of bottom (e.g., sand, mud, rocky, algae or seagrasses covered).

Water quality parameters may be derived from hyperspectral data [2] [3] [4].

Methodology and results

In the last years, we have investigated the capability of multi and hyperspectral remote sensing data to meet the information needs of end users in the coastal zone and we present some case studies which describe data acquisition and processing, outline improvements in the advanced methodologies and provide examples of gaps and barriers to producing useful applications.

During satellite and airborne overpasses on the Adriatic Sea (Lagoon of Venice , 2001-05; Sacca di Goro Lagoon, 2005-06; Montenegro, 2007-09, see Fig. 1), we acquired an extensive in situ data set: the field campaigns retrieved inherent optical properties, apparent optical properties, substrate reflectance spectra, and water quality parameters with advanced instruments. The efforts aim at making a first step in the construction of a feasible and timely methodology for quantitative assessment of water quality parameters detectable from hyperspectral data. The adopted analysis techniques of satellite and airborne imagery were: the empirical algorithm for CDOM/chl-a retrieval; the classification techniques for algae and submerged vegetation identification with spectral libraries; the complex physically based model that considers analytical formulations of radiative transfer equations and the application of numerical simulations (Hydrolight software).

In particular, for the Venice Lagoon the authors have been involved in the tuning of a physical model for the highly turbid Venice lagoon waters and developed an inversion technique appropriate for hyperspectral data processing to retrieve water constituent concentrations from remotely data.

Conclusions

Within the hyperspectral VIS-NIR spectral range, several parameters are detectable from space: presence/absence of algal blooms, concentration of phytoplankton with some information on content of different pigments. suspended matter and yellow substances concentrations, diffuse attenuation coefficient, water colour, water transparency and, over shallow waters, bathymetry, submerged vegetations and substrate types.

The selected applications of hyperspectral observation techniques in the Adriatic sea, financed and conducted in the framework of international projects (i.e. NERC, ESA, ASI, Italian Environmental Ministry), provide examples of the remote sensing efficiency in the field of integrated coastal environmental management.

MARINE MESSINIAN IN EASTERN TUNISIA

Pierre-Felix Burollet 1*

¹ GEA, 04300, Forcalquier, France - burollet.gea@voila.fr

Abstract

Deep dessication in Western Mediterranean has been proposed in 1973 by W.B.F.Ryan and al. Leg. 13 of Joides. Subsidence in Tunisia was proven in Eastern Tunisia both in Kerkennah Islands (La Mer Pélagienne, Geol.Med.t VI.1.1979) and Eastern Tunisia on land and off shore.

Keywords: Messinian, Salinity

In Eastern Tunisia, South of Sousse, outcrops of Marine Messinian are known near Zeramedine and Bou Merdas with fossils including Bryozoa, Oysters and microfauna. They overlay the Tortonian Somaa sands and are followed by the continental Segui Formation Off-shore, above the Somaa sand there is a marine unit called Melqart Formation with a few beds of limestone and a rich Messinian microfauna. In the upper part it begins to be lagoonish with gypsum layers and is named Oued Bel Kredim Formation. They are overlain by the marine Early Pliocene Raf-Raf shale. In North East Tunisia (Bizerte and Raf-Raf area) the post-orogenic molasse presents above the Kechabta Tortonian detritic unit, the Oued Bel Kredim Formation: open marine at base with Messinian microfauna, it becomes lagoonish in the upper part and presents some lacustrine limestone layers. It is overlain, with angular unconformity, by the Early Pliocene Raf-Raf shale. It is evident that the presence of open marine Messinian sediments excludes the presence of deep holes with dessication in the Western Mediterranean. On an other hand, a thick sequence of Salt is known. The western Mediterranean was a lagoon with concentration of halite. The hypothesis of a deep dessication was due to an erroneous tectonic interpretation. In fact, there has been a regular subsidence during and after the salt sedimentation: a present rate of subsidence of 1 or 2 millimeters by year is known in numerous places around the Mediterranean.

MEDITERRANEAN DEEP ANOXIC HYPERSALINE BASINS: AN OVERVIEW

Claudia Elena Casalino¹*, Gert J. De Lange¹ and Sara Borin²

¹ Utrecht University, 3508 TC Utrecht, Netherlands - c.casalino@geo.uu.nl

² Consorzio Nazionale Interuniversitario per le Scienze del Mare (CoNISMa), Ulr Università degli Studi di Milano, 20133, Italy

Abstract

Several brine basins appear to occur in the deep waters of the Eastern Mediterranean. These are characterized by extreme environments with high pressure and density, redox conditions and saturated salt concentrations. These basins are probably the result of the dissolution of Miocene salt deposits that became exposed to seawater after tectonic activity. The high densities of the brine fluids contrast with seawater limiting the mixing with overlaying oxic seawater. As a consequence, isolated habitats evolved in which adapted microbiological life exists. Distinct differences occur between the various basins related to chemical composition and density. *Keywords: Anoxia, Eastern Mediterranean, Interfaces*

At the bottom of eastern Mediterranean Sea (~3500 m water depth) several deep hypersaline anoxic brine basins have been discovered in the last 30 years. Amongst these are : Atalante (AB), Bannock (BB), Discovery (DB), Nadir (NB), Medee (MB), Tyro (TB), and Urania (UB) all names after the ships involved in their initial discovery (Fig. 1). The general composition of the brine pools resulted from the dissolution of subterranean late-Miocene evaporitic salt deposits, underlying the Mediterranean sediments . It is most likely related to the collision of the African beneath the Eurasian tectonic plate [1, 2]. Alternatively the deep submarine basins might have been formed by accretionary processes and may have subsequently been filled with fossils and highly concentrated relics of Messinian water trapped in the interstitial area of the deep-sea sediments [3]. Waters enclosed in these depressions are characterized not only by high pressure and density, but also and for most by their redox state, lack of oxygen and saturated salt concentrations. Strong salinities and density gradients prevent mixing with the oxic seawater above and hence lead to stratification of the water column forming sharp and distinctive seawater/brine interfaces of 1 - to 2 m (Fig. 2). Moreover the elevated density and salinities basically tend to reduce biodiversity [4]. Despite these extreme conditions and the limited exchanges between brine and overlying seawater, anoxic basins are not biological deserts since several microbial communities appear to have developed under these conditions, usually considered as harsh [2]. In particular the oxic/anoxic boundaries are considered to be a hot spot for biological activity where the sharp redox potential differences create favourable conditions for different types of sequential metabolic processes [3]. The main microbial reaction in the lower part of the interface is thought to be the anoxic oxidation of methane (AOM) directly coupled to the reduction of sulphate (equation 1), where sulphide oxidation and possibly ammonia oxidation are more dominant in the upper reach of the seawater - brine interface (equation 2), according to the following equation [4]: $CH_4 + SO_4^{2-}$ à $HCO_3^- + HS^- + H_20$ (eq. 1) $HS^- + 2O_2$ à HSO₄-(eq. 2) According to the most recent bio-explorations the deep hypersaline basins are mostly dominated by Bacteria rather than Archaea with a great variety of microorganisms adapted to the different chemical interfaces composition. All brine basins show a relatively stable structure according to the geochemical composition and temperature gradient. Despite that, 3 specific lakes (AB, DB, UB) geographically close to each other (Fig. 1), show the largest differences in terms of geochemical composition and density. For instance in Urania concentrations of Methane and Sulfide are relatively higher, whereas the salinity is lower. The most remarkable difference is referred to the composition of Discovery mainly dominated by MgCl₂ in concentration considered as a limit for the life [6]. The existence of microbial life in such hostile environments suggests the high capability of microbial adaptation to salinity. It also hints to the possibility of life in other extreme environments such as the planet Mars, where the occurrence of high-salinity waters have been suggested [7]. The study of these brine basins is part of the European MIDDLE project with the general aim to investigate the extreme habitats of deep hypersaline basins of the Eastern Mediterranean Sea. Preliminary results from a multidisciplinary study of water and sediment samples collected during the 2008 DOPPIO cruise with RV Pelagia will presented.

Abstract

During the last two decades an increasing number of anoxic hypersaline lakes has been discovered in the eastern Mediterranean and characterized in successful EU projects such as PALAEOFLUX, MEDRIFF, SAP, and BIODEEP, and the French-Dutch MEDINAUT programme. Brine basins are extreme environments with one of the highest dissolved sulphide concentrations ever reported for the 'open marine' environment (up to more than 12 mM), and demonstrating large compositional differences between different brine pools: going from a nearly 5 M MgCl2 solution and below seawater Na content (Discovery Basin) to a nearly saturated 5.3 M NaCl solution(Tyro Basin). The recently discovered Nadir brine is high in NaCl, methane, and possibly sulphide, and seems rather 'recent'. The Medee Basin, recently reported, is also NaCl-rich. *Keywords: Eastern Mediterranean, Deep Sea Processes, Deep Sea Basins*

One of the most extreme environments thus far discovered is Urania Basin which contains the highest radiogenic supersaturations ever observed for the marine environment (3He / 4He of 1.10-7 and 40Ar / 36Ar of 470) [1], the most extreme d11B (28‰) [2], the highest methane content (> 260 μ l/ml), and the highest bottom water temperature (> 48oC). Irregular methane-driven mud-eruptions appear to occur from the latter bottom at least up to 600 m above the basin-floor, i.e. to a water depth of 2900 m. The composition of most of the brines seems to relate to a 'relict brine' or the dissolution of evaporites both originating from the Messinian period during which the Mediterranean is thought to have been desiccated (Bannock, Atalante and Tyro Basins). On the basis of various isotopes for most of these basins the 'relic brine' option seems the most plausible. In addition, the compositions of relevant major and minor elements appear to be in near coincidence with the theoretical seawater evaporation path. Urania brine is the most extreme exception to this picture, its major and minor element composition, but in particular its isotopic signature clearly relates to a source area that must be much deeper than that of the Messinian evaporites, and which is clearly influenced by high-temperature interactions with old sediment and volcanic units. In addition to their individual compositional characteristics, each brine demonstrates a typical and for most of them rather stable internal brine structure of various different brine levels. Subtle as well as outspoken temperature and compositional differences occur between the different brine levels in individual basins. The transition between different brine levels, and between brine and seawater may be relatively gradual but usually is extremely abrupt. In particular the seawater/brine transition is dramatic changing from seawater to 10x seawater concentration within a depth interval of 100 cm. The interface is further characterized by a strong dip in Transmission (= high suspended matter content, but possibly partly related to reflection of waters of different densities) [3, 4].

Abstract

The sediment of the shallow water areas of the Venice Lagoon was investigated by collecting 50 cm-long cores from 380 sites. Samples were analysed for heavy metal, polycyclic aromatic hydrocarbon (PAHs) and polychlorinated biphenyls (PCBs) contents. Pollutant concentration shows a wide variability both spatially and along the vertical profile, but not evident situation of acute contamination are observed. However, the contamination level of mercury deserves attention, its value resulting quite often above the NOAA-ERM limit.

Keywords: Metals, Pcb, Pah, Sediments, Lagoons

Sediments are widely recognized as a suitable medium for assessing environmental quality, as they both reflect and integrate contaminant inputs to the marine environment, thereby allowing sources and sinks to be investigated [1]. The lagoon of Venice is a coastal shallow waterbody with a surface of 550 km² and an average depth of about 1 m. The impact of the human activities affects the various shallow water areas to a different extent, in response to local water renewal and position with respect to the pollution sources. This study focused on heavy metals (Al, Cd, Cr, Cu, Fe, Hg, Mn, Ni, Pb and Zn), arsenic, polycyclic aromatic hydrocarbon (PAHs) and polychlorinated biphenyls (PCBs) distributions in the sediment of the whole lagoon. In 2008, fifty centimetres-long cores were collected in 380 sampling sites (Fig.1). Each core was sliced in five parts, obtaining 1900 samples corresponding to the following depth layers: 0-5 (named layer "A"), 5-10 ("B"), 10-20 ("C"), 20-30 ("D") and 30-50 ("E") cm. Metal concentrations were determined by inductively coupled plasma atomic emission spectrometry (ICP-AES) [2]. Concentrations of 14 PAHs (USEPA priority pollutants) and 7 PCB congeners (named indicator-PCBs) were analyzed in the 760 samples from layers "A" and "B" with high performance liquid chromatography (HPLC) and by capillary gas chromatography (GC), respectively [3]. Analyses of grain-size distribution and nutrient (C, N, P) contents were also performed. The obtained 3D dataset updates and upgrades the knowledge on the lagoon sediment characteristics, and permits to investigate their spatial and temporal variations as well as quality conditions with a great detail. Pollutant concentration shows a wide variability both spatially and along the vertical profile. Higher metal concentrations (particularly Cd, Cu, Hg, Pb and Zn) are found in the correspondence of knew sources (freshwater tributary inlets, industrial area, city of Venice), but also new situations of sediment contamination are evidenced in some areas. Mean concentration values calculated in the five sampling layers (Table 1) give a first picture of the contamination level of the whole lagoon sediment. For comparison, the table also shows the percentage distribution of concentration data measured in the 1900 samples with respect to the NOAA sediment quality guidelines (SQGs): effect range-low (ERL) and effect range-median (ERM) [4]. Arsenic, Cd and Ni concentration exceeds the ERL value in a significant number of samples (37%, 29%, and 16% respectively). However, the most relevant outcome is the high concentration of Hg, which exceeds the ERL and the ERM values in 76% and 27% of the samples, respectively. Concerning the two superficial layers, it is worth to observe that the mean concentration in "A" is lower by about the 10% with respect to "B", for all metals. Mean PAH and PCB concentrations, instead, do not show variation with the depth.

Abstract

The distribution of cold seeps in relation to the seabed tectonic features of the Calabrian Arc is examined using multibeam data.Integration of swath bathymetry with backscatter data indicates the presence of at least 40 seepage sites, recognized as subcircular to elongate high backscatter patches of varying form (*e.g. cones, calderas, domes, pies, scarps*). Many resemble mud volcanoes, proven at several sites by seismic and core data. Most cold seeps lie on the inner to central Arc, a distribution inferred to reflect the long-term dynamics of the accretionary prism.

Keywords: Mud Volcanoes, Swath Mapping, Active Margins, Geomorphology

A new Mediterranean cold seep province was discovered offshore southern Italy during the summer 2005 campaign of the Italian research vessel OGS Explora, which acquired the first regional multibeam coverage of the Calabrian accretionary prism [1, 2]. Detailed investigations at two sites provided seismic and sample evidence of tectonically-driven mud volcanism since the late Pliocene [3]. These two sites were further investigated during two campaigns equipped with remotely-operated vehicles (ROVs), which found seabed evidence of geological and biological seepage activity [4, 5]. Here we present new information regarding the wider distribution of cold seeps across the accretionary prism in relation to its main tectonic features.

Fig. 1. Distribution of seepage sites across the Calabrian accretionary prism as inferred from integration of multibeam swath bathymetry and backscatter data

Multibeam data across water depths of c. 1000-4000 m reveal the main seabed tectonic features of the Calabrian Arc, within three main zones [cf. 6]: inner forearc basins (Spartivento-Crotone), a central thrust-fold belt and the outer cobblestone area (underlain by Messinian evaporites). Integration of swath bathymetric and backscatter data indicates the presence of at least 40 sites of seabed seepage across the inner and central Arc, recognized as sub-circular to elongate high backscatter patches of varying form. Some features lie along linear trends that appear to correspond to seabed fault scarps. Many features have forms that resemble mud volcanoes (cones, calderas, domes, broad pies). Mud volcanoes (MVs) are proven at three main sites by cores of mud breccias, complemented by seismic profiles: the Madonna dello Ionio MVs (including three extrusive centres, 1.5-3 km in diameter), the Pythagoras mud volcano (a mud pie up to 9 km in diameter) and the Sartori MV (a small dome c. 1.5 km across). The latter is identified from cores of 'chaotic sediments' recovered in 1981 and originally interpreted as tectonic breccias [7]. The former two features have been shown to be the tops of subsurface extrusive edifices >1 km thick that record extrusive activity and subsidence over several million years, triggered by the rise of fluids from deep within the accretionary prism [3]. This model of tectonically-driven fluid escape is consistent with the

observed distribution of cold seeps, which (as on the Mediterranean Ridge) are absent on the outer Arc where thick evaporites have been incorporated into the accretionary prism.

Seabed investigations of the Madonna and Pythagoras mud volcanoes provide evidence of ongoing seabed seepage of gas (methane) and warm mud, in places supporting chemosynthetic ecosystems [4, 5]. Gas seepage is also indicated by acoustic data acquired by OGS in 2009 across a mud volcano 6 km offshore Catanzaro Marina (Calabria , Italy). At present we have no information as to how many other seepage sites on the Calabrian Arc are currently active, whether gas hydrates are present, the type and quantities of gases and/or fluids that are being released into the water column, or the forms of chemosynthetic microbial and macrofaunal life that may be supported by seabed emissions of hydrocarbons. Preparations are underway to undertake further multidisciplinary investigations of seabed hydrocarbon seepage in the Calabrian Arc cold seep province (OGS HYDROCAL proposal).

Abstract

Theseabed dynamics of the Ionian Calabrian Margin are currently being examined in the context of the project MAGIC (Marine Geohazards along the Italian Coasts). Multibeam and shallow seismic data show that the seafloor within X km of the Calabrian coast is characterized by the presence of canyons, slump, slides, diapirs, mud volcanoes and cold seeps. The presence of these morphologies, indicative of ongoing processes of sediment transfer and fluid flow, makes this area particularly interesting in relation to assessments of seafloor geohazards.

Keywords: Ionian Sea, Continental Margin, Geomorphology

The Ionian Calabrian Margin (ICM, Fig.1) is a tectonically active convergent margin, the structures of which reflect two main processes: frontal compression and fore-arc extension during the SE advance of the Calabrian accretionary prism since the late Miocene[1]; and a rapid uplift (up to 1 mm/yr) of onshore and shallow shelf areas since the mid-Pleistocene [2].

Fig. 1. Bathymetric map of the Ionian Calabrian Margin

The morphological expression of these processes at seabed is a broad, irregular offshore area that comprises the southern Apennine fold-and-thrust-belt, overlain southwards by the Spartivento-Crotone fore-arc basins. The IMC is currently being investigated in the framework of the MAGIC project (Marine Geohazards along the Italian Coasts). The objectives of the project are the definition of elements that may constitute geological risks for coastal areas. This study is based on geophysical data acquired by the r/v OGS Explora in summer 2005 in the framework of the WGDT project, carried out in collaboration with Universities of Calabria and Trieste, and in Spring 2009 in the framework of the MAGIC project. The dataset consists of a swath bathymetry DEM with variable cell size (5-50 m), plus Chirp sub-bottom profiles (2-7KHz) and available multichannel seismic (MCS) reflection data (Ministeriali Zona F) [3], [4]. The interpretative method adopted at OGS for MAGIC consists of mapping seabed morpho-bathymetric elements in relation to the acoustic facies of near-seabed sediments identified on the sub-bottom data. This allows the identification of the principal depositional and erosional features on the margin, as well as indicators of recent seismo-tectonic activity. This approach has been used to construct maps of morphological lineaments and units in order to assess principal sites of geological risk. Morphologically, the seabed of the ICM is characterized by a narrow (in places absent) continental shelf above depths of c. 150 m, above a slope of irregular morphology that extends to depths of 2000 m. In the north, the slope is broad and dominated by the ridges and intervening basins (e.g. Amendolara Ridge and Basin, Corigliano Basin), which are morphological expressions of the southern Apennine fold-andthrust belt. The fold-and-thrust belt is overlain to the south by the late

Miocene-Pleistocene deposits of the Crotone basin. The northern area includes two main canvon systems (Corigliano and Neto) that feed into the Taranto valley. The main geological risks identified along the ICM during the first two years of the MAGIC project are the retrogressive headwall activity of the Capo Colonna, Esaro, Neto, Punta Alice e Capo Trionto canyons along the southern part of the margin in proximity to the coastline. Other possible risks are are due to the presence of canyons, slump, slides, diapirs, mud volcanoes and cold seep and their relative proximity to the coastline.

PALYNOLOGICAL STUDY OF CLIMATIC AND OCEANIC VARIABILITY DURING "ROMAN WARM PERIOD" IN EASTERN MEDITERRANEAN

Liang Chen 1*, Karin Zonneveld 1 and Gerard Versteegh 1

¹ Fachbereich-5, Geowissenschaften, Universität Bremen, 28215, Bremen, Germany - lichen@uni-bremen.de

Abstract

Keywords: Primary Production, Paleoceanography, Temperature

To date there is a strong debate about the question if the current rise in global temperature is in range of the normal climatic "noise" or if it is a significant positive anomaly. A way to obtain more insight into this question is by studying past time intervals where potential analogue conditions existed. One of these time intervals is the "Roman Warm Period" (RWP: ~200 BC - 600 AD). Although it is generally thought to be an time interval where global temperatures were relatively high, reconstructions vary remarkably for different regions. Even within a region, reconstructions are not always uniform. For example, the SST in Bermuda Rise studied by Keigwin (1996) shows a temperature decrease between 200 BC and 200 AD. Mangini et al. (2005) and Taricco et al. (2009) also suggest a cold and dry period based on ¹⁸O isotopic records of stalagmite from the Central Alps and foraminifera from Central Mediterranean. However, a recent review (Reale and Dirmeyer, 2000) of Mediterranean climate history indicates a gradual warming during the Late Roman Period, and Sicre et al, (2008) reports SST between 0 and 100AD that are similar to those observed during the MWP from the Atlantic, off North Iceland. To obtain more insight into the climatic variability during the RWP there is an urgent need for highly detailed climatic reconstructions.

It has been proved that Mediterranean is a suitable area for paleoclimate studies as it is located between low and mid-latitudes and is influenced by both monsoonal and NAO climate systems. In this study we will present the results of a high temporal resolution study on the climatic and paleoceanographic changes during the "Roman Warm Period" in the Eastern Mediteterranian region (off southern Italy). Excellent time control based on AMS dating and tephra-chronology allows the establishment of three-annual resolution reconstructions. Detailed information about the variability in the organic dinoflagellate cyst associations of piston core DP30PC (39° 50.07' N, 17° 48.05' E, water depth 270 m) allows the reconstruct of short term climatic steered cyclic changes in upper water temperature, productivity and bottom water oxygen concentrations as well as of Italian local river discharge/precipitation signals. Possible mechanisms behind the observed records will be discussed.

Abstract

Fault motion and basin evolution in the Marmara Sea are 4 dimensional. The Sea of Marmara developed along the highly active, right lateral North Anatolian Fault, which produced devastating historical earthquakes along its 1600 km length. A cruise took place in July 2008 of high-resolution MCS data throughout the Marmara Sea under TAMAM (Turkish-American MArmara Multichannel) Project. Seismic sections across the Western Ridge, a transverse ridge separating the Tekirdag and Central Basins, show folding of strata above a blind thrust. Growth structures show that the eastern anticline of these folds is active and rapid subsidence and tilting in the Marmara Trough are responsible for widespread gravitational collapse. Keywords: Tectonics, Seismics

The Sea of Marmara developed along the highly active, right-lateral North Anatolian Fault (NAF), which produced devastating historical earthquakes along its 1600 km length. A cruise took place in July 2008 using the R/V K. Piri Reis collecting >2700 km of high-resolution MCS data throughout the Marmara Sea under TAMAM (Turkish-American MArmara Multichannel) Project. TAMAM was supported by NSF and used the facilities of Seismic Laboratory at Institute of Marine Sciences and Technology (Fig.1). The seismic source was 45-45 cubic inch GI gun, - fired every 12.5 m and sometimes 18.75 m. The streamer had 72 channels with a group spacing of 6.25 and a - maximum ofset of 55 m. The North Branch of the NAF accounts for most of the current plate motion and is associated with all three main basins in the Marmara Sea. Seismic sections across the Western Ridge, a transverse ridge separating the Tekirdag and Central Basins, show folding of strata above a blind thrust. Growth structures in the sediments show that the eastern anticline of these folds is active and probably propagating eastward above the blind thrust. Some profiles show that rapid subsidence and tilting in the Marmara Trough are responsible for widespread gravitational collapse. One of the major regions of geological interest is the area close to the North Anatolian Fault (NAF) where evidence of gas hydrates and fluid escapes have been observed during previous scientific cruises (Géli, L., et al., 2008). Helium gas, gas hydrate and oil leaks on western high and biogenic gas have been sampled in Cinarcik basin. Most of the gas appears to be focused on the Western and Central Highs and in the Imrali Basin. The near future goal of the demonstration mission project (MARMARA-DM) is to contribute to the establishment of optimized permanent seafloor observatory stations for earthquake monitoring in the Marmara Sea, as part of European Seas Observatory Network (ESONET) of Excellence Project (6th FrameWork Program of European Union) and includes high-resolution seismic surveys to image the fluid conduits in the upper (1 km) sediment layer.

THE MELILLA CARBONATE MOUNDS: DO DEEP-WATER CORAL MOUNDS COUNT ON SEEPING FLUIDS IN THE ALBORAN SEA?

Menchu Comas ¹* and Luis M. Pinheiro ²

¹ Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), Universidad de Granada, 18002, Spain - mcomas@ugr.es ² University Of Aveiro, Department Of Geosciences, 3810-193, Aveiro, Portugal

Abstract

A large cluster of Holocene to Present deep-water coral mounds -the Melilla Mound Field (MMF)- occurs in the southeastern margin of the Alboran Sea. High-resolution and multichannel seismic, side-scan swath bathymetry, acoustic sub-bottom profiling, and sampling have investigated the MMF. The mounds are ridge-like buildups 100–250 m wide, 2-6 km long, and 20–60 m (up to 200 m) high above the seabed, which lie in water depths ranging from 230 to 500 m. Sampling proves that mound are largely formed of cold-water corals with a muddy matrix. Seismic profiles across the MMF show that faults exist beneath the mound-ridges, so that mounds nucleation would have influence from fluid venting via fractures that may leak thermogenic gas or cold hydrocarbon seepages in addition to any likely oceanographic control in mound's origin.

Keywords: Alboran Sea, Bio-Accumulation, Deep Waters, Sediments, Seismics

A cluster of Holocene deep-water carbonate mounds -the Melilla Mound Field (MMF)- was discovered in the southeastern margin of the Alboran Sea (Morocco margin) during the MARSIBAL-06 Cruise (R/V BIO Hespérides, 2006) [1]. The carbonate-mound field was revisited and sampling during the TTR-17 Leg 1 survey [2]. The MMF occurs from the upper to the middle slope, with NW-SE trending, on a gentle-dipping margin segment and covers an area of more than 20 km². Deep-water carbonate mounds, comparable to those of the MMF, have not been documented before in the Alboran Sea. Swath bathymetry, acoustic sub-bottom profiling, high-resolution MAK-1 side-scan sonar, multichannel seismic, high-resolution seismic, and coring have investigated the MMF Seafloor mounds appear as ridge-like buildups 100-250 m wide, 2-6 km long, and 20-60 m (up to 200 m) high above the seabed; which lie in water depths ranging from 250 to 500 m. They are also surrounded by elongated erosional moats, probably caused by bottom currents on the sea floor, which are 5-10 m deep and 50-100 m wide. Some ridges have no linear but branched shapes. Buried or partly buried mounds, as showed by sub-bottom profiles, are elongated and domed families of buildups (transparent acoustic facies) rooted on highly reflective sedimentary layers and surrounded by dark reflective moats, with dome-size increasing seaward. They grow beneath the upper slope off the shelf break (water depth from 230 m), producing bulges in the seafloor, and give way to seabed mounds with depth. At least three generations of successive mound-growth families are observed. Some ridged-mounds nucleated upon former ones so that buried constructions (columnar appearance in acoustic sections) grow up to 160 m high. The internal architecture of mound-cluster prograding seawards suggests that mounds developed during a period of sea-level drop or slope tilting. Sampling by coring, TV grab and dredging during TTR-17 Leg 1 encountered that mounds are formed of biogenic accumulations made up of corals (Madrepora occulata, Caryophyllia sp, Desmophyllum sp, Lophelia pertusa) and other common associated fauna. Colonies of dead scleratinean corals and a diverse community dominated by soft corals, sponges and asteroids were observed in TV runs. So that it is proved that mounds from the MMF correspond to modern cold-water carbonate knolls The MMF occurs about 200 km to the east of the Alboran Mud Diapir Province were mud volcanoes, pockmarks fields, seepages (methane) and fluid vents are well documented as controlled by recent or actual tectonics. The geological setting indicates the entire Alboran Basin, which is depleted of Messinian evaporites, is affected by a significant Plio-Quaternary and still active wrench tectonics producing local subsidence and uplifting. Seismic profiles across the MMF show that faults exist beneath the mound ridges, so that we propose and argue that in addition to probable oceanographic control, mounds nucleation may have some influence from fluid venting via fractures that may leak thermogenic gas or cold hydrocarbon seepages. in addition to any likely oceanographic control in mound's origin. Abstract

This study aims to better understand the processes of formation and evolution of six submarine canyons along the western margin of the Ligurian Basin, in relation to the regional geological context and to do a comparative preliminary analysis with the Calabrian Margin.

Keywords: Geomorphology, Continental Slope, Continental Margin, Ligurian Sea, Sediment Transport

Sediment transfer from continental shelves to deep-water basins is an important control on the morphological and architectural evolution of continental margins. Downslope transfer of sediments via processes of erosion and deposition result in the construction of typical features such as submarine canyons. This study aims to better understand the processes of formation and evolution of six submarine canyons along the western margin of the Ligurian Basin, within an offshore area extending from Nice (France) to Imperia (Italy). Processes of slope failure are analyzed within the same zone in order to investigate a wide range of gravity-driven sediment transfer processes.

Analyses of seabed morphology, subsurface structures and present-day sedimentary processes are based respectively on swath bathymetric data, seismic-reflection profiles (24-channel) and side-scan sonar imagery, acquired during the MALISAR 1 and 2 surveys. These data allow an analysis of the main geometric characteristics of the canyons and of failure scars (width, depth, incision shape), and of their internal structures, in order to better understand their origin, construction mechanisms and evolution in relation to the regional geological context. We show that submarine canyons adjust to the general evolution of the margin topography, via processes including regressive erosion and deviation of the thalweg axis. Canyons can therefore be used as markers of deformation of the Ligurian Basin margin, which is an example of a passive margin that has been reactivated in a compressive sense since later Pliocene time. Deformation of the Ligurian Basin increases eastward and basinward, in response to uplift of the Ligurian coast. Thus, canyons in the west are considered as mature canyons, with concave longitudinal profiles, their upper parts characterized by V-shaped thalwegs (in cross-sections), and high slopegradients, while their lower parts by U-shaped and low slope-gradients. In contrast, canyons in the east present convex longitudinal profiles and V-shaped thalwegs (in cross-sections), with increasing slope-gradients towards their lower parts, and are described as immature canyons that are being readjusted by regressive erosion.

A similar study is in progress for the Ionian continental margin of Calabria, using similar data to undertake a first analysis of slope-to-basin sedimentary processes over Pliocene timescales. This will facilitate a comparative analysis of these two tectonically active margins, the Ligurian Margin (passive margin reactivated in compression) and the Calabrian Margin (active subduction margin).

EASTERN MEDITERRANEAN ANAXIMANDER AND NILE MUD EXPULSION STRUCTURES: DEEP ORIGIN FOR FLUIDS AND GASES.

Gert J. De Lange ¹*, Vincent Mastalerz ¹ and Anke Daehlmann ¹ ¹ Geosciences, Utrecht University, 3584CD, Netherlands - gdelange@geo.uu.nl

Abstract

Mud expulsion structures occur in eastern Mediterranean Passive and Active Margin settings. Active structures have major fluxes of methane and also higher hydrocarbons. The porefluid and hydrocarbon isitopic composition idicate a deep source for the water and for the gases. Variable salinities of the porefluids are encoutered as related to the presence or absence of underlying Messinian evaporites.

Keywords: Active Margins, Passive Margins, Eastern Mediterranean, Mud Volcanoes

In the Eastern Mediterranean not only the Mediterranean Ridge (Äctive Margin") but also the Nile Fan area ("Passive Margin") are characterized by active mud expulsion structures. These structures at Anaximander area and Nile fan have been sampled for the integrated study of fluid and gas systematic, including the potential occurrence of Gas Hydrate (GH). At Anaximander, the active top part of mud volcanoes is usually characterized by fluids of reduced salinities (~10 ‰), whereas in the Nile area, these structures have fluids of near-normal salinity to brine composition (> 300 ‰). The low salinity waters are related to deep dewatering during smectite-illite transition, whereas the high salinities result from dissolution of underlying Messinian evaporites [1]. It seems therefore, that the salinity of the advecting fluids is dramatically different between the two areas, whereas the measured methane concentrations are similar, ranging from 1 to 3 mM for Anaximander and from 1.5 to 3.5 mM for the Nile area. In addition, in both areas but in particular that of the Nile, major expulsions of gas occur into the water column [2,3]. In the Anaximander area low sub-bottomwater temperatures occur associated to GH decomposing during recovery, whereas in particular the Cheops and Chefren mud volcanoes in the Nile area have enhanced salinities & temperatures being 150 ‰ & 57°C at Chefren and > 300 ‰ & 37 / 25°C at Cheops. The latter two mud volcanoes situated inside the large Menes Caldera, 8 km diameter, have a distinct chimney-like brine/mud pit. Inside these muddy brine structures, the liquid mud has been sampled for gas, and for porewater. At both sites, the profiles are rather constant with depth and do not differ between cores and accompanying brine-CTD's. The depth of the brine is approximately 300 meters at Chefren and 10 meters at Cheops, which needs to be compared to a 80 m depth of the Menes Caldera itself. Concurring with the enhanced temperatures, the Si concentration in the cores has higher values at Chefren (500-600 μ M) and lower values at Cheops (300 μ M). Hydrogensulfide was found in higher concentrations in the central cores of Chefren MV (up to 1.5 mM), and only in minor amount at Cheops. Two camembert-like more shallow structures have also been studied in detail: Isis and Amon mud volcano (MV). IN the central part of both MV's methane has similarly high concentrations af for the earlier mentioned sites, but salinity is below normal for Isis and slightlyl above normal for Amon. It is in particular the high sulphate that is remarkable for the latter, pointing to a gypsym evaporate contribution. This results in the peculiar co-occurrence of high methane and sulphate within these sediments, where only in the topmost interval methane is noticeably being degraded [3]. This work is supported in part by the EUROMARGINS Programme of the European Science Foundation (NWO 855.01.032, MEDIFLUX project) and the EU ANAXIMANDER project (EVK-2001-00123).

Abstract

Initial deposition and preservation of the most recent sapropel S1 took place basin-wide and iso-chronous. Our basin-wide approach further elucidates that the watercolumn below ~ 1.8 km must have remained predominantly anoxic during sapropel S1 deposition. A marked Mn-rich sediment bed formed during the onset of reventilation at the end of sapropel S1. Its postdepositional preservation is dependent on organic matter and sulphide content and subsequent sedimentation rates. Keywords: Sediments, Paleoceanography, Deep Sea Processes

Mediterranean marine deposits found on land and at the seafloor, all demonstrate a clear cyclic pattern in their composition that appears related to Milankovitch astronomical variations [1-2]. The clear expression of these climate cycles in Mediterranean deposits in particular is partly related to restricted circulation in this semi-enclosed ocean basin. This restricted circulation results not only in a delicate oxygen balance, but also in a bottomwater formation and residence time that is very sensitive to Global climatic variations in past, present, and future. Variations in riverine fluxes concording with humidity-related climate cycles not only lead to variations in bottom water conditions but also in nutrient fluxes [3]. These variations have resulted in alternating organic-rich (sapropels) and organic-lean (marls) sediment intervals. This astronomical cyclicity serves as a perfect time-marker for Mediterranean Miocene to recent sediments, which permits an unprecedented comparison of samples in identical time-slices but from different locations. Some of these organic-rich units have a high degree of lamination [e.g. 4], thus permitting high-resolution studies, whereas the sedimentary expression of precessional cycles, volcanic ash layers and other time markers permit a high degree of age control. Potentially basin-scale reconstructions are possible for such time-slices, in particular for the most recent S1 period [5]. Such reconstruction may not only involve the oceanographic aspects of this model-ocean, but also the various land-ocean interactions, such as riverine and eolian inputs from various surrounding landmasses [6].

Fig. 1. In dark grey: deep water, thought to have been (nearly) permanently anoxic during sapropel S1 formation (5.7-9.8 ka 14C BP); Analysed core sites are indicated.

As a consequence, climatic variations are accurately recorded not only by giving variations in typical 'marine' signals, but also in typical 'continental' signals. The 'Monsoonal index' is strongly associated with the paleoclimatic conditions in the area around the Eastern Mediterranean, i.e. Sahara/ Africa, Middle East, Southern Europe. This association is clearly present in its sediments, mainly in a ~ 21 kyr precession-controled cycle: during 'humid' climatic periods organic-rich sediment (Sapropel) is deposited containing strong river and marine productivity signals, whereas during 'arid' climatic periods organic-lean sediment is deposited containing high dust input signals. As a consequence of the increased fresh water (monsoon) input between 10.4 - 5.0 14C ky BP, sapropel S1 formed basin-wide synchronously between 9.8 and 5.7 14C ky BP at all water depths greater than a few hundred metres [5]. Another effect of the increased precipitation over evaporation is water-column stratification, and the resulting restricted deep-water ventilation. This has caused predominantly anoxic water column conditions and as a consequence preferential preservation of organic matter has occurred below 1.8 km during 4,000 years of S1 formation (Fig. 1). Several diagenetic features are associated to sapropels, during their formation and during subsequent more oxic environmental conditions [7]. During sapropel formation the downward export of excess sulphide has resulted in an interval of reduced sediment immediately below S1 [8], whereas the post-depositional excess oxygen content has resulted in the downward removal of the topmost S1 interval [e.g. 9]. In addition, the deep-water reventilation thus re-oxygenation event has resulted in a marked MnO2 bed (previously referred to as Marker Bed; [10]). Using the S1 as a case study similar features can be recognized in older sapropel units.

Abstract

During four cruises within the ADRICOSM-STAR project high-resolution CHIRP profiles, morphobathymetric data and bottom samples were collected along the seismically active Montenegro and northern Albanian margin. Preliminary analysis of our data suggest that seismogenic structures are marked at the seafloor by morphological features due to deformation of the sediments and possibly to fluid and gas escape.

Keywords: Adriatic Sea, Continental Margin, Geophysics, Tectonics, Bathymetry

The Montenegro coastal region is characterized by intense seismicity and by the occurrence of large historical earthquakes, such as the Great Dubrovnik Earthquake (M=7, 6 April 1667), the June 13, 1593 event (M=6.5), with epicenter located close to Kotor, and the June 1, 1905 event, with epicentre near Skadar. The last large earthquake affecting the region is the M=7.1 (15 April 1979) whose epicentre was located fifteen kilometers from the Montenegro coast between Bar and Ulcinj (Fig.1). This last event stressed the importance of studying the Montenegro offshore to localize seismogenic features and trying to understand their behaviour in time. The Montenegro offshore and coastal area has been included in the northern segment of the Ionian-Adriatic coastal earthquake belt ([1]). This area constitutes the eastern boundary of the Adria microplate, a block of continental lithosphere presently colliding with the Dinarides chain since the late Miocene ([2], [3]); it constitutes the most external sector of the chain. Along the Adriatic coast of Montenegro, the 200 km-long plate boundary consists of a WNW trending thrust belt (Fig. 1), cut by NS and rarely ENE oriented strike-slip faults which laterally segment the major thrust front ([1], [2], [4]).

Fig. 1. Structural map of the Montenegro margin ([4] modified). Circles indicate local seismicity and main historical events ([5]). Boxes indicate areas where morphological features possibly related to tectonic deformation were observed

Despite its geological interest and the high seismic hazard, the Montenegro offshore has been poorly investigated in the past, if we exclude extensive multichannel seismic reflection surveys carried out by oil companies, not available to the wider scientific community, and few seismic lines collected during the '90 in the Albania offshore ([3]). During 4 oceanographic cruises, carried out from May 2008 to July 2009 with the Italian CNR research oceanographic ships Urania and Mariagrazia in the frame of ADRICOSM-STAR project (ADRIatic sea integrated COaStal and river basins Management system: Montenegro coaSTal ARea and Bojana river catchment), we collected a set of marine geological and geophysical data offshore Montenegro and northern Albania. Our dataset includes high-resolution seismic reflection profiles and multibeam morphobathymetric data, as well as several sediment samples, gravity cores, grabs, and box corers collected in key areas, selected through interpretation of geophysical data. The sediment accumulation in the coastal area is variable along the margin, probably due to the effect of strong alongshore bottom currents. First results from combined interpretation of seismic profiles and sediment samples suggest that wide areas in the shelf are presently starved, and LGM (Last Glacial Maximum) sedimentary features,

such as dunes and sand ridges are present on the seafloor. These features are mostly observed in the bathymetric range 60-120 m and are mainly made of relict coarse sandy material that seems to be cleaned by bottom current reworking.

Fig. 2. Morphobathymetric image of compressive deformation along the margin. See figure 1 (box 1) for location

Typical geo-morphological and structural features observed along the margin through integrated analysis of seismic reflection profiles and high resolution bathymetric maps are: 1) hundreds-meter scale bathymetric swells, possibly interpreted as mud volcanoes; 2) elongated, heavily deformed ridges, marking compressive deformation fronts (Fig. 2); 3) rectilinear scarps offsetting the seafloor. All of these features appear aligned with regional tectonic boundaries, described by several authors ([1], [2], [4]) and are thus probably genetically controlled by deep-seated faults. Moreover, a correlation between these features and local seismicity (moderate to large historical earthquakes and recent events) is also observed ([5]). Preliminary analysis of our data suggest that seismogenic structures along the margin, such as thrusts and strike-slip faults, are marked at the seafloor by morphological features due to deformation of the sediments and possibly to fluid and gas escape. This very preliminary results need to be confirmed by further analysis and collection of new data along the margin.

Abstract

The Nile Deep Sea Fan hosts numerous active fluid escape structures associated with large gas emitting mud volcanoes, authigenic carbonates, pockmarks and briny mud volcanoes. During the Medeco2 expedition (HERMES Program), some of these seeps were investigated with the research vessel Pourquoi pas?. Subbottom profilers and water column imageries were acquired with a CHIRP and an EA600 echosounder. Near bottom geophysical investigations were conducted with the use of the Victor ROV that was equipped with 1) a Reson 7125 multibeam system for high-resolution bathymetry and backscatter seafloor imagery and 2) an OTUS camera for black and white imaging. We present here the geophysical characterization of the large mud volcano Menes caldera complex located in the Western Nile Province.

Keywords: Deep Sea Processes, Eastern Mediterranean, Geophysics, Mud Volcanoes

The Menes Caldera discovered on the foot of the northwestern Egyptian continental slope [1, 2] was surveyed in 2007 in great details with in particular the use of the Victor ROV for near bottom geophysical surveys and in situ samplings and measurements. The dataset previously acquired [1, 2] was completed by geophysical imageries of the sediments, the seabed and the water column.

Extending by 3000 m water depths with a diameter of \sim 8 km, the Menes Caldera contains several active mud volcanoes. Chephren and Cheops mud volcanoes located in the south and roughly in the centre of the caldera, respectively, are the most spectacular.

The Chephren structure is composed of two craters of 250 to 300 m in diameter each. The northern crater is filled up with muddy brine sediments. Within this brine lake, salinity reaches high values (120 to 145 psu). Gas analysis in the water column revealed high methane concentrations, 0.4 to 5.6 mmol/l. The temperatures within the lake indicate uniform values with depth, reaching ~60°C. In contrast, the southern crater is relatively cold with thermal gradients similar to background values. This crater 10 to 20 metres deep corresponds to a former brine lake that is at present inactive in terms of brine seepage. Running outflows emitted from the northern brine lake are visible all around the mud volcano with the most recent activity located at the northern side. The seepage activity there corresponds to highly unstable seafloor environment. The fauna is mostly restricted within the close periphery of the brine lake. The small and narrow subcircular plateaus that composed the upper part of the crater attracts many crabs and polychaete tubeworms. Within the brine lake, the less unstable areas appear to be characterized by dense accumulation of white filaments that correspond to sulfur associated with arcobater, sulphide oxidizing bacteria (Boetius et al.).

Cheops mud volcano, similarly to Chephren, exhibits high salinity values and methane concentrations (respectively 210 to 240 psu and 2.4 to 3.7 mmol/l). Cheops mud volcano, with an average diameter of ~250m, is composed of a brine lake surrounded by an almost continuous depression ring, covered in some places with recent outflows. This latter probably corresponds to a former edge of the lake. As previously suspected by [2], the inner domain of this mud volcano correlates with an almost flat top where numerous muddy brine pools, decimetre to metre in scale and covered by whitish filaments, were observed at the surface of the lake. An average temperature of ~43°C was recorded from the surface of the lake down to 440m through a very unconsolidated material. The uniformity of the temperature profile with depth clearly supports the occurrence of first order active convection within a mud/brine/fluid conduit.

The newly acquired geophysical dataset and high-resolution seabed photographic images brought more details, in particular, in the seabed morphology and spatial distribution of the seepage activity. The seepage activity is not restricted to the major mud volcanoes. The entire caldera is disturbed by fluids associated in depth with numerous faults and fractures and at the seabed with brine-related features. Acoustic anomalies were detected in the water column using the 38 kHz echosounder of the R/V Pourquoi pas?. An echo contiguous to the seafloor was recorded up to 600 m above the seafloor at the south-western border of the Menes. This acoustic anomaly is interpreted as a gas flare associated with a listric fault in relation with salt

INVESTIGATION OF SEISMO-GEOMORPHOLOGIC FEATURES OF FLOWER ISLANDS FAULT OF THE GULF IZMIR

Can Eytemiz ¹*, Atilla Ulug ¹ and Faik Erdeniz Ozel ¹

¹ Dokuz Eylul University Institute of Marine Sciences and Technology, 35340, Izmir, Turkey - can.eytemiz@deu.edu.tr

Abstract

Gulf of Izmir is located within a weakness zone known as Izmir – Balikesir transfer zone which is dominant by strike-slip faults. This zone's last activity has verified by 17-20 October 2005 dated "Gulf of Sigacik Earthquakes". The aim of our study is to investigate the seismo-geomorphologic features of Flower Islands Fault which we consider as a part of this zone. *Keywords: Geophysics, Hydrography, Aegean Sea, Seismics*

The relation between gulf's seabed deformations and regional stress fields is known from Ocakoglu ve dig. [1]. Large numbers of strike-slip faults are indicated in the region according to their multi-channel seismic studies in the Gulf of Izmir and Gulf of Kusadasi. The cinematic analysis studies of the Gulf of Izmir and it's environs show a NNE – SSW directed expansion and WNW – ESE directed compression during the Quaternary – Holocene period [2]. The region changes it's shape under the influence of the transtensional tectonic regime in which NE and NW directed faults work together. Approximately N-S directed Flower Islands Fault is a fault which is located in this tectonic system. In this study, multibeam sonar (240 Khz – 480 beams), sub-bottom profiler seismic (3.5 Khz) and magnetometer methods are conducted to determine the fault with it's geomorphologic features (Fig. 1).

Fig. 1. Seabed surface fracture of the Flower Islands Fault.

Our reviews show a surface fracture of the fault more than 12km and a vertical component more than 2m - 3m. Seismological fault analyses are still being performed for the determination of the fault's other properties.

Abstract

Wave climate exerts a significant influence on the development of Holocene sedimentary prograding wedges. This is demonstrated by the fact that near-bed orbital velocities between 0.10 and 0.14 m/s (threshold for resuspension) occur in the vicinity of the infralittoral prograding wedges (IPW) offlap-breaks during storm-weather conditions, but during medium wave energy conditions in the case of prodeltaic wedges.

Keywords: Alboran Sea, Continental Shelf, Waves, Sediment Transport

Introduction

Holocene prograding wedges are sigmoidal-shaped sedimentary bodies located between the infralittoral zone until the mid continental shelf. They are basically composed both infralittoral and prodeltaic wedges depending if littoral and fluvio-deltaic processes are dominant. The offlap-break determines an important physiographic change in the morphology of these aforementioned wedges and its depth in the infralittoral wedges has been related with the mean level of the storm wave base ([2],[1]).

Fig. 1. Near-bed orbital velocity distribution in the study area.

Inner and middle shelf persistenly undergo bed stress exceeding the threshold of sediment motion. The magnitude and frequency of sediment transport , testing its role in the offlap-break point location.events are critical controls on the intensity of physical reworking ([4]). In this contribution, we aim to understand the controlling effect of different wave base levels on the prograding wedges deposits processes and evolution

Methods

Wave-generated near-bed flows are dependent on wave height, H, period, T, wavelength, L, and water depth, h. Near-bed wave orbital velocities (U_b) at the seabed have been calculated by using the following equation ([3]):

$U_b = H/T \sinh(2\pi h/L)$

Three energetic wave levels have been used off the coasts of east-southern lberia (Figure 1), following the classification by Ortega et al. (2004), to calculate U_b : a) High-energy storm conditions, with H=3.5 m and T=8 s (Figure 1); b) Medium-energy, for 50th-percentile of the wave height, with H=1.5 m and T=7s; c) Low-energy fair-weather conditions, with H=0.75 m and T=4s. Water depth values (h) were collected with a 300 kHz Simrad EM3000D multibeam echosounder.

Results and discussion

Near-bed orbital velocities can be used to identify wave-driven sediment transport at a site given representative erosion thresholds. In the study area, those near-bed orbital velocities range between 0 and 1.33 m/s, with maximum values occurring over the topsets (Figure 1 and 2). Bottom wave velocity thresholds for resuspension range between 0.10 and 0.14 m/s, corresponding to bed shear stresses of 0.1-0.2 N/m² ([5]). The spatial distribution of this velocity interval correlates with IPW offlap-break location during highest stormy conditions, and with the offlap-break location of prodeltaic wedges during medium-energy conditions. This important difference must be due to the fluvio-deltaic processes dominance in the prograding wedges evolution, which determined differences on sediment supplies and sediment grain sizes.

Fig. 2. Near-bed orbital velocity for three different wave conditions and water depth profiles in two locations of the continental shelf. A) Prodeltaic wedge. B) Infralitoral prograding wedge.

Conclusion

Wave energetic conditions have control the Holocene sedimentary prograding wedge morphology and evolution, since they conditioned the offlap-break position in time.

Abstract

An integrated approach, combining the directly measured individual radium contributions and hydrodynamic model results, allowed for the calculation of the mass balance of naturally occurring short-lived Ra isotopes (^{223,224}Ra) in the Venice Lagoon. Hydrodynamic data allows for the calculation of the Ra mass balance in sub-areas of the Venice Lagoon, which are characterized by physically homogeneous properties, instead of the entire lagoon. Both the seasonal and spatial variability of the submarine groundwater discharge (SGD) in the Venice Lagoon were investigated. SGD estimates were correlated with the residence time calculation to better understand spatial and seasonal variation.

Keywords: Circulation Models, Hydrology, Lagoons, Water Transport

Introduction - Methods

Submarine groundwater discharge (SGD) has gained increasing attention, both from the scientific community and coastal resource managers over the last decade [1]. Previous investigations showed that SGD plays an important role in the physical and biological properties of the Venice Lagoon ecosystem [2, 3]. In this study we extended the investigation of SGD to the whole lagoon, through the use of Ra measurements and hydrodynamic modelling. The mass balance for Ra can be expressed by the equation:

 $L_{out} + L_{decay} = L_{in} + L_{river} + L_{diff} + L_{marsh} + L_{desorp} + L_{SGD} (1)$

which considers the different Ra sources and sinks from the lagoon: water exchanges at the inlets (Lin, Lout), river discharge (Lriver), desorption from sediments (L_{desorp}), diffusion from sediments (L_{diff}), percolation of porewater from marshes (L_{marsh}), and SGD (L_{SGD}). Each of these contributions were calculated by using the experimental data obtained from an extensive field and lab campaign (APAT research project "Afflusso di Acque Sotterranee in Laguna di Venezia", 2005-2008) and the application of a hydrodynamical model (SHYFEM), as described by Ferrarin et al. [4]. The lagoon was divided into 4 sub-basins with similar physical characteristics to better characterize SGD using the ^{223,224}Ra mass balance and to allow a more precise estimate of the fluxes from the different sub-basins and through the inlets which connect the lagoon to the Adriatic Sea. Integrating the results of the hydrodynamic model and the point measurements of Ra enabled the calculation of the different sources of Ra for each sub-basin in every season and the volume of the flux associated with SGD. The Ra mass balance calculation utilizes the hydrodynamic information and was effective for both ²²³Ra and ²²⁴Ra. In addition, the application of the hydrodynamic model and a transport model allowed for the calculation of the residence time in each sub-basin per season.

Results

Surface distribution of ^{223,224}Ra showed significant seasonal variation during the six surveys, however, in general, the spatial pattern of distribution within the lagoon was similar with higher activities in the northern and southern subbasins. In all seasons activities were elevated in the lagoon as compared to river and open Adriatic Sea waters. 224Ra activities were much lower, throughout the lagoon, during the winters of 2007 and 2008 (avg. 43 ± 21 and 55 ± 27 dpm 100 L^{-1} respectively) than during the falls of 2006 and 2007 (avg. 75±52 and 90±33 dpm 100 L⁻¹ respectively), the spring of 2007 (avg. 108±41 dpm 100 L⁻¹), and the summer of 2007 (avg.108±65 dpm 100 L⁻¹). ²²³Ra activities were lower in the winters of 2007 and 2008 (avg. 2.8 \pm 1.4 and 3.2 \pm 1.6 dpm 100 L⁻¹ respectively) than in the falls of 2006 and 2007 (avg. 4.9±2.8 and 6.4±3.1 dpm 100 L^{-1} respectively), the spring of 2007 (avg. 6.3±3.3 dpm 100 L^{-1}) and the summer of 2007 (avg. 5.4 ± 3.6 dpm 100 L⁻¹). The activities of ²²³Ra in lagoon waters show a similar pattern. Average ^{233,224}Ra activities for the whole lagoon in all seasons are 4.8±3.5 and 79.1±43.6 dpm 100 L^{-1} . The results of the hydrodynamic model show that the residence time of the lagoon has an average value of 7.7±4.6 days and has a marked seasonal variation. The average and standard deviation of the water residence times in the four sub-basins are 8.8±3.6 and 4.9±2.8 days for the two northern sub-basins, 8.3±4.8 and 5.9±3.1 for the central sub-basin and southern sub-basin. More than half of the total Ra entering the lagoon cannot be accounted for by the inputs detailed above and the significant excess of short-lived Ra observed in the Venice Lagoon can, reasonably, be attributed to submarine groundwater discharge. The calculated

total input of groundwater into the Venice Lagoon is 43±25 and 40±17×109 L d⁻¹ using the ²²³Ra and ²²⁴Ra mass balance respectively. Remarkably, both ²²³Ra and ²²⁴Ra suggest that SGD accounts for 6% by volume of all water flux into the lagoon. Fig. 1 shows the pattern of clear seasonality in the Venice Lagoon. The discharge calculated by both short-lived isotopes is lowest in winter, and higher in spring, summer, and fall. Some divergence occurs between the isotopes in the spring and summer of 2007 which is likely a function of residence time. It is possible that the same forces that determine residence time also drive a re-circulation of seawater through the sediment as there is a strong inverse correlation between residence time calculated using a hydrodynamic model and SGD as calculated by the Ra mass balance method (R2 values are 0.85 and 0.66 for ^{223,224}Ra respectively.

Fig. 1. Seasonal SGD (223Ra and 224Ra) and residence time (dashed line) variation in the Venice Lagoon

LONG-TERM SEDIMENT TEMPERATURE OBSERVATION REVEALS RAPID COOLING AFTER A RECENT ERUPTION AT NORTH ALEX MUD VOLCANO ON THE WESTERN NILE DEEP-SEA FAN

Tomas Feseker¹*

¹ IFM-GEOMAR, 24103, Kiel, Germany - tfeseker@ifm-geomar.de

Abstract

The West Nile Delta Project at IFM-GEOMAR aims to analyze the relationship between deep gas reservoirs and mud volcanoes on the western Nile deep-sea fan. Long-term monitoring of sediment temperature as an indicator of fluid seepage and mud expulsion at North Alex mud volcano revealed that infiltration of cold bottom seawater accelerates the cooling of the sediments after an eruption and points to rapid transitions between extremely active and dormant stages of this mud volcano. *Keywords: Mud Volcanoes, Nile Delta, Temperature, Models*

North Alex mud volcano (MV) is located on the upper slope of the western province of the Nile deep-sea fan at a water depth of around 500 m. It is a circular structure with a diameter of less than 2 km and an elevation of nearly 50 m above the surrounding seafloor at its highest point. The central plateau is characterized by gentle slopes towards a steep edge of about 40 m height, which separates the central mud pie from a surrounding moat. Based on a geophysical mapping campaign, North Alex MV was described as a deeprooted active gas chimney that may have triggered slope destabilization associated with significant northward sediment flows and slumps, following the local slope gradient [1]. Further investigations in 2003 showed a moderate sediment temperature anomaly of around 0.8 °C/m and sporadic gas ebullition at the center [2], indicative of a minor level of activity.

More recently, North Alex MV has been the focus of the West Nile Delta Project at IFM-GEOMAR, aiming to study the relationship between deep gas reservoirs and mud volcanoes on the Nile deep-sea fan. A first detailed assessment of the sediment temperatures in the mud volcano during the P362-2 cruise of R/V Poseidon in February 2008 revealed extremely high temperatures of up to more than 70 °C at around 6 m below the seafloor (mbsf) at the center, corresponding to temperature gradients of more than 10 ° C/m [3]. The focus of the temperature anomaly was found at the highest point and the temperature gradients decreased rapidly towards the flanks of the mud volcano, such that the temperature gradient generally correlated with the morphology. Particularly in the central area, however, the sediment temperature distribution was heterogeneous, which suggested a very recent eruption.

A second assessment of the sediment temperatures at North Alex MV was conducted during the 64PE298 cruise of R/V Pelagia in November 2008 [4]. While the sediment temperatures at the center had remained as high as 9 months before, the outer parts of the plateau had cooled significantly and the lateral extent of the main temperature anomaly had decreased by around 50 percent. Using an ROV, numerous gas seeps were observed in the central area of the mud volcano, where a very rough morphology of the seabed with fresh cracks and superficial faults pointed to recent mud eruptions. During the same cruise, an uncabled seafloor observatory was installed close to the center of North Alex MV. Bottom water temperature and pressure, temperature at the seabed, and sediment temperature down to a depth of 5 mbsf is recorded at an interval of 30 minutes in order to monitor the activity of the mud volcano.

The first data from the observatory was obtained via an acoustic link to the R/V Poseidon during the P388 cruise in July 2009 [5]. Unfortunately, due to a malfunction in the modem software, the time series could not be downloaded completely. However, the currently available sediment temperature data documents clearly that the temperature of the sediments decreased more rapidly than by simple conductive cooling in contact with the relatively cold bottom seawater. The most likely explanation for the accelerated cooling is the infiltration of seawater into the mud volcano sediments. This hypothesis is supported by several concave-upward shaped sediment temperature profiles measured on the central plateau, which also indicate downward flow of porewater. In addition, the time series revealed small temperature fluctuations over time scales of several days to months, suggesting that intermittent pulses of rapid fluid expulsion interrupt the general cooling trend.

TRACE ELEMENT DISTRIBUTION IN SEA WATER AND SEDIMENT PORE WATER FROM THE NOVIGRAD SEA AREA (EASTERN ADRIATIC)

Zeljka Fiket^{1*}, Nevenka Mikac¹ and Goran Kniewald¹

¹ Rudjer Boskovic Institute, Zagreb, 10000, Croatia - zeljka.fiket@irb.hr

Abstract

In order to study water geochemistry, digenetic changes within the sediment and processes at the water/sediment interface, levels of trace elements (As, Ba, Co, Cr, Fe, Li, Mn, Mo, Ni, Rb, Sb, Sr, Ti, U and V) in sea water and sediment pore water from the Novigrad sea area were investigated.

Keywords: Adriatic Sea, Geochemistry, Sediments

Introduction

The Novigrad sea is a small, semi-closed bay located in the central part of the eastern Adriatic coast, about 20 km from Zadar (Figure 1). It is connected to the Adriatic sea in the northwest by Velebit channel and the Karin sea in the southeast. Sedimentation processes in the Novigrad sea are dominantly influenced by small karstic river Zrmanja, which discharges in its eastern part, forming highly stratified estuary [1]. Smaller streams like Bašcica, Draga and Slapaca, as well as water inflow from Karin sea have less pronounced but still important influence on the sedimentation in this basin. The aim of this study was to investigate geochemistry of sea water and sediment of the area and establish possible natural and anthropogenic influences on the trace element levels.

Fig. 1. The map of investigated Novigrad sea area.

Sampling and methods

Samples were taken at four locations, including Novigrad sea, Karin sea and Velebit channel (Figure 1). The sea water was sampled from the surface and bottom layers, whereas pore waters were extracted by centrifugation from sediment cores previously cut into subsamples at 2 cm intervals. Immediately after sampling Eh and pH were measured in sediments, at the same locations. Concentrations of trace elements in sea water and pore water were measured by high resolution inductively coupled plasma mass spectrometry (HR ICP-MS).

Results

The Eh values in the cores became negative almost immediately bellow the sediment-water interface, while the pH values exhibited small variations along the profile. The measured Eh values imply anoxic conditions starting already from the sediment surface. Comparing to the sea water, the pore waters were found to be generally enriched in trace elements. The redox-sensitive elements, Fe and Mn, generally follow the Eh distribution pattern. Co is often associated with Mn oxides which could explain their similar depth profiles (Figure 2). The concentrations of Ba, Mo, Sr and Rb were variable in the upper 8 cm, whereas As, Cr, Li, Ni, Ti, U and V concentrations show variations throughout the profile in all cores. Concentration levels of all analyzed elements in examined surface and bottom water samples were in the range of values reported by Mikac et al. [2] for Krka river estuary and are considered to reflect natural

levels. Pore water trace element content is believed to reflect mineralogy of sediments and ongoing diagenetic processes in anoxic environment.

Fig. 2. Vertical distribution of Mn and Co concentrations in the sediment cores from sampling stations NM3, NM8, JM and KM.

TSUNAMI POTENTIAL IMPACT IN THE LEVANTINE BASIN AT THE ISRAELI COAST BY EARTHQUAKES AND BY SUBMARINE LANDSLIDES USING VERY HIGH RESOLUTION COASTAL GRIDS

Barak Galanti¹, Sergiu Dov Rosen¹* and Amos Salamon²

¹ Israel Oceanographic and Limnological Research, National Institute of Oceanography, Haifa 31080, Israel - rosen@ocean.org.il

² Geological Survey Of Israel, Jerusalem, 9550, Israel

Abstract

This paper presents detailed quantification of tsunami impact by application of a very high resolution numerical model studying a number of the worst tsunami feasible scenarios in the eastern Mediterranean and their impact on the Levantine coasts, focusing particularly on the Israeli coast.

Keywords: Bathymetry, Levantine Basin, Models, Waves

Introduction

The study reported here [1] is the first stage in thepreparation of a data bank of potential tsunami scenarios for the Israeli coast, which would enable early tsunami warning upon receipt of tsunami alerts from regional tsunami watch centers being established under the IOC/UNESCO Intergovernmental Coordination Group for the Tsunami Early Warning and Mitigation System in the North-eastern Atlantic, the Mediterranean and Connected Seas ICG/NEAMTWS) or from local tsunami detection sea level sensors operated by IOLR. Here we present outcomes of a numerical study of the impact of tsunami scenarios for a number of the worst potential events in the eastern Mediterranean's sea, focusing on their impact on the Israeli coast.

Study overview

The simulations were carried out by a state of the art open source numerical model named GeoClaw. It is based on a larger software package called ClawPack that is aimed to solve hyperbolic partial differential equations up to 3 space dimensions, including nonlinear systems of conservation laws. Furthermore, a special feature of the numerical method is its adaptive mesh refinement (AMR), which enables the implementation of meshes with a large range of scales, property that is extremely important when one is interested in solving problems with a multitude of geometric scales, such as for tsunamis. The adaptation of the code and other changes were checked against well accepted benchmark runs. Two mechanisms for tsunami generation were considered: i) submarine earthquake resulting from the Crete-Helenic arc, and ii) submarine landslides induced by earthquakes at the Dead Sea Transform. Based on older studies [2], the worse cases were chosen accordingly. The movement of the undersea terrain was modeled for the above two mechanisms. Our results were compared with those of older studies and showed agreement for the large scale features. The modeling of the sources in the GeoClaw package is in general a description of the time change of the sea ground. In order to generate these changes, we reconstructed models that describe both earthquakes and landslides. Schematically, the model for the earthquake is taken as a translation of certain quadrilateral region (the moving region) in a linear way. For landslides, a volume in a general form of half elliptic paraboloid is sliding on given chosen track and velocity profile (depends on time). Significant progress has been made by implementing high resolution digital bathymetric and topographic data. The nearshore (shallower than 500m) bathymetry and the topographic data at the coast and river estuaries are on a grid of about 5m cell size.

Results

Maps for maximum inundation, maximum set down, maximum wave height and various time snapshots are produced. The maps for inundation and set down were generated by supplementary Matlab codes which were developed by the first author. Because the solution is found on an adaptive grid (that is also time dependent), one has to interpolate it on a uniform grid for the various snapshots in order to create maximum or minimum maps. For the maximum wave height we introduced for the GeoClaw package a list of sea level gauges located at the lines of zero sea level. From the raw output of a run, we filter out time intervals where the grid is coarse and the information is inaccurate. Next step is to write the maximum of the waves for each gauge point. Example of an inundation map at Haifa bay coast is shown in Fig.1 for the case of an 8.3 earthquake off the eastside of Crete.

In order to understand the generation, evolution and dispersion of the tsunami waves, animations were produced. They enable observing complex wave refraction, wave reflection and wave-wave interactions, and the corresponding forcing on the nearshore and coastal structures, cliff, beach erosion, etc.

The presentation will show results of computed flow velocities, flow flux and momentum at various positions and times, where structures such as breakwaters, coastal cliff and other structures are located, as well as the extreme forces assessed for these locations.

Abstract

Redox sensitive metals enrichment has been used for the reconstruction of deep water ventilation in the Eastern Mediterranean. We compare fixation of Mo and U on the Black Sea, the present day largest anoxic basin, and sapropels from different periods to elucidate formation conditions based on the recent analogues. Most sapropels present preferential Mo enrichment, attributed to different degrees of water column anoxia and primary productivity. Some layers present Mo:U ratio similar to present day seawater, suggesting anoxic bottom water and constant turnover. Basin stagnation comparable to the Black Sea is only punctually observed in the Mediterranean for the most intense sapropel events. Keywords: Anoxia, Black Sea, Sapropel

Redox conditions of the water column and circulation in the Eastern Mediterranean during sapropel formation has been extensively discussed [e.g., 1, 2, 3], yet stagnation is still under debate [1, 2]. Using ICP-MS geochemical data, we compare the behaviour redox sensitive elements on Mediterrranean sapropels spanning from 2Ma to recent, from 4 ODP sites, and sediments from a cores in the Black Sea and data from [4]. The co-variation between Mo and U in the sediment depends on sea water chemistry, water column circulation, and shuttle transport adsorbed to organic matter, [4]. The rate of turnover and different fixation process for Mo and U must also have an effect.

Fig. 1. Mo:U variations (in Enrichment Factors) for Black Sea (a) and Eastern Mediterranean (b-e) sediments. Sea water line marks average Mo:U ratio on sea water (7,8 aprox.). Shading on 1-a distinguish platform (solid grey) and basin (stripes) sediments. Data from the deep basin are from [4].

Black Sea sediments show two trends (Fig.1-a): Samples from the platform (grey shading) are either slightly enriched only in U or following the trend of sea water Mo:U. Fixation of U begins earlier than Mo, and occurs by diffusion into the sediment, whereas Mo can be scavenged from the water column. These evidences indicate a variable chemocline and a constant input of both elements

so that none is depleted in the waters. Recent sediments from the deep basin (stripes) follow the same sea water trend, whereas the last sapropel shows relatively constant Mo concentration and progressive U enrichment. This was interpreted [4] as the result of stable stagnant condition that depleted Mo from the upper water layers. A similar representation on Mediterranean sapropels samples shows similar trends. A cloud of background sediments are slightly enriched in U under sub-oxic conditions. Only when the redoxcline shifts upwards into the water column Mo starts to be fixed. Where deepwater circulation allows U and Mo input, a steady state is reached and Mo:U runs parallel to the sea water line. This is the case for S1 at sites 964 and 967 (Fig.1-b and 1-d) and Pleistocene sapropels at 966 (Fig 1-e). Most Plio- Pleistocene levels are preferentially enriched in Mo on sites 964 and 969, which may imply restricted bottom water circulation and thus limited U fixation. However, intermediate water circulation and Atlantic input was not restricted so Mo was continuously scavenged from the anoxic water column, favoured by organic matter shuttle, [4]. A situation similar to the Black Sea sapropel, with a stable shallow chemocline and long term stagnation, is only inferred locally for S5 and S7 at sites 969 and 964 (Fig. 1-b and 1-c, discontinuous black line).

Abstract

An integrated study is presented on the lower Messinian, pre-/syn-evaporitic Legnagnone section, located in the Northern Apennine. The study of ostracodes, foraminifers, benthonic macrofossils and pollen associations, together with magnetostratigraphic and foraminiferal biostratigraphic data, allow reconstructing a chronostratigraphic framed paleoenvironmental evolution during the uppermost phase leading to the Messinian salinity crisis and an high resolution stratigraphy of the pre-/syn-evaporitic transition. *Keywords: Messinian, Paleoceanography, Stratigraphy, Evaporites*

An integrated approach to the study of the pre-evaporitic sediments in the Mediterranean basin [1] permitted to define a precise time frame of the evolutionary steps towards the MSC (Messinian salinity crisis). Unfortunately, these studies are often carried out in sections lacking primary gypsum (PLG [2]); conversely, they record the deposition of clastic evaporites, both sulphates and carbonates (RLG and Calcare di Base, [2]). Due to these problematic, comprehensive palaeoceanographic reconstructions of the evolution towards the MSC are related to different geological settings. An integrated study of the Legnagnone section (Northern Apennines) was carried out to reconstruct the chronology and palaeoenvironmental evolution of the latest pre-evaporitic events preceding the MSC onset in a marginal area. The Legnagnone section is located in the Northern Apennines chain. It rests unconformably on Miocene calcarenites and it shows a fining upward trend from deltaic conglomerates and sandstones to marls with limestone intercalations. At the top of the prevalently marly portion of the section, two limestone/organic-rich shale couplets are present just below the first gypsum bed that is up to 10 m thick. Based on facies and stacking pattern characteristics of PLG evaporites in the western Mediterranean [3], the two basal cycles are here missing. Thus the first local gypsum bed can be correlated with the third PLG cycle. Biomagnetostratigraphic data allow to correlate the Legnagnone section with the Molinos-Perales section [4] and thus with astronomical curves. The presence of two Turborotalita multiloba influxes, an influx of Globorotalia scitula, several influxes of planktonic foraminifera, the coiling ratio of Neogloboquadrinids, and the Gilbert chron base indicate that the Legnagnone section is comprised between ca. 6.15 Ma and 5.9 Ma.

On the basis of benthonic macrofossils, foraminifers and ostracods, three distinct intervals can be recognised, depicting a palaeoenvironmental evolution from infralittoral well-oxygenated domain (up to ca. 6.13 Ma) to upper circalittoral-upper bathyal settings (from 6.13 to 6.03 Ma) and back again to infralittoral depths (from 6.03 Ma up to the MSC onset), both characterized by dysoxic bottom water.

The high percentage of reworked palynomorphs, especially dinocysts, makes unreliable the climatic value of palynological data from the base (54 m) up to 35 m (ca. 6.13 Ma). On the contrary the quite rich pollen assemblages in the upper part of the section, dominated by arboreal taxa (*Taxodium* type, *Engelhardia, Quercus, Ulmus, Juglans*), testify for a prevalent humid and warm climate.

Concluding, the proposed age of 5.96 Ma [5] for the onset of the MSC is marked by the disappearance of benthonic foraminifers and ostracods, preceded by the disappearance of planktonic foraminifers. However, data indicate that the deposition of sulphates is here delayed of at least two cycles. The lack of several gypsum cycles, replaced by laminated limestone, at the base of PLG deposits is a common features observed also at Sorbas basin and in Piedmont [6] casting a new light on the onset of the MSC.

GEOCHEMICAL COMPOSITION OF RECENT SEDIMENT FROM THE SW ADRIATIC SEA AND THE GULF OF TARANTO (S. ITALY) COMPARED WITH THAT OF THE LAST 400 YEARS FOR ONE SITE

Marie-Louise Goudeau¹*, Shauna Ní Fhlaithearta¹, Brice Robert¹ and Gerrit Jan De Lange¹ ¹ Utrecht University, 3508 TC Utrecht, Netherlands - m-l.goudeau@geo.uu.nl

Abstract

Previous studies from the Gallipoli shelf area indicate continuous sedimentation and high accumulation rates with low disturbance from bioturbation ([1]) permitting high resolution paleoclimate investigations. In this study major and trace elemental composition bulk organic Carbon and Nitrogen, δ^{13} C and δ^{15} N from a multi core (NU04MC) from the Gallipoli shelf is presented. These data is used for a paleoclimate reconstruction using results from 47 surface sediments from the area (Gulf of Taranto and SW Adriatic). Preliminary results indicate a strong anthropogenic influence in the last 100 years. *Keywords: Geochemistry, Eastern Mediterranean, Global Change, Paleoceanography*

To improve our understanding of causes and consequence of climate and environmental change on decadal to millennial time scales more comprehension is needed on the underlying processes. The Mediterranean lies between low and mid-latitudes and is influenced by both the monsoonal and NAO climate systems making it a key area for paleoclimatic investigations. Continuous, high resolution sedimentary paleo climatic archives permit us to study in sufficient resolution the required time scale. Previous studies from the Gallipoli shelf area (39N46;17E54) indicate continuous sedimentation and high accumulation rates with low disturbance from bioturbation (e.g[1]) high resolution investigations. Carbonate contents, permitting thermolumuniscense, oxygen and carbonate isotopes ([2]) and sea surface temperatures ([3]) all display compositional cycles at frequencies known from solar cycles. The origin and processes related to these variations, however, remain unclear. Therefore, a study is presented here in which recent surface sediments elemental composition from the area are compared and calibrated with recent environmental factors. These results can then be used for a paleoclimatic reconstruction of the last few hundred years using multicore NU-04-MC . For this study the first centimeter of 47 multicores has been sampled (Fig 1.)The multicores are from the area and recovered during the Cappuccino cruise ([4]). These samples have previously been analysed for their foraminiferal isotope composition and Dinoflagellates ([5]). In addition, these samples were analyzed for their total inorganic geochemistry using total destruction and ICP-OES. These data and Bulk organic carbon have been correlated with local environmental variables such as Primary Productivity. Temperature, Oxygen levels and Salinity. Preliminary results show a decreasing trend along the surface sediment transect (Fig 1.) for some elements (e.g. Ba/Al, Cr/Al) indicating them as an indirect proxy for the amount of Adriatic Surface water. Furthermore correlations were found within a range of cores between oxygen penetration levels and redox elements. Bulk organic Carbon and Nitrogen content showed correlations with satellite-derived chlorophyll-a concentrations in different seasons. Furthermore a multicore was retrieved from the area (NU04-MC) which contains finely laminated sediments. Preliminary dating resulted in an estimated age of 400 years for the 380mm core depth. Every 2.5 mm was sampled and analyzed. Correlations found for the surface sediments are used to explain the variability within the core. First results of the core NU-04-MC show increasing trends of some elements know as anthropogenic indicators together with an increase in Ba/Al ratios (Fig 2.) from a depth of 100 mm towards the recent. Increased Ba/Al ratio's can be indicative for an increase of primary productivity but could also indicate a different source for clay minerals [6]). The timing of the increase in a variety of elements including Ba, however, suggests an anthropogenic origin. This work is supported by the EUROCORES/EUROMARC Program of the European Science Foundation (NWO.817.01.002 MOCCHA project).

A UNIFYING BIOGEOCHEMICAL MECHANISM FOR SHALLOW GYPSUM VS. DEEP DOLOMITE FORMATION DURING THE MESSINIAN SALINITY CRISIS

Marie-Louise Goudeau ¹*, Gerrit Jan De Lange ¹ and Wout Krijgsman ¹ ¹ Utrecht University - m-l.goudeau@geo.uu.nl

Abstract

The Messinian Salinity Crisis (MSC) is an event ~ 5.9 Ma ago that resulted in deposition of 0.3 - 3 km thick evaporites at the Mediterranean seafloor (1-3). Controversy existed on the formation mode, but recently a consensus was reached on several aspects (3). The latter has also clarified remaining issues, such as for the observed shallow gypsum versus deep dolostone deposits (3-5). A recently proposed scenario for the Lower Gypsum units of the MSC infers that primary gypsum only formed in silled marginal basins while dolostones are found at deeper settings. We agree but reject the suggested coincidental presence of similar sills for all marginal basins. Alternatively, we present here a unifying mechanism in which gypsum formation occurs at all shallow water depths but its preservation is mostly limited to shallow sedimentary settings. *Keywords: Messinian, Evaporites*

The onset of the Messinian Salinity Crisis is marked by the deposition of gypsum-sapropel alternations (Lower Gypsum unit). Increasing evidence has recently been put forward to show that this gypsum precipitation only occurred at marginal settings, while non-evaporitic rocks have been reported from deeper settings (5-7). The difference in sedimentary environment between marginal and deep Mediterranean settings is only tentatively explained by physical properties like tectonic restriction and/or sea level lowering, for which there is no solid evidence. The chemical processes of gypsum formation during the Messinian salinity crisis, however, are poorly understood and commonly neglected. These may, however, explain that different MSC deposits formed in shallow versus deep environments without the necessity of exceptional physical boundary conditions.

a. Water column stratification due to continuing (but episodic?) inflow of oceanic water and enhanced evaporation thus enhanced salinity of Mediterranean water

to consider the following processes that are important:

b. Organic Matter (OM) debris fluxes settling into the deep waters and being decomposed through oxygen and sulphate

c. Gypsum precipitation is controlled by the product of Ca^{2+} and $\mathrm{SO4}^{2-}$ concentrations

Gypsum precipitation in evaporating seawater takes place at 3-7 times concentrated seawater (8 and refs therein); seawater is always largely oversaturated relative to dolomite but its formation is thought to be inhibited by the presence of dissolved sulphate (9). Thus the conditions for formation of gypsum exclude those for the formation of dolomite and vice versa. Another process that links the saturation states of gypsum and dolomite is that of OM degradation by sulphate reduction. In stagnant deep water oxygen is rapidly depleted through OM degradation, then sulphate becomes the main oxidant for OM mineralization, thus reducing the deep-water sulphate content. In the latter process also considerable amounts of dissolved carbonate are formed. Implicitly this means that low-sulphate conditions (as anticipated for the MSC deep waters), i.e. unfavorable conditions for gypsum formation, always coincide with anoxic, i.e. oxygen-free conditions, although there is no direct relationship between the two. the Messinian Mediterranean would have been characterized by a reasonably well-mixed upper water mass ('shallow waters'), and a strongly stratified lower 'deep-water mass'. The MSC stratification with deep concentrated brines, is very stable, and can only be replaced by an even higher salinity water mass. As a result, continued evaporation and water replacement leads to (episodically) enhanced Ca and SO4 concentrations in the shallow waters, thus potentially to gypsum precipitation. Decreasing sulphate and concomitantly increasing dissolved carbonate in the deep waters limit gypsum preservation and permit dolomite formation to occur. Ultimately, it is the balance between OM-fluxes (primary productivity) and sulphate supply to the deep-water (ventilation, settling gypsum fluxes) that determine the environmental deep-water conditions, thus formation rate of dolomite. On the basis of this unifying mechanism, we have shown that gypsum precipitation in shallow water depths and dolomite formation in deep water settings during the early phase of the MSC in the Mediterranean is not incompatible. As a consequence one would expect a bath tub rim of gypsum at all shallow depths but gyupsum appears mainly at silled marginal basins. However, a thick package of heavy gypsum on top of more liquid mud in a marginal/slope setting is highly unstable, thus any physical disturbance such as tectonic activity or sealevel change, would easily lead to downslope transport of such marginal gypsum deposits. The absence of gypsum and the presence of erosional unconformities at the sill-less Mediterranean passive margins concord to such removal mechanism. In addition, large-scale resedimentation of gypsum has also been found for deep Messinian settings in the Northern Apennines and Sicily. Only at those marginal settings that were silled, the marginal gypsum deposits have been preserved (3-7,10).

HIGH RESOLUTION BATHYMETRY AND SHALLOW SEISMIC STUDIES IN THE IZMIR GULF, AEGEAN SEA

Tarik Ilhan¹*, Derman Dondurur¹, Dogan Yasar¹ and Erdeniz Ozel¹

¹ Dokuz Eylul University Institute of Marine Sciences and Technology, 35340, Izmir, Turkey - tarik.ilhan@deu.edu.tr

Abstract

A new poster, based upon high resolution multibeam sonar surveys, shows the bathymetry of the Izmir Gulf basin. The image reveals in detail many features of the offshore. The shallow seismic investigations was done on the same profile of bathymetry and interpreted at advance geophysics processing and G.I.S programs. *Keywords: Bathymetry, Aegean Sea, Seismics, Swath Mapping, Gis*

Material and Methods

The bathymetry of Izmir Gulf off western Turkey [1] is shown in this poster at 1:50,000 scale on the Universal Transverse Mercator (UTM) Projection (Zone 35), with WGS-84 datum. Water depths change from about 1m to over 60m in the Izmir Gulf. The survey was carried out between on June 2009 and April 2010 by the vessels R/V K.Piri Reis and Dokuz Eylul-1 using an ODOM ES3 multibeam echo sounder. The ES3 has 480 beams operating at 240 kHz spread over an arc of up to 150⁰ total coverage, giving maximum swath coverage of up to 3 times of the water depth. Besides, seismic data collected by Triton SB-Logger and Strata Box Marine Geophysical Instrument. The study area approximately 380 km² and in this area the survey involved some 685,218 km of track.

Results

a) We produce high quality and standardized database of the seafloor in the Izmir Gulf, organized in the Marine G.I.S. b) This cartography will help at all sectors with interests in this area and allow to have an element of great help for the integral management of the coastal area and continental shelf and show the variety of the relief, the superficial geology [2], different types of sediments, and sedimentary bedforms generated, etc..

Abstract

This study aims to introduce mechanisms of sediment supply and processes and to investigate their effects on the formation of ecosystem and habitat, based on the grain size distribution of recent deposits of Homa Lagoon. According to the grain size distribution analyses, Homa Lagoon shows the typical characteristics of the following environments from the land to the sea. Samples of Homa lagoon pond show typical characteristics of lagoon pond deposits which are rich in coarse to medium-sized silt with negative skewness and imply that the lagoon was lack of effects of high-energy waves, storms and terrestrial sediment supply. It is concluded in this study that the Homa Lagoon has recently been supplied by low-energy fluids from the land and wave effect was very slow and low in sediment distribution.

Keywords: Sediments, Sediment Transport, Lagoons

Homa Lagoon covers an area of 1852 ha and is located in Izmir Bay, 40 km to the northwest of Izmir and 500 m to the south of Izmir Bird Paradise. More than 200 bird species live in the lagoon where fishery is one of the important occupations of local population. Birds and fishes use the lagoon for feeding, habitat, reproduction and maturation.

This study aims to introduce mechanisms of sediment supply and processes and to investigate their effects on the formation of ecosystem and habitat, based on the grain size distribution of recent deposits of Homa Lagoon.In order to accomplish this aim, Homa Lagoon is divided into three transverse and seven longitudinal sampling stations. Samples are 24 cm in thickness and were collected by Gravity Corer. According to the grain size distribution analyses, Homa Lagoon shows the typical characteristics of the following environments from the land to the sea:Marsh, landward lagoon beach, seaward lagoon beach, lagoon pond, sand barrier (dune) and shoal (back and front) (Reineck & Singh, 1980; Reineck, 1971).

That the coast and the sand barrier are rich in fine sand grains and include fine silt shows that wave effect is poor. Seaward lagoon beaches and poorly developed landward lagoon beaches are represented by medium to well sorted, fine sand with approximately symmetric skewness degree and reflect low wave effect. Samples of Homa lagoon pond show typical characteristics of lagoon pond deposits which are rich in coarse to medium-sized silt with negative skewness and imply that the lagoon was lack of effects of highenergy waves, storms and terrestrial sediment supply(Visher, 1969). It is concluded in this study that the Homa Lagoon has recently been supplied by low-energy fluids from the land and wave effect was very slow and low in sediment distribution. These conditions would be expected not to have sudden and disturbing impacts on habitat and ecosystem.

THE LEVANTINE INTERMEDIATE WATER IN THE WESTERNMOST MEDITERRANEAN DURING THE LAST 20 KY CAL BP: GEOCHEMICAL PROFILES OF MANGANESE AND REDOX CONDITIONS.

Abstract

The Mediterranean thermohaline circulation plays a major role in the transference of energy between climate and ecosystems. The Levantine Intermediate Water (LIW) is a distinctive water mass that occupies intermediate layers in the entire Mediterranean Sea. Redox sensitive elements can be used in order to reconstruct the physic-chemical changes and the evolution of the LIW during the last glacial peridod. Different paleoceanographical proxies have been studied in three cores from the Alboran Sea and the Mn/Al ratio has been selected to reconstruct redox oscillations associated with redoxcline variations.

Keywords: Alboran Sea, Intermediate Waters, Paleoceanography, Redox

Introduction

The LIW is formed during winter in the Levantine basin and spreads to the entire Mediterranean until reaching the Alboran basin and the Gibraltar Strait. The LIW is essential to the Mediterranean thermohaline circulation and is the main contributor to the Mediterranean outflow (MOW), which has been associated to the recovery of the Atlantic thermohaline circulation and the subsequent end of the past glacial conditions [1].

Main text

Three cores have been analyzed that were recovered at different water depths in the Alboran slope: core TTR-300G (36° 21,532 N,1° 47,507 W 1860 mbsl), TTR-302G (36° 01,906 N, 1° 57,317 W at 1989 mbsl) and TTR-304G (36° 19,873 N,1° 31,631 W at 2382 mbsl). The studied time interval spans the last 20 ky cal BP.

Fig. 1. Bathymetric map of the western Mediterranean showing the location of the studied cores, TTR-300G, TTR-302G and TTR-304G. Arrows represent the main oceanographic currents Levantine Intermediate Water (LIW) and Western Mediterranean Deep Water (WMDW)

The Mn/Al ratio profiles support that that this ratio is highly sensitive to paleoceanographical changes associated to different climate/oceanographic events as the Younger Dryas, the S1 sapropel deposition and the cold event 8.2 (Fig. 2). It is worth mentioning the obtained Mn/Al ratio obtained in the TTR-320G, that clearly records the changes occurred in the easten Mediterranean, as the end of the S1a and S1b sapropel deposition (Fig. 2). This location is therefore of key importance for the reconstruction of the physic-chemical conditions of the LIW when reaching the westernmost Mediterranean. When comparing the analyzed records, the Mn/Al enrichment peaks are not time coincident, especially during certain events such as the Last Glacial Maximum and the Heinrich event 1 (HE1) (Rectangles in Fig.2).

Fig. 2. Mn/Al ratio vs. age plots show profiles from the sallowest to the deepest sites: TTR-300G TTR-302G and TTR-304G. Grey vertical bars indicate Heinrich 1 event (H1), Younger Dryas (YD) and sapropel S1 (S1a and S1b) time intervals. Grey rectangles indicate discussed Mn/Al peaks.

Mn enrichment disparity is especially relevant because it is not observed in others geochemical profiles as as the Ba/Al ratio or the detrital record linked to the Mg/Al ratio [2]. In addition, the Mn/Al peaks are not coincident with the major climatic changes occurred in this region. Instead, the Mn content in these sediments mainly reflects redox conditions in bottom waters, and maximum Mn fluxes have been recognized when changes in bottom waters redox conditions occurred [3]. The most plausible explanation for the described Mn/Al enrichments is the presence of a redoxcline at the studied depths. The redoxcline could have beeen originated in relation to the boundary between the LIW and the WMDW water masses. Our data suggest a redoxcline deepening during the H1, as occurred with the base of the MOW in the Gulf of Cadiz at the same period. During the Last deglaciation and YD the Mn/Al enrichment peaks are no recorded, probably due to major changes in the water column in the WMS that allowed the formation of the Last Organic Rich Layer [3]. During the Middle and Late Holocene newly Mn/Al enrichement peaks are observed, after the ORL deposition, probably linked with WMDW variations associates to Bond cycles. MECHANISM OF THE LAND-SEA INTERACTIONS IN THE NERETVA RIVER DELTA (CROATIA): THE DISTRIBUTION PATTERN OF SEDIMENTS AND TRACE ELEMENTS

I. Jurina ¹*, M. Ivanic ¹, N. Vdovic ¹, N. Mikac ¹ and I. Sondi ¹

¹ Rudjer Boskovic Institute, Zagreb, 10000, Croatia - ijurina@irb.hr

Abstract

This study, for the first time, examines the transport of sediments, their longitudinal distribution pattern, and their role in disposal of metals in river-dominated deltaic depositional system of the Neretva River and its adjacent coastal region. The results have shown that longitudinal distribution of metals in sediments follows the deposition pattern of the river-borne clayey mineral particles. The highest concentration of metals was found in the semi-enclosed area of the Neretva Channel. This region is characterized by deposition of fine-grained particles and prevalent accumulation of metals. This study exemplifies the role of Fe oxide and oxyhydroxide coatings on the clay mineral surfaces as a major factor in the adsorption and deposition pathways of trace elements. *Keywords: Adriatic Sea, Sediments, Trace Elements*

Study Area

The Neretva River is the largest river on the Croatian part of the eastern Adriatic coast, and the only one forming a deltaic system. The length of the river is 240 km with the catchment area of about $10,100 \text{ km}^2$ [1]. Most of the sediment load carried by the river originates from the mountain region in the upper part of drainage area. At the river mouth, Neretva discharges its water into a semi-enclosed narrow bay called the Neretva Channel.

Materials and Methods

The field surveys in the Neretva delta and its adjacent coastal region were conducted in May and October 2009. Sediment cores up to 50 cm long were retrieved using Uwitec gravity corer at locations marked in Figure 1. The sediments were analysed in order to determine mineral composition, grain size distribution, SSA, CEC, and the concentration of trace elements.

Fig. 1. The Neretva River delta system showing the sampling stations.

Results and Discussion

The Neretva River and its mouth provide a good example of the biogeochemical land-sea interactions occurring in a microtidal, low-wave energy, and riverdominated deltaic environment of the eastern Adriatic coast. As a result of a simple sedimentation dynamic, the distribution pattern of trace elements can be easily determined. According to Shepard's classification scheme [2] and the ratios of different grain size fractions, obtained by granulometric analyses, the surface sediments along the investigated area, were classified as sandy silts and silty sands with variable content of clay ranging from 1 to 12 %. All sediments were composed of quartz, calcite, dolomite, clay minerals, and feldspar and plagioclase. A significant difference in distribution of clay minerals was found. Their share is significantly higher in the adjacent coastal area, especially at the sampling station N1. The concentrations of metals showed a prevalent accumulation in the fine-grained, clayey fraction. Numerous studies have shown that clay minerals are important vehicles of transport of trace metals [3, 4]. They are involved in simultaneous and complex physico-chemical interactions with metal ions, organics, and iron and manganese oxides and oxyhydroxides. The latter, in the form of surface coatings, have significant impact on the adsorption, transport and deposition of metals. Figure 2 shows good correlation between content of Fe and the concentrations of Pb, Cu, Ni, and Co, in surface sediments. Accordingly, the distribution pathways of these metals are mainly

governed by their direct binding on clayey particulate surfaces and/or on coprecipitated inorganic coatings.

Fig. 2. Concentrations of trace metals (M) vs. Fe content in the surface sediments of the Neretva Channel (N1) and the Neretva River (N2-N7).

GEOMORPHOLOGICAL CHANGES OBSERVED BETWEEN 2006 AND 2009 IN A FRESHWATER SUBMARINE GROUNDWATER DISCHARGE (SGD), KALOGRIA BAY, SW PELOPONNISSOS, GREECE

Aristomenis P Karageorgis ¹*, Kostas Katsaros ¹, Theodore D Kanellopoulos ¹ and Evangelos Papathanassiou ¹ ¹ Hellenic Centre for Marine Research, Institute of Oceanography, 19013, Anavyssos, Greece - ak@ath.hcmr.gr

Abstract

An impressive SGD in Kalogria Bay (SW Peloponnissos) was surveyed for the first time in 2006, revealing the existence of 2 major and 2 minor point sources of freshwater (salinity \sim 1-2); the discharge was \sim 1000 m³ h⁻¹. The major point source was located inside a karstic cavity at 25 m depth. In July 2009, the site was revisited and divers reported that only the largest point source was active, whereas the roof of the cave had collapsed. The underwater discharge was not very strong, the water was flowing from many dispersed points, and salinity range was 20-36. Following visits will show if the SGD has turned to a diffused type and if changes in salinity are permanent, thus hampering the possibilities of water exploitation.

Keywords: Geomorphology, Hydrology, Coastal Processes, Salinity, Eastern Mediterranean

Introduction

Knowledge concerning submarine groundwater discharges (SGDs) has existed for many centuries [1]. However, SGDs were neglected scientifically for many years because of the difficulty in assessment and the perception that the process was unimportant [2]. Within the last two decades, that notion has changed, and now there is growing agreement that groundwater inputs can be chemically and ecological important to coastal waters [2]. Here we present new data regarding a large karstic freshwater SGD situated in Kalogria Bay, near Stoupa town, in SW Peloponnissos (Fig. 1). We focus on the geomorphological changes that were observed between 2006 and 2009, which may have consequences on the salinity of the discharged water.

Fig. 1. Study area location map

Materials and Methods

The site was first visited in November and December 2006. During the latter visit, a multifaceted operation with divers, a remote operated vehicle, a portable CTD, and other equipment was implemented, which provided ample samples, videos, and other data from the site. Another visit was conducted in February 2008, and then in July, September, and October 2009. During 2009, apart from sampling with divers, a lander equipped with conductivity, temperature, current velocity, and g-ray spectrometer sensors was deployed permanently.

Results and Discussion

In 2006, the entire submarine spring feature formed an ellipsis with dimensions approximately 60 m x 40 m. Two major point sources discharged from Pleistocene conglomerates; the strongest, in terms of discharge, underwater spring emanated from the bottom (diameter ~2 m) of a cave, at 25 m depth. Salinity was ~1-2. Two minor SGDs discharged from the sandy seabed. Using ²²²Rn measurements [3], the discharge was estimated at ~1000 m³ h⁻¹ at the second point source (water depth ~26 m). This morphology was maintained unaltered between 11-2006 and 2-2008. In July 2009, the underwater morphology appeared completely changed, as the roof of the cave, where the

strongest SGD emanated, had collapsed almost entirely. The second SGD was completely filled with sand, and similarly, as the two smaller ones, they were inactive. The behavior of the major point source was also different, because the water was not any more concentrated as a single jet flowing from the bottom of the cave towards the surface, but it was scattered and emanated under rocks, from little cracks, and was generally rather diffused. Salinity measured in various spots was high (20-36). Elevated salinity can be attributed to the altered morphology of the submarine spring and particularly to the much more diffused character of the flow. However, it should not be disregarded that all measurements conducted in 2009 reflect summer and early autumn conditions, where rainfalls are practically absent in this territory, and therefore freshwater supply from the land should be at the lowest levels. In this perspective, the entire SGD represents minimum freshwater outflow allowing faster mixing with the sea water and brackish character of the outflowing water.

Measured flow velocity was on average 0.25 m s⁻¹, which corresponds to 900 m³ h⁻¹ if we assume that all small discharges cover a surface of just 1 m². This is a very conservative assumption, and the discharge can be many times higher. A possible explanation for the collapse of the conglomerates could be related to the extremely high rainfall that occurred during the winter and spring of 2009. Residents of Kalogria stated that during March 2009, after an intense rainfall, the SGD was 'boiling' at the sea surface, other smaller SGDs in the bay were also very active, and the sea was colored red. The red color is probably attributed to 'terra rossa', which is the final product of limestone dissolution during karst formation, and was transported to the sea.

In September and October 2009, a small freshwater spring (salinity ~3-4, temperature 12-13 °C) was spotted in Kalogria beach discharging exactly at the coast. According to geological observations conducted by the Agricultural University of Athens, this freshwater springs from the mountains and is hydrologically connected to the studied SGD. Most likely, freshwater reaches the SGD, but due to low discharge, it gets rapidly mixed with seawater between the impermeable marble bedrock and the sea bottom, where permeable formations prevail (sand, gravel, etc.). The available geological evidence suggests that a fault line or an impermeable rock formation (e.g. schist) blocks the freshwater flow on the marble bedrock and creates the SGD at this site.

Conclusions

Significant geomorphological changes have occurred in the studied SGD, which may have consequences on the type of the flow (from point to diffused), and possibly to the salinity of the water. Winter observations will reveal if elevated salinity is due to the sampling period (summer, low terrestrial water supply) or due to the changes of the rocky structure. Potential water exploitation will depend on a full year of observations.

ORGANIC DINOFLAGELLATE CYSTS AS BIO-INDICATOR OF MARINE POLLUTION, SOUTHEASTERN MEDITERRANEAN, EGYPT

Suzan Kholeif¹*

¹ National Institute of Oceanography and Fisheries, Alexandria, El Anfoushy, Egypt - suzan_kholeif@yahoo.com

Abstract

This study depends on the detection of water pollution by means of the organic dinoflagellate cysts in bottom sediments collected from the coastal waters, southeastern Mediterranean close to Alexandria, Egypt. For the first time in the Egyptian Mediterranean waters, the dinoflagellate cysts are used as indicators of pollution to formulate environmental considerations on the effects of anthropogenic activity in the Abu Qir Bay. Fifty-two different dinoflagellate cyst morphotypes representing 15 genera were identified in the top 2 cm surface sediments. The most common cysts that were detected (*inter alia, Alexandrium minutum, A. affine, Alexandrium spp., Gymnodinium catenatum, Protoperidinium denticulatum*) are capable of producing paralytic shellfish poisoning (PSP), as a result of severe pollution.

Keywords: Eutrophication, Sewage Pollution

Introduction

Abu-Qir Bay(Figure 1) which islocated between Longitude 30° 50' and 30° 22' E and Latitude 31° 16' and 31° 28' N (about 35 km east of Alexandria), was considered before 1965, as one of the most important breeding and nursery ground for economically important fish and shellfish. The Bay receives considerable amounts of waste waters sources including drainage water from El-Behera province as well as industrial waste from several industries (Tayel, 1992). Such pollutants have a drastic effect on various aquatic fauna and flora.

Question To what extent has the current polluted marine environment effect on dinoflagellate cysts types and distribution in the bottom sediments? The answer to this question is the aim of the present study.

Materials and Methods

Eighteen bottom sediment samples from 18 stations covering nearly different sites of the Bay (Figure 1), were collected, during the end of May and December 2006, using Van Veen grab sampler, in addition to short core sample (~25 cm length). The selected bottom sediments and core samples were treated for palynological study by standard palynological technique for marine sediment. The quantitative and qualitative results for dinocysts identification were based on the published references such as: Fensome et al. (1993), Williams et al (1998), Rochon et al. (1999) and Matsuoka and Fukuyo (2000).

Fig. 1. Location map of Abu Qir bay, showing locations of core and bottom sediment samples

Result and Discussion

Dinocysts abundance varied greatly among studied locations. The high number of cysts was observed in the near shore stations can be explained as the extensive human activities in this area which led to the accumulation of muddy sediments. The number of cysts, particularly heterotrophic ones, (7646 cyst/g) is significantly high (Figure 2), most of them are toxic species.

Fig. 2. Diagram showing the concentration of *Alexandrium* and other Cyst orders in the bottom sediments collected during May 2006

Conclusion

1. *Alexandrium* cystshave been seen in surface sediment layers in the vicinity of the most coastal stations. This species was the most abundant of the cyst types in the area. However, *Alexandrium* cysts showed lower surface concentrations or are missing in several stations of the center of the bay.

2. Cysts of three potentially toxic dinoflagellate species, *Alexandrium minutum*, *A. affine* and *Gymnodinium catenatum* were detected at E-Mena, El Madia, in bottom sediments and in the core sediments at 5-15 cm depth.

3. The high concentration and occurrence of dinoflagellate cysts in the Abu Qir Bay are suspected to reflect the serious changes in the environment and anthropogenic activities in that coastal zone.

CORE-TOP CALIBRATION USING THE LIPID-BASED TEMPERATURE PROXIES U^K'₃₇ AND TEX₈₆ ON THE SOUTHERN ITALIAN SHELF (SW ADRIATIC SEA, GULF OF TARANTO)

Arne Leider¹*, Kai - Uwe Hinrichs¹, Gesine Mollenhauer² and Gerard J.M. Versteegh¹

¹ Dept. of Geosciences, University of Bremen, D-28359 Bremen, Germany - ar_le@uni-bremen.de

² Alfred Wegener Institute for Polar and Marine Research, D-27570 Bremerhaven, Germany

Abstract

The core-top calibration of lipid-based temperature proxies along the south Italian shelf suggests that $U^{K'_{37}}$ primarily records winter temperatures while TEX₈₆ tend to reflect summer temperatures, in particular in offshore regions. Additionally, a bias of TEX₈₆ due to terrestrial input or transport cannot be excluded. Our study provides a robust basis for future reconstructions of winter climate variability in this region during the last two millennia in sediment cores with a temporal resolution of 4 yrs, which is likely to provide important information on the extension of the AO/NAO in the Mediterranean. *Keywords: Adriatic Sea, Temperature*

Introduction The southward extension of the AO/NAO during winter is crucial for the Mediterranean water budget. The ESF project MOCCHA aims at providing climatic reconstructions for the Gulf of Taranto (S. Italy) with a <4-year resolution. The sediments in this region are excellently suited for this purpose [e.g., 1]. To fully exploit the sedimentary archive, a better understanding of the relation between environmental conditions and sedimentary composition is needed. Therefore a core-top calibration of molecular paleotemperature proxies has been performed. The lipid-based U^{K'}₃₇ and TEX₈₆ proxies presumably reflect the temperature in the habitat of the source organisms, i.e., haptophytes and crenarchaeota, respectively [Fig. 1].

Fig. 1. Structures of GDGTs and alkenones and their related temperature proxy indices, TEX_{86} and $U^{K'}_{37}$, respectively [2, 3].

Fig. 2. Map of southern Italy showing the difference between alkenone-derived SST and satellite-based mean annual SST (Δ SST_{UK}, _{37-MA}) at the SW Adriatic coast and the Gulf of Taranto.

Usually, the transfer functions applied to the lipid composition of the surface sediments closely agree with the annual mean temperature in the overlying surface waters [2-5]. In many open oceanic settings the main productivity takes place when ambient water temperatures are close to the annual mean [4], which is not necessarily the case in the Mediterranean [e.g., 6]. Here, we elucidate the temporal relation between the lipid composition of sediment surface samples and monthly satellite-derived sea surface temperature and productivity data at

the south Italian shelf.

Material and Methods The analysed sediments represent the top 2 cm of multicores from 48 stations obtained during P339 POSEIDON cruise 'CAPPUCCINO' in June 2006. Homogenized samples were extracted by using an accelerated solvent extractor (ASE 200, DIONEX). Alkenones were quantified using GC-FID. Analysis of GDGTs was based on HPLC-APCI/MS [7]. The most recent global transfer functions were used for temperature conversion [4, 5]. Satellite based environmental data and mean annual sea surface temperatures (SST_{MA}) derive from OBPG MODIS-Aqua Monthly Global 9-km data base [8].

Results and discussion In our study, the alkenone-based U^{K'}₃₇ reflects winter/spring SST [Fig. 2]. This agrees with maximum haptophyte production in the colder season as evidenced by chlorophyll data and sediment trap analysis. In contrast, the TEX₈₆ data are more complicated. For the near-shore sites the TEX₈₆ suggests that the GDGTs have been produced in winter but with increasing distance from shore the inferred ambient water temperature increases; consequently most offshore sites reflect summer SST. This is probably due to differences with respect to timing and/or depth of production, or transport of allochthonous GDGTs. Our core-top calibration documents varying degrees of seasonal bias of the two SST proxies in a regional context. This improved understanding of SST signal formation at the Gallipoli shelf provides a robust basis for future examination of temperature changes in sedimentary records covering the last millennia.

ARGUMENTS IN FAVOUR OF A HOLOCENE RAPID TRANSGRESSION IN THE BLACK SEA

Gilles Lericolais ¹*, Nicolas Loget ¹ and Guillaume Soulet ¹

¹ IFREMER BREST, Département Géosciences Marines, 29280, Plouzané, France - gilles.lericolais@ifremer.fr

Abstract

Since Ryan et al. ¹ theory about a rapid reconnection between the Black Sea and the Marmara Sea in the Holocene, an important international work have been undertaken to study the Quaternary water level fluctuations of these two bodies. It is now well established that the Black Sea has encountered complex water level fluctuations with high lake levels occurring during wet and melting period after the LGM and low lake levels occurring during drier conditions as the Younger Dryas was for this region. This presentation will summarise results obtained in the Black Sea from different research cruises and compare them with other semi-enclosed basins. These permit a rise in the understanding of the mechanisms linked to high resolution sequence stratigraphy preservation and how they have recorded the abrupt climate changes of the last deglaciation *Keywords: Black Sea, Bosphorus, Seismics*

The location of the Black Sea, between Europe and Asia, makes its water level dependent on Eurasian climatic fluctuations. This inland sea is a perfect present-day example of what is a marginal basin where connection changes dramatically with sea level. The Black Sea is at present the world's largest anoxic basin, making it an important modern analogue for past anoxic conditions, while during the last glacial period, it was a low salinity oxygenated lake, isolated from the Mediterranean. The Black Sea and the low sea level periods when were deposited lake sediments represents valuable archives for the study of past climate changes. Actually, the glacial period northern ice cap prevented major East European rivers to flow north as they do today. During ensuing interglacial periods, these rivers were diverted to the south in the direction of the Black Sea and Caspian Sea receiving basins and consequently have increased the size of these Drainage Basins Therefore, unique conditions specific to the Black Sea were established while this water body became isolated from the Global Ocean. This results in avoiding the hysteresis effect which is the latent period needed by the Global Ocean to respond to the consequences of ice melting. This presentation is part of one of the objectives of the INQUA/IGCP 521 project (Black Sea-Mediterranean Corridor during the last 30 ky: sea level change and human adaptation) which is to obtain a good as possible reconstruction of climate dynamics and the changes from wet to arid periods together with the determination of palaeodepths. Such results are of interests for the CIESM as they will lead to a cooperation in the construction of a sea-level curve for the Black Sea. Presently, it is well established that the Black Sea has encountered complex water level fluctuations with high lake levels occurring during wet and melting period after the LGM and low lake levels occurring during drier conditions as the Younger Dryas was for this region. As the Black Sea, abrupt Sea-level rises have been recorded in many different semi-enclosed basins around the world. The link to rapid transgressions is easy to do, even if the mechanisms are completely different. Large and rapid releases of freshwater from ice sheets since the LGM to sensitive areas may also arise from several mechanisms. The last deglaciation provides the level of preservation necessary to identify specific mechanisms of ice-sheet forcing and attendant climatic responses. The presentation will summarise results obtained in the Black Sea from different research cruises and compare them with other semi-enclosed basins. These permit a rise in the understanding of the mechanisms linked to high resolution sequence stratigraphy preservation and how they have recorded the abrupt climate changes of the last deglaciation. When the Black Sea was isolated, both the lack of saltwater input and the increase of fresh water run-off from the rivers, led to reduced salinity levels in the Black Sea. This process happening during the glacial periods, linked to water level fluctuation, is measured in the fauna succession showing an abrupt change from salt-water to fresh/brackishwater species. The initial hypothesis of a rapid saltwater flooding of the freshwater lake that was the Black Sea in the Late Glacial Maximum (LGM) was proposed since 1996 by Ryan et al. The flood hypothesis raised controversy and initiated refutation, but recently also received supports The European Project ASSEMBLAGE (EVK3-CT-2002-00090) provided geophysical and sedimentary data collected in the north-western part of the Black Sea from the continental shelf and slope down to the deep-sea zone. This project focused on applying sequence stratigraphic models to seismic data recorded on the north-western Black Sea shelf, in order to correlate the sequences interpreted using seismic stratigraphy methods to sea-level fluctuations. To achieve the project's objectives, very high resolution seismic data were acquired during the BlaSON cruises (1998 and 2002) on board the research vessel LE SURO; and during the ASSEMBLAGE 1 (2004) cruise on board the research vessel LE MARION DUFRESNE. During the first two cruises paleo-shorelines and sand ridges were identified and a set of seismic

data was acquired on these targets to support pseudo 3D analyses. This coupled with a multiproxy approach emphasizes that the Black Sea water level is dependent on Eurasian climatic fluctuations. This sequence stratigraphy study is validated by dated samples obtained from long cores (up to 50 m long) providing a firm calibration of Black Sea water level fluctuation since the LGM. It especially shows that the Black Sea experienced a contemporary rise in water level with the melting of the Fennoscandian Ice sheet followed by a drop of the water level from the Younger Dryas to the Pre-Boreal. This recent lowstand is confirmed by the presence of the forced regression sequences, the wave cut terrace and the coastal dunes still preserved on the shelf, even after the Black Sea was rapidly invaded by Mediterranean/Marmara marine waters.

Abstract

High resolution Multi Beam data and sediment samples were collected across the outer shelf region of the Columbretes Islands (Southern Ebro continental shelf, Western Mediterranean Sea). Very large subaqueous dunes were observed across relict sand bodies and their distribution and morphological characteristics have been analyzed to evaluate possible potential formation mechanisms. It is discussed that these bedforms could be produced by the action of the Liguro-Provencal-Catalan (LPC) geostrophic current, flowing southward and reaching very intense near-bottom curents when interacting with the local geomorphology of the study area. *Keywords: Continental Shelf, Geomorphology, Swath Mapping, Western Mediterranean*

Large and very large subaqueous dunes [1] have been observed in a number of outer shelf regions around the world, usually developing on fossil sand bodies and ridges [2,3]. Dunes observed on outer shelves usually display large dimensions with maximum longitudes reaching up to 500 m and heights up to 20 m [3,4]. Forcing mechanisms able to induce their formation have been described as strong bottom currents related to tidal variations and water masses flowing under geostrophic conditions, usually controlled and enhanced by local geomorphologic configurations [2,3,5]. In this study, such bed features have been recognized around the Columbretes Islands, mapped and measured, with the aim to reconstruct which are the forcing processes that could generate them in relation to the local settings of the area.

Swath-bathymetry around the Columbretes Islands was collected using the Simrad EM-300 30 kHz (R/V Vizconde de Eza) and the Elac Seabeam 1050D 180 kHz (R/V Garcia del Cid) Multi Beam echo-sounders for a 50-400 m water depth range. Additionally, sediment samples were recovered by means of a Van-Veen grab and a HAPS corer, to carry out grain size analysis of surface sediments. Bathymetric data revealed the presence of three main relict sand bodies along the outer shelf, for a 80-116 m depth range, above which asymmetrical, slightly asymmetrical and symmetrical large and very large 2D and 3D subaqueous dunes were observed (Fig.1). Dunes range from 150 to 760 m in wavelength and from tens of cm to 6 m in height.

These bedforms are composed of sandy sediments, presumably coming from the degraded relict sand bodies on which they developed, mixed to fine fractions, coming from the recent draping holocenic sediments. The orientation of the dunes is SSW and progressively turns to W directions moving towards the southernmost sector of the area, following the trend of the shelf-edge. Observed dunes display a strong asymmetric profile for those occurring along the shelf-edge (Symmetry Index (SI): 2.6) and lose progressively their asymmetry towards the inner portion of the shelf (SI: 0.5), being 0.6 the minimum SI value to classify the dunes as asymmetric [6]. The subaqueous dunes observed and use studied region are amongst the largest ever recognized on an outer shelf setting. Morphologic characters and the orientation towards SW and W directions suggest the LPC current as the primary forcing factor in their formation.

Contemporary hydrodynamic measurement at the Ebro continental shelf-edge show that near-bottom wave action is negligible in this area, whereas maximum shear stresses induced by currents are able to resuspend fine sand particles and prevent the relict transgressive deposits from being covered by mud [7]. However, recorded values are below the critical shear stresses for transport the relict coarse sands found in the study area and form large bedforms. The comparison of successive bathymetric images and the aspect of the wavelenghtheight regression curve suggest that the described very large dunes are inactive features over long periods, as observed in similar environments along several continental margins. Thus, the morphological configuration of the Columbretes outer shelf must have played a crucial role in enhancing the southward flowing bottom currents during energetic hydrodynamic events, giving them the potential to generate bedforms.

A GEOSTATISTICAL ANALYSIS OF PRODELTAIC UNDULATIONS OFF THE GUADALFEO RIVER IN THE NORTHERN MARGIN OF THE ALBORAN SEA, WESTERN MEDITERRANEAN BASIN

F. J. Lobo¹, J. A. Goff², L. M. Fernández-Salas^{3*}, P. Bárcenas⁴ and V. Díaz-Del-Río³ ¹ Instituto Español de Oceanografía. Centro Oceanográfico de Málaga. - luismi.fernandez@ma.ieo.es

Abstract

A geostatistical analysis of multibeam bathymetric data in two fields of prodeltaic undulations located off the Guadalfeo River, northern margin of the Alboran Sea, was conducted in order to obtain useful insights into genetic mechanisms. The geostatistical analysis was based on the determination of characteristic parameters and derived relationships. Our results support the contention that prodeltaic undulations off the Guadalfeo River should be regarded as sediment waves, mainly generated by strong normal-to-contour sediment flows with a riverine origin.

Keywords: Deltas, Continental Shelf, Geomorphology, Swath Mapping, Alboran Sea

A detailed study of the along- and across-shelf variability of geostatistical parameters such as rms (H), strike azimuth with respect to north (Θ_s) , characteristic width (Ln) and characteristic length (Ls) defining the von Kárman covariance function, as well as the wave or vertical form index (Ln/H) and aspect ratio (L_s/L_n), provides valuable information about the genetic interpretation of submarine undulations found in highly dynamic prodeltaic systems. Those systems have been particularly documented in several settings of the Mediterranean Sea [1, 2, 3], a region characterized by seasonal climatic patterns and strong physiographic control on drainage basins. Our analysis provides evidence to support the hypothesis that the prodeltaic undulations can be considered as a type of sediment waves, resulting as the final products of energetic sediment flows emanating from river outlets.

Overall, geomorphological statistics indicate that the undulations under consideration bear high similarity with prodeltaic undulations developed in deltaic systems where a primary control of hyperpycnal flows has been proposed. The parameter values in the Guadalfeo River prodelta (Fig. 1) suggest the imprint of very intense sediment flows, with increased proportions of bedload sediment transport in relation with other undulation areas. This may be a consequence of the extreme seasonality and torrentiality dominant in the drainage basin of the feeding system.

Most of the geostatistical parameters are disposed in basically consistent distribution patterns, especially in the along-shelf direction. Amongst them, the L_n/H ratio observes the most clearly discerned geomorphological patterns, by defining two identifiable depositional axes, whose location seems to be controlled at large by changing river mouth position. The most recent, western undulation field is highly symmetrical, with higher H and lower Ln/H and Ls values, suggesting the action of very intense and focused flows, with relatively high amounts of bedload sediment with decrease rapidly both laterally and downslope. In contrast, the eastern field shows lower H and higher L_n/H and Ls values, indicating the influence of less energetic flows with increased proportion of suspended sediment. In the end, those differences are also indicating a temporal change, as the western field undulations appear to be active, relatively in equilibrium with recent/present flow regime, whereas the more subdued profile of the eastern field undulations would indicate a higher auiescence.

Changes of Θ and L_s also support a main genetic mechanism through normalto-contour flows, as the undulations are disposed around two adjacent lobes and show relatively low lateral continuity when compared to other Mediterranean undulations. Those parameters fit with the depositional model, described by two main point sources that irradiate sediments concentrically. In contrast to the previous parameters, Ln does not show a predictable pattern, as no significant systematic change is detected in the study area.

RESUSPENSION EVENTS AND SEDIMENT FLUXES ACROSS BARCELONA CONTINENTAL SHELF

Laura López ¹*, Jorge Guillén ¹, Albert Palanques ¹ and Pere Puig ¹ ¹ Institut de Ciencies del Mar (CSIS),08003 Barcelona, Spain - llopez@icm.csic.es

Abstract

Near-bottom sediment fluxes were measured at several locations across the Barcelona continental shelf (NW Mediterranean) during the SEDMET Study. Current meters equipped with turbidimeters were installed on instrumented tripods deployed at 20, 30 and 40 m water depth. Measurements of near bottom currents and water turbidity, from October 2007 to June 2008, in combination with wave data provided information about the physical forcing and resulting resuspension and sediment fluxes on this Mediterranean continental shelf. This contribution analyses the results obtained during the first recording period (September – December, 2007) characterized by a high wave-energy regime. During this period, six moderate storms occurred, being identified as the main contributors to the sediment resuspension events recorded between 20 and 40 m depth.

Keywords: Sediment Transport, Continental Shelf, Western Mediterranean

Sediment resuspension in the Western Mediterranean Sea is caused primarily by the wave-storm activity when wave periods increase significantly. Some authors showed that sediment resuspension in response to storm waves on the Ebro Margin (NW Mediterranean) is mainly effective on the inner-shelf region [1] [2]. The present project involves studying resuspension and sediment transport events in a littoral system affected by industrial and urban activities, Barcelona (NW Mediterranean) (Figure 1).

Fig. 1. Map of the Barcelona continental shelf showing the three tripods locations. Depth contours and UTM units are in meters.

During the SEDMET Project, three benthic tripods were deployed in the northern Barcelona continental shelf at 20, 30 and 40 m water depth (Figure 1). Each tripod was equipped with an Aanderaa Doppler current meter (RCM9) coupled with a pressure sensor, a temperature sensor, and 2 Aanderaa turbidimeters of different ranges. These sensors were measuring at 0.6 meters above bottom (mab). In addition, an NKE ALTUS 2 Hz altimeter and a sediment trap were incorporated to the tripods structures. For this study, the current meter recording intervals were set at 20 minutes, and the observational period lasted in total 8 months in 3 deployments of 2-3 months, beginning 28 September 2007 and ending 19 June 2008.

The meteorological and the waves conditions were obtained from "Puertos del Estado" WANA model calibrated with data obtained from the Llobregat buoy of the XIOM ("Generalitat de Catalunya"). In addition, vertical hydrographic profiles were made monthly using a SBE 25 CTD, coupled with a Seapoint turbidimeter. Water samples were collected during each cast near the bottom and at the surface. To obtain time series of suspended sediment concentration (SSC), turbidity sensors were calibrated with estimations of SSC measured from filtered water samples.

This paper analyses the data recorded during the high-energy season, from the 28^{th} of September to the 29^{th} of November 2007, at the three tripod locations (20 m, 30 m and 40 m). During this first deployment, there were six moderate storms with significant wave height (Hs) of about 2-3 m and peak wave period (Tp) around 10 s, increasing during the strongest storm to Hs up to 3 m and a Tp of 12 s (Figure 2).

The highest near-bottom current speed at the three locations were associated with storms events, reaching maximum values up to 25 cm/s. During those

events, the mean component of the near-bottom currents was 1-2 orders of magnitude higher alongshelf than across-shelf with a resultant flow predominantly directed towards the SW.

Fig. 2. Time series of significant wave height (Hs), peak wave period (Tp), near-bottom current vectors and SSC (0.6 mab) at 20 m depth during the high wave-energy period. Vertical lines identify the six resuspension events.

The near-bottom SSC during the recorded period showed a high temporal and spatial variability, and mean values decreased offshore. At 20 m depth, the SSC was less than 0.5 mg/l during fair-weather conditions and increased up to 50 mg/l during storms (Figure 2). Finally, regarding to the sediment flux, the mean alongshelf sediment fluxes at all the recording sites were higher than the across-shelf component and decreased with increasing depth.

Acknowledgments This work was funded by the Spanish Ministry of Science and Technology within the SEDMET project (CTM2006-06919).

Abstract

The geochemical features in surficial sediments on seamounts of the Djibouti Banks allow determining a boundary between two sediment groups which fits with the seamounts summit break. The differences between these groups seem to be related not only with a physiographic limit but also with the influence of bottom currents, external inputs and geochemical processes. *Keywords: Sediments, Geochemistry, Trace Elements, Alboran Sea*

Introduction and oceanographic setting

Changes in sediment features on seamounts can be related with both source and oceanographic conditions, but also geochemical interactions can be involved once particles are settled or along the water column. In order to ascertain the relation of those processes with the geochemical composition of recent deposits, a group of 28 sediment grab samples have been analyzed on two seamounts of the Djibouti Banks area (NW Alboran Basin). The studied seamounts are Avempace and Djibouti that show a tabular configuration at top with both tectonic and volcanic origin. The water masses involved in this area are the salty and dense Mediterranean water and the lighter Atlantic surficial water, which mixing process causes valuable effects on the geochemical transference between dissolved and particulate phases.

Results and discussion

Studied sediments are sandy mud and muddy sand with sand-sized foraminifera and ostracoda tests that also include variable amounts of glauconite grains. Neither heavy minerals nor quartz grains are observed in quite amount, what implies the sediment origin is mainly related to authigenic. pelagic and dust sources. Rare earth elements (REE) are quite sensitive to environmental changes. In order to evaluate the length of the fractionation along the series (Fig. 1), they have been normalized by Shale [1]. It can be observed an increase on (La/Yb)Shale index with depth as a result of the progressive enrichment of Light REE (LREE: La to Gd) that it is not showed by Heavy REE (HREE: Tb to Lu). This is due to the preferential removal of LREE by adsorption and/or scavenging onto clay-sized Al-bearing minerals. Otherwise, HREE are preferentially retained in solution as consequence of the formation of steady carbonate-ion complex in seawater [2] and almost do not show variation with depth, except if any external input is involved. In this latter case a possible Sahara dust input could enhance the Yb concentration observed in the sediment, but further studies are required to find the right relationship with this source.

Fig. 1. Range of REE-Shale normalized pattern for sediment (ppm) with depth and average Mediterranean seawater (pmol kg⁻¹) [3].

Additionally, the depth evolution of selected elements has been studied in order to be used as geochemical proxies of sediment origin. The relation of Fe/K and Ca/Sr with depth (Fig. 2) show two main depths related to glauconite formation from foraminifera tests. Those depths are around 300 and 380 m for Djibouti and Avempace, respectively, and imply a low sedimentation rate on both summits. It is also in good agreement with the minimum content of lithogenic elements (Al, Li, Th, V, Ti) observed in the sediment composition that later increase with depth as a consequence of the

phyllosilicate dominance on deep water sediments. This could be related with sedimentary inputs coming from bottom currents of Mediterranean origin that somehow prevent biogenic deposition at the slope of the seamounts.

Fig. 2. Geochemical features of sediments with indication of the depth boundary (dashed line) where main changes occur on Avempace (open dot) and Djibouti (black dot) seamounts.

Conclusions

Preliminary results suggest a change on geochemical features in sediments deposited around 300 and 380 m depth for Djibouti and Avempace, respectively, that approximately fits with the physiographic summit break of both seamounts. According to this boundary two different sediment groups can be identified in recent deposits on the Djibouti Banks area. Shallower sediments are depending on geochemical reactions along the water column and biogenic deposition, while deep water sediments could be related with Mediterranean bottom currents and external inputs of Sahara dust.

MUD BRECCIAS AND HEMIPELAGIC DRAPES OF MUD VOLCANOES FROM THE WEST ALBORAN BASIN: GEOCHEMICAL AND MINERALOGICAL CHARACTERIZATION.

Carmina López-Rodríguez ¹*, Maria Carmen Comas ¹ and Francisca Martínez-Ruiz ¹ ¹ Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), Universidad de Granada, 18002, Spain - carmina@ugr.es

Abstract

Mud volcanoes from the West Alboran Basin were first discovered and surveyed during several TTR cruises. Provenance and nature of the mud breccias extruded by the Alboran mud volcanoes have been investigated by using geochemical and mineralogical proxies. This study presents preliminary results obtained from the analyses of mud breccia and pelagic drapes from gravity cores collected at different mud volcanoes (Perejil, Dhaka, Carmen and Maya). Mineralogical analyses showed a clay dominant composition of mud breccias, and major and trace element composition have revealed potential differences in parental affinity. *Keywords: Alboran Sea, Mud Volcanoes, Geochemistry, Mineralogy*

Mud volcanoes were first discovered in the West Alboran Basin (WAB) during the TTR-9 cruise, in 1999 [1] and further investigated during the following TTR cruises (TTR-12, TTR-14 and TTR-17). The mud volcano field is located in the inner part of the Gibraltar Arc, where the major sedimentary depocenter is recorded (up to 7km). Previous studies have proved that this depocenter matches with an extensive Mud Diapir Province, which feeds mud diapirism and associated mud volcanoes. The mud diapirs are formed by undercompacted shales and olistostromes from the lowermost marine sedimentary sequence early to middle Miocene in age, as show both seismic interpretations [2] and micropaleontological studies of the extruded materials [3]. In order to investigate the provenance and nature of the mud breccias extruded by the Alboran mud volcanoes, we have analyzed three gravity cores (MS283G, MS285G and MS419G) from the top of Perejil, Dhaka and Maya mud volcanoes respectively, and one (MS385G) from the flank of the Carmen mud volcano. Perejil MV is located in the northern whereas Dhaka, Carmen and Maya MVs are located in the southern of the Mud Diapir Province. All of them occur between 400m and 850m depth and they are showed as positive structures. However, their morphologies are variable, ranging from semicircular to elongated; as well as size in high, from 25m to 90m and in diameter, from 120m to 1600m. Continuous samples were taken from the hemipelagic drapes in all mud volcanoes and every 2cm at the top of the mud breccias. The rest of the mud breccias were sampled every 5 or 10cm at 2cm intervals. Samples were processed for mineralogical and geochemical analyses and different techniques were used: X-ray Diffraction (DRX), Atomic Absorption (AA) and Inductively Coupled Plasma-Mass Spectrometry (ICP-MS). The analyzed cores evidence similar bulk mineral composition at the four studied MVs. However, differences in mineral abundances could suggest a major contribution of clays in the northern volcano field as shown by the clay content at Perejil MV. In contrast, MVs from the southern volcano field (Carmen and Dhaka MVs) show similar abundances in bulk mineral components, thus supporting similar source contribution. Maya MV shows mixed bulk mineral composition. Such differences between the northern and the southern fields are further supported by the composition of the clay mineral assemblages. Differences are found in the smectite and illite abundances, being the smectites the predominant clays at Perejil MV, while illite is more abundant in Carmen and Dhaka MVs, whereas Maya MV shows particular proportions of smectite and illite. Such dissimilarities allow us to suggest distinct composition and/or depth of the source feeding materials between the northern and the southern volcano fields [table 1].

Tab. 1. Bulk mineralogy and clay mineral assemblages in mud breccias from Maya, Carmen, Dhaka and Perejil mud volcanoes.

		MAYAMV	CARMENMV	DHAKA MV	PEREJIL MV
BULK MINERALOGY	% Quartz	5-15	15-20	15-20	5-15
	% Calcite	<5-10	10-15	<5-20	<5
	% Clays	65-90	65-75	55-75	80-90
CLAY ASSEMBLAGES	% Smectite	40-75	30-40	25-40	55-70
	% Illite	10-50	40-55	20-60	20-30
	% Kaolinite+Chlorite	10-20	10-20	15-20	<5-10

The distribution of major and trace elements across the studied intervals resulted from a large number of processes. Typical detrital elements (Al, Si, K, Mg, Rb, Th and REE), which preserve the characteristic trace-element distribution of source rocks, show that mud breccias are not chemically homogeneous, because reported down core differences in detrital-element content from Perejil, Carmen and Dhaka MVs suggest potential differences in parental affinity as divergences in the relative contribution of the diverse

source layers and depths. Oscillations in redox-sensitive elements (U, Mo, V, Cr, Ni, Pb and carbonate associated elements as Sr) are observed at about the same depth than those reported for detrital elements, which also support a potential link with the nature of the source materials. Further investigation in clay mineral transformations will be need, in order to verify a potential smectite transformation in relation with a different depth source. Statistical analyses and chemical index of compositional maturity is in progress to confirm the relationship between chemical composition and source materials of the muc breccia as well as the influence of fluid activity in diagenetic process.

3D PALAEOCHANNEL RECONSTRUCTION IN THE LAGOON OF VENICE THROUGH GEOPHYSICAL EXPLORATION

F. Madricardo ^{1*}, J. A. De Souza ², S. Donnici ¹, R. Serandrei-Barbero ¹, I. Correa ² and A. Lezziero ³ ¹ Istituto di Scienze Marine, Castello, 1364a, 30122,Venezia, Italy - fantina.madricardo@ismar.cnr.it ² Center of Studies in Coastal and Oceanic Geology, UFRGS, 91501-970 Porto Alegre, Brazil ³ PHAROS sas, 30175 Venezia, Italy

Abstract

From 2003 to 2009 an extensive survey in a large area of the Venice Lagoon was carried out by means of acoustic techniques. The measurements were performed in extremely shallow water (up to 0.5 m). The acoustic data revealed the presence in the sediments of a complex network of buried palaeochannels and palaeosurfaces confirmed by numerous ground truth analyses carried out on the cores extracted in the area. In this note, a high spatial resolution sub-bottom mapping of the central Venice lagoon is presented. *Keywords: Lagoons, Geomorphology, Acoustics, Mapping*

Introduction

The Lagoon of Venice is the result of natural processes and intense human activities that determined its morphological evolution. The shallowness of the lagoon environment (average depth of about 1m) has for long time prevented the use of acoustic methods in this area. However, recent studies demonstrated that the use of sub-bottom profilers can be very useful to describe different phases of the lagoon evolution ([1], [2], [3] and refs. therein). In this contribution, we present the results concerning ultra shallow water (<1m) acoustic survey in the central lagoon between the industrialised area of Marghera and the city of Venice. The aim of our work is to reconstruct the complex subbottom architecture of a very anthropized environment through a multidisciplinary approach using acoustic and environmental data.

Methodology

With this purpose, a high spatial resolution survey was carried out using a traditional 30 kHz ELAC echosounder (with vertical resolution of about 10 cm) together with a DGPS system. Given the complexity of the buried morphologies, a 50 m parallel line survey grid was carried out in south-north direction (fig. 1).

Fig. 1. Study area and acoustic survey line grid (on the right), quasi 3D palaeochannels reconstruction (on the left) and cores SG33 and SG25 position.

In correspondence with interesting acoustic discontinuities, several ground cores were extracted. Here, we present the results of the two cores SG25 and SG33, drilled inside and outside the palaeochannels, respectively.

Results and discussion

The high spatial resolution grid of the acoustic survey allowed a 3D reconstruction of three palaeochannels. Their meandering paths is presented in fig. 1, where, at the same time, the information about the palaeochannel acoustic signal depth is mapped. In particular, the central palaeochannel was intersected by the core SG25. The SG25 stratigraphic record presents mainly clayey-silty sediments from -1.2 to -5.2 m and sandy sediments from -5.2 to -6.60 m from the mean sea level (m.s.l). The ¹⁴C dating taken at -5.2 m between the two facies allows the reconstruction of the palaeochannel shape of about 1600 \pm 90 cal yrs BP (grey line in fig. 2). The inclined reflectors in the southern side of the acoustic profile correspond to the palaeochannel point bar migration. The grey line seems to separate two different phases: an earlier high energetic regime with

sand deposition and channel migration and a later low energetic regime with a finer filling and apparently no migration. The two phases can be related to a change of the area hydrodynamics due to a climate worsening between the IV and VI century AD [4].

Fig. 2. Buried palaeochannel intersected by the core SG25 (black vertical line). The thick black lines show the channel point bar migration and stratification, while the dashed lines indicate palaeosurfaces. The grey line corresponds to the channel's shape about 1600 ± 90 cal yrs BP.

These palaeochannels probably incided the alluvial sediments, as, in this area, we found the lagoonal sediments down to about 2-3 m from m.s.l.. In particular, the core SG33 shows a transgressive sequence related to the expansion in historical age of the lagoonal margin over the mainland. This sequence is underlined by an environmental succession that goes from the alluvial to the high salt-marsh (at -1.47m) and, eventually, to the low salt marsh environment (at -0.77m m.s.l.).

This multidisciplinary approach allows for the first time a very detailed 3D reconstruction of palaeochannel paths and internal structures, of their meandering behaviour and of the palaeosurfaces evolution related to possible change of the central lagoon hydrology.

PRESENT-DAY REACTIVATION IN THE EASTERN IBERIAN AND BALEARIC MARGINS: MESSINIAN AS VERTICAL MARKERS.

Agnes Maillard ¹* and Christian Gorini ² ¹ LMTG, University of Toulouse, 31400, France - maillard@lmtg.obs-mip.fr ² University of P. et M. Curie, Paris 6, France

Abstract

The offshore Eastern Spain and Balearic margin area is studied with seismic lines and bathymetric data. The aim of the study is to use the MSC markers (erosions and deposits) in order (1) to provide a complete scenario of the Crisis from land to deep basin and (2) to quantify the vertical movements and recent tectonics implications. *Keywords: Messinian, Tectonics, Balear Islands, Continental Margin*

The Balearic area is located between two extensive basins, the Valencia Oligo-Miocene aborted rift to the North and the Algerian oceanic basin to the south. It is however the place of intense compressive activity as it has been affected by the Betic thrusts ([1], [2]), well known in the Ibiza and Mallorca Islands. The north of the Balearic promontory was during the Miocene a compressional front, whereas its southern border was the northern "passive or transform margin" of the Algerian basin ([3], [4]). From the Tortonian to now on, the northern edge of the Balearic promontory seems to have been affected mostly by extension. In southeastern Spain, the Western Internal Betics Ranges are actually affected by deformation like strike-slip, thrusts faults and uplift and by an important seismicity, as well as the adjacent Alboran Sea ([5], [6]). Between the Alicante Margin and the Ibiza Margin a strait connects the Valencia Trough and the Algerian Basin. An important work [5] studied the Present day deformation in the Alicante Region and showed a recent reactivation of the structures. Offshore, we show that the Eastern Margin of South Spain and south Balearic margin are also submitted to inversion. A dense net of seismic lines is used and the structural information is correlated with the very accurate multibeam maps that have been acquired [7] and show highs correlated to uplifted Miocene and/or Plio-Quaternary units. For example, a 650 m bathymetric high (150 m high relative to the surrounding seafloor, "El Cid" High) forms an E-W threshold between the La Nao Cape and Ibiza, also

observed by the seabeam map ([8]; figure 1).

Fig. 1. Bathymetric map and sonar between the Eastern Spain and Ibiza Island, from [8].

The Messinian unconformity between Miocene and Plio-Quaternary units is well marked in the area (M on figure 2). It has been followed and mapped from the Valencia Basin to the Algerian Basin through the high Balearic area and is a precious chrono-stratigraphic marker of the end of the Miocene. The El Cid fold is E-W elongated, in that parallel to the Betic front. The Betic front clearly predates the actual deformation, as shown by the Messinian unconformity that sealed the deformation. Figure 2 shows the proximity of structures deformed before the Messinian Salinity Crisis (MSC) and structures deformed after. Uplift can be important as eroded Miocene units and even MSC units can reach the sea-floor. The MSC resulted in the Balearic promontory not only in erosions but also in thin depositional units (combination of clastic, fluvio-lacustrine sediments, reworked material and/or evaporites?) that can be compared to the ones deposited in the Valencia Basin [9]. Those thin deposits are distributed in several small basins between Valencia and Algerian Basins. An isobaths map of the base of the Pliocene units (Maillard et al., in prep) shows that the area is however shallower than the Valencia area. The MSC markers must thus record the recent tectonics that uplifted the area. The location of these basins should however question the

relationship between deep basin evaporites and marginal evaporites. The studied area is well located because it records the MSC continuously from the land (evaporites in Salinas area, Bajo Segura Basin) to the deep basin, and from the intermediate depth basin (Valencia) to the deep basin (Algerian). The observations in this area provide a new basis to discuss not only the development of the MSC, but also the reconstruction of the uplifted and compressive structures in this area since 5 millions years. One important point is to understand how the compressional stress transmits from Algerian Sea once, but also through the thinned continental crust of the Alboran Sea once, but also through, which is more complex, the Algerian oceanic crust.

Abstract

Based on the age model put forward by the CIESM in 2008 a new Strontium (87 Sr/ 86 Sr) isotope curve for the Messinian salinity crisis (interval 6.5 Ma to 5.2 Ma) has been obtained plotting the available data from the literature and new data obtained from various regions of the Mediterranean area during the last years.

Keywords: Messinian, Stratigraphy, Geochemistry, Evaporites, Paleoceanography

Isotope geochemistry based on ${}^{87}Sr/{}^{86}Sr$ ratio have been used during the last decades to reconstruct the hydrological changes affecting the Mediterranean Sea during the Messinian salinity crisis ([1], [2], [3], [4]).

Unfortunately, the age models adopted for the calibration of these data appear not sufficiently accurate and not well stratigraphically constrained.

Following the new age model put forward by the CIESM consensus report ([5], [6]) and its successive refinements ([7], [8]) the strontium isotope data (87 Sr/ 86 Sr) available from the literature have been re-plotted, from 6.5 Ma to 5.2 Ma, together with new data obtained from various regions of the Mediterranean area during the last years.

According to the two-steps/three stage stratigraphic model ([5], [6]) the Messinian salinity crisis can be split into three main hydrological stages sharing different isotope trends.

Stage 1 (5.96-5.6 Ma)

The first stage, dominated by $CaSO_4$ evaporites, corresponds to the deposition of Primary Lower Gypsum (PLG). Most of the samples yield non-oceanic Sr isotope ratios with several exceptions that plot within coeval oceanic waters suggesting an evaporite basin dominated by continental waters that received significant marine recharges ([9]).

This stage was characterized by selenite precipitation in small and moderately deep (< 200 m), periodically oxygenated basins, and deposition of organicrich, barren shales and dolostones in larger, deeper basins characterized by oxygen-depleted seafloors. Evaporite facies and isotope characteristics suggest precipitation from a relatively homogenous Atlantic-fed water body with a partially reduced outflow with a significant contribution of continental waters.

Stage 2 (5.6-5.55 Ma)

The second stage, mainly characterized by $CaCo_3$ -NaCl-K salts, is characterized by a maximum Sr isotope data dispersion ranging from the global ocean field to lower values.

This phase marks the MSC acme and was triggered by a combination of pan-Mediterranean tectonic and climatic factors which caused a drastic reduction of the Atlantic connections and a possible short-lived blockage of the Mediterranean outflow, leading to salt and evaporitic carbonate precipitation during the TG14-TG12 interval.

Stage 3 (5.55-5.33 Ma)

The third stage, characterized by $CaSO_4$ evaporites, saw the deposition of the Upper Gypsum (UG) and Lago Mare sediments and is characterized by overall lower values of strontium isotope ratio than the coeval oceanic waters. Furthermore, the lower portion of this interval (Stage 3.1) is characterized by a depletion-upward trend, whereas the upper portion (Stage 3.2) is characterized by lower and less dispersed values.

UG selenite precipitation occurred from a large, residual water body only partially connected with the Atlantic. Surface waters sporadically undergoing progressive dilution due to a change in the precipitation regime and periodic inflow of evaporated continental waters. Tectonic quiescence and more generalized subsidence, also comprising the delayed effects of salt loading, were responsible for the progressive reestablishment of full connections with the Atlantic and the final Zanclean flooding.

Abstract

Microbial processes played a major role in mineral precipitation throughout the Earth's history. Such processes have been widely discussed for the last few decades with regard to carbonate precipitation. Other than microbial precipitation of carbonates, in natural environments is also of great interest the potential role of microbes in the precipitation of marine barite. Regarding carbonates, our experiments show how certain isolated bacteria from the Alboran Sea surface waters are able to precipitate different Mg-rich carbonates at modern marine seawater salinity. Ongoing work also focuses on bacterial precipitation of marine barite and its role in the biogeochemical cycle of barium and in the record of this element in Mediterranean paleoenvironments. *Keywords: Bacteria, Mineralogy, Alboran Sea, Sediments*

Introduction

Microbial processes have played an important role mediating carbonate production throughout the Earth's history [e.g., 1]. In particular, precipitation of microbial dolomite has been the focus of extensive research [e.g., 2], being this mineral is of key importance for understanding biogeochemical processes and cycles in past and modern environments. Thus, understanding of the microbiogeochemical processes involved in the precipitation of Mg-rich carbonates is essential to further understand the dolomite production in ancient environments. In this context, recent experiments have revealed that Ca-Mg kutnahorite, a mineral with a dolomite-ordered structure, can also be precipitated by bacteria [3]. As for dolomite, precipitation of Ca-Mg kutnahorite has been mostly obtained in hypersaline bacterial culture experiments. However, our recent work has demonstrated that marine bacteria were also able to precipitate this mineral at modern marine seawater salinity [4]. In addition to the investigation of microbial processes in relation to carbonates and the carbon cycle, the investigation of the biogeochemical cycle of Ba is also of major importance since both cycles are closely related and Ba is considered and excellent proxy of past marine biological productivity. The mechanism by which barite precipitates in undersaturated seawater still remains unknown. Considerable research has focused on this element over the last decades, but living organisms that directly precipitate barite have not yet been identified in seawater. Nevertheless, a reasonable proposal would seem to be that bacteria could play a role in this process. As an initial approach to this hypothesis we carried out an experiment using Myxococcus xanthus, an abundant and ubiquitous heterotrophic soil bacterium, and it was demonstrated that this microorganism induced barite precipitation [5]. As myxobacteria are recognized mainly as soil bacteria, ongoing work is being focused on the role of marine bacteria in sulfate precipitation.

Materials and methods

For carbonate precipitation experiments, a bacterial strain, MAH1, has been isolated from a seawater sample collected from the Alboran sea surface waters. It has been characterized using polyphasic taxonomy as Gram-negative, growing between 2-43 °C, heterotrophic, aerobic and required NaCl for growth. Results of phylogenetic analyses evidenced that the strain belongs to Idiomarina loihiensis species. For biomineralization experiments, the solid medium used was the marine medium (MM) (% w/v, yeast extract 0.5%, triptone 1%, purified agar-agar 2% in seawater from Alboran Sea, pH 7.6). For sulfate precipitation experiments, M. xanthus cells were inoculated on a solid culture medium with Ba (CM-Ba) (0.4% yeast extract, 2 mM BaCl2 · 2H2O, 2% purified Difco agar-agar in distilled water). To recover the precipitates formed, a needle was used for the largest crystals, and the small ones were recovered by melting the solid medium in a microwave oven. After this, crystals were washed with distilled water to eliminate culture medium remains and cell debris. Precipitate composition and morphologies were studied by Scanning Electron Microscopy (LEO Carl Zeiss GEMINI-1530, coupled with energy-dispersive X-ray microanalysis). Precipitate mineralogy was determined by X-ray diffraction using a Bruker D8 Advance diffractometer.

Results and dicussion

The MAH1 produced Ca-Mg kutnahorite and struvite at seawater salinity conditions. In this case, the amino acid metabolism resulted in a release of ammonia and CO_2 . Such release increased the pH and CO_3 ²⁻ concentration of the culture medium, creating an alkaline environment where saturation is

reached and thus carbonate precipitation occurred. It has also been suggested that specific attributes of certain bacteria promote calcium carbonate formation [6]. Precipitation of carbonates may thus be related to heterogeneous nucleation on negatively charged bacterial superficial structures. Furthermore, the nature of the organic matrix determines which ion is preferentially adsorbed and, consequently, which mineral phase is formed. Bacterial carbonate precipitation could therefore be strain specific. In this sense, a significant characteristic of the Idiomarina genus is its uniquely high content in odd-iso-branched fatty acids, suggesting that this particular membrane characteristic could induce Ca-Mg kutnahorite production. In fact, this production is not related to the medium composition since other bacteria also cultivated in the MM medium did not produce this mineral. In this regard, the precipitation of Mg-Ca kutnahorite by the investigated Idiomarina strains strengthens the hypothesis that the precipitation of a carbonate with a dolomite-type-ordered structure also occurs in marine environments at standard salinity [4]. In the case of sulfate precipitation by M. xanthus, crystal growth evolves from spheres to aggregates in which barite crystals become visible. The initial phase is a P-rich precursor phase, which suggests that phosphoryl and carboxyl groups in the structural polymers of the cell wall outer membrane may be sorbent constituents, which play an important role in the precipitation process [5]. These results were the first to indicate that barite precipitates in bacterial cultures, and the results support the hypothesis that the origin of this mineral may be bacterially mediated. Such precipitation suggests that in marine environments, bacteria may enhance barite production by providing nucleation sites and by producing crystal growth. This is, however, only an initial approach for future investigation regarding the role of bacteria in the Ba biogeochemical cycle.

Abstract

High-resolution swath data acquired using ship-borne and near-bottom multibeam systems have considerably increased our knowledge and understanding of active sea floor processes in the Mediterranean Sea. Swath mapping of large areas with ship-borne systems has revealed the regional distribution of seabed seepage structures in particular across the Eastern Mediterranean Sea deep-sea basins. Near-bottom multbeam data have revealed remarkable details of seabed features resulting from the expulsion of mud, fluid and gas. The latter data almost bridge the gap between ship-borne data and visual observations, and have been especially useful for planning in situ observations, measurements and sampling.

Keywords: Eastern Mediterranean, Swath Mapping, Mud Volcanoes

Multibeam seabed surveys conducted during the last decade in the Mediterranean Sea [1] have modified our understanding of the active geological and related biological processes that impact the seafloor of this oceanic space over time. One of the most spectacular results concerns the numerous seepage structures mapped and studied on the sea floor of the Eastern Mediterranean Sea, within two different tectonic settings: (a) tectono-sedimentary accretionary wedges (the Calabrian Arc and the Mediterranean and Florence rises) resulting from subduction of Africa beneath Europe [2] and (b) passive margin segments (particularly off northern Egypt) that have been the locus of huge sedimentary accumulations since Mesozoic times [3]. In this presentation, we briefly discuss and illustrate different types of data obtained using swath multibeam systems operated at different frequencies, and the potential level of interpretation they are providing to better image, study and understand the various fluid expulsion features and processes within the Eastern Mediterranean Sea. Multibeam systems provide two types of swath data: morpho-bathymetric data, and acoustic reflectivity (also often called backscatter or acoustic imagery). Swath data may be acquired using either ship-borne systems, typically located on research vessel's hull, or at much higher resolution using systems operating at near-bottom depths (10 to 50 m above the seabed), carried by Autonomous Underwater Vehicles (AUV) [4] or Remotely Operated Vehicles (ROV) [5] (Figure 1). - Swath bathymetric and acoustic imagery from ship-borne systems have allowed regional mapping of extensive fields of fluid escape structures, only some of which were previously known from either standard bathymetric mapping or discontinuous sonar studies. Compilation of data from numerous multibeam surveys [1] have provided regional maps at various scales (DTMs with pixel sizes ranging from 30-500 m depending on the area and the system used), which reveal the regional distribution of relatively large-scale features (a few hundred metres up to several km in diameter, and a few tens metres in elevation) such as mud volcanoes, mud flows, gas chimneys and caldera-like features [2,3]. These results have afforded insights into the relationship between seepage structures and the regional tectonic framework. For example, a clear link between back-thrusting and the distribution of mud volcanoes on the Mediterranean Ridge implies a fundamental role of tectonic lineaments as conduits for mud and fluid expulsion [2]. Similarly the non-random distribution of gas chimneys along the Egyptian continental margin may be explained by specific regional characteristics such as the presence or absence of underlying seals (Messinian salt deposits), the occurrence or lack of buried organic-rich deposits, and the re-activation of former fault zones [3]. In addition to regional mapping, ship-borne swath data have provided the necessary morphologic and acoustic backgrounds to better locate "in situ" studies of active fluid seepage using manned submersibles (e.g. the Nautile from Ifremer) [5] and/or ROVs (the Victor from Ifremer or the Quest from Marum) [4] - High-resolution swath data from near-bottom multibeam systems were first recorded over seabed seepage features in the Mediterranean Sea only 4 years ago (at least on the academic side). On the Egyptian continental margin, the first use of a multibeam system mounted on an Autonomous Underwater Vehicle (AUV) allowed the construction of morpho-bathymetric and backscatter maps with 1 m pixel resolution from mud volcanoes in water depths of 1200 m [4]. Elsewhere on the Egyptian margin, maps with pixel sizes of 30 cm have recently been obtained using a ROV over two active mud volcanoes in water depths of 3000 m. These data provide new insights into the functioning of fluid escape structures and facilitate in situ samplings and measurements at high accuracy. The acquisition of seafloor bathymetric and acoustic imagery of such high-resolution almost fills the gap in spatial scale between conventional ship-borne multibeam data and in situ direct or video observations made from submersibles or remotely operated vehicles.

Fig. 1. 3D high-resolution bathymetry view of "Chephren" twin mud volcanoes (1m grid) by 3000 m water depth (Northern Egyptian Margin) acquired with a multibeam mounted on the Victor ROV and operated at 400 kHz.

HIGH-RESOLUTION SWATH MAPPING OF SUBMARINE LANDSLIDES ON THE NICE SLOPE (LIGURIAN SEA) BY AUV SURVEYS: IMPLICATION FOR GRAVITY-FLOW TRANSFORMATION

S. Migeon ¹*, A. Cattaneo ², V. Hassoun ¹, A. Dano ¹, C. Larroque ¹ and E. Ruellan ¹ ¹ Géosciences Azur, Observatoire Océanologique, 06235, Villefranche sur Mer, France - migeon@geoazur.obs-vlfr.fr ² IFREMER BREST, Département Géosciences Marines, 29280, Plouzané, France

Abstract

The continental slope offshore the city of Nice was investigated in 2006 and 2009 using an AUV operating a multibeam EM2000 system. Abundant evidences of past and more recent failures were identified. Processes of flow transformation were also deduced from the changes of seafloor morphology suggesting that rapid processes of transformation of cohesive debris flows into turbulent flows occurred over short distance, less than 6-8 km downslope from the scars. *Keywords: Ligurian Sea, Swath Mapping, Sediment Transport, Deep Sea Processes*

Submarine failures are probably the sedimentary process which has the strongest impact on the erosion, shaping and evolution of continental slopes through time. Large-scale failures of volumes exceeding several hundreds of km³ are fortunately rare, with a return period of several thousands of years or more. Small-scale failures with volumes of several hundreds of m³ are still difficult to detect using conventional geophysical tools but are probably much more common, as return periods of 5 years or less have been evaluated where repetitive surveys were conducted (Smith et al., 2007). Thus, repetitive small-scale failures could also have a strong impact on the evolution of continental slopes over a short time, and lead to the deposition of high-frequency turbidites in the deep basins.

For marine environments, valuable geohazards and risk assessments require the precise identification of the different types of slope instabilities and evaluation of their recent or past activity, recognition and discrimination between several pre-conditioning and triggering factors (Locat, 2001). Identification of potential areas where slope movements could be triggered requires data whith higher resolution than those classically used until now in marine geosciences researches. Similarly, return frequency and triggering factors of slope failures are usually deduced from the study of past and buried landslides. It is then speculated that return frequency and triggering factors of future, present-day and past landslides are similar, but without any certainty. To address the problems of small-scale morphology of failures, recent triggering of landslides and volumes of slope deposits that could be remobilised during a failure event, the continental slope offshore the city of Nice was mapped in 2006 and 2009 using an AUV (Autonomous Undersea Vehicle) operating an EM2000 multibeam system.

The Nice slope is a real natural laboratory to investigate submarine landslides and gravity-flow processes. Using classical EM300 bathymetry (spatial resolution of 25 m) collected in the frame of the MALISAR project, 150-200 scars with volumes less than 8 x 10⁸ m³ were identified on the continental slope from the shelfbreak to a water depth of 1200 m (Migeon et al., Soumis). The HR bathymetric data (spatial resolution of 2 m) collected on the NIce slope using the AUV during the AUVGEO and MALISAR4 cruises revealed a greater number of failure-related scars with several morphologies: some scars are themselves affected by retrogressive processes of erosion, suggesting failures were triggered a long time ago, while some scars are still steep with no evidence of post-failure erosion, suggesting they could have been triggered recently. Downslope from the scars, seafloor exhibits the presence of abundant blocs, 5-m high and 40-m wide as an average, then well-developed asymmetrical waves, 1-m high and 20 m in wavelength as an average. Such evolution could evidence the transformation of the deposits reworked in the scars into cohesive debris flows responsible for the transport of blocs of undisturbed sediment, then into turbulent flows responsible for the construction of the waves. Such transformation took place usually in less than 6-8 km. In the areas of the continental slope where AUV data were collected in both 2006 and 2009, changes of the seafloor morphology were always identified. They consist in the apparition of new sacrs 10-20-m high or in the refreshing of pre-existing scars. These observations reveal the failure processes on the NIce slope are still active over very short periods of time.

INVESTIGATING THE ROLE OF MECHANISMS LEADING TO STAGNATING DEEP WATER IN THE EASTERN MEDITERRANEAN

Uwe Mikolajewicz 1* and Fanny Adloff 1

¹ Max-Planck-Insitut fuer Meteorologie, 20146, Hamburg, Germany - uwe.mikolajewicz@zmaw.de

Abstract

An ocean general circulation model is used to study the effect of several mechanisms that could have led to to stagnating deep water and thus formation of sapropels in the eastern Mediterranean. *Keywords: Paleoceanography, Circulation Models, Sapropel, Eastern Mediterranean*

During the early Holocene, the Mediterranean circulation has undergone considerable changes. These changes are reflected in the occurrence of organicrich marine sediment (called sapropels) in the eastern Mediterranean, which indicate the presence of oxygen depleted deep waters. The relative isolation of the basin together with a good coverage of available proxy data make this region an ideal test bed for modelling past climate changes.

The work presented here is a first step towards elucidating the mechanisms responsible for the formation of the sapropels. A regional version of the ocean general circulation model MPIOM (has been set up for the Mediterranean. This model was forced with daily atmospheric data derived from equilibrium time slice simulations with the global coupled atmosphere-ocean-dynamical vegetation model ECHAM5/MPIOM/LPJ (Mikolajewicz et al. 2007) for 9000 years before present. As the forcing data set has a length of 100 years, interannual as well as decadal variability are contained in the model forcing. The model derived river-runoff and ocean hydrography were used as additional forcings, the latter used as boundary condition at the Atlantic margin of the regional ocean model. Starting from homogeneous water, the model has been integrated for several centuries until a quasi-steady-state was reached. For the early Holocene, the runoff from the Nile is increased in comparison with present day conditions due to the enhanced African monsoon. The Bosphorus is assumed to be closed for this time period. These changes in freshwater input largely compensate each other in their effect on the upper-ocean salinity in the Levantine basin. The amplified seasonal cycle with reduced incoming short-wave radiation in winter leads to a general cooling. The enhanced summer warming is restricted to the uppermost layers. The model simulates the Adriatic as the main source of deep water for the eastern Mediterranean. Convection in the northern Aegean is strongly enhanced. Deep water ventilation rates show a marked decadal variability due to variations in the forcing. The obtained steady-state for 9000 years before present serves as baseline state for several perturbation experiments, which aim at elucidating potential mechanisms leading to stagnant deep water in the eastern Mediterranean. These experiments show that a sudden onset of an outflow from the Bosphorus or and or a sudden surface warming due to a reorganization of the Atlantic meridional overturning circulation are more effective to reduce the deep ventilation of the eastern Mediterranean, than a gradual freshening of the inflow from the Atlantic due to melting ice sheets. The vertical mixing reduces the effect of the initial perturbation and ventilation of the deep water slowly increases. An initial perturbation is sufficient to produce stagnant deep water for several centuries. In order to keep the deep water stagnant over several millennia, a strong initial perturbation needs to be combined with a weak, but permanently acting change forcing, e.g. the freshening due to the melting ice sheets.

INTRAANUAL VARIABILITY OF BIVALVIA ASSEMBLAGES IN THE TRANSITIONAL COMMUNITY OF DETRITC BOTTOMS OF THE NORTHERN ADRIATIC SEA

Vedrana Nerlovic 1* and Ana Travizi 1

¹ Ruder Boškovic Institute, Center for Marine Research, 52210, Rovinj, Croatia - vedrana.nerlovic@cim.irb.hr

Abstract

Present study is a part of comprehensive investigation of the soft bottom benthic communities in the northern Adriatic circalittoral zone. The goal of this study was to estimate intraanual dynamics of Bivalvia assemblages in the transitional community of detrict bottoms. Bivalvia assemblages structure was determined by the presence of 58 species, dominance of *Nucula nitidosa, Phaxas pellucidus, Tellina distorta, Thyasira flexuosa, Kurtiella bidentata*, and diversity ranged 19-31 species or 3,37-4,13 bits./ind. The results indicated abundant, diverse and stable community.

Keywords: Adriatic Sea, Bivalves

Introduction

The major part of the Adriatic Sea bottom belongs to the circalittoral zone and nearly all of the area of the mobile bottom is of the costal detrict type [1]. In this zone, variability of abiotic parameters is less pronounced than in the shallow infralittoral. Such environment support sustainable and stable benthic communities if strong environmental gradients and/or disturbance are not present. However, the northern Adriatic Sea is characterized by the full range of features associated with sensitive marine ecosystems, including temporary oxygen depletions [2, 3]. The community considered in this paper experienced heavy disturbance due to anoxia in 1989 [3, 4], but from that time severe oxygen crisis was not repeted [5]. Macrobenthic fauna and Bivalvia assemblages, in particular, are considered as very good indicators of ecocystem instability. In order to assess stability of transitional community of detritic bottoms, intraanual dynamics of Bivalvia assemblages was studied.

Materials and Methods

Bottom samples were collected with a 0,1 m² van Veen grab (five replicates) at sampling station SJ 007 (45° 17,0N; 13° 16,0'E) in the northern Adriatic Sea from February 2003 to January 2004. This site is caracterized by depth 31 m and silty-sand type of sediment dominated by fine and very fine fractions [3]. Benthic biocoenosis is classified according Pérès and Picard [6] as transitional community of detritic bottoms [7]. The material was treated according to standard field and laboratory procedure: sieving (1 mm mesh), fixation (neutralized 4% formalin and 70 % ethanol), sorting and counting of macrofauna [8]. Collected bivalves were counted and identified to the species level [9]. The bivalve assemblage structure was analyzed with the PRIMER v. 5 software package [10].

Results and Discussion

A total of 58 species belonging to 25 families were recorded. Classification analysis based on Bray-Curtis similarity matrices separated three group of samples with moderate to high affinity (Q=53-75%), associated with higher (>15 °C), intermediate (10-15 °C), and lower near-bottom water temperatures (<10 °C), Fig. 1.

Fig. 1. Hierarchical classification of samples. The affinity level based on Bivalvia assemblages structure was expressed as % of faunistic similarity among months

The global ANOSIM test showed significant differences (R=0,186, p=0,1%) in assemblages structure between months but without a clear seasonal pattern

(Tab. 1). In order to examine intraanual diversity changes, several univariate indices were calculated (S, d, J', H'). Statistically significant differences were found only for abundance values between March and May and for Shannon-Wiener diversity index between March and July, at p<0.05 level. Compared with results of previous study, provided at the same site in disturbed and unstable environmental conditions [3], this study revealed rather high values of univariate indices as well as its low intraanual variability. This investigation figured out rather abundant, diverse and stable Bivalvia assemblages with no clear seasonal distribution and thus, suport the hypothesis of sustainable and stable benthic community.

Tab. 1. Results of ANOSIM test (R=0,186, p=0,1%). Statistically significant differences between pair of months where indicated with asterisk (*).

Abstract

Rapid climate variability in the Western Mediterranean for the last 4000 years is reconstructed using high resolution marine sediments. Fluctuations in chemical and mineralogical sediment composition are linked to fluvial-eolian input and redox conditions coinciding with wet (Roman Humid Period, Medieval Warm Period) and dry (Little Ice Age, Late Bronze Age-Iron Age) periods. Such oscillations support the coupling of the Mediterranean climate with the North Atlantic climate system. Keywords: Western Mediterranean, Alboran Sea, Paleoceanography, Geochemistry, River Input

Introduction

Although relatively more attention has been traditionally devoted to major climate changes during the last glacial cycle, the Holocene has also been punctuated by significant rapid climate variability including polar cooling, aridity and changes in the intensity of the atmospheric circulation [1]. During the Late Holocene (last 4000 years), the Medieval Warm Period (650-1150 cal. BP) and the Little Ice Age (150-650 cal, BP) have been the best identified climate fluctuations worldwide[2]. Previous work has revealed that Western Mediterranean is a highly sensitive area to abrupt forcing at millennial scales during the last glacial cycle ([3], [4]), supporting its link with the North Atlantic ocean-atmosphere system. The aim of this work is to reconstruct the paleoenvironment of the last 4000 yrs based on a multi-proxy approach that includes major and trace element-content and mineral composition of marine sediment records.

Material and methods

Two gravity-cores (305G, 306G) recovered during the Training Through Research Cruise 14, Leg 2, in the East Alboran Sea basin in 2004 have been selected. Both cores were sampled at 1 cm thick slices, to obtain a high resolution record of the last 4000 years. Samples were air-dried and homogenized to carry out mineralogical and geochemical analyses: X-Ray Diffraction, Transmission and Scanning Electron Microscopy, Atomic Absorption and Inductive Coupled Plasma-Mass Spectrometry. Grain size was also determined as a cumulative mass percentage using Sedigraph. The age-depth model has been based on six 14C-AMS dates performed on planktonic foraminifera (Globigerina Bulloides) extracted from the >125 µm fraction. Redundancy analyses of the datasets were carried out using the R software.

Results and discussion

Fluctuations of chemical and mineral composition of marine sediments coincide with significant Late Holocene climate oscillations. A decrease in fluvial-derived elements/minerals (e.g., Rb, detrital mica) occurred during the so-called Late Bronze Age-Iron Age and the Little Ice Age Period, while an increase is recognized during the Medieval Warm Period and the Roman Humid Period. This last trend is parallel to a decline of element/minerals of typical eolian source (Zr, kaolinite) with the exception of the Roman Humid Period when the Zr/Al ratio increases. Although barium has been proposed and used as a paleoproductivity proxy in the Mediterranean Sea at time of sapropel deposition, geochemical and statistical analyses show that during the Late Holocene, instead it provides information on detrital input, being associated with alumino-silicates. Furthermore, during this period, productivity reached low levels in relation to previous productive episodes (e.g. sapropels, Heinrich events). In fact, biogenic barite has not been detected in the studied cores. In the most recent sediments, an anthropic contribution is evidenced by a significant increase in the Pb content.

MODÈLE MATHÉMATIQUE CONCERNANT LE TRANSPORT ALLUVIONNAIRE PAR LE DANUBE VERS LA MER NOIRE

Mihai Horia Oprica 1*

¹ University politehnica of Bucharest, 060042, Roumanie - hoprica@yahoo.com

Abstract

On considère un modèle mathématique pour le transport alluvionnaire. Le modèle est basé sur l'équation de convection-diffusion de l'écoulement non permanent. Les équations sont intégrées numériquement à l'aide d'un schéma de différences finies. Keywords: Water Transport, Models

Introduction

On présente un modèle mathématique pour le transport alluvionnaire en courant naturel dans différentes conditions. Parmi les processus impliqués dans ce phénomène, on prête une attention spéciale au transport alluvionnaire par l'eau courante et son interaction avec les sédiments de fond. Le modèle est basé sur les équations de Saint-Venant, caractéristiques du mouvement unidimensionnel non permanent des fluides à surface libre et l'équation de convection-diffusion.

Modèle mathématique concernant l'écoulement unidimensionnel non permanent avec la surface libre.

On applique les équations de Saint-Vénant :

$$\begin{split} B\frac{\partial z}{\partial t} &+ \frac{\partial^2 Q}{\partial x^2} = 0\\ \frac{\partial Q}{\partial t} &+ \frac{Q}{A}\frac{\partial Q}{\partial x} - \frac{Q^2}{A^2}\frac{\partial A}{\partial x} + g\frac{n^2Q|Q|}{AR^{1/3}} + gA\frac{Q}{A}\frac{\partial z}{\partial t} + Vg = 0 \end{split}$$

où : V - vitesse moyenne en section, g - accélération de la gravitation, A - surface de la section transversale, x - distance au long de l'écoulement, t - temps, z - côte de la surface libre, Q - débit qui passe par une section d'écoulement, B - largeur moyenne, R - rayon hydraulique, n - coefficient de Manning [1].

Les déversements en mer posent un important problème de pollution lié à l'accroissement local de la turbidité et au dépôt de sédiments sur le fond. La turbidité, associée à la concentration de particules solides en suspension, provoque une extinction plus rapide de la lumière solaire et une réduction de la synthèse chlorophyllienne.

Dans les mers peu profondes, on se limite généralement à l'étude de la concentration moyenne dans la colonne d'eau et de la concentration du dépôt sur le fond.

L'équation décrivant l'évolution de la concentration moyenne des suspensions est obtenue à partir des équations de dispersion tridimensionnelles par intégration sur la profondeur. La moyenne sur la profondeur des termes quadratiques de convection donne deux contributions : la première contient le produit des moyennes, la seconde, la moyenne du produit des déviations autour de la moyenne. Cette seconde contribution a une structure analogue à celle des tensions de Reynolds et les expériences montrent qu'elle est effectivement responsable d'une dispersion turbulente, mais souvent beaucoup plus intense. Cet effet porte le nom "d'effet cisaillant" [2] parce qu'il est lié à l'existence d'un gradient vertical de vitesse. Il a été décrit par de nombreux auteurs dans des conduites, des canaux ou des estuaires. Dans ces cas, l'effet cisaillant apparaît après intégration sur toutes sections droites de l'écoulement et se traduit par un terme de dispersion longitudinale dans une équation de diffusion unidimensionnelle. Le mécanisme de diffusion est essentiellement bidimensionnel et les modèles établis pour diffusion doivent être généralisés [3].

Les particularités de l'équation de dispersion (présence de dérivées croisées et du terme de sédimentation, dominance des termes d'advection) imposent l'utilisation d'une méthode numérique spéciale [4] et [5].

Résultats et Discussions

Dans le cas du fleuve Danube, le cours entre Tulcea et la Mer Noire, les débits liquides varient entre 5 000 m³/s et 12 000 m³/s, tandis que les débits solides entre 10 kg/s et 22 kg/s. Le diamètre granulaire varie entre 74 et 100 micromètres. Dans l'évaluation des résultats, on a tenu compte du relief du lit du Danube, de la granulométrie, ainsi que d'autres paramètres hydrauliques (vitesses d'écoulement, pente hydraulique, coefficient de Maning, rayons hydrauliques des sections tranversales données). Les résultats théoriques d'observation organisées dans le cadre d'un programme national roumain sur

l'environnement.

Abstract

The joint analysis of the data of iron and manganese species distributions (dissolved Fe(II) and Fe(III), dissolved Mn(II), dissolved bound Mn, particulate Fe and Mn) obtained in the Black Sea and the Oslo Fjord allowed to reveal the common features, that testify the similarity of the mechanism of the redox layer formation in these regions. *Keywords: Black Sea, Redox, Vertical Profile, Metals, Anoxia*

Distributions of chemical parameters in the redox zone were studied in the Black Sea (northeast region, central and coastal parts) and Oslo Fjord (Bunnefjorden and Baerumsbassenget), during spring-summer 2008 and 2009. The specific features of the hydrochemical structure observed in the studied objects are summarized in Table 1.

Tab. 1. Parameters of Mn and Fe distributions in the redox zones of the Black Sea and the Oslo Fjord

	Black	k Sea	Os	lo Fjord
	Center	Periphery	Bunnefjorden	Baerumsbassenget
Main features	stable hydrophysical structure	enhanced mixing due to RIM current	flushing ones per several years	anoxygenic photosynthesis and river inflow
Depth, m max / redox interface	2100 / 70-90	500 / 140-155	160 / 80-90	31 / 16-23
Thickness of suboxic zone, m	10-17	0-12	0-12 14	
c(Mn_diss)max, uM	8-9	7-8	8-10	4-4.6
c(Mn_part)max, uM	0.2-0.4	1-2	1.3-2.1	0.7-1
c(Mn_bound)max, uM	1.8	0.5	1	0.6
grad(Mn_diss)max, uM/m	0.55	0.4	1.1	5.5
c(Fell)max, uM	0.34	0.45	0.33	0.4-1.4
c(FellI_diss)max, uM	0.08	0.05	0.03	0.04
c(Fe_part)max, uM	0.15-0.29	0.22-0.48	0.18-0.22	0.60-0.85
grad(Fell)max, nM/m	5-10	5	19	500

Iron and manganese species distributions and redox zone structure at all are very similar in the Black Sea and the Oslo Fjord/Bunnefjorden. The abnormality of the biogeochemical structure in the Baerumsbassenget can be connected with the influence of a river or/and anoxygenic photosynthesis, because this redox interface is in a very shallow position, about 20 m. The suboxic zone in this fjord has a reducing character [1].

Our investigations demonstrated that Mn bound in stable complexes with hypothetically organic matter or pyrophosphate is observed in the redox zones in significant concentrations (up to 2 uM) [2], and is likely presented by Mn (III), an intermediate product of Mn(II) oxidation. On the base of the recent data obtained in the 100^{th} cruise of RV "Professor Shtokman" (March-April, 2009) it was found that the bound Mn could exist in two forms – colloidal (0.02-0.40 um) and truly dissolved (<0.02 um) that perhaps results from complexing with different types of ligands. Bound Mn in colloidal form amount to 50-90% of total bound Mn in coastal and central parts of the Black Sea respectively.

Redox interfaces are characterized by a formation of a so-called "phosphate dipole" with a minimum above the sulfidic boundary and a maximum just below, with a steep increase in concentrations between the two. The hypothesis that P and Mn cycles are interconnected by the formation of complexes between Mn (III) and P-containing ligands can explain the presence of the shallow phosphate minimum above the sulfide-interface [2, 3]. The presence of the deep phosphate minimum (below the sulfidic boundary) is probably due to the formation of P-containing iron particles [4]. This dipole structure serves as a geochemical barrier that decreases the upward flux of phosphate from the anoxic layer.

Modeling results shown that exactly manganese cycle (formation of sinking down Mn(IV) and presence of dissolved Mn(III)) is the main reason of oxygen and hydrogen sulfide direct contact absence [3]. The model experiments

enabled the role of a number of factors (amount of Mn, intensity of mixing, sinking rate, anoxygenic photosynthesis) to be assessed [1]. We suggest that in nature all the factors analyzed are not constant and can vary from region to region and from time to time. Their exact combination results in the shape of the distributions of the observed parameters.

MONITORING THE FLOW AND THE PHYSICAL PROPERTIES OF A SUBMARINE GROUNDWATER DISCHARGE IN MESSINIAKOS GULF (SOUTHERN GREECE).

Vassilis P. Papadopoulos ¹*, Aristomenis P. Karageorgis ², Dimitris Georgopoulos ² and Evagelos Papathanassiou ² ¹ Hellenic Centre for Marine Research, Local Office of Achaia - vassilis@ath.hcmr.gr ² Hellenic Centre for Marine Research, Institute of Oceanography, 19013, Anavyssos, Greece

Abstract

We present the first obtained time series of a monitoring project studying a submarine groundwater discharge (SGD) in Kalogria Bay, Greece. During a previous survey in the area, salinities ~1-2 were detected. The emerging flow and the physical characteristics of the upwelling water are recorded by means of a rotor flow meter and a CT probe. Both were deployed on a metallic frame which was placed at the sea bottom inside a karstic cavity. Salinity values between 20 and 36 have been recorded, indicating a brackish water outflow during the dry season of the year (July-October 2009). The water outflow exhibited velocities ranging from 8 to 28 cm/sec. *Keywords: Salinity, Monitoring, Brackish Water, Eastern Mediterranean*

Submarine groundwater discharges (SGDs) are detected in many coastal areas on a global basis and today they are recognized as important factors of landocean interaction, with potential socioeconomic benefits [1]. In the Mediterranean Sea, they are traced mainly along coasts with karstic structures within the inland coastal zone [2]. In December 2006, an expedition carried out on board the R/V AEGAEO of the Hellenic Centre for Marine Research, visited the eastern Messiniakos Gulf coasts around the Kalogria-Stoupa marine area (SW Peloponnissos). A CTD probe, carried by a diver inside a submarine karstic cavity, where groundwater discharged, recorded salinities ~1-2 at a water depth of ~25 m. The low salinity encouraged a monitoring project in prospect of exploitation of the discovered fresh water. In July 2009, a flow meter (model Sensordata 6000), and a conductivity-temperature (CT) recorder (model SBE-37) were deployed, attached on a stainless-steel frame close to the sea bottom inside the cavity. The instrumentation is scheduled to be recovered for

Fig. 1. Salinity fluctuation near the disharge point.

maintenance and data uploading from time to time, usually at monthly intervals. Figure 1 shows salinity variations during the first two deployments, from 22 July 2009 to 8 October 2009. The main feature observed is the relatively high salinity values, when compared against the value of salinities ~1-2, which were recorded in December 2006. Salinities fluctuate between 20 and 36, accompanied by a persistent high frequency oscillation with an amplitude range between 2 and 6. Another characteristic is that the oscillation amplitude is fluctuating proportionally with the salinity. As salinity values decrease, the oscillation amplitude is apparently reduced. We can also observe the remarkable jump in salinity values between the recovery and redeployment of the CT probe on the 1st of September (Fig. 1). This sudden rise could be primarily attributed to the very low discharge of the SGD (dry period, summer-early autumn), which results in an extremely unstable turbulent regime around the discharge point, and secondly to a possible slight different position of CT probe after the redeployment. The latter could be related to a possible rotation of the frame, and a consequent slight increase of the distance from the water discharge point. Another possible explanation could be attributed to external factors associated with the local circulation patterns. The coastal sea current may drive the upward flow and cause a declination from the vertical direction. Such persistent sea currents prevail at times in Messiniakos Gulf with their maximum speed occurring near the coastline [3]. However, still this jump remains unclear, since the temperature

variation does not exhibit a similar behavior, but a normal transition between the 1st and the 2nd deployment period. Contrary to salinity, temperature follows a normal fluctuation with the highest values of 24-26 °C occurring during the last days of August. The strong turbulence also affects the temperature variation with a constant oscillation amplitude of 2-4 °C. As far as it concerns the flow measurements, the values recorded during the first few days of the deployment, they were between 20-27 cm/sec. Unfortunately, an instrument malfunction truncated the first deployment period to a total length of only 4 days (30 minutes interval). To ensure a total coverage of the deployment period during the second deployment, a pair of flow meters were installed on the frame, one at the same position as the previous, and another one exactly at the base of the frame. The latter covered the period from 2 to 15 September 2009, and the span of useful data was limited to the half of the deployment period due to a blockage of the rotor by a coarse sand grain with a diameter of 1-2 mm. During that period, upward water flow velocity ranged from 18 to 24 cm/sec, with an ascending trend during the last days of recording. In order to extend the recording period, the upper flow meter was set to take measurements at a time interval of 3 hours. This flow meter provided a useful period of flow velocity records until 30 September 2009, with velocities strongly fluctuating between 8 and 28 cm/sec. A spectral analysis performed to the flow measurements highlighted both diurnal and semidiurnal peaks of the power spectral density. This is expected, as in general the SGDs can be modulated by the prevailing tidal regime [4]. In summary, the obtained monitoring data demonstrate a strongly turbulent and unstable SGD, regulated by the geomorphologic (karstic) structure of the coastal zone and modulated by factors as the local yearly precipitation cycle and the tidal regime. Continuous monitoring of the SGD will reveal in detail, the annual cycle of the discharged water velocity, volume, and salinity variations, since they are the crucial parameters for the potential exploitation of the outflowing water. In summary, the obtained monitoring data demonstrate a strongly turbulent and unstable SGD upflow, regulated by the geomorphologic (karstic) structure of the coastal zone and modulated by factors as the local yearly precipitation cycle and the tidal regime. The monitoring of the SGD will reveal in details, the annual cycle of the upward flow and the salinity fluctuation since they are the crucial parameters for exploiting the upwelling water.

Abstract

Active methane seeps are present at the sea floor in the Eastern Mediterranean and Marmara Sea. The flow rate, temperature and chemistry of venting fluids differ largely from one site to another, depending on the source and depth of fluids. We present here the mineralogical and stable isotope compositions of carbonate crusts and concretions that were precipitated at or close to the sea floor and have registered the great variability of the fluids from the Mediterranean Ridge, Nile Deep Sea Fan and Marmara Sea cold seeps. *Keywords: Bacteria, Eastern Mediterranean, Marmara Sea, Deep Sea Processes, Mud Volcanoes*

Active cold seeps in the Eastern Mediterranean were described since years 80's and their study was completed by deep-sea observations and sampling during oceanographic cruises using submersibles (MEDINAUT in 1998, NAUTINIL in 2003, MEDECO in 2007). In the Marmara Sea, cold seeps were observed in 2002 during the MARMARASCARPS cruise with ROV dives [1] and they were sampled using the submersible Nautile during the MARNAUT cruise in 2007. A few articles refer to the carbonate crusts from the MEDINAUT and NAUTINIL cruises [2],[3],[4].

Methane-rich fluids venting at sea-floor through geological structures as mud volcanoes, pockmarks and faults support specific chemosynthetic ecosystems where the microbial communities are particularly active in the carbon and sulfur cycles. The most important microbial process involved in these environments is the Anaerobic Oxidation of Methane (AOM) that is coupled with Bacterial Sulfate Reduction (BSR). During this process, the methane contained in the advected fluids is oxidized by the sulfate ions provided either by diffusion from bottom seawater or by advection of sulfate-rich brines.

The overall reaction describes the transfer of oxidized and reduced carbon and sulfur components:

 $3CH_4 + 3SO_4^{2-} + Ca^{2+} \implies 3HS^- + CO_2 + HCO_3^- + 4H_2O + CaCO_3$

Carbonate and sulfide minerals are the two most important by-products of this reaction; their mineralogy may vary, depending on the cations and metal elements that are available in the fluids. Calcium carbonates (aragonite, calcite and magnesian calcite) dominate, especially in the upper sediments whereas magnesium-rich and iron-rich carbonates (dolomite, ankerite, siderite) increase progressively at depth.

The oxygen and carbon isotopic compositions of the diagenetic carbonates display very wide ranges that define three groupings :

1] The Mediterranean Ridge: the carbonate crusts are characterized by ∂^{13} C values mostly in the range from -15 to -30‰ and more rarely down to -45‰; they include the highest ∂^{18} O values (from 2.4 to 7.1‰).

2] The Nile Deep Sea Fan : the carbonate crusts display generally lower ∂^{13} C values than the previous grouping, from -25 to -41‰; the range of ∂^{18} O values is relatively narrow (2.4 to 4.8‰), except rare outlier lower values (-0.5 to 1‰).

3] The Marmara Sea : the carbonate crusts show the largest range of $\partial^{13}C$ values from -13 to -47.6‰; the range of $\partial^{18}O$ values is shifted to negative values (3.6 to -2.1‰).

The very low $\partial^{13}C$ values of diagenetic carbonates at all cold seep sites confirm that they are methane derived; the close association of carbonate with pyrite in the diagenetic crusts as well as biomarker proxies indicate that AOM was operating in conjunction with BSR.

The ∂^{18} O values of carbonates mostly reflect isotopic equilibrium with the present-day bottom sea water; the heaviest ∂^{18} O values from the Mediterranean Ridge are explained by the contribution of 18O-rich fluids originating from clay mineral dehydration at great burial depth; the lowest ∂^{18} O values are due either to high heat flow in Amon mud volcano or to the contribution of brackish fluids in the Marmara sea.

Abstract

The Calabrian Arc (CA) is part of the most active seismic belt in the Central Mediterranean region and it has been struck repeatedly by very strong historical earthquakes often associated with destructive tsunami. We addressed CA tectonics through an integrated geological/geophysical approach which has the potential to reveal if subduction is active, to map location and geometry of major faults absorbing plate motion, and to unravel relationships between tectonics, sedimentation and fluid flow in the accretionary wedge. *Keywords: Ionian Sea, Active Margins, Tectonics, Sedimentation, Seismics*

The Calabrian Arc (CA) subduction complex connects the E-W trending Sicilian Maghrebian belt with the NW-SE trending Southern Apennines (Fig. 1) and develops along the African-Eurasian plate boundary in the Ionian Sea.

Fig. 1. Tectonic map of the study area with location of profile CROP M2B. Tectonic model from [1]. Seafloor bathymetry: GEBCO One Minute Grid.

At the toe of the CA, the thick sedimentary section of the African plate has been scraped off and piled up along thrust faults. This contributed to emplace a thick and about 300 Km wide subduction complex represented by a well developed accretionary wedge, multiple slope sedimentary basins and a seaward dipping continental backstop (Fig. 2). Although the regional architecture of the margin geometry has been described through the analysis of high penetration seismic data [2,3,4], some major questions are still debated: where is located the outer deformation front marking the Africa/Eurasia plate boundary? What is the location, nature and geometry of active faults absorbing plate motion? Are there evidences of the geological record of past catastrophic events in the subsurface?

Fig. 2. Line drawing of pre-satck depth migrated MCS line CROP M-2B across the CA subduction system.

In order to address these issues we analysed in detail the structure and the evolution of the external CA through an integrated multi-scale geophysical approach that involves the combined analysis of multi-channel and single channel reflection profiles together with morpho-bathymetric data [5]. The interpretation of this multi-scale data-set represented the basis for a geophysical/geological cruise (CALAMARE cruise - Calabrian Arc Marine Geophysical Experiment) carried out in April-May 2008 with R/V CNR Urania [6]. We acquired geophysical (high resolution MCS reflection profiles and sub-bottom CHIRP) and geological data (gravity cores) in three key-areas selected

through the interpretation of available data (outer and inner deformation fronts and the western lateral boundary of the subduction complex at the foot of the Malta escarpment). Sediment cores have been collected above morphological swells related to argilo-kinetic processes and within sedimentary basins in order to apply submarine earthquake geology in the CA and analyze the geological record of past catastrophic events in the subsurface. We collected well targeted sediment samples in tectonically controlled sedimentary basins to study the indirect effects of fault activity (i.e. mass wasting events, sand injections, turbidites, etc). Sediment cores from the Ionian abyssal plain and slope basins on the accretionary wedge have sampled turbidite sequences which likely contain a record of the great earthquakes or catastrophic events in the region. Radiocarbon ages will be obtained from monospecific planktonic foraminiferal samples above and beneath suspected seismic related deposits, while Pb210 and Cs137 radiocarbon dating will be applied to selected cores to resolve sedimentary structures associated with some recent events. If we will be able to make correlations between the sedimentary record (of earthquake-triggered submarine landslides or turbidites) and the earthquake catalogue in Southern Italy, we will try to extend the paleoseismic catalog further back in time. This approach has the potential to determine which portions of the arc have recorded catastrophic events in the past and which is the recurrence time of major events in the different regions of the subduction system. The lack of seismicity along the CA subduction fault plane (with a characteristic shallow dipping thrusttype focal mechanism) can mean either that subduction has ceased or that subduction is active but aseismic or locked. Diverse earthquake scenarios can be envisioned depending on which of these hypotheses is taken into account and the implication of each scenario for the hazard facing this region vary widely. The integrated analysis of the multi-scale geological/geophysical data-set acquired in the frame of the CALAMARE project has the potential to reconstruct CA active deformation and improve seismic risk assessment in the Central Mediterranean region.

Abstract

Multidisciplinary studies of mud volcanoes at two sites on the Calabrian Arc provide evidence of post-glacial eruptions, and of ongoing seabed seepage that supports 'hotspot' ecosystems. Mud breccias within gravity cores record at least one extrusive episode since the last glacial maximum c. 20 ka. Seabed investigations using ROVs document ongoing seepage of gas, at one of the sites associated with chemosynthetic ecosystems and with localized outflows of warm mud. Gas hydrates are theoretically stable on the Calabrian Arc and their post-glacial destabilization represents a possible driver of seabed extrusive and seepage activity. Keywords: Eastern Mediterranean, Ionian Sea, Deep Sea Sediments, Mud Volcanoes

Mud volcanoes were discovered offshore southern Italy during the 2005 HERMES-HYDRAMED campaign of the Italian research vessel OGS Explora, which acquired the first regional multibeam coverage of the Calabrian accretionary prism [1]. Many possible seepage sites were recognised [see 2], of which two were proven to be mud volcanoes through the acquisition of multichannel seismic data and gravity cores containing mud breccias. Seabed investigations of these two sites were subsequently undertaken using remotely operated vehicles (ROVs) during campaigns of the r/v Meteor (M70/1, 2006) and the r/v Pourquoi pas? (MEDECO, 2007). In this presentation we summarise evidence for recent eruptions and ongoing seabed seepage.

The two investigated sites lie in water depths of 1600-2300 m on the inner and central Calabrian Arc. Within the inner Spartivento forearc basin, the Madonna dello Ionio comprises three MVs, twin cones each up to 140 m high and 1.5 km wide, and a caldera up to 3 km across. On the central thrust-fold belt, the Pythagoras MV is a single mud pie up to 9 km wide, rising up to 350 m above a seabed moat. Seismic data grids across both features show the seabed mud volcanoes to be the tops of extrusive edifices that extend over 1 km into the subsurface and interfinger with the flanking sedimentary succession above a regional unconformity of mid-Pliocene age, c. 3.5-3.0 Ma [3].

Recent extrusive activity is indicated by sediment cores from the Madonna dello Ionio and Pythagoras MVs that show oxidized mud breccias to lie near seabed, beneath a veneer of hemipelagic sediments. At the Madonna dello Ionio MVs, mud breccias have erupted since the last glacial maximum (c. 20 ka), based on radiometric dating and stratigraphic markers within the hemipelagic sediments. In the caldera at the head of the Madonna, mud breccias are overlain by sediments dated to c. 15.5 ka, and appear correlative to a mud breccia lens in a nearby core 1 km from the edge of the caldera. A younger extrusive episode may be recorded by mud breccias at the base of one of the twin cones of the Madonna which are overlain by marine sediments dated to c. 2 ka.

Seabed investigations using ROVs (video observations, geothermal probes, sediment and water samples) provide evidence of ongoing seepage. At both sites, bottom waters contain methane concentrations 100-200 times normal background levels. At the Madonna dello Ionio, all three MVs have elevated geothermal gradients, 2-20 times higher than adjacent areas, and fresh outflows of warm mud were observed on two of the MVs. The tops of all three MVs are otherwise characterized by a metre-scale relief comprising mud breccia flows mantled by hemipelagic sediments, the latter exhibiting intense bioturbation in the form of conical burrows; a 30 cm blade core contained chemolithotrophic tubeworms (polychaetes) and other fauna consistent with reduced conditions. At the Pythagoras MV, an area of chaotic seabed, with irregular relief developed in exposed mud breccias, suggests a recent and violent local extrusive episode.

Glacial-interglacial changes in sea level and bottom water temperatures suggest a possible climatic influence on mud volcanism. Gas hydrates are theoretically stable on the Calabrian Arc and their post-glacial destabilisation in response to warming bottom waters could provide a driving mechanism for recent eruptions and ongoing seepage.

Abstract

Climate variability for the last 20.000 years in the western Mediterranean Sea has been reconstructed using geochemical and mineralogical proxies. An excellent high-resolution record from the East Alboran Sea basin has been analyzed. Geochemical data have provided detailed information on paleoclimate conditions and have allowed to establish fluvial and eolian input oscillations during abrupt climate changes, as well as the paleoxigenation conditions at time of sediment deposition. *Keywords: Western Mediterranean, Alboran Sea, Deep Sea Sediments, Atmospheric Input, Geochemistry*

Introduction

Eolian input from the Sahara and other arid regions surrounding the Mediterranean has provided a considerable amount of dust particles contributing to the terrigenous sedimentation [e.g., 1]. This contribution was especially significant during glacial times when the eolian dust into the atmosphere increased through intensified surface winds, lower surface humidity and enhanced desertification [2]. The high sedimentation rates from the westernmost Mediterranean provide excellent conditions for reconstruction of the eolian input record at very high resolution and in turn atmospheric response to climate variability.

Material and methods

A gravity core 293G (402 cm length), recovered in the East Alboran Sea basin during the cruise Training Trough Research 12 Leg 3 (Lat. 36'10.414N, Long. 2'26.071W, water depth 1840m) was chosen for this study. It contains hemipelagic sediments composed of homogeneous green-brownish mud with some shell fragments, foraminifera and bioturbated layers. A continuous sampling every 1.5 cm was carried out for the interval spanning the last 20 kyr. Radiocarbon ages and stable oxygen isotope record from planktonic foraminifera (*Globigerina bulloides*) have provided a detailed age model. Sediment samples were analyzed using X-Ray Diffraction, X-Ray Fluorescence and Inductively Coupled Plasma Mass Spectrometry.

Results and discussion

Preliminary results indicate that the Heinrich event (H1) has been a generalized cold and dry period as shown by high δ^{18} O values and increasing ratio of eolian input proxies such as Zr/Al, Ti/Al and Si/Al (Fig. 1). In addition, an increase in deep water ventilation points to the injection of large volumes of freshwater from melting iceberg that reached the westernmost Mediterranean, causing a weakened in the Mediterranean thermohaline circulation [3]. During the Bölling-Alleröd period (B-A), a stable trend in thermohaline circulation is evidenced by lower oxygen bottom conditions and the oxygen isotope record. Therefore, this warm and humid period has been characterized by a decrease in values of eolian detrital proxies, indicanting a weaker atmospheric circulation as also supported by pollen records from this region [4]. Geochemical proxies also evidence a particular atmospheric configuration during the Younger Dryas chronozone (YD). Variations in detrital proxies suggest an increasing fluvial activity at the onset of this period, which points to a coupling between the hydrological cycle and the cold atmospheric configuration due to enhanced sporadic rainfalls. More stable climate conditions characterized the Holocene that is also punctuated by significant climate fluctuations such as the 8.200 yr cold event.

Abstract

Based on a revisitation of the main outcropping Messinian successions on Cyprus, Zakynthos, Crete and of subsurface data from offshore areas, a preliminary stratigraphic model for the Eastern Mediterranean basin has been reconstructed and compared to the Western and Central Mediterranean basins.

Keywords: Messinian, Stratigraphy, Evaporites, Eastern Mediterranean

The Eastern Mediterranean record of Messinian events is mainly preserved in deep offshore basins. The limited and scattered Messinian outcrops of marginal basins offer a unique opportunity to find out a key for interpreting coeval offshore successions and thus reconstructing the development of the Messinian salinity crisis (MSC) of this area. This is a fundamental step for establishing the stratigraphic relationships between western and eastern Mediterranean Messinian units and testing the MSC two steps/three stages scenario recently put forward by CIESM [1], [2]. We focussed in particular on the Messinian successions of Cyprus and Zakynthos. A complete revisitation of Southwestern Cyprus Messinian basins (Polemi, Pissouri and Maroni/Psematismenos) led to point out that the local Lower Gypsum unit actually consists of clastic evaporites associated with subordinate gypsum cumulates deposited in very shallow depocenters, thus suggesting that only the second MSC step is here recorded (stages 2 and 3). The basal part of the unit usually comprises clastic carbonates ("barre jaune") containing resedimented selenite fragments formed during the first MSC step (PLG-Primary Lower Gypsum). This unit passes upwards to both stratified and/or chaotic gypsum-bearing clastic deposits. Gypsum cumulates commonly occur in the intermediate part of the unit; at Maroni the latter deposits show evidence for precipitation in very shallow water (bird tracks), but no clear desiccation features have been observed throughout the succession. We interpret these deposits as a shallow-water equivalent of the RLG unit (Resedimented Lower Gypsum), defined in western and central Mediterranean [1], [2] and recording the very short second MSC stage during which large volumes of halite and K-salts precipitated in deeper basins. These deposits are conformably overlain by the Upper Gypsum and Lagomare units which are very similar to their Sicilian equivalents [2], [3]. According to this interpretation, the base of the local Lower Gypsum unit is actually a regional unconformity corresponding to the Messinian erosional surface (MES) which can be traced downbasin in the offshore domain at the base of the deep basin evaporitic unit (Mobile Unit in [4], [5]). Halite is not preserved in this basin, but according to the regional scale considerations [6] it is possible that small lenses can be found included within the RLG unit. The Zakynthos Messinian succession shows a complex evaporite distribution largely controlled by synsedimentary compressive tectonics, very similar to what we have observed in the Northern Apennines and Sicily [2], [7], [8]. Step 1 Primary Lower Gypsum cyclically stacked selenites (PLG), cut on top by the MES and unconformably capped by thin paleosoil-bearing Lago Mare deposits, occur in shallow wedge-top basins (Kalamaki section); deeper depocenters formed in front of the main thrust fronts are characterized by the accumulation of thick clastic gypsum (RLG), also comprising displaced selenite blocks (Agios Sostis section). Subsurface data indicate that the RLG unit also contains thin lenses of halite developed in the more subsiding sectors of the basin(s) (K. Nikolaou, Hellenic Petroleum, 2009, pers. comm.). These results suggest that, like in the western and central Mediterranean areas, the eastern Mediterranean record of the 2nd MSC stage is characterized by the generalized dismantling of first step primary evaporites (PLG). This was probably triggered by tectonic activity coupled with sea-level falls during TG12-TG14 glacials which caused a concurrent short-lasting block of deep Mediterranean water outflow and the consequent widespread precipitation of halite in deeper basins and of gypsum cumulates in shallow marginal basins. However, the lack of evidence for desiccation in the latter settings suggests that the amplitude of the associated sea-level drop could have been considerably lower than the usually envisaged 1.5 km. A revisitation of available cores suggests that the evaporites included in the Upper Evaporites seismic unit in both western and eastern deep Mediterranean basins have mainly a clastic and subaqueous nature. Moreover, the high 87Sr/86Sr values of halite and/or anhydrite recovered from DSDP sites

374 and 376 suggest that, similarly to what observed for the Lower Evaporites, the usually envisaged correspondence between the seismically defined and the outcropping Upper Evaporites units is highly questionable. These data and observations result in a comprehensive MSC evolutive scenario based on more reliable stratigraphic correlations between marginal and deep basins across the western and eastern Mediterranean basins.

Abstract

The present work reports the main results obtained from a number of different acoustic and video investigations carried out at different spatial scales within the Mediterranean Santa Maria di Leuca (SML) Cold-Water Coral (CWC) province (south eastern Italy – northern Ionian Sea). The different scale of data sets here presented and discussed vary from small scale maps that resolve regional geomorphology of the Apulian plateau, to large scale maps provided for one representative site, where video-data, high resolution side scan sonar mosaic and micro-bathymetry well describe micro-scale variations in mound geomorphologic attributes and associated habitats.

Keywords: Geomorphology, Swath Mapping, Mapping, Ionian Sea, Biodiversity

Along the oceanic margin and in particular in the Mediterranean Sea, CWC distribution has been better known during the last decades thanks to the new technologies nowadays available for exploration in deep sea environments. The recent use of acoustic survey techniques and remotely operated vehicles (ROVs) revealed the presence of living CWC at different locations in the Mediterranean sea (i.e.: the Straits of Gibraltar [1], the Alboran Sea [2, 3], the Sicily Channel [4, 5], the Ionian Sea [5, 6, 7], and the Southern Adriatic Sea [5, 8]); although the Ionian Santa Maria di Leuca (SML) CWC province represents the largest occurrence of a living white coral community known in the Mediterranean so far. Several national and international oceanographic expeditions (e.g. the 2002 CNR COR2 cruise, the three cruises of the 2003-2005 Italian aplabes project, the 2006 CNR CORSARO cruise promoted by the cooperation between Euromargins/Eurocore 'Moundforce' ESF program, the 2006 METEOR M70 cruise and the 2007 MEDECO cruise of the EU 'Hermes' project) were initiated after the SML province's discovery, producing a number of different "seafloor mapping data". From these, three different scale of data sets are here presented and discussed: (1) a small scale morphobathymetric map (1/1000000) that resolve the regional geomorphology of the Apulian plateau; (2) a detailed medium scale morphobathymetric map (1/50000) obtained from multibeam data acquisition; (3) a large scale morphobathymetric map of one representative coral mound, where video-data, high resolution side scan sonar mosaic and micro-bathymetry have been collected. Small scale map (coming from the Gebco Digital Atlas) shows that the SML CWC province is located along the upper slope of the gently southeastward dipping Apulian continental margin, the large-scale morphology of the area is related to a strong tectonic control. The multibeam data set collected between -300m and -1300m of water depth, over more than 900-km2 survey area, provided a detailed medium scale morphobathymetric map, in which several geomorphic processes are recognized, superimposed on the regional large-scale morphology [7]. In particular broad slope erosion, sediment sliding, block tilting and collapse and prominent downslope massmovements were identified and drift sedimentation is also recognised along a central large ridge [6, 7]. Within this dataset CWCs are found along a depth belt between 500 and 900 m and in different physiographic settings, although they look to be abundant within the broad area affected by downslope masstransport deposits [7], [9]. Here a detailed ROV-based survey, carried out in the framework of the Hermes project by the use of the VICTOR6000 ROV (MEDECO cruise - R/V Pourquoi Pas?), provided a high resolution mapping survey [10] at one representative seafloor feature identified as a coral colonised positive structure (coral-mound) during previous cruises. The relevant seafloor mapping data here presented, collected at different spatial scales, show how the large-scale mapped coral distribution and the mound morphology are well correlated to the environmental controls under which coral mounds can develop. These results also show how large scale maps can help in provide a proper assessment on CWC distribution along small scale maps and therefore show how such methodologies are essential to support deep-sea habitat mapping purposes, finding a way to extrapolate substrate maps into habitat maps based on acoustic proprieties.

TAPES PHILIPPINARUM (ADAMS & REEVE) HARVESTING EFFECTS ON SEDIMENT SETTLEMENT RATES AND EROSION PROCESSES IN THE LAGOON OF VENICE (ITALY).

Adriano Sfriso¹*, Chiara Facca¹ and Sonia Ceoldo¹

¹ Department of Environmental Sciences, University Ca' Foscari Venice - sfrisoad@unive.it

Abstract

Tapes philippinarum harvesting by means of mechanical and hydraulic dredging systems heavily affects the benthic habitats and the water column as huge amounts of sediments are resuspended. In the present paper the results obtained in three areas of the lagoon of Venice (Italy) are compared in order to quantify such effects and to highlight the different impacts occurring in the free clam-harvesting areas against the clam-farming ones. In field the sediment settlement rates were measured by means of sedimentation traps and the changes of bottom level were recorded by means of suitable devices fixed to the sediment surface. Results proved that clam-farming areas were affected by a minor sediment loss. In addition, marine seagrasses appeared to significantly favour the sedimentation and trapping of resuspended particles. *Keywords: Bivalves, Sedimentation, Erosion*

Introduction

Tapes philippinarum (Adams & Reeve, 1950) was introduced in the lagoon of Venice in the early 1980s for economical proposes. In a few years' time it colonized large lagoon areas triggering an intense and indiscriminate harvesting activity. Until the late 1990s, harvesting areas, boat efforts and number of employees were not regulated, producing dramatic consequences for the environmental conditions. Since 2000 the local authorities have promulgated a plan for the management of clam resources in order to safeguard the ecosystem and to guarantee the maximum sustainable yield [1]. The main idea was to turn the free clam-harvesting into clam-farms, identifying suitable areas for this activity. The present paper aims at describing the effects of both free clam-harvesting and clam-farming activities on the sedimentation rates and bottom erosion.

Materials and Methods

Three areas were identified in the lagoon of Venice: one north of the Venice historical centre (northern area), the second in the central (central area) and the third in the southern (southern area) parts of the lagoon. The northern and central areas were still characterized by free clam-harvesting whereas the third was among the first licensed zones. Two sites were chosen in each area in order to have a harvesting/farming area and a control area. In each site a sedimentation trap, which collects settling sediments [2], and a device, to measure changes in bottom level [3], were placed. The sites were monitored monthly from February 2001 to January 2002.

Results and discussion

The results showed that the northern area (Fig. 1), with 268 kg dwt $m^{-2}\ y^{-1}$ in the control site and 735 kg dwt m⁻² y⁻¹ in the harvesting site, was affected by a high sediment settlement so highlighting the strong impact of clam-catching. As in this part of the lagoon the water residence time is quite high, it can be considered that the resuspended sediments settled in almost the same zone where they were removed. On the other hand, the central area is characterized by a high water renewal, so the resuspended sediments are mainly lost seawards. In fact, in such area, the annual sedimentation (control: 119 kg dwt m⁻² y⁻¹; harvesting site: 282 kg dwt m⁻² y⁻¹) was, approximately, 2-3 times as low as in the northern one, although the harvesting pressure was even higher. In the site of the southern area, where clams are farmed, the sedimentation rates were not significantly different from the control one (control: 266 kg dwt $m^{-2}\ y^{-1};$ farming site: 257 kg dwt $m^{-2}\ y^{-1}).$ In the farming area the low harvesting impact (1 harvest per m⁻² in two years instead than 10-15 harvests per m⁻² each year, as in the free clam-harvesting areas) and the role of seagrasses to avoid sediment loss were observed to be relevant. In fact, sedimentation rates were strongly different only in spring, because of seagrass unrooting inside the farming area, whereas in the other period sedimentation rates were similar (Fig. 1). In addition, the dense seagrass populations growing all around the farming area reduced the loss of fine sediments which were resuspended during the farming activities. Although the different sedimentation rates observed in the fishing and control areas, all the studied sites, on a yearly basis, showed an increase of the bottom level and hence a depositional trend; only few observations had negative values. Because a significant loss of fine material was recorded in other studies [1, 2, 3], these results probably depend on the fact that the selected stations were placed in areas low affected by the lagoon hydrodynamics or inside seagrass meadows. However, the results show that, in general, the sedimentations rates were significantly higher in the harvesting areas than in the control areas, whereas no significant differences between the clam-farming area and the control one were found. The planning of seeding and harvesting activities can be a really

efficient tool to reduce the sediment resuspension. Moreover, the presence of seagrass meadows around the clam-farming areas can contrast the loss of fines reducing the environmental impact of such activities.

SEDIMENTOLOGICAL AND GEOCHEMICAL CHARACTERISTICS OF MODERN ARAGONITE-RICH SEDIMENTS IN MEDITERRANEAN KARSTIC MARINE LAKES (MLJET ISLAND, ADRIATIC SEA)

I. Sondi ¹, N. Mikac ¹, I. Jurina ¹*, N. Vdovic ¹ and D. Barišic ¹ ¹ Rudjer Boskovic Institute, Zagreb, 10000, Croatia - ijurina@irb.hr

Abstract

Sedimentological and geochemical characteristics of aragonite-rich sediments in semi-enclosed, karstic, marine lakes on the island of Mljet (Adriatic Sea), have been investigated. The lakes and their sediments are a unique sedimentological environment characterized by authigenic formation of aragonite mud in a restricted Mediterranean environment [1,2]. The results have shown that distribution, diagenesis, and the historical record of the presence of trace metals are mostly dependent on sedimentological processes associated with the inorganic formation of aragonite, and prevailing physico-chemical conditions. *Keywords: Geochemistry, Trace Elements, Adriatic Sea*

Study Area

Veliko and Malo Jezero (the Mljet Lakes) are located in the western part of the island of Mljet (42° 47' N, 17^{\circ} 21' E; Adriatic Sea) (Fig.1A). These are two typical semi-enclosed karst depressions (*doline* or sinkholes) which were formed under subaerial exposures, and are today submerged due to the Holocene sea-level rise [3]. Being connected with the sea, they contain sea water and therefore, can be termed marine lakes. Due to their depth of 47 and 29 meters, respectively, they can not be termed lagoons, because these are usually defined as shallow semi-enclosed water bodies having depths that seldom exceed a couple of meters.

Materials and Methods

Undisturbed sediment cores were collected at three sampling stations (Fig. 1A) by an Uwitec gravity corer, and immediately frozen and kept at -20°C until further analyses were performed. Cores were cut into 2 cm segments and analyzed by Xray diffraction, scanning electron microscopy, laser diffraction particle size analysis, high resolution inductively coupled plasma mass spectrometry, and gamma spectrometry.

Fig. 1. The investigated area of the Mljet Lakes with: (A) sampling stations; (B), SEM microphotographs of needle-like aragonite particles; and (C) framboidal pyrite in sediments from Malo Jezero (Station 1).

Results and Discussion

The results have shown that sediment cores consist of muddy sediments which, according to Folk & Ward [4] can be classified as slightly gravely mud (Stations 1 and 2) and gravely mud (Station 2). There were no changes in the granulometric characteristics in core sediment samples with depth. Samples were mainly composed of aragonite, calcite, Mg-calcite, and dolomite. However, the ratio of carbonate polymorphs in surface sediments varied. Aragonite, in the form of needle-like particles (Fig. 1B), was the most abundant mineral phase in sediments at Station 1, with approximately 70% in total carbonate content. The vertical distribution patterns for redox sensitive trace elements, particularly Mo (Fig. 2), together with the presence, morphological characteristics and size of framboidal pyrite at the deeper part of core sediments (Fig. 1C), suggest the existence of euxinic conditions in the sedimentary system in lake history of the Malo Jezero (Station 1) [5]. Higher concentration of Cu, Cd, Zn, Sn, and Pb in surface sediments, taken from the sediment core from Station 2, indicates a substantial increase in their loads in the last 50 years. The only cause for this enrichment could be anthropogenic activities. However, the measured concentrations still reflect a relatively low level of anthropogenic metal pollution. The observed high

concentration of Sr, and its distribution in sediments, is directly influenced by authigenic formation, deposition pattern and the content of aragonite. The obtained results should help to understand the processes involved in distribution of trace metals, governed and accompanied by early diagenetic processes and physico-chemical conditions, in aragonite-rich sediments in the Mediterranean marine environments.

Fig. 2. Vertical distribution of redox potential (Eh) and concentration of Mo in the sediment cores from sampling Sations 1 and 2.

Abstract

Our micropaleontological investigation on the mud breccia matrix from three mud volcanoes in the Alboran Sea (Western Mediterranean) reveals that the extruded sediments are from olistoliths of different ages contained in the main olistostromic complex. The ages of their more recent activity has been dated with AMS ¹⁴C. The mud breccia acts as an ideal substratum for cold-water coral colonies, whose development is, however, not linked to seepage activities. *Keywords: Alboran Sea, Mud Volcanoes, Foraminifera*

The Dhaka, Maya and Carmen mud volcanoes (MV), located in the Mud Diapir Province in the Western Alboran Basin along the Moroccan Coasts were cored during the TTR-17 Leg 1 research cruise. Cores were taken on the top of mud volcanoes at Dhaka (water depth of 370 m) and Maya (water depth of 410 m) and on the flank at Carmen MV (water depth of 806 m).

Recent volcanic activities have been dated by mean of AMS 14 C. At Maya MV the most recent activity is as old as 15583 +/- 185 yrs BP. At Dhaka MV the most recent volcanic activity occurred between 4346 +/- 60 yrs BP and 4165+/- 62 yrs BP.

Mud diapirism and mud volcanism in the area are supposed to originate in the lowermost sedimentary sequence on the basis of both seismic interpretation [1] and micropaleontological analysis of the extruded mud breccias [2]. A new micropaleontological study was undertaken to better constrain the age of the source sediments.

At Dhaka MV the planktonic foraminiferal assemblages present in the mud breccia matrix result to be mostly composed by rare Recent-Holocene forms and more abundant mixed Late Cretaceous (Lower and Late Maastrichtian), Miocene (generally Serravallian) and Pliocene species. Late Eocene and Oligocene specimens, together with very rare shallow water benthic forms such as *Amphistegina* sp. and *Elphidium* spp. are also documented.

At Maya MV planktonic foraminifera of Late Cretaceous (Campanian - Maastrichian) are dominant, while Miocene and Oligocene forms are very rare. Shallow water specimens of *Elphidium* are present but generally rare.

At Carmen MV the mud breccia contains dominant planktonic foraminifera from Zones N8-N10 (Middle Miocene). Late Cretaceous species are very rare and only very rare specimens of Upper Albian species have been observed. Shallow water species include *Ammonia beccarii* and *Elphidium* spp.

Based on these observations we identify the lowermost olistostromic sedimentary unit present in the Alboran Sea and documented in [1] as the main source of the extruded material at Dhaka, Maya and Carmen Mud Volcanoes [2]. We also suggest that the age difference in the source sediments of the three mud volcanoes is due to the presence of olistoliths of different ages in the main olistostromic complex.

On top of the mud breccia extruded by both Dhaka and Maya MVs small patch reef and/or isolated cold-water corals found an ideal substratum for colonization. However, no relation with seepage is observed at both mud volcanoes as indicated by carbon isotopes values of benthic foraminifera in the range of "normal" marine waters not affected by hydrocarbon.

This study is funded by the Swiss National Science Foundation Projects 200021-111694 and 200020-117928.

GAS BUBBLING AND ROCKS FORMATION IN THE ADRIATIC SEA

Antonio Stefanon^{1*} and Antonio Campagnol²

¹ Ca'Foscari University of Venice Dept of Environmental Science, 30123, Venezia, Italy - stefanon@unive.it ² Antonio Campagnol Capitaneria di Porto. Fondamenta delle Zattere, 30100, Venezia, Italy

Abstract

Gas seeps and related rocks are known both in the northern and central Adriatic sea. Gas imageries – "ghosts" included – in boomer records appear to be limited north of the Jabuca deep only but are very frequent north of the Po delta. The rocky outcrops in the northern Adriatic – locally named "tegnue" by fishermen – are made up by organic reefs grown upon base rocks (methanites) formed by the cementation of local sediments because of methane seeps. The timing of these processes is certainly related to the sea level and climatic changes and will be properly defined, as hereby outlined *Keywords: Shoreline Evolution, Sediments*

The rocky outcrops off the Italian coasts both in the northern and central Adriatic are related to gas seeps, but the ones in the northern part lie at limited depth (less than 50 meters) and host abundant organic growth capable of forming luxurious algal reefs [1]. The others, in the central Adriatic, are relevant to the pock marks area in about a 100 meters water depth, east off Ancona. They are located over a large oil/gas field [2], and the dredged rock samples appear free of organic growth. The area is poorly studied and the situation appears to be very similar to the much better known North Sea pock marks. The Northern Adriatic Sea rock outcrops are formed by hard substrata supporting the growth of algal reefs [3], locally named "tegnue" by fishermen. These base rocks are locally sea bed sediments lithified by methane seeping through them [4]. Depending upon the sediments permeability (both horizontal and vertical), the seeping methane forms horizontal slabs, sometimes superimposed and cemented to one another, or vertical pinnacles less than 2 meters high. Since all these rocks must have been cemented only under a sediment cover, their outcropping must be due to a strong erosion, responsible of wiping out at least 7 metres of loose sediments, as one of the rocks is about 6 meters high [5]. The ages of the algal reefs (not vet properly determined) which now live at depths from about 8 to 45 metres are strictly depending on the time the base rocks were uncovered and/or submerged during the last deglaciation. Other questions are the age of the bed rocks found at different depths: the ages of their datable carbonates might have been corrupted by the age of the methane involved in their cementation New outcrops of base rock have been found last year off Grado, in about 2.5 metres water depth only, close to the remains of a ancient church, submerged now at 3.5 metres water depth. And yet archive documents testify that church hosted a holy service in 1723 ! These unexpected findings suggest further new ideas on the Northern Adriatic Sea evolution since at least the last glaciation.

GAS DETECTION CAPABILITIES, GAS INDUCED ACOUSTIC STRUCTURES AND GHOST IMAGERIES IN UNIBOOM RECORDS IN THE ADRIATIC SEA

Antonio Stefanon¹* and Andrea Falconi²

¹ Ca'Foscari University of Venice Dept of Environmental Science, 30123, Venezia, Italy - stefanon@unive.it ² CAM IDROGRAFICA, 30126, Venezia, Italy

Abstract

UNIBOOM and similar boomer systems can easily monitor the presence of even the slightest gas content in the sediments, because of the relevant variations in the sound velocity and in the acoustic impedance The gas behaviour related to the grain size and the permeability versus the frequency and the signature of the acoustic impulse give sometimes inexplicable or at least very difficult imageries and records.

Keywords: Stratification, Sediments, Geophysics, Acoustics

For a proper appreciation of the importance of gas in the acoustic behaviour of wet sedimentary sequences we must take into account the strong variations in the sound speed in the different systems, according to the gas percentage in the interstitial waters. The relevant sound velocity in waters can vary from about 1500 m/s down to about the same speed in air, that is in the order of 350 m/s! This implies large variations of the acoustic impedance and very strong gradients in limited space, depending from the gas content only. The history of sedimentary sequences may be better described [1] if different gas diffusion and/or intrusion can be attributed to episodes of the same type but occurring in different times. A good example is offered by the sedimentary sequence of the Jabuka deep [2] in the central Adriatic, where surface pockmarks and buried ones (aborted?) appear to have occurred in different times, but driven by the same and much more deeper gas source. Gas concentrations in sedimentary layers give more problems than help in evaluating the acoustic records given by UNIBOOM, boomers or similar high resolution microseismic systems. In any case the presence of gas always reduces more or less the acoustic penetration. Vertical penetration of 100 metres or more can be easily achieved, in fine, no-gassy sediments as in the southern part of the central Adriatic sea, where a resolution of about 20 centimetres can be achieved. Penetration over 200 metres is rather unusual and achievable only in areas free from potential gas sources as in the gulf of Taranto, in the Jonian see. Some other examples are given, as also "ghost" imageries and geologic hazards [3]. The excellent results can be achieved only if the behaviour of the used system is very well "understood" by the user, with special regard to the geometry of the towed gears. Most of the "tricks" used to achieve the best results lie in regulating the distances and the reciprocal position of the hydrophone and the boomer plate, respectively emitting and receiving the signals. If the geometry is perfectlyset, the acoustic multiples will disappear and there will be no need at all to filter the received echoes. In some cases the geometry must be adjusted to the acoustic characteristics of the boat or ship used. Such difficulties are generally underestimated by the "standard" users, who are not always satisfied with their results. The conclusion is that in the last ten to twenty years the use of UNIBOOM and similar sound systems has largely diminished in favour of systems that are much more simple and easier to handle, like sub-bottom profilers, CHIRP and similar ones

PATELLA RUSTICA FROM OFFSHORE SHELL ASSEMBLAGES IN THE CENTRAL ADRIATIC RECORDS HUMAN USE OF LIMPETS IN MEDIEVAL TIMES

Marco Taviani¹, Lorenzo Angeletti¹ and Alessandro Ceregato^{1*}

¹ ISMAR - CNR, Via Gobetti 101, I-40129 Bologna, Italy - alessandro.ceregato@bo.ismar.cnr.it

Abstract

Empty shells of the upper intertidal limpet *Patella rustica* were recovered in the central Adriatic at a depth of c. 200 m. These shells dated at 1050 ± 97 yrs BP cal. were likely discarded by medieval seafarers, probably using limpets as food or fish baits. *Keywords: Adriatic Sea, Gastropods, Fisheries*

Introduction

Offshore sampling of death shell assemblages in the central Adriatic during CNR cruise ARCO of RV *Urania* recovered empty shells belonging to *Patella rustica* Linnaeus, 1758 (Fig. 1) at an average depth of c. 200 m. This common upper intertidal limpet inhabits rocky substrate in the Mediterranean Sea and Eastern Atlantic Ocean (e.g. [1]).

Fig. 1. Patella rustica Linnaeus, 1758. - St. ARCO 40

Two adult shells were identified at stations ARCO 40 and 50 (tab.1) characterized by an abundance of deep water corals (*Lophelia pertusa*, *Madrepora oculata* and *Dendrophyllia cornigera*)dated at the latest Holocene, and last glacial molluscs (predominantly the subtidal bivalves *Pseudamussium peslutrae* and *Panomya norvegica*). Since *Patella rustica* is ecologically inconsistent with both assemblages, the reason of its occurrence in such deposits was inquired.

Tab. 1. Two adult shells were identified at stations ARCO 40 and 50

Station	Gear	Lat Start N	Long Start E	Lat End N	Long End E	Depth m (Start/End)
ARCO 40	Epibenthic dredge	42°52.90'	15°03.67'	42°55.24'	15°02.33'	187/190
ARCO 50	Epibenthic dredge	43°10.86'	15°09.86'	43°10.80'	15°08.10'	210/232

Discussion and results

One shell (ARCO st. 50) was AMS-14C dated providing a calibrated age of 1050 ± 97 yrs BP. The presence of limpets of such an age in these offshore deposits may be accounted by (i) natural transport from a nearby insular rocky shore, (ii) dropping from birds (for example a seagull), or (iii) by human interference. The absence of suitable rocky substrates in this area permits to

discard the first option; bird discard so far from the nearest coastline is a remote possibility. Therefore, in all likelihood, these medieval limpets were deliberately discarded by humans, possibly Adriatic seafarers. In general limpets were and are collected either for human consumption or as baits for fishing (e.g., [2; 3]). We cannot identify at present neither who were the users of limpets nor the limpets' actual utilization. As a working hypothesis we suggest that seafarers possibly came from Dalmatian coasts characterized by abundant and accessible limpet populations because of the widespread of suitable rocky shores.

Acknowledgments : Thanks are due to Captain , cruise and colleagues onboard RV *Urania* during cruise ARCO (December 2008). Partial funding provided by CNR and EU Hermione project.

GEOLOGICAL RISK AND CLIMATIC CHANGES ON THE IONIAN CALABRIAN COASTAL ENVIRONMENT: A CASE STUDY

Chiara Tessarolo¹* and Alessandra Savini¹

¹ Dip. Scienze geologiche e geotecnologie, Università Milano Bicocca, Milan, 20126, Italy - chiara.tessarolo@gmail.com

Abstract

The recent origin and the active dynamism of the Italian margins, associated to the sea level variations and the climate, represent an important aspect connected to the actual coastal environment. Recent Morpho-Bathimetric survey allows to map a wide area of the Calabrian margin, pointing out interesting features and characteristics suitable for the geomorphology and the possible coast modification comprehension.

Keywords: Coastal Systems, Swath Mapping, Active Margins

The tectonic evolution of the italian region, connected to the climate impact and to the sea level oscillation [1], make the coastal domain a very variable and interesting zone to study and comprehend.

Going beyond this environmental point of view, the strong colonization of the coasts in the past decades has strongly impacted its actual conformation, pushing both the research and politic interests to a deeper consideration of this zone [2]. One of the main aim of these studies is based on the comprehension and evaluation of the coastal zone evolution, in function of climate changes and of the directly connected suitables risks [3]. From this point of view, the Geologic Sciences and Geotechnologies Depattment of the Milano Bicocca University has been recently involved in the study of a sector of the Ionian Calabrian Margin, first with the VECTOR Project (Vulnerability of the italian coastal area and marine Echosystems to Climatic changes and Their rOle in the mediteRranean carbon cyrcles), and more recently by the MAGIC Project (Marine Geohazards Along the Italian Coast).

These two projects lead to the realization of an high detail Morpho-Bathymetric data mapping on a wide sector of the Calabrian seafloor, realized using a Multibeam Echosounder System (Reson Seabat 8160).

Fig. 1. Location and detail of the realized swath survey on the Ionian calabrian Margin (Magic-Vector Projects)

The data processing and elaboration allow to investigate the shelf and slope domains, recognizing interesting features developed at different scale (Canyons, incisions, slope and slide scars and deposits,.. [4]), and to advance preliminary hypothesis about the local margin evolution.

The actual configuration of this margin is in fact the result of the traslation of the calabrian Arc linked to the Tyrrhenian basin opening (Miocene), and of the coupled occurrence of compressive stress on the Eastern advancing front, cause of the local high relief, of the narrow shelf, and of the still active tectonic [5], with an evaluated uplift trend of 0.89 - 1.4 mm/y [6].

These elements, coupled to climate regime, contribute to the occurrence of mass wasting episodes on the shelf and upper slope, increasing the local instability of the whole submerged margin, and stressing the possibility of risks, for the human infrastructures and cities wide extended on the coastal zone, whose comprehension is the main aim of the indicated studies.

Fig. 2. Risk elements on the considered margins: the canyons head, deep incided on the shelf and very close to the coastal line, and the seismo-stratigraphic evidence of creep like, instable features, observed on channel rim.

Abstract

The integration between high-resolution multi beam bathymetry, side scan sonar data, high resolution chirp sonar provide a frame functional to the identification and mapping of a variety of deep-sea benthic habitats including healthy Lophelia, Madrepora, Dendrophyllia and Desmophyllum often associated with sponges and polychaetes. Coral growth took place in areas of irregular topography, created by large slide blocks such as Gondola slide, or on the steep flanks of Bari canyon and Dauno seamount. In both cases a key factor is the concurring action of dense NAdDW water mass impacting seasonally the SW Adriatic margin. Keywords: Continental Slope, Currents, Swath Mapping, Deep Sea Ecology

The SW Adriatic Margin stretches NW-SE for about 150km and it is affected by numerous failure events that generated slide scars up to 10 km wide and extensive slide deposits with run out distances greater than 50 km from the shelf edge to the slope base (Gondola slide). On the open slope, the interaction between cascading and contour-parallel bottom currents with the irregular morphology of the margin leads to the definition of locally enhanced energetic condition at the sea-floor, as suggested by a suite of intermingled bottom current deposits and related erosional features (sediment drifts, bifurcated sediment waves, furrows and scours) ([3]). Bari Canyon is the main sediment conduit deeply entrenched in the SW-Adriatic Margin formed approximately 400ky ago through mass failures and turbidity-current down cut during successive glacial sea-level low stands (Fig. 1).

Fig. 1. High Resolution Multi Beam Bathymetry of the SW Adriatic Margin (Grid size 20m).

The integration between high-resolution multi beam bathymetry, side scan sonar data, high resolution chirp sonar provide a detailed morphological reconstruction of the entire margin and the characterization of the main geological features and sedimentological processes. Furthermore, it provided a frame functional to the identification and mapping of a variety of deep-sea benthic habitats ([2]). Under this respect noteworthy is the discovery along the SW Adriatic margin of a number of deep-water coral occurrences including healthy Lophelia, Madrepora, Dendrophyllia and Desmophyllum often associated with sponges and polychaetes ([1]). Coral growth took advantage of the irregular topography with positive relief created by large mass wasting deposits, such as Gondola slide and the concurring action of dense NAdDW water mass on the irregularly shaped SW Adriatic margin (Fig. 2).

Fig. 2. Multi beam Bathymetry of the Gondola slides integrated with chirp profile and coral occurrences. Coral growth took advantage of the irregular topography with positive relief created by large mass wasting deposits

THE IMPACT OF DENSE SHELF WATER CASCADES ON THE SEAFLOOR OF THE SW ADRIATIC SLOPE

Fabio Trincardi ¹ and Frederica Foglini Foglini ¹* ¹ CNR Ismar Bologna, 40129, Italy - federica.foglini@bo.ismar.cnr.it

Abstract

Cascading North Adriatic Dense Water (NAdDW) impact energetically the seafloor of the SW Adriatic margin, eroding and depositing large amounts of fine-grained sediment below a markedly erosional upper slope. This cascading NAdDW is generated in the broad and shallow North Adriatic shelf through intense winter cooling and evaporation. The NAdDW flows, southward along the Italian coast, reaches the shelf break, typically over a prolonged interval (several weeks) at the end of the winter season, and sinks across the slope By cascading across the slope, the dense NAdDW impinges the seafloor and interacts with the complex margin morphology, generating: 1) patchy fields of large-scale mud waves, 2) a variety of erosional bed forms, such as moats, furrows and comet marks, 3) an area of widwspread sea floor erosion.

Keywords: Currents, Deep Sea Sediments, Adriatic Sea, Swath Mapping

The North Adriatic Dense Water (NAdDW), represents the densest water of the whole Mediterranean and generates in the broad and shallow North Adriatic shelf through intense cooling and evaporation. The NAdDW forms during the winter months, flows southward along the Italian coast and cascades off the shelf break, over a prolonged interval (typically several weeks) at the end of the winter season. The South Adriatic basin is also intruded by the LIW (Levantine Intermediate Water), a salty water mass that enters the south Adriatic through the Otranto Strait and flows southward along the western Adriatic, along the upper slope ([2]). The NAdDW is active every year for a short interval can exceed speeds of 60cm/s ([4]), depending on the meteorological conditions for each year, and may or may not reach a density capable to allow sinking all the way to the basin floor (in 1200m); the LIW, less energetic, impacts the sea floor only at depths less than 600m. By cascading across the slope, the dense water impinges the seafloor and interacts with the complex margin morphology, caused by the presence of active faults and exposed slide scars and a variety of mass-transport deposits, generating patchy fields of large upslope-migrating mud waves that are spatially associated with moats, furrows and comet marks ([3], [4]) (Fig. 1)

Fig. 1. 3D image of the Multi Beam Bathymetry of the SW Adriatic Margin

Sediment cores and seismic correlations suggest that all these bed forms, both erosional and depositional, are primarily active during the modern interglacial as well as during the last interglacial, when climatic forcing also allowed the formation of the NAdDW on the shallow north Adriatic shelf ([5]). The spatial distribution and inferred genetic association of erosional and depositional bedforms on the SW Adriatic slope define two preferred paths along which the NAdDW cascade into deeper waters before exiting the Adriatic through the Otranto Strait. Both pathways: 1) represent the time-averaged response of repeated dense-water cascading; 2) extend to the bottom of the basin (1200 m); 3) define a few-km-wide "core" and a "fringe" area where mudwaves develop and show increasing continuity away from the "core" (Fig. 2).

More in general, the sedimentological study of the modern sea floor in relation to near-seafloor oceanographic processes, inevitably relies on implicit assumptions on the equilibrium between the sea floor (and its erosional and/or depositional bedforms) and processes that can only be observed (and measured) over a time span of few months to few decades, at the most ([1]). A major theoretical and practical question is therefore establishing whether the modern sea floor "landscape" is the product of 1) extreme events, 2) rather uniform events that repeat themselves with some sort of regularity or 3) a combination of both.

By reviewing the main morphological and stratigraphic products of the densewater cascading process in this area, this contribution aims at addressing the following, more general questions: 1. Do oceanographic processes on the shelf lead to focussing of cascading processes along preferred slope pathways 2. How does the interannual variability in production of dense water, affect the location where cascading is initiated, the duration of the process (few days to several weeks) and its capability to reach the bottom of the basin (1200m) 3. During its downslope flow, does the NAdDW spread laterally, entraining ambient water, or remains focussed along a narrow belt In this context, what dynamic interaction occurs between the NAdDW and the slope parallel (salty) LIW 4.The upslope-migrating mud waves have furrowed seaward limbs indicating that they undergo erosion. Is this an indicator of an ongoing intensification of the bottom current regime or, rather, of a reduction of sediment supply.

Fig. 2. 3D image of theBari Canyon System (BCS) representing the major sediment conduit on the SW Adriatic margin. The figure shows two preferred paths along which the NAdDW cascade into deeper waters before exiting the Adriatic through the Otranto Strait.

Abstract

A preliminary study has been performed estimating the residence time of a submarine groundwater discharge in Kalogria Bay (SW Peloponnissos, Greece). A number of naturally occurring radio-nuclides (²²²Rn, ²¹⁴Pb, ²¹⁴Bi, ²²⁸Ac, ²⁰⁸Tl, ⁴⁰K) have been used as tracers measuring samples of sea, rain and groundwater by means of LSC and HpGe. Radon daughters measurements were also performed using the *in situ* underwater autonomous gamma-ray detection system "KATERINA". The estimation of the residence time of groundwater has been attempted using a different approach to standard methods, based on activity ratio concentrations of radium daughters

Introduction

During the last decades, submarine groundwater discharge (SGD) has been recognized as an important hydrological mechanism affecting numerous phenomena (e.g. elements cycles, contamination by heavy metals and radionuclides, eutrophication) relating to the coastal zone. The main methods for detection and quantification of SGD are based on: a) direct physical measurements with e.g. seepage flux meters; and b) tracer techniques, estimating the concentrations of geochemical substances which are naturally enriched in groundwater paths. Amongst the tracer techniques, those based on radioactive isotopes as radium, radon and their daughters were used in several studies to investigate the temporal and spatial distribution of SGD [1, 2], the coastal mixing rates [3] and the residence time of groundwater through the aquifer paths [4]. In this work, a radiological study is presented involving numerous radiotracers (40 K, 222 Rn, 214 Bi, 226 Ra, 228 Ac, 208 Tl, 3 H) for the estimation of groundwater residence time of the SGD point source located in Kalogria Bay (SW Peloponnissos).

The study area, materials and methods

The Kalogria Bay is located in southwestern Peloponnissos, in the Messinia prefecture. Many locations of submarine groundwater discharges are easily visible around the bay, although the main SGD point source is located ~180 m offshore. At this location, groundwater is emanating into the sea mainly through a small submarine cave at 25 m depth. The site is reached by small boats and divers are occupied to collect water samples and to deploy inside the cave a small lander equipped with several sensors. In situ measurements are performed by "KATERINA", an autonomous underwater gamma-ray NaI (T) detector [5, 6], monitoring the radioactivity concentration of radon daughters (²¹⁴Pb, ²¹⁴Bi), ²²⁸Ac, ²⁰⁸Tl and ⁴⁰K. Also, for subsequent measurements in laboratory, a quantity of 10 mL from the water samples is immediately added by syringe inside plastic vials containing 10 mL of scintillation cocktail. The vials are transported to the laboratory within the first 24 hours after sampling, for gross alpha and beta counting of radon and its daughters by a Liquid Scintillation Counter (LSC) TriCarb 3170 TR/LS. Furthermore, 0.6 L of water samples are measured in the laboratory by means of a High Purity Germanium detector (HpGe) for any gamma-ray emmiter. In addition, after a simple distillation procedure 8 mL of groundwater, water from terrestrial springs, and rain are added in glass vials containing 12 mL of scintillation cocktail for tritium (³H) concentration measurements by LSC method

Results and Discussion

In situ gamma-ray spectra from "KATERINA" detector exhibits radon daughters contributions since gamma-ray emitters at 351 keV (²¹⁴Pb), 609 keV (²¹⁴Bi) are clearly observed. Measured ²¹⁴Pb and ²¹⁴Bi activities are 550 \pm 45 Bq/m³ and 575 \pm 45 Bq/m³, respectively. The activity of ⁴⁰K is 11300 \pm 95 Bq/m³ while ²²⁸Ac and ²⁰⁸Tl exhibit activities of 130 \pm 11 Bq/m³ and 160 \pm 15 Bq/m³ respectively. Radon activity concentration by the LSC method during the same period (July 2009) exhibited values varying from 1200 \pm 100 Bq/m³. Regarding ³H concentration, the estimated values varied between 4.3 \pm 1.7 to 5.9 \pm 1.7 TU. These measurements have to be combined with ³H measurements of rainwater collected from the same region in order to achieve an ageing of the water. Also, a method for the residence time

estimation of groundwater was applied, as proposed in the literature [4]. This model assumes the investigating system is in steady-state which means that radium isotopes additions (radium flux from groundwater) are balanced with losses (mixing and radioactive decay). The activity ratio of 224 Ra/ 228 Ra has been substituted by 208 Tl/ 228 Ac as 228 Ra and 228 Ac reach a secular radioactive equilibrium after 1.5 days while the activity ratio of 224 Ra to 208 Tl remains constant (≈ 2.6) after 2 days. By means of a HpGe detector, radium daughter isotopes 208 Tl (224 Ra) and 228 Ac (228 Ra) concentration activity ratios was calculated into the groundwater path (outlet region), as well as in the inventory where the groundwater discharges. The residence time using the aforementioned model was calculated at 2.5 ±1.3 days. The increased uncertainty is due to low concentrations mainly of 228 Ra daughter (228 Ac). The sensitivity of the applied method for the estimation of the residence time would drastically be improved measuring in a lower gamma-ray background environment.

Conclusions

During the period 2009-2010, a comprehensive study is in progress at the SGD site in Kalogria Bay (SW Peloponnissos). Radioactive tracer techniques are being applied estimating groundwater's residence time by means of HpGe gamma-ray spectrometry, and the water age by means of ³H concentration by LSC method. Also, the application of *in situ* gamma-ray spectrometry method based on "KATERINA" detector offers simultaneously concentration), which are strongly correlated with the mixing processes between ground and sea water at the SGD site. These long term measurements will also contribute significantly to the estimation of water velocities and water flux rate of the specific SGD source.

HOLOCENE SEA LEVEL CHANGES OF HISARONU GULF, SOUTHEASTERN AEGEAN SEA

Atilla Ulug ¹* and Nilhan Kaser ¹

¹ Dokuz Eylul University Institute of Marine Sciences and Technology, 35340, Izmir, Turkey - atilla.ulug@deu.edu.tr

Abstract

The relative sea level change during the Holocene geologic times for the Hisaronu Gulf (SE Aegean Sea) and surroundings were investigated performing high resolution seismic and bathymetric survey. Hisaronu Gulf is affected by sea level rising in the last glacial period (20.000 BP) and local tectonic movements. Comparing with the eustatic sea-level curve and our seismic stratigraphic interpretations considered paleo-shoreline positions, it can be said that the relative sea level change for the Holocene period is result of the tectonic subsidence of the coastal plain.

Keywords: Sea Level, Sedimentation, Tectonics

Introduction

The global eustatic sea level in the Aegean Sea and surroundings in the Late Pleistocene-Holocene time (20.000 yr BP) rose from -120m below present sea level to its modern position because of melting ice sheets since the last glacial period ([1], [2]). The aims of this paper are to describe the seismic units that formed the Hisaronu shelf during the Holocene period from high resolution seismic data and reveal the model of sequence stratigraphic analysis to seismic profiles to interpret the relative sea level change controlled by eustatic rise and local tectonic movements comparing with similar studies performed on Mediterranean coasts.

Study area

The Hisaronu Gulf is bordered by the Datça Peninsula to the north, the Simi Island to the south, and the Bozburun Peninsula to the east (Fig. 1). The Gulf is a part of the western Anatolia – southeastern Aegean Sea regions, which are currently under an N–S regional extensional tectonic framework dominated by the westward escape of the Anatolian plate as a result of collision of the Arabian and African plates with Eurasia ([3]).

Fig. 1. Bathymetric and seismic line map of the Hisaronu Gulf

Materials and Methods

This study is mainly based on high-resolution seismic reflection profiles using ORE Subbottom Profiler System and using Bathy 2010 Chirp System in 2002 and 2008 with 3.5 kHz frequency collected during a cruise of R/V K. Piri Reis of Institute of Marine Science and Technology (Fig. 1).

Results

The relative sea level changes are the result of eustatic sea level fluctuations and tectonic movements. The seismic sedimentary chronology suggests that the average rate of vertical tectonic movement in Aegean Sea for the last 120.000 years has been around 0.5 mm/yr in Gokova Gulf ([4], [5]). During the Holocene geological times, glacio-eustatic sea level changes formed two major depositional units in the Hisaronu Gulf and surroundings: transgressive systems tract (TST) related to the last post-glacial transgression (20-8 ka); and highstand systems tract (HST), related to the Holocene higher sea level (8 ka to present) ([2]) with maximum 25 ms thickness. The conceptual model of sequence stratigraphy, has been applied to our high resolution seismic data which allows the study of the youngest depositional sequence during the last sea level rise in the Holocene (Fig. 2). By considering the global sea-level curve and paleo-shoreline positions, we found out the relative changing in sea level result from local tectonic movements. Besides eustatic reasons, tectonic subsidence due to

the half graben structure of the area is the main trigger of the relative rise in sea level.

Fig. 2. Seismic reflection profile from Datça Shelf (A) and the chronology of depositional sequences suggested from [2] sea level curve (C).

Abstract

In this study 3D seismic and well data from the Ebro Margin, NW Mediterranean Sea are used in combination with backstripping and coupled isostasy and river transport and drainage evolution modeling techniques. The objective is to present new lights on the origin and sedimentary processes that took place on the Messinian Erosion Surfaces (MES) of the Valencia Trough (Mediterranean Sea), to provide a minimum estimate of the sea level fall in the Ebro Margin and to offer new constraints on the evolution of the adjacent subaerial Ebro Basin.

Keywords: Continental Margin, Erosion, Evaporites, Messinian, Models

The recognition of subaerial erosional surfaces at the rims of the Mediterranean basin has been one of the first and strongest evidences put forth to support the hypothesis of an exceptional Messinian sea level low stand that exceeded substantially any possible eustatic change (e.g., [1]). This study builds on a large 2700 km² 3D seismic survey, which provides unprecedented detail and areal coverage of the Messinian Erosion Surface (MES) on the Ebro margin. The aim of this paper is to present new lights on the origin and sedimentary processes that took place on the MESs of the Western Mediterranean Sea, provide a minimum estimate of the sea level fall in the Ebro Margin and offer new constraints on the evolution of the adjacent subaerial Ebro Basin, particularly with regard to the time when full open drainage conditions towards the Mediterranean of this formerly endorheic basin were reached. Four major seismic units are identified on the Cenozoic Ebro Margin, based on the seismic data, including two major prograding megasequences (Serravallian-Tortonian Castellón Group and Pliocene-Pleistocene Ebro Group) that are separated by a major unconfirmity: the MES (see also [2] and [3]). Offshore, the MES evolves into a paraconformity and is onlapped by shallow water detrital bodies. The 3D seismic data provide an unprecedented view of the MES displaying characteristic features of subaerial incision including a drainage network with tributaries of at least five different orders, terraces and meandering rivers. The Messinian landscape of the Ebro Margin presents a characteristic stepped-like profile that allows to subdivide the margin in three different regions roughly parallel to the Present Day coastline. Such a stepped profile is also evident in numerous areas of the Mediterranean Sea [4, 5]. No major tectonic control exists on the boundary between the different regions. The boundary between the two most distal regions can be identified to mark the location of a relatively stable water table, and this is used in backstripping analysis to identify the sea level drop associated with the Messinian Salinity Crisis on the Ebro Margin: in the order of ~1300 m, in agreement with the maximum amount of fluvial incision on the margin. The MES on the Ebro Margin is dominated by a major fluvial system. The observed width of the channel and modelling results suggests that this major valley corresponds to the Messinian Ebro River that should have already attained a drainage area comparable to the present one. Constraints provided by the data set, onshore geology and coupled isostasy and river transport and drainage evolution modeling techniques indicate that drainage of the Ebro River into the Mediterranean Sea occurred prior to the Messinian, most probably during the Serravallian/Tortonian, which is the age of the first significant >1-km thick siliciclastic deltaic megasequence deposited in the Ebro Margin.

GEOMORPHOLOGICAL EVIDENCES OF CATASTROPHIC WAVES IMPACT IN SOUTHERN LESVOS (NE AEGEAN SEA)

Matteo Vacchi^{1*}, Alessio Rovere¹, Nickolas Zouros² and Marco Firpo¹

¹ DipTeRis, Department for the Study of the Territory and its Resources, University of Genova. Italy - matteo.vacchi@unige.it

² Faculty of Geography, University of Aegean. Mytylene, Lesvos Island (Greece)

Abstract

Eastern Mediterranean and in particular the Aegean Sea have been often affected by catastrophic events such as strong earthquakes and related tsunamis. However, field evidences of tsunamis from the late Holocene are quite rare. This study, carried out in southern Lesvos Island (NE Aegean), individuated a large accumulation of boulders dislocated by tsunami events providing important information concerning the current coastal hazard of the area. *Keywords: Aegean Sea, Coastal Processes, Waves, Coastal Management*

Geomorphological evidences of past catastrophic events represent an important tool to assess the current hazards, especially in coastal areas. In particular, large boulder deposits have been often used to determine wave heights, age of deposition, magnitude and frequency of extreme waves or tsunami events along the Mediterranean coasts [1]; [2]; [3]. Due to its tectonic setting, the Aegean Sea region is particularly susceptible to earthquakes and related tsunamis but few field evidences of the impacts of these catastrophic waves are reported in literature [4] This study was carried out in Lesvos Island (NE Aegean), the third largest Greek island with an area of 1,630 km² and about 300 kilometres of coastline. In particular, the study area is located in the southern part of the island, between the towns of Plomari and Vatera, where the coastline develops for more than 30 km, being characterised by high cliffs and large sandy beaches, often interrupted by beachrocks outcrops. Here, a big amount of large boulders (up to almost 15 t) were individuated in four sites having different geomorphologic and geological frameworks. Direct observations on each boulder were carried out in order to measure it (size and weight, distance and elevation respect the shoreline) and individuate the pretransport setting (underwater or sub-aerial position) [5]. A further survey of their long axis orientation and distribution was carried out in order to recognise the geographical origin of the waves. The Nott [5] approach was applied to understand if the boulders displacement was compatible with the local storm wave regime or if they were dislocated by tsunami events. The orientation of elongated boulders allowed to detect two main provenience of the catastrophic waves, one comprised between 150N and 180N and the second between 210N and 240N. The study of wind-wave climate of the area excluded a surge storm origin as cause of the large boulder accumulation. A tsunamitic origin was then attributed to the studied blocks. Moreover, the bimodal distribution suggested that two different events could have affected the area and further datation on the fossil material found on the boulders (bryozoa, vermitids, serpulids) could confirm this hypothesis. The radiometric datation will also allow to confront the events with the historical ones present in different Greek and Mediterranean tsunamis catalogues [6]; [7]. In conclusion, this study provided new and important information in terms of current level of coastal hazard in southern Lesvos and, in particular, in Plomari, the second largest town of the island, with almost 5000 inhabitants where the results should be converted to recommendations for the local governments in order to plan different activities for the mitigation of the vulnerability.

SEDIMENTARY INSTABILITIES ALONG THE SOUTHWESTERN SLOPE OF THE ALBORAN RIDGE (SW **MEDITERRANEAN**)

Abstract

Detail reprocessing and analysis of a multibeam bathymetric data set and seismic profiles have allowed identified several complexes of sedimentary instabilities along the southeastern flank of the Alboran Ridge. A Large Slope Apron System could be defined in this area that includes isolated slides, complex of slides and slope apron systems. These features show different sizes and evolutionary stages. Seismicity and the Quaternary tectonic activity are considered the main factors controlling their development. Keywords: Geomorphology, Sedimentation, Tectonics, Alboran Sea, Western Mediterranean

Introduction

The development of sedimentary instabilities and mass movements on active tectonic reliefs has been described frequently [1, 2]. The Alboran Ridge is the most relevant physiographic feature of the Alboran Sea Basin, it extents along approximately 200 km in a WSW-ENE trend and is constituted by five aligned seamounts. This complex feature is a tectonic relief uplifted from the Miocene to the Ouaternary, by means of folding, lateral and compressive faulting, and volcanism. The structure of the Alboran Ridge has been described as a main anticline bounded by oblique left-lateral/reversed faults [3]. Nowadays, only few sedimentary instabilities have been analyzed in the Alboran Basin [4], but a more important development can be expected. This study focuses on the sedimentary instabilities occurred on the southern flank of the farthest east seamount of the Alboran Ridge. Several methods were used to investigate these features including multibeam bathymetry and a scarce net of ultrahigh (Subbottom Profiler and TOPAS systems) and high (Airguns) resolution seismic profiles.

Results and discussion

Sedimentary instabilities have been identified along both flanks of the Alboran Ridge, northeastern and southwestern. Their occurrence has been recognized based on features indicative of the disappearance of sediments and of deformational features. The southeastern flank forms an abrupt scarp (6-10 km wide) that extends between 70 to 1050 m water depths and displays average slope gradients between 8 and 18°. Both types of features, mass-movement deposits (from slides to turbidites) and valleys (canyons and channels) are identified. The following systems have been differentiated based on genetic processes and relationships (Fig. 1): isolated slides (box 2), complexes of slides (boxes 1 and 4), and slope apron systems (boxes 3 and 5). The slide scars are mainly located at upper part of the flank (70-140 m) where gradients average $20^{\circ}\!\!,$ and have lengths between are 1.5 and 7 km.

Fig. 1. Bathymetric map of eastern Alboran Ridge segment illustrating the different systems of sedimentary instabilities (Boxes 1 to 5) identified in the southern flank.

The complexes of slides have lengths between 1.8 and 6.6 km, and comprise

concomitant slides, some remain on the surface but mostly extend from the slope break toward the Southern Alboran Basin where the deformed and disrupted slide material deposits forming lobes/wedges of chaotic facies with a rough seafloor surface (boxes 1 and 4). Thus, these complexes would represent slides and associated mass-flows deposits.

Two types of slope apron systems are identified based on their internal sediment source that conditions the resulting architecture: point source apron (box 3) and multiple source apron (box 5). The point source apron (box 3) comprises a submarine canyon (3.5 km length) whose head indents into the summit of the ridge and extends down to the break of slope and from that point develops a turbiditic apron (5 km wide, 7.5 km length) defined by chaotic facies with numerous shallow channels (6 km length). The multiple source apron (box 5) comprises several channel systems of different orders of magnitude that extends downslope from the summit of the flank and converge at 870 m water depth, a little before to reach the break of slope of the flank, and develops a depositional turbiditic apron (4 km wide, 5.7 km length) from that point spreads to the Southern Alboran Basin.

From a sedimentary point of view, the southern flank of The Alboran Ridge forms a Large Slope Apron System that is made up of minor-order systems consisting of both constructional and erosional architectural elements. All these elements reflect the occurrence of sedimentary instabilities associated to the general mass-wasting process that affects to the southern flank of the ridge. The continuous moderate seismic activity in the Alboran Sea region and the Quaternary tectonics of the Alboran ridge must be invoked as the main controlling factors of this intensive mass wasting.

MAGNETIC SIGNATURE OF ADRIATIC SEDIMENT FROM LATE GLACIAL TO PRESENT: NEW INSIGHTS FOR THE BASIN EVOLUTION

Luigi Vigliotti ¹*, Annamaria Correggiari ¹ and Andrea Gallerani ¹ ¹ CNR Ismar Bologna, 40129, Italy - luigi.vigliotti@bo.ismar.cnr.it

Abstract

Changes in the depositional environment of the Adriatic Sea during the late Glacial-Holocene sea-level rise have been investigated by means of magnetic measurements. Both concentration and grain size dependent parameters show a different magnetic signature that reflect differences in the source area of the sediments and diagenetic processes as well as modification in the shape of the basin. *Keywords: Adriatic Sea, Geomagnetism, Sea Level, Sedimentation*

Rock-magnetic techniques applied to marine deposits provide informations about the amount, the grain size and the mineralogy of the magnetic fraction within the sediments. In a first instance, these properties are a function of the supply of the clastic fraction, but they also represent post-depositional processes occurring within the sediment. So they reflect physical changes in the depositional environment that are strictly related to paleoclimatic and paleoceanographic changes as well as human environmental impact. In this study we present the results of natural (magnetic susceptibility, X) and laboratory-imparted rock magnetic properties such as anhysteretic (ARM) and isothermal (SIRM) remanence measured from marine cores collected in the

Fig. 1. Location map of the studied cores and Late-Holocene mud wedge areal distribution dated post 5.5 kyr.

Adriatic Sea from the northern shelf to the Mid Adriatic Depression (MAD) (Fig.1). The studied parameters are indicative of magnetic concentration, but they are sensitive to different grain size implying that interparametric ratios (i.e. SIRM/ARM) are indicative of change in grain-size. The Late Pleistocene-Holocene age of the cores is constrained by the stratigraphic framework of the area supported by C^{14} datings and paleomagnetic record of the secular variations of the earth magnetic field. During the Last Glacial Maximum (LGM), a wide part Adriatic shelf was subaerially exposed. The drainage network on this large alluvial plain likely comprised the paleo Po as the main river, with the Alpine and Apenninic rivers as tributaries. With the postglacial sea-level rise, the low shelf gradient (40 m/100 km), and low sediment input, favors significant landward shifts of depositional environments. The late Holocene Po delta formed after the present sea-level highstand represents a major component of

the rapidly accumulated mud wedge that with the contribution of Appenine rivers stretches for 600 km along the Adriatic italian coast. In the northern part of the basin rivers from the Venetia-Friulan plain (Adige, Piave, Tagliamento) control the sedimentation. As the catchment of these rivers are different it is expected that the magnetic signature in the sediments reflect the primary signal when diagenetic processes do not introduce significant alterations. The differences are confirmed by mineralogical data showing a significant presence of dolomites in the sediments collected in the northern shelf. The results from recent sediments obtained from a core retrieved in the Po Delta were used as reference signature and compared with the results from other cores. Concentration-dependent parameters (X, ARM, SIRM) point out to an increasing contribution of ferromagnetic minerals in the sediments belonging to the Po with respect to the other sources. The magnetic properties also indicates a time-dependent signature of both concentration and grain size that represent a signature of the different physiographic conditions of the basin during the Late Glacial/Holocene times. Coarse grained detrital magnetite (high SIRM, X and SIRM/ARM values) characterizes Late Glacial deposits from Central Adriatic with an increasing contribution of fine grained magnetic materials

during the Holocene (high ARM, low SIRM/ARM values) (Fig. 2) with peak values after the maximun flooding [1]. The dominance of finer materials reflects the increasing contribution of bacterial magnetite to the remanence of the younger sediments, but could be also related to the landward shift of the source area of the terrigenous input during Holocene time.

Fig. 2. Plot of mass specific magnetic susceptibility (units: $10^{-9}m^3kg^{-1}$) vs SIRM/ARM for the studied samples.

Abstract

A study of nutrient concentrations in Dor Bay suggests that the groundwater discharging directly to the bay is a mixture of three components: (1) nitrate and silica-rich groundwater, (2) nitrate and silica-depleted recirculated seawater, (3) depleted saline water (salinity of 31), which is the result of mixing between recirculated seawater and denitrified fresh groundwater. Subterranean estuarine processes are reflected just in the slightly elevated concentrations of ammonium and possibly phosphate in the discharging water. This suggests that the nutrients are being mainly carried to the bay by the fresh groundwater, while the role of recirculated seawater in this conveyor is merely secondary.

Keywords: Coastal Processes, Estuaries, Hydrology, Eastern Mediterranean, Nutrients

Submarine Groundwater Discharge (SGD) is now widely accepted as a major factor affecting coastal water quality. More specifically, it was suggested by several authors [1,2] that the recirculation of seawater and the mixing with fresh groundwater in the aquifer (the 'subterranean estuary') is a dominant factor in the transport of some nutrients and other solutes to the sea. During 2006-8, we conducted a detailed study of the composition of groundwater discharging from the sea floor at Dor Bay (Carmel coast, northern Israel). As detailed below, our results suggest that while fresh groundwater is a major source of nutrients to the coastal water, recirculated seawater, even when mixed with fresh groundwater, carries a relatively small amount of nutrients to the sea. Two different geological units are discharging to Dor Bay, a Pleistocene calcareous sandstone (locally called 'Kurkar') and an overlying Holocene sand unit. The two are hydrologically separated by a confining clay unit. ²²²Rn time series and seepage meter studies suggest that SGD at Dor is on the order of 10 cm/d, and that about half of it is recirculated seawater. Based on radon and salinity, it was established that fresh goundwater discharge was mainly from the underlying Kurkar unit, while seawater recirculation was restricted to the shallow sand. Nitrate concentrations were high in onshore groundwater and very low in the bay water (200-400 and <3 µM NO₃+ NO₂, respectively). The concentrations in water discharging from seepage meters deployed on the bay floor were at the mid range (2-130 μM NO3+ NO2). On a diagram of nitrate versus salinity, all discharging water plot in a narrow zone between two mixing lines that meet at the high-nutrient fresh water end. Silica concentrations also suggest mixing between nutrient-rich groundwater (100-400 µM) and nutrient-poor seawater. These results suggest that the groundwater discharging to Dor Bay is composed of three components: (1) nutrient-rich Kurkar groundwater, (2) nutrient-depleted recirculated seawater and (3) nutrient-depleted water with salinity of 31. Component (3) is probably the result of mixing between recirculated seawater and fresh groundwater that underwent denitrification. We identify the latter as sand groundwater, which likely resided for a relatively long time in the bay sediments. This implies that in Dor Bay, nitrates and silica are conveyed to the sea just by the fresh groundwater (which also suffered partial denitrification), and that seawater recirculation and its subterranean mixing with fresh water have no effect on nitrate and silica mobilization. Phosphate was very low both in the seawater and in the Kurkar groundwater, while relatively high in the sand groundwater (0.1-0.2 and up to $>4 \mu M$, respectively). Seepage meter water contained up to $>1 \mu M$ of PO₄, probably due to a contribution from the sand groundwater or to the recirculation of seawater in the subterranean estuary. Similarly, ammonium was quite low both in bay water and in all onshore groundwater ($\leq 4 \mu M$), while higher in saline groundwater and in water discharging from the bay floor (up to 20 µM), obviously due to seawater recirculation. However, it was still one order of magnitude lower than the nitrate concentrations in these water samples. To conclude, the main conveyor of nutrients (nitrate and silica) to Dor Bay is the fresh groundwater, while the effect of seawater recirculation in the subterranean estuary is restricted to a relatively small load of ammonium, may be also of phosphate, that is carried by the discharging water. Low nutrients in the recirculated seawater as compared with the fresh groundwater were also reported from other SGD sites (e.g. [3,4]). However, in other cases (e.g. northern Gulf of Mexico) recirculated seawater was characterized as nutrientrich [5]. It is suggested that the difference between the SGD sites is in their

nutrient source. While at Dor and similar sites, nutrients are mainly landderived, thus bwing mainly transported by fresh groundwater, the nutrients at other sites are derived by remineralization of marine organic matter in the subterranean estuary [5], thus being enriched both in the fresh groundwater and in the recirculated seawater.

Abstract

Since the 90' ENEA CRAM is involved in the environmental monitoring of the Eastern Ligurian coastal marine ecosystem. The observatory includes meteo-marine observations from fixed platforms (meteorological station, buoys and moorings), at sea campaigns with in situ sampling and underwater surveying of benthic and pelagic communities. The aim is to control the evolution of environmental conditions for climatic studies as well as for the management of the coastal area. The long-term observations allowed to detect the "intrusion" of alien and harmful invasive species favored by the warmer surface water temperatures, and to approach a comprehensive study of the mortality events which affected benthic species in this area. *Keywords: Monitoring, Time Series, Coastal Systems, Ligurian Sea*

Since the 90' ENEA CRAM is involved in the environmental monitoring of the Eastern Ligurian coastal marine ecosystem within ELIOS (Eastern Ligurian Interdisciplinary Observing System). In addition to the scientific need to monitor coastal ecosystem changes and predict future trends, there is an increasing request to provide data for a science-based management of a coastal zone subject to increasing anthropogenic pressures. This observation network offers an ideal platform to study specific processes characterized by seasonal and higher temporal resolution time scale.

Within ELIOS, the monitoring activities are carried out multidisciplinary. The meteo-marine conditions are provided by integrating different systems of measurements, to ensure the necessary spatial and temporal resolution including: a coastal meteorological station [1] measuring wind speed and direction, solar radiation, air temperature, relative humidity and atmospheric pressure, precipitation; a shelf sea meteo oceanographic buoy located at a sea depth of 28 m providing meteorological measurements, sea temperature, salinity, fluorescence, oxygen and ph profiles in the upper 25 m of the water column; an oceanographic mooring deployed at 30 m depth providing currents, temperature and salinity measurements at 15 m and 25 m depth. Some autonomous temperature sensors have also been fixed to the rocks. Repeated (weekly during summer) synoptic surveys in the Gulf of La Spezia include temperature, salinity, fluorescence, profiles; nutrients and turbidity (Secchidisk) in the water column and sampling of phytoplankton. Open-sea meteo oceanographic observations (atmospheric parameters, sea temperature and salinity, ADCP currents profiles in the thermocline) are available from the meteo-oceanographic buoy ODAS ITALIA 1 located in the Central Ligurian Sea and form the oceanic mooring deployed nearby. Benthic communities (coralligenous and Posidonia meadows) and the presence of invasive and harmful species (Ostreopsis ovata) are regularly investigated through underwater surveys and sampling at fixed locations.

Data collected by the two buoys allowed to investigate thermal anomalies below the sea surface, how these affected at different degree the coastal and the open sea area and to follow the evolution and the response of the ocean-atmosphere system to that particular event. In particular, the persistence of calm weather conditions caused a sea temperature anomaly of about 4 degree down to 25 m. Twelve-year monitoring of gorgonian population trends allowed to analyse population size structure, colony and recruitment density of a damaged Paramuricea clavata population after 1999 and 2003 mortality events and to identify changes in biological, ecological and demographic features [2]. This population supplies a paradigmatic example of the response of a population living from 16 to 25 m depth, thus near the edge of the summer thermocline, to the mortality associated to anomalous temperature increase. The high colony recovery and recruitment rates found (4 fold increase) suggest a good resilience for this population due to the reproductive output of the smaller-younger colonies [3]. Nevertheless, its geographical isolation, together with an increased frequency of mortality events, could challenge its persistence.

The long-term observations allowed to detect the "intrusion" of alien and harmful invasive species favored by the warmer surface water temperatures. In the Gulf of La Spezia the first *Ostreopsis ovata* bloom took place during the hot summer of 1998. When meteo-marine conditions favourable to *O. ovata* development, mainly high temperature and flat sea, persisted for weeks blooms took place with the production of millions of cells causing hypoxia and sometime damage to human health. On the contrary, rough sea and waves caused a sharp reduction of *O. ovata* density.

This observing system, providing a continuous environmental and meteo-marine monitoring, allows a better understanding of the sensitivity of marine organisms and communities to the rapid changes of the environmental conditions, particularly in time of climate change. In addition, the real time surveillance could support local administrators in the management of navigation and environmental emergencies.

MODEL ESTIMATES OF M2 INTERNAL TIDE ENERGETICS IN THE SICILIAN CHANNEL

Jihene Abdennadher ¹* and Moncef Boukthir ¹

¹ Institut Preparatoire aux Études d'Ingenieurs de Tunis, Montfleury, Tunisia - jihene.abdennadher@ipeit.rnu.tn

Abstract

The M₂ internal tide energetics in the Sicilian channel have been investigated by using a three-dimensional sigma coordinate model (ROMS). Realistic topography and stratification from existing observations were used. We have identified three potential sites of M₂ internal tide generation, namely the western sill of the Adventure Bank, northwest of Sicily and north of Pantelleria isle. The conversion rate from the M₂ surface to internal tide energy integrated over the whole model domain amounts to 47.5 MW, 75 % of which are found to be generated over the three prominent topographic features mentioned above <u>Keywords: Tides, Sicilian Channel</u>

Introduction

The Strait of Sicily has been extensively studied during the last years [1, 2]. However, very few is known about the generation of the internal tide in this strait. Indeed, except sparse observations [3, 4], the vertical structure has not been sufficiently addressed. Within the framework of what has previously been studied concerning the internal tides generation and propagation in some potential areas, we try to clarify the distribution of the M₂ internal tides in the Strait of Sicily as well as its energetics. We use a fully three-dimensional sigma coordinate model, the Regional Ocean Modeling System (ROMS). The horizontal resolution is $1/32^{\circ}$ in both longitudinal and latitudinal directions.

Internal tidal energy budget

The governing equation for the baroclinic energy is given by

$$\frac{\partial}{\partial t} \left(\bar{\rho}_0 \frac{\vec{u}_i^2}{2} + \frac{g{\rho'}^2}{2} \left(-\frac{d\rho_0}{dz} \right)^{-1} \right) = -\vec{\nabla} \cdot (p_i \vec{u}_i) + g{\rho'} w_{bt} + D + A(1)$$

where $\bar{\rho}_0$ is the reference water density, ρ_0 is the background basic density stratification, ρ' is the water density perturbation, \vec{u}_i is the baroclinic velocity, w_{bt} is the vertical velocity induced by the barotropic tide flow, p_i is the internal pressure perturbation, D and A denote the dissipation and the advection of the baroclinic energy, respectively. The left side of (1) is the rate variation of the baroclinic energy density, $p_i \vec{u}_i$ is the energy flux that is associated with the propagation of the internal tide, and $g\rho' w_{bt}$ represents the conversion rate from surface to internal tide energy.

Assuming that the advection of baroclinic energy is neglected, integration of the equation (1) over a given domain and taking the average over one tidal period (denoted by an overbar) yields:

$$\iiint g \ \overline{\rho' w_{bt}} dV = \iint \overline{p_i \vec{u}_i} d\vec{S} + \iiint \bar{D} dV$$

The model-predicted distribution of the depth-integrated conversion rate from the M_2 barotropic to baroclinic tidal energy shows that there are three distinct sites of strong generation, one at the narrowest passage through the western sill of the Adventure Bank, and the two others are in the northwest of Sicily and the north of the Pantelleria isle. The M_2 mode conversion integrated over these prominent topographic features sums up to 35.6 MW, which is 75% of that integrated over the whole model domain. M_2 internal tide is mostly efficient over the narrowest passage through the western sill where the baroclinic energy conversion amounts to 17.1 MW. It is about 11.3 MW in the northwest of Sicily and 7.2 MW in the north of the Pantelleria isle. The net M_2 baroclinic energy flux away from the region including the western sill accounts for 8.5 MW, 5.5 MW of which is directed toward the north and 3 MW toward the south. For the region including the Pantelleria isle, the energy flux divergence has been estimated to be 60% of the integrated conversion energy, mainly directed toward the Tunisian coasts (2.6 MW).

The local dissipation within the western sill of the Strait of Sicily amounts to 8.9 MW corresponding to 52 % of the baroclinic energy conversion where it is about 40 % within the north of Pantelleria isle and about 71 % in the northwest of Sicily. It is important to note that 42.3% of the barolinic energy generated in the whole modelled region is dissipated in close proximity to the baroclinic M_2 generation sites already identified.

The baroclinic energy flux divergence (Figure) emphasizes the localised nature of generation and depicts the propagation of energy away from the narrowest passage through the western sill toward the north and southwest. The main direction of propagation from the Pantelleria isle is toward the Tunisian coasts.

Abstract

A simulation and two re-analyses from 1985 to 2005 have been produced for the Mediterranean sea circulation using different assimilation schemes: a Reduced Order Optimal Interpolation and a new three-dimensional variational scheme. The general circulation model used is the OPA 8.1 code. The observational data sets assimilated are vertical temperature and salinity in situ profiles and along track satellite sea level anomalies (SLA); daily mean fields of Sea Surface Temperature are used for correcting the fluxes. The results of both reanalysis are comparable and they are qualitatively consistent to the known structures of the circulation in the period of interest.

Keywords: Circulation Models, Inverse Methods

Introduction

Re-analyses are different from analyses because they are consistent for the whole period since the oceanic state estimates are produced without changes in the modelling assumptions and they are usually done with systems, which are more advanced then the available systems at the time of the observations collection. A fundamental part of a re-analysis system is the data assimilation scheme, which minimizes the cost function penalizing the time-space misfits between the data and the numerical solutions, with the constraint of the model equations and their parameters. In this work we will compare ocean circulation estimates provided by pure simulation, a system in which the assimilation scheme is based on a sequential algorithm: Optimal Interpolation (OI) and a three-dimensional variational scheme (3dvar).

Method

The OGCM used in this work is based on OPA 8.1 code [1], which has been implemented in the Mediterranean Sea by Tonani et al.[2]. The model has 1/16th horizontal resolution and 71 unevenly spaced vertical levels. The present model formulation uses a realistic water flux with river runoff that improves the realism of the simulation. One re-analysis is produced with the Reduced Order Optimal Interpolation (ROOI) [3] and the other with OceanVar[4]. The observational data sets assimilated for both reanalysis are: 1) the historical data archive of MedATLAS [5] which contains vertical in situ profiles of temperature and salinity from bottles, XBT, MBT and CTD sensors;2) temperature and salinity profiles collected in the framework of MFSPP and MFSTEP (Mediterranean Forecasting System) projects;3) CLS along track satellite sea level anomaly data from ERS1. ERS2. Envisat. Topex/Poseidon, Jason1 satellites [6]. Reanalyzed daily mean fields of Sea Surface Temperature (SST) from Medspiration [7] and the Delayed-Time operational product of CNR-ISAC have been used to relax the model SST. The Mean Dynamic Topography of Dobricic [8] has been used for both experiments. The model is forced with a combined dataset of ECMWF analysis when available and ERA-15. The precipitations are monthly mean climatology of the NCEP re-analysis [9], the river runoff data are monthly mean climatology from the Global Runoff Data Centre (GRDC) and from Raicich [10] for the minor Adriatic Sea rivers.

Results

Both re-analyses show significantly better results than the simulation reducing both bias and root mean square error even though the structure of the error remains almost the same of the simulation: the largest error for tracers is confined in the thermocline especially in summer, highlighting a problem in the mixing parameterization; the major error for SLA is confined in the most dynamically active areas. Satellite altimetry observations appear to be a fundamental dataset to constrain model solution. Since its homogeneity in the sampling the SLA dataset permits a consistent assessment of the model behaviour. During the years without SLA observations in-situ observations give a less accurate assessment, because their sampling is extremely inhomogeneous both in time and space. The model results permit the recognition of gyres, jets, boundary currents, recurrent eddies, etc, typical of the Mediterranean Sea mean circulation. The results are promising for the detection of the timing of current reversal in the Ionian Sea, the salinity changes and the outflow from the Aegean Straits, its spreading and accumulation phase.

Conclusions

This study describes the development of modelling and data assimilation tools for the production of re-analysis for the entire Mediterranean Sea. In order to carry out a re-analysis two major steps were undertaken in this work. In the first, the general circulation model was upgraded to have the correct air-sea water fluxes. In the second, two assimilation schemes, one new and the other consolidated, were compared to show their impact on the quality of the reanalysis. The general circulation model used in this study is shown to be capable of reproducing quite accurately the ocean dynamics of the Mediterranean Sea. The results have shown that the model solution is in agreement with data and observations, even though some parameterizations of the model should be improved (i.e. heat flux and mixing processes). The new implementation of a realistic water flux, proposed in this study, has improved the model solution so that re-analysis is possible. The study of these reanalysis shows that both products are sufficiently accurate for appropriate climate studies. Both assimilation schemes show good capabilities in correcting the solutions provided by the dynamical model. Moreover the ability of both systems in retaining this information and projecting it in the future has been shown. Eventually, even for very complex non linear systems, with millions of prognostic variables, the equality between the Sequential Kalman Filter Approach and the Variational method as been demonstrated.

Abstract

The patterns of the vertical distribution of mesozooplankton in relation to physical and biological heterogeneities were studied in a 5day time series at a fixed station in the Catalan Sea (NW Mediterranean). CTD, microturbulence, and TAPS® (high-resolution acoustic probe) profiles, and depth-stratified LHPR® hauls from 15 depth-strata (from 0 to 200 m depth), were alternated along the time series. Strong density gradients and microturbulence (epsilon), related to deep fluorescence layers were determinant for the daylight distribution of zooplankton.

Keywords: Zooplankton, Vertical Profile, Western Mediterranean, Phytoplankton, Hydrography

Introduction

In most of the plankton production models, space is not taken into consideration, as if the pelagic trophic relations took place in an evenly distributed universe. Food or predators are parametrised as average concentration values, although spatial heterogeneity and time variability (patchiness) at all scales is a constant characteristic for marine physical and chemical variables, as well as for plankton communities. The vertical structure of plankton in patches or layers has been described since long [1], but their effects on the coupling between the different trophic components and the oceanographic singularities that control the matter and energy transfer have been poorly studied. In order to allow us to explain some paradoxical features of consumers production under conditions of low average resource availability, in the Framework of the PERFIL-MED cruise we studied the time-changes on the vertical pattern distribution of meso- and microplankton in relation to physical heterogeneities during the summer stratification period.

Study area and methodology

The study took place on board the R/V García del Cid, from the 27/06/09 to the 01/07/09 in the Catalan Sea, NW Mediterranean, at a fixed station (40.45 °N, 2.39 °E). Profiles of physical (T, S), chemical (O₂) and biological (fluorescence) data were made with a CTD SBE 911plus. The high-resolution vertical distribution of the rate of turbulent mechanical energy dissipation, epsilon, was obtained with a MST micro-structure profiler®. The vertical distribution of organisms ranging from 50 µm to 2 mm ESR was obtained with a TAPS® (high resolution acoustics, 6 frequency channels from 265 to 3000 KHz). For depthstratified plankton hauls (15-level, from 0 to 200 m depth) we used a LHPR® fitted with 200 and 50 μm -mesh gauzes, and the on-board analysis of microplankton was made with a FlowCam® on depth-selected water samples. All the profiles were obtained in the 0-200 m depth water column. The analysis of zooplankton biovolume, the organic $\mathrm{C}_{\mathrm{ZOO}}$ contents (from biovolume and a conversion factor, [2]), individual numbers and the identification of taxonomic groups, was made using the free software ZooImage® [3], which uses ImageJ® for the step of image analysis, and R for classification and data analysis.

Results and discusion

A clear deep phytoplankton (fluorescence) layer, accompanied by higher microplankton biomass (data not shown) had developed at the base of the thermocline (Fig. 1 A), the depth of the peak slightly differing for day and night profiles (52 m night, 58 m day). The same pattern was observed for daylight zooplankton biomass (Biovolume, BV, Fig. 1 C) both directly measured in LHPR samples and that obtained using acoustics (TAPS). Nocturnal zooplankton profiles showed not only higher BV both for LHPR and TAPS, but a shallower peak (vertical migration). The zooplankton LHPR maxima coincided with higher microturbulence (epsilon) values (Fig. 1 B), and during the day with the fluorescence maxima.

The pattern of TAPS profiles was very similar to that of LHPR, although appeared shallower probably due to the effect of internal vawes in the time interval between both samplings. The higher food concentration in the deep fluorescence layer (both phyto and microzooplankton) could explain the coincidence of zooplankton day maxima with the deep fluorescence layer. A better comprehension of the control exerted by physical and biological variables for the vertical heterogeneity of zooplankton biomass would be obtained after a

detailed study of the time series for the corresponding variables.

Fig. 1. Examples of two vertical profiles at day (grey lines) and night (black lines) of A: Temperature (°C) and fluorescence (relative units). B: Microturbulence; C: Zooplankton biovolume (mm³ m⁻³ from high-resolution acoustics, TAPS (thin lines) and LHPR samples (thick lines). The horizontal dashed line indicates the depth of the fluorescence maximum at day.

TEMPERATURE, SALINITY AND FLOW VARIATIONS IN THE STRAIT OF ISTANBUL (BOSPHORUS)

Husne Altiok ¹*, Halil Ibrahim Sur ¹, Ahmet Edip Muftuoglu ¹ and Huseyin Yuce ¹

¹ Institute of Marine Sciences and Management, Istanbul University, 34116, Turkey - altiokh@istanbul.edu.tr

Abstract

Monthly temperature and salinity of the upper and lower layers in the Strait of Istanbul are evaluated between February 1996 and February 2009 to obtain long term changes in physical parameters in the strait. The volume fluxes of the layers are also calculated by using monthly ADCP transects data collected in both exits of the strait, from June 1999 to February 2009. Long term variations of temperature, salinity and volume fluxes supplies calculation of the water budget in the strait. *Keywords: Bosphorus, Temperature, Salinity, Water Transport, Time Series*

The Strait of Istanbul (Bosphorus) connects the Sea of Marmara and the Black Sea. It has a two-layer exchange flow system. The upper layer with ~18 psu flows from the Black Sea and the lower layer with ~38 psu flows from the Sea of Marmara [1]. The southward barotropic flow in the upper layer and baroclinic flow in the lower layer are separated from each other by a thin interface. The average volume fluxes of the layers (600 km³year⁻¹ in the upper layer, 300 km³/year⁻¹ in the lower layer) were calculated in terms of the salt and water budget of the Turkish Sea Straits [1, 2].

The data given in this study were collected in the Strait of Istanbul (Figure 1) by R/V ARAR of the Istanbul University, Institute of Marine Science and Management (IMSM-IU).

Fig. 1. Stations and ADCP transects locations

Investigation of monthly temperature, salinity and ADCP measurements at the two ends of the strait indicate that these parameters vary in wide range. The temperature changes between 1.9°C in February 1996 and 26.7°C in July 2002 in Black Sea enters. The salinity is in the range of 15.01-18.64 psu.

Our observations indicate that hydraulic control sections agree with a two-layer numerical model [3]. The composite Froude number (G^2) is generally found greater than unity in the southern exit of the strait, in the contraction and in the northern sill. However, current speeds are not high enough to generate hydraulic controls in some situations. For maximal exchange flow two control sections are required in the strait southern exit or the contraction and in the northern sill. We found critical flows at the two ends of the strait at the same time in some months. Usually supercritical flow is observed in only one control section. Especially when the flow is critical in the contraction and southern exit of the strait the lower layer is very thin in the northern section.

The flow exchange is mostly influenced by the hydraulic conditions, the

geometry of the strait and rapid changes in the atmospheric conditions [3]. In

the strait of Istanbul, the volume fluxes given in Figure 2 vary in an extensive

range (upper layer: 5-1051 km³y⁻¹ lower layer: 0.6-866 km³y⁻¹ in the northern

Abstract

Climate change, resources management or environmental protection are some of the questions that scientists have to deal with in the current century. The management of the marine environment requires multidisciplinary and multitask observing systems which have to consider oceanographic structures, coastal/open sea interactions and those between different basins. This can only be achieved through the international cooperation of national monitoring programs. Here we describe the monitoring system RADMED, implemented in the Spanish Mediterranean by the Instituto Español de Oceanografía. We provide examples of results obtained in the frame of RAMED in such different fields as climate change, distribution of biochemical variables or resources management. Keywords: Monitoring, Western Mediterranean, Time Series, Hydrology, Plankton

The Instituto Español de Oceanografía carries out four cruises per year covering a large set of oceanographic stations (fig. 1). These stations cover the Spanish Mediterranean and are distributed along transects normal to the coast. The basic strategy is to cover the different areas where differences in the large scale oceanographic conditions could be expected.

Fig. 1. RADMED and DESMMON stations (upper panel) and time evolution of the WMED heat content along the twentieth century

This monitoring includes productive areas such as the Alboran Sea, oligotrophic waters as those to the north of Cape Palos and around the Balearic Islands, or areas of special interest as those surrounding the Ebro river. Coastal, shelf and deep stations are included. Deep stations provide a description of the water column along the time. The sampling during the four seasons of the year allow us to filter out the seasonal cycle for the purpose of long term climate change studies. At the same time permits the study of some seasonal phenomena such as the intermediate water formation. We can accomplish the description of coastal/open sea and latitudinal gradients in the biochemical distributions of the waters surrounding the Spanish coast. We calculate climatological values for different variables along the Spanish waters, including surface and deep

ones. Deviations or anomalies along time can be followed. In all the stations the following sampling is included: Temperature, salinity, dissolved oxygen, chlorophyll-a, inorganic nutrients, phyto and zooplankton abundance and taxonomic composition. At present, other variables of key importance for the analysis of the sea health state are being included. These variables are: pH, Total Inorganic Carbon, nitrous oxide and methane, thanks to the collaboration with IFM-GEOMAR and IMEDEA under the umbrella of DESMMON project.

The objective of this monitoring program is to make an along shore and crossshore description of the variables mentioned above, defining ranges of variability and mean values. This is possible thanks to the length of time series available. such as temperature (fig.1). Long term changes in temperature, salinity and heat absorbed have been evaluated showing the present warming and salinification of Mediterranean waters in the frame of climate change [1]. The evolution of these time series has many purposes. As an example, it has been shown that monitoring programs can be used in the management of short life cycle species such as O. vulgaris (fig. 2) which, in the case of the Alboran Sea, seems to be highly influenced by temperature variability [2]. In the near future we expect to extend the basic description of the health state of the Spanish Mediterranean to gases of greenhouse effect such as carbon dioxide, methane and nitrous oxide.

Abstract

The Rhône River Observatory Station in Arles (SORA) allow quantifying suspended sediment fluxes to the marine environment as well as liquid and solid fluxes of major nutrients and various natural and artificial radionuclides. This instrumented platform is especially devoted to the survey of flood events through high frequency flux monitoring *Keywords: Sediment Transport, Hydrology, Monitoring, Radionuclides, Rhone Delta*

Riverine fluxes towards the marine environment of suspended solids and associated potentially contaminating trace elements (PCTE) represent key environmental data because rivers constitute the main link between continent and ocean in most biogeochemical cycles. This especially concern the Rhône River as its inputs affect primary production significantly in the North-Western Mediterranean area and play a leading role on the marine ecosystem functioning in the whole Gulf of Lions [1]. The importance of floods in annual sediment budgets is now basically known and has been demonstrated in case studies [2-4]. Flood monitoring is nevertheless sensitive as high frequency flux measurements have to be carried out to register such hazardous events [5]. The Rhône River Observatory Station (SORA) was developed by IRSN to register such episodic events. The Station is located at Arles on the right bank of the Grand Rhône River, 3.5 km downstream the diffluence between the Grand Rhône and the Petit Rhône and 45 km upstream the River mouth. The Grand Rhône branch exports to the Sea 85 to 90% of the liquid and solid Rhône river flows. Water is collected at a distance of 7 m from the bank and 0.5 m under the surface whatever the discharge and continuously supplies the Station. High frequency monitoring is displayed into two main modes depending on the liquid flow rate of the River:

- Below 3000 m³s⁻¹: Daily samplings for TSS and particulate and dissolved nutrients analyses result in 16 sub samples of 150 ml automatically collected each 90 minutes. Radionuclides activities within the dissolved and particulate phases are determined onto monthly integrated samples obtained through sub samples of 151 automatically collected each hour.

- Above 3000 m³s⁻¹: Samples for TSS analyses are collected each 4 hours resulting in 8 sub samples of 150 ml taken each 30 minutes. Particle bound radionuclides are measured onto samples taken each 8 hours through 24 sub samples of 51 automatically collected each 20 minutes.

The threshold flow rate of 3000 m³ s⁻¹ was chosen on the basis of previous studies: [6] observed a breakdown in the relation between liquid flow and TSS concentrations corresponding to the beginning of the sediment transport under flood condition. These observations were confirmed by [7] that furthermore observed higher TSS concentrations with depth. Samples for TSS analysis are poisoned with HgCl₂ and conserved at 5°C until they are filtrated on 1µm pre conditioned glass fiber filters (dried at 450°C for one hour). Uncertainty on TSS concentrations is estimated to 5 10⁻⁴ g¹⁻¹. Daily and hourly liquid discharges in Arles are made available by the CNR (Compagnie Nationale du Rhône). These data allow quantifying liquid and solid fluxes associated with each sampling periods and especially with flood events.

Acknowledgements

The SORA Station received the support of "Agence de l'eau Rhône-Méditérranée-Corse", the French National Research Agency (ANR) through the ANR-EXTREMA project (ANR-06-VULN-005, 2007-2010) and from the competitive poles "Mer PACA (Provence Alpes Côte d'Azur)" and "Gestion des Risques et Vulnérabilité des territoires". Additional funding supports are delivered by ORME program (Observatoire Régional Méditerranéen de l'Environnement). Liquid discharges values in Arles were made available thanks to the CNR (Compagnie Nationale du Rhône).

Abstract

Long-term ecological research (LTER) plays a crucial role in tracing and predicting ecosystem trends in response to environmental changes. Within the LTER-Italy network, which is part of the International LTER network, a great scientific effort is concentrated on the marine environment. To this end several different Italian institutions, working in four coastal sites, are networked with the aim of sharing methodologies, experimental approaches, and ecological data. This intellectual and experimental partnership among disciplines and researchers represents an essential requirement also for knowledge driven environmental policy.

Keywords: Time Series, Plankton, Biodiversity, Coastal Systems

Long-term ecological research (LTER) is fundamental to assess the main trends of marine ecosystems and relate them to variations in climate and anthropogenic impact at the interannual and decadal scales. LTER is also essential for testing ecological theories, enhancing our capacity for short- and medium-term forecasting and the managing of the environmental resources. The LTER-Italy network, which is part of the European (www.lter-europe.net) and international LTER (www.ilternet.edu) ones, presently includes 20 sites, 4 of which are marine (Fig. 1): the Northern Adriatic Sea, the Gulf of Naples, the Sardinian coastal waters and the Portofino Marine Protected Area.

Fig. 1. Marine sites in the LTER-Italy network

Intensive monitoring programmes and interdisciplinary experimentation at these sites are carried on at six Italian scientific institutions. The main common ecological investigations concern: i) patterns and trends in plankton and benthos communities, ii) carbon pathways and budgets in the pelagic food web, iii) trophic state and biodiversity variations, in relation to local and global changes. Relevant examples of results of these activities concern mainly the detection of interannual changes in plankton patterns and scales of variability as well as significant shifts [1, 2, 3] (Fig 2). In some key areas advanced automatic acquiring systems are operating, as early warning systems for dystrophic events and a validating centre for numerical models. An intense effort has been done to disseminate this kind of information among different stakeholders. For a couple of examples see: www.e.ismar.cnr.it/piattaforma/, sl.bo.ismar.cnr.it. and portofino.macisteweb.com/.

While the research carried so far has been based on efforts of individual institutions, it is predictable that the LTER network will help generating and sharing ideas, protocols, data sets and research facilities, in order to address and answer research questions on important environmental topics in a coordinated way, giving also a scientifically sound support to environmental management.

AQUA ALTA - THE OCEANOGRAPHIC TOWER OF ISMAR-CNR AFTER ALMOST 40 YEARS OF ACTIVITY

Mauro Bastianini 1*

¹ Institute of Marine Sciences - CNR, Venice, Italy - mauro.bastianini@ismar.cnr.it

Abstract

The oceanographic tower "Aqua Alta" of the Institute of Marine Sciences of CNR is located in the Northern Adriatic Sea, 15 km offshore the Venice lagoon on 15 m of depth. The tower, operational since the early '70s, hosts a very large variety of instruments, meteorological, oceanographic, physical and chemical. Some of the time series collected on board are among the longest ones in the world. The tower allows both long term automatic instruments deployment, connected in real time with the land station, and extended periods for people on board for devoted campaigns. Multiple power sources, also controlled from land, are available. Measurements done during one of the worst historical storms has led to the evidence of one of the key processes controlling the tidal level in the lagoon in Venice in cases of serious floods.

Keywords: Adriatic Sea, Monitoring, Time Series

The oceanographic tower "Aqua Alta" of ISMAR-CNR (see Figure 1) is located 15 km offshore the coast of the Venice lagoon, in the Northern Adriatic Sea, on 16 metre of depth. It is the only fixed marine scientific structure in Italy, and one of the very few in Europe, that allows people on board for prolonged periods for intensive campaigns in the middle of the sea. The capability of having a structure in the open sea, large enough to withstand the worst storms, but small enough not to interfere, as with the large oil or gas platforms, with the surrounding environment allows highly accurate and hard to get measurements also in heavy difficult conditions.

Fig. 1. The oceanographic tower "Aqua Alta".

The tower has three floors plus the terrace at 12 metre height above the mean sea level. The structure is composed of four 60 cm diameter vertical poles, a few metres apart, connected at four different levels by multiple smaller poles. The tower is fully self-sufficient for what energy is concerned, powered by two diesel power generators complemented by a very large set of batteries plus solar and wind generators. "Aqua Alta" is fully equipped with a very large set of

instruments, devoted to meteorological, oceanographic and chemical parameters. Measurements go back to the early '70s, so that some time series provide sufficient information to consider climate changes. The abundant, sometime too much, submarine life has provided ample material for biological researches. Most of the instruments are devoted to long term measurements. However, a substantial part of the use of the tower concerns specific campaigns carried out for prolonged periods with people on board. Cavaleri provided in 1999 an extensive review of the researches on board till that year [1].

The wind and wave data available from board have provided essential information for the design of the barrages, presently under construction, that will save the Venice lagoon from the worst floods. The floods are associated to the sirocco storms.

An extremely intense one, the strongest in memory after the catastrophic 1966 one, happened in December 1979. Heavy damage was caused on board, with the second floor completely destroyed. Notwithstanding the lack of power, two mechanical instruments, an anemometer and a mareograph, provided essential data. In particular the latter provided the first evidence in the world of coastal set-up, the accumulation of water, with the consequent local sea level raising, that takes place as a consequence of wave breaking toward the coast.

This finding, properly modelled [2], is now integral part of the local tidal forecast system. Recently a substantial upgrading has been done on the tower, with the introduction of extensive remote control and data handling in real time. A new tide-wave recording system is in operation at 50 m distance from the tower, with direct connection, together with meteorological data, to the display in ISMAR. Some webcams have been installed for direct visualisation of the meteo-oceanographic situation and control of the area. An advanced experiment has just started with an automatic system, controlled from land, capable to obtain at high rate continuous 3-dimensional measurements of the sea surface under storm conditions.

CIRCULATION VARIABILITY IN THE ADRIATIC SEA AND IN SMALL DOMAINS ALONG THE EASTERN **ADRIATIC COAST DURING 2007 AND 2008**

G. Beg Paklar¹*, I. Janekovic², M. Dutour Sikiric², I. Vilibic¹, V. Dadic¹ and B. Grbec¹ ¹ Institute of Oceanography and Fisheries, Split, Croatia - beg@izor.hr

² Rudjer Boskovic Institute, Zagreb, Croatia

Abstract

POM and ROMS ocean models were used to perform a year-long simulation of the Adriatic circulation. Both models had almost the same setup which allowed for a reliable comparison between their results. Although these models successfully reproduced the basic characteristics of the Adriatic circulation, some differences appeared and they could be related to the different numerical formulation of two models. Model results were evaluated with the CTD and HF radar measurements. Simulated fields from both Adriatic models were used for the open boundary conditions in several coastal domains along the eastern coast through a nesting procedure. The impact of the selected open boundary conditions on the circulation and thermohaline properties in the coastal domains was assessed with ADCP and CTD measurements.

Keywords: Adriatic Sea, Circulation, Circulation Models, Coastal Models, Air-Sea Interactions

Current variability in the Adriatic Sea from November 2007 to October 2008 has been simulated with two three-dimensional nonlinear sigma models: Princeton Ocean Model (POM) [1] and Regional Ocean Modeling System (ROMS) [2]. In a year-long simulation both numerical models were forced with atmospheric, river and tidal forcing. Atmospheric forcing for the ocean models was calculated from the output fields of the meteorological mesoscale model ALADIN [3] having 8 km horizontal resolution and 3 hour resolution in time. A tidal function was applied on the southern open boundaries of both models for denivelation and transport, while the radiation condition was applied for the three-dimensional current field. The ocean models had horizontal resolution of approximately 2 km while along the vertical 22 and 30 sigma layers were defined for POM and ROMS respectively.

Surface mean monthly current fields obtained by the POM model show significant resemblance with the corresponding fields from the ROMS. Although considerable variability can be observed in the modelled current fields they also indicate some common features in accordance with wellknown characteristics of the Adriatic scale circulation. The general circulation is cyclonic with several imbedded, mostly cyclonic, gyres. Two cyclonic gyres are around the main pits - South Adriatic and Jabuka Pit, and one can be observed in the northernmost part of the Adriatic. Current fields in the winter period resemble bora induced current fields [4], indicating the bora wind as an important driving mechanism for the Adriatic general circulation. Current intensities during summer decreased and numerous small-scale eddies appeared. A South Adriatic cyclonic gyre over the deepest Adriatic area is present in all monthly current fields but with variable intensities. A cyclonic gyre above the South Adriatic Pit is a well-known characteristic of the Adriatic circulation and it is supposed to be topographically controlled by the South Adriatic Pit and Palagruža Sill.

The main difference between POM and ROMS monthly averaged current fields is manifested through the current velocity intensities, mainly in jet currents that are attached to the outer boundary of the Croatian outer islands, as well as through the intensities of the cyclonic South Adriatic gyre. The evaluation of the modelled fields was based on the thermohaline measurements along the Split-Mt Gargano transect and HF radar measurements in the northern Adriatic.

The results obtained from both Adriatic-scale models were used to define open boundary conditions for the coastal shelf model embedded along the eastern coast using one-way offline nesting procedure. The horizontal resolution of the shelf model was approximately 1 km. Furthermore, two local models with resolution of 200 m were nested in the coastal shelf model by using the same methodology. The evaluation of the modelled fields in the coastal area, as well as the assessment of their sensitivity to the choice of the open boundary conditions was made through CTD and ADCP measurements via RMS errors and correlation coefficients.

PROCESS STUDY SIMULATIONS OF THE DENSE SHELF WATER CASCADING INTO THE CAP DE CREUS CANYON

A. Bergamasco¹*, K. Schroeder², P. Puig³, S. Carniel¹ and M. Sclavo¹ ¹ Istituto di Scienze Marine CNR ISMAR, Venice, Italy - andrea.bergamasco@ismar.cnr.it ² CNR-ISMAR, La Spezia, Italy ³ Institut de Ciències del Mar, CSIC, Barcelona, Spain

Abstract

Intense dense shelf water cascading events occurred in the North-Western Mediterranean Sea in early 2005. These events have contributed to the basin-wide spreading of a deep thermohaline and turbid anomaly, which has been extensively observed by many authors. The major volume of dense shelf water formed on the Gulf of Lions shelf is exported through the Cap de Creus Canyon, at the western edge of the gulf. The intensity of the 2005 events gives the chance to perform numerical process study simulations of the down-canyon dense water flow. The Regional Ocean Modeling System (ROMS) is used to study the dense plume cascading dynamics, first using an idealized but realistic canyon topography and then the multibeam derived bathymetry. *Keywords: Gulf Of Lions, Western Mediterranean, Models*

The Gulf of Lions is one of the regions in the Mediterranean where dense water formation occurs by open-sea convection process as well as by dense shelf water cascading when coastal surface waters over the wide shelf become denser than the underlying water masses and cascade downslope until reaching their equilibrium depth [1]. Dense shelf water cascading is one of the main processes of shelf-ocean basin exchanges, enhanced by the presence of submarine canyons that deeply cut the continental shelf-edge and slope.

Fig. 1. Bathymetric map of the southwestern end of the Gulf of Lions showing the location of the Cap de Creus Canyon. Symbols represent the location of near-bottom instruments deployed along the canyon axis, at 145 m depth (tripod) and at 200, 500 and 750 m depth (moorings).

The occurrence and characteristics of dense shelf water cascades from the Gulf of Lions have been continuously monitored at the Cap de Creus submarine canyon head (between 145 m and 750 m depth), in terms of near-bottom current velocities, temperature, salinity and turbidity (Fig. 1).

The Regional Ocean Modeling System (ROMS), a free-surface, hydrostatic, primitive equations, general circulation ocean model, that uses stretched, terrain-following coordinates in the vertical and orthogonal curvilinear coordinates in the horizontal was setup with an idealized and a realistic bottom topography. The horizontal resolution was variable increasing from 500 m up to 100 m across the canyon axis (y direction of the model) to better describe the steep topography. Along the canyon (x direction of the model) the resolution was 500 m, while in vertical 40 levels were used, with higher resolution in the bottom boundary laver.

Different sets of numerical experiments have been done to explore how the downslope flow develops into a gravity current cascading event, and the time scales characteristics of such events.

Since the objective of the work was a process study, the background thermohaline field has been defined using the MEDAR winter climatology and the characteristics of the simulated plume from the mooring data available along the canyon. According to [2] and [3] the Cap de Creus Canyon is the main pathway for dense shelf water cascading, due to its strategic position at the point where the cyclonic circulation of the dense water formed in the Gulf

converges. Dense waters preferentially enter the Cap de Creus Canyon across the southern canyon wall due to the coastal constrain, showing a pulsating nature with a periodicity of 3–6 days, presumably associated with the cross-slope fluctuation of a topographic wave [4]. For this reason, the model was setup with the plume entering the domain at its southwestern edge.

In order to compare model results with available data, the tripod and mooring mooring measurements (Fig. 1) were analyzed, focusing only on the beginning of the 2005 cascading event. In particular we chose the first plume, detected at the deepest mooring, from February 3^{rd} to 8^{th} 2005 (Fig. 2). Despite this event being constituted by a succession of 8-9 smaller impulses, each of them lasting less than 1 day (Fig. 2), its time scale resulted to be particularly suitable for being modelled with a process study approach, focusing on the dynamics of a "single" plume, instead of the dense water cascading during the whole winter.

Fig. 2. Temporal evolution of potential temperature, recorded by the 750 m depth mooring, during the selected plume event extracted from the whole record.

This study could be the framework of a model-based experimental design, since the numerical results can provide helpful information about the most suitable locations of continuously measuring instruments along the canyon, increasing the probability to detect the main flow of the descending plume.

STRUCTURE HYDRODYNAMIQUE ET VARIATION DE LA CHLOROPHYLLE A AU NIVEAU D UN TRANSECT DANS LE DETROIT DE GIBRALTAR

Amina Berraho¹*, Omar Ettahiri¹, Ahmed Makaoui¹ and Abdellatif Orbi¹

¹ Institut National de Recherche Halieutique, 20000, Casablanca, Morocco - amina_berraho@yahoo.fr

Abstract

Les paramètres hydrologiques (température, salinité, sels nutritifs) et biologique (chlorophylle 'a') ont été étudiés au niveau d'un transect vertical dans le détroit de Gibraltar (radiale Camarinal) en 2006 et 2007. Les diagrammes T/S et les profils CTD montrent l'existence de deux masses d'eau : l'une superficielle d'origine atlantique, chaude et moins salée et l'autre profonde, froide et plus salée, d'origine méditerranéenne. La variation de la teneur en chlorophylle 'a' est moins accentuée le long de la colonne, par contre elle diffère d'une période à l'autre, avec une faible richesse en période froide (décembre). *Keywords: Chlorophyll-a, Strait Of Gibraltar, Temperature, Salinity, Nutrients*

Introduction

Le détroit de Gibraltar est le siège d'une circulation complexe caractérisée par l'existence de deux systèmes de masses d'eau : l'eau atlantique entrant en surface de direction est et l'eau méditerranéenne sortant en profondeur de direction ouest [1] et dont le débit moyen d'échange à travers le détroit est estimé à 0,7 Sv [2]. La couche d'interface AMI (Atlantic-Mediterranean Interface), a une épaisseur significative, caractérisée par une halocline bien marquée, définie à 37 psu avec des valeurs plus élevées vers l'est [2], [3]. A ce niveau, l'abondance de la chlorophylle et du microplancton, a tendance à augmenter du sud-ouest au nord-est et coïncide avec l'élévation graduel de la profondeur de l'interface dans la même direction [4].

Matériel et Méthodes

Le transect étudié est situé sur la longitude 05°45'W et comporte 5 stations entre 35°52,7 et 35°58,5N. Les périodes d'étude correspondent à mars, mai, décembre 2006 et mai, juillet, novembre 2007. La température et la salinité ont été mesurées par la CTD et les échantillons d'eau ont été prélevés selon un dispositif de bouteilles associé à la CTD. Le dosage de l'oxygène dissous a été réalisé par la méthode de Winkler, les sels nutritifs par spectrophotométrie et la chlorophylle 'a' par fluorimètrie (Turner Desings-10 AU).

Fig. 1. Profils de CTD, d'oxygène dissous et des nutriments au niveau de la station 3

Résultats et Discussion

Les diagrammes T-S et les profils des paramètres physiques (CTD), montrent l'existence de deux masses d'eau, séparées par une interface d'épaisseur variable (40 à 50 m) et dont la position est variable (100 m à 160 m) selon la profondeur maximale de la station. Cette zone est marquée par une halocline très nette surtout au niveau de la station 3, située dans le chenal principal. Ainsi, en surface, l'eau atlantique est caractérisée par une salinité moyenne de 36,3 psu et une température variable en fonction de la saison (>15°C) ; alors que l'eau méditerranéenne plus salée (> 38 psu) et froide (< 13,5°C) est située au delà d'une profondeur de 200 m (station 3). La variation des nutriments le long de la section Camarinal montre une richesse qui suit l'apparition de l'eau méditerranéenne marquée par une nitracline importante à partir de l'interface jusqu'au fond (Figure 1, cas de la station 3). La zone d'étude se caractérise également par la présence d'ondes internes qui peuvent modifier le profil des paramètres hydrologiques le long de la colonne d'eau, (cas de la station 3, mai 2006). Ces ondes internes sont générées près du chenal Camarinal [5].

La distribution de la chlorophylle 'a' est peu variable le long de la colonne d'eau et les concentrations sont faibles (< 0,5 µg/l). Généralement, l'eau atlantique est relativement plus riche en chlorophylle 'a' que l'eau méditerranéenne profonde, malgré sa forte richesse en nutriments. Dans les couches sub-superficielles, les conditions en lumière sont optimales mais limitées en éléments nutritifs, alors que la situation est inverse au fond. Le suivi temporel de la teneur en chlorophylle 'a' au niveau de la station 3, montre des valeurs très faibles le long de la colonne d'eau, enregistrées en décembre, en relation avec la variation saisonnière. Le maximum (0,47µg/l) est observé en mai, à 80 m de profondeur, associé à la thermocline (Figure 2). Le développement et l'importance du maximum de chlorophylle (DCM = Deep Chlorophyl Maxima) sont inversement liés à la distance entre l'AMI et la thermocline [4]. Cette position est décisive, car la vitesse à proximité de l'interface est faible ce qui permet une accumulation préférentielle des cellules phytoplanctoniques à ce niveau [4].

Fig. 2. Distribution de la chlorophylle 'a' au niveau de la station 3

WIND WAVE FORECAST IN THE ADRIATIC SEA – A TOOL FOR BETTER TIDAL FORECAST IN THE NORTHERN ADRIATIC SEA

Luciana Bertotti ¹*, Paolo Canestrelli ², Luigi Cavaleri ¹ and Franca Pastore ² ¹ Institute of Marine Sciences, Venice, Italy - luciana.bertotti@ismar.cnr.it

² Istituzione Centro Previsioni e Segnalazioni Maree, Venice, Italy

Abstract

The present tidal forecast system in Venice has been operational for more than 20 years. The present average accuracy is of better than ten cm for forecasts up to 6-hours. In highly severe storms wind waves contribute substantially to the tide level in the Venice lagoon via the set-up effect. Therefore ISMAR and IPSM are jointly managing an operational wave forecast system for the Adriatic Sea. The driving is given by the surface winds produced by ECMWF as input to the WAM wave model with 1/12 degree resolution. The results are validated using the data collected at the ISMAR oceanographic tower, 15 km offsahore the Venice lagoon *Keywords: Models, Adriatic Sea*

The area of interest

Large scale wave modelling are openly available. For instance, the European Centre for Medium-Range Weather Forecasts (ECMWF, Reading, U.K.) provides ten day forecast worldwide. However, these large models, while very accurate in the open oceans, fail to provide comparably accurate results in the inner seas, like the Mediterranean or, at greater extent, the Adriatic Sea. This led to the development of systems as NETTUNO, a combined product of the Italian National Meteorological Service and ISMAR, and HENETUS, here described, a system devoted to the Adriatic Sea [1] with the aim, among others, of improving the tidal forecast in the Northern Adriatic Sea. The grid used for our purposes has 1/12 degree resolution. A higher resolution can be used in front of the Venice lagoon to take into proper account the coastal effects of breaking waves (see below).

Previsione per il : 27 Aprile 2009 ore 15 UTC Altezza d'onda significativa (m) + direzione media

Fig. 1. Wave field forecast in the Northern Adriatic Sea

Input information

The input to the model is the daily forecast provided by ECMWF. However, the ECMWF winds on the Adriatic are strongly underestimated. Therefore, before passing them to the wave model, the wind speeds are corrected with an objective procedure based on long term comparison between the ECMWF winds and the extensive data available from the QuikSCAT scatterometer [2].

Modelling

The WAM wave model [3] is used for the daily application. WAM has been the first advanced, so-called third-generation wave model.. The ECMWF wind data are daily received by ICPSM and passed to ISMAR. The wave results are available early in the day and transferred immediately to ICPSM. Tidal forecast by ICPSM has been operational for more than 20 years with ever increasing accuracy, presently between 5 and 10 cm at 6-hour distance. However, to avoid an underestimate during the most severe sirocco storms associated to set-up, wave effect on coastal sea level needs to be taken into account.

Model results

The output of the model is available both as numbers and graphics. The

graphical output for the most northerly part of the Adriatic Sea is shown in Figure 1. It represents a strong event of sirocco happened in April 2009. The use of shading plus the arrow pointing to wave height and direction provides a clear and intuitive representation of the situation. These maps are available at 3-hour intervals for the next 72 hours. These forecasts in front of the Venice coastline are verified by comparison with the data recorded at the ISMAR oceanographic tower. The statistics is shown in Figure 2, showing the results for the later analysis (AN) and for the forecasts at 1 (F1), 2 (F2) and 3 (F3) day distance. The comparison shows clearly the high quality of the forecasts, more than enough for any practical use.

Fig. 2. Comparison between analysis and forecast wave heights versus the measured values on the "Aqua Alta" ISMAR oceanographic tower.

Abstract

We study the climate variability of the Mediterranean Sea and the Eastern Mediterranean Transient by carrying out a simulation over 1961-2000 with a Mediterranean OGCM driven by realistic interannual high-resolution air-sea fluxes. Interannual databases for Atlantic T-S characteristics and rivers and Black Sea runoff are used. The sequence of the EMT events is well reproduced: the high winter oceanic surface cooling and drought over the Aegean Sea in the early 1990's, the high amount of dense Cretan Deep Water formed during these winters and the overflow and the spreading of this CDW in the eastern Mediterranean. *Keywords: Eastern Mediterranean, Water Convection, Circulation Models, Aegean Sea, Air-Sea Interactions*

In this work, we study the Mediterranean interannual variability and in particular the Eastern Mediterranean Transient, by using NEMOMED8, an eddy-permitting Mediterranean OGCM at 1/8° of resolution (about 10 km), regional version of the NEMO model. A realistic hindcast is performed from 1961 to 2000, forcing the model with daily atmospheric fluxes produced with ARPERA, a dynamical downscaling of the ERA40 reanalyses (resolution of about 50 km). Interannual datasets are used to represent the hydrological fluxes of the river runoff [1], the Black Sea discharge [2] and the Atlantic Water characteristics [3], in addition to the freshwater flux from the atmosphere.

Considering heat and salt contents at basin-scale, the simulation show a good agreement when comparing to an interannual gridded database based on observations [4]. This simulation is able to reproduce the sequence of the EMT events in very good agreement with the observations [5]:

- the strong heat and water losses at the surface of the Aegean Sea observed during the winters 1991-92 and 1992-93 (respectively -73 W/m² and -2.0 mm/day in NDJF 1991-92, -65 W/m² and -2.8 mm/day in NDJF 1992-93, in agreement with [6]), due to the relatively high resolution of the ARPERA atmospheric dataset,

- the strong winter convection in the Aegean Sea triggered by these strong atmospheric fluxes (1.22 Sv of waters denser than 29.2 kg/m3 formed in 1993, in which 0.48 Sv are denser than 29.3 kg/m3),

- the huge outflow of dense waters from the Aegean Sea to the Ionian and Levantine basins through the Cretan Arc straits, especially through the eastern part during the two years following the intense convection event,

- the spreading of this water mass in the eastern Mediterranean, with a scheme of the path followed by this dense water mass from 1993 to 2000 (Fig. 1): the waters exiting the Aegean Sea through the western straits of the Cretan Arc spread in a cyclonic manner in the Ionian Sea; the waters exiting the Aegean Sea through the eastern straits of the Cretan Arc spread in the Levantine basin: a part of them crosses the Cretan Passage and joins the waters outflowing from the western straits while another part sinks at deeper levels in the Levantine basin. That part first spreads southwards following the bathymetry in a cyclonic manner and also propagates eastwards mainly driven by diffusive processes or trapped by eddies.

Among the preconditioning hypotheses proposed in the literature, we find that in the simulation:

- the surface circulation was modified in the late 1980's and the early 1990's, changing the AW path in the Levantine basin; combined with a long drought period over the far eastern Mediterranean which induces a salt increase of the surface layer in this area, this led to a salt increase of the Aegean Sea through a saltier Asia Minor Current,

- the three anticyclonic eddies observed in 1991 play a role in deviating and trapping the AW in the Levantine basin, rather than the LIW as mentionned in the literature, whereas those eddies are not at the observed locations,

- there was no huge decrease of the Black Sea freshwater discharge during the early 1990's according to our interannual dataset,

- several convection events in winters 1987, 1989 and 1990 took place before the major events of winters 1992 and 1993; they induced a steady filling of the Aegean Sea by the dense waters formed during these winters. The sensitivity of using different hydrological fluxes on the simulation of the sequence of the EMT is investigated in [7].

Fig. 1. Scheme of the path followed by the CDW after having exited the Aegean Sea. In full lines: direct advective path. In dashed lines: indirect diffusive path. Contours in back: bathymetry (in meters) of the NEMOMED8 model, interval of 250 m from 1000 m to 4000 m.

A MULTI-SCALE MODEL OF THE TURKISH STRAITS SYSTEM

Cheryl Ann Blain^{1*}, Mustafa Kemal Cambazoglu² and Ewa Jarosz¹ ¹ Oceanography Division, naval Research Laboratory, Stennis Space Center, MS, USA - cheryl.ann.blain@nrlssc.navy.mil ² Dept. Marine Science, University of Southern Mississippi, Stennis Space Center, MS, USA

Abstract

A multi-scale coastal ocean model representing the entire Turkish Straits System (Aegean-Marmara-Black Seas and connecting straits) is one-way coupled to a 1 km basin-scale ocean model of the same region. The modeled three-dimensional circulation and density structure of the TSS is examined through comparison to observations of currents and density taken during the TSS08 sea trial. *Keywords: Coastal Models, Circulation, Bosphorus, Dardanelles, Marmara Sea*

Two narrow, shallow straits, i.e. the Dardanelles and the Bosphorus, form a physical connection between the Marmara Sea and its adjacent water bodies, the Aegean Sea to the southwest and the Black Sea to the northeast. This collection of seas and straits is known as the Turkish Strait System (TSS). Saline, dense water from the Aegean flows in a deep, lower layer through the Marmara Sea to the Black Sea while fresher, lighter Black Sea water flows in a surface layer to the Aegean Sea. Though the TSS dynamics are the result of interconnections between the interconnected straits and ocean basins, earlier modeling efforts (e.g., Staneva et al., 2001; Oguz, 2005; Kourafalou and Tsiaras, 2007; Kanarska and Maderich, 2008) have focused on dynamical studies of individual straits or seas. Often the geometric complexity, broad range of spatial scales present, and computational requirements to represent such disparity have prevented study of the TSS as a whole.

For this study, we utilize state-of-the-art modeling practices to capture the range of spatial scales, geometric complexity and interconnected dynamics of the TSS (Figure 1). A model based on unstructured grids has the resolution, using a minimum element edge length of 20 m, necessary to model flow in the narrow straits whose minimum width is approximately 600 m. The ADvanced CIRCulation Model (ADCIRC), solves the three-dimensional flow and transport equations using a finite element discretization with a terrainfollowing, generalized, stretched coordinate system applied in the vertical (Luettich and Westerink, 2004: Dresback and Kolar, 2009). Flexibility of the finite element mesh not only captures the fine scales within the straits but is also able to represent mesoscale variability in the Marmara Sea while coupling to a basin scale model in the Aegean and Black Seas. Basin-wide dynamics are captured by the HYbrid Coordinate Ocean Model, HYCOM, which applies the finite difference method over a structured grid to solve the primitive mass and momentum balance equations (Bleck, 2002). HYCOM's hybrid vertical coordinate allows the use of three vertical coordinate types (depth, terrainfollowing and isopycnal) which better represents thermohaline dynamics in waters of rapidly varying bathymetric change. Within the HYCOM Aegean-Marmara-Black Sea model (HYCOM-AMB), both straits are represented as idealized channels since the current resolution (~1.3 km) is not sufficient to resolve the geometry of the straits.

Fig. 1. ADCIRC finite element model domain for the Turkish Strait System including a zoom of the mesh refinement in the Dardanelles Strait (upper left) and Bosphorus Strait (lower right).

Model experiments presented focus on the period of the TSS08 sea trial (a joint project between the NATO Undersea Research Center and the U.S. Naval Research Laboratory), starting in late August and extending through November 2008. During one-way coupling as shown schematically in Figure

2, ADCIRC is initialized by temperature, salinity, velocity and water surface elevation fields from HYCOM-AMB solutions. At the open ocean boundaries, HYCOM-AMB values for elevation, temperature and salinity are updated daily throughout the ADCIRC model simulation. Surface forcing for both models is derived from the Navy's Coupled Ocean-Atmospheric Mesoscale Prediction System (COAMPS). The capability of ADCIRC to represent two-layer stratified flow dynamics both in the straits and in the Marmara Sea is examined along with the response of the currents and density structure over the water column to wind forcing. Observations include measured currents from ADCP moorings located at the ends of each strait in the TSS, CTD casts along the Dardanelles Strait and drifter deployments in the straits during strong storm events, high-frequency current variability, and the persistence of circulation gyres in the Marmara Sea.

Fig. 2. The ADCIRC-HYCOM coupled model system.

Abstract

Eddy processes of the Western Adriatic Current near Cape Gargano are highly modulated by the wind, growing during calm periods following strong wind events. Both single anticyclones and trains of multiple eddies with a regular spacing are observed. Suppression of a single anticyclone in the lee of the Cape was observed by profiling SEPTR moorings to occur when the horizontal gradient of the thermocline depth was increased by the wind. Eddies also form cyclonic filaments extending offshore. Such a filament was observed through the new technique of seismic oceanography to have downslope tilting isotherms and a long, thin, offshore extension in the bottom boundary layer.

Keywords: Fronts, Mesoscale Phenomena, Adriatic Sea, Instruments And Techniques, Turbulence

Recent measurements from two international collaborative research programs reveal new details of eddy activity and instability of the Western Adriatic Current (WAC) as it rounds Cape Gargano in the central Adriatic Sea. The "Dynamics of the Adriatic in Real-Time" (DART) program was focused on understanding the predictability of this system with observation and modelling from October 2005 through September 2006. These included, among other things, measurements from long-term current moorings, profiling SEPTR moorings, tow-yo CTD profiles, remote sensing, and high-resolution modelling using the U.S. Navy Coastal Ocean Model. Remote sensing and modelling, supported by in situ observations, revealed two distinct cases of WAC eddy activity [1]. In the first case, a single anti-cyclonic circulation cell (typically 20-30 km horizontal and 25 m vertical scale) forms on the downstream side of the cape in the Gulf of Manfredonia (Figure 1a). In the second case, a multiple eddy train (30-40 km crest-to-crest wavelength) forms along the coast upstream of the cape and proceeds around it (Figure 1b). Both cases are linked to wind patterns; eddies grow and propagate as southeastward winds relax, and are suppressed when these winds are strong. Profiling SEPTR mooring measurements observed anticyclonic eddies in the lee of the Cape when the thermocline slope was weak and the absence of eddies when strong southeastward winds strengthened this thermocline slope.

Fig. 1. Remote sensing Chlorophyll-a images from MODIS Aqua showing representative cases of (a) single anticyclonic WAC eddy downstream of Cape Gargano and (b) multiple eddy train around the Cape. This is a reproduction of Figure 2 from [1].

The AdriaSeismic09 research campaign used the new technique of seismic oceanography [2] to image the temperature gradient structure of the WAC frontal system during March 2009 at very fine horizontal scales (order 10 m). Sampling captured the details of a third WAC eddy case, a cyclonic filament extending offshore following a strong wind event (also observed during DART

[3]). Both microstructure profiler and seismic sections crossed the filament multiple times. The filament frontal structure was baroclinic with downsloping isotherms. Near the bottom, the tilt extended into a long, thin, offshore extension of coastal waters in the bottom boundary layer, followed by a subtle up-tilting structure offshore. These structures were all successfully imaged (Figure 2) by seismic measurements, revealing new fine-scale details of the filament structure that couldn't have been measured otherwise.

Although Adriatic wind regimes and Cape topography provide the background setting for eddy formation, frontal instabilities and mixing processes determine many details of eddy structure and evolution.

Fig. 2. Seismic reflectivity image showing the structure of the vertically tilting WAC filament edge (left), thin offshore extension of cold bottom water (center), and offshore up-tilting structure (right). Reflectivity is measured at 5-10 m horizontal resolution and is associated with band-limited vertical temperature gradient. E.g., the colder water at the bottom causes a decrease in sound speed and a negative reflection (black over white). The largest reflections correspond to temperature changes of about one degree C over ten meters of depth.

Abstract

From September 2008 through February 2009, Acoustic Doppler Current Profilers (ADCPs) measured flow in pairs at the four entrances and exits to the Turkish Strait System. Barotropic tide structures were observed for both diurnal and semidiurnal frequencies in the Aegean/ Dardanelles entrance. At the Dardanelles/Sea of Marmara entrance some baroclinic structure was observed with diurnal tides having higher energy in the upper layer compared to the lower layer. Baroclinic structure in the semi-diurnal tides was observed at the Bosphorus/Sea of Marmara entrance and diurnal oscillations were weak. Both diurnal and semi-diurnal oscillations were weak at the Bosphorus/Black Sea entrance as the temporal evolution of the flow was more concentrated at low frequencies in the form of a mid-water-column jet. *Keywords: Aegean Sea, Black Sea, Bosphorus, Dardanelles, Tides*

Keywords. Aegean Sea, Black Sea, Bosphorus, Daraanenes, Haes

The U.S. Naval Research Laboratory in collaboration with NATO Undersea Research Centre and the Turkish Navy Office of Navigation, Hydrography and Oceanography, undertook a scientific research program, Exchange Processes in Ocean Straits (EPOS) that included an observational effort from September 2008 through February 2009 of maintaining pairs of bottom-mounted, upward-looking Acoustic Doppler Current Profilers near all entrances (exits) of the Turkish Strait System. Simultaneous current measurements allow connectivity ranging from high-frequency to seasonal processes to be investigated. One aspect of EPOS was to examine the frequency response of this system which includes very narrow passages and two vertical layers of opposed and energetic flow and exchange [1]. E.g., how do processes that are forced synoptically or faster propagate through the system and what is the baroclinic structure of their evolution?

To investigate this, rotary spectra were calculated from all the ADCP records separately for all depths. We used Welch's averaged periodogram method over block lengths of 43 days and 50% overlapping Hanning windows. No significant polarity differences were found between clockwise and counterclockwise spectra suggesting the absence of inertial activity at all four sections. There is a remarkable difference in the spectra results for each ADCP current section, particularly with regard to tidal oscillations. Diurnal and semidiurnal tides were clearly present at both ends of the Dardanelles Strait. The structures were primarily barotropic at the Aegean/Dardanelles entrance (Fig. 1, left). In contrast, at the Dardanelles/Sea of Marmara entrance the diurnal fluctuations in the lower layer entrance were notably weaker than fluctuations in the upper layer (Fig. 1, right). This suggests that the Dardanelles Strait geometry and/or its baroclinic structure has acted to extract some energy from the barotropic tide and convert it into baroclinic processes. Also, the differences between the diurnal and semidiurnal responses show a frequency dependence on this action.

At the Bosphorus/Sea of Marmara entrance the tidal frequency spectral peaks were different than those observed at the Dardanelles/Sea of Marmara entrance. Diurnal fluctuations were mostly absent and the semi-diurnal fluctuations had baroclinic structure, again with stronger spectral peaks in the upper than the lower layer (Fig. 2, left). This suggests that oscillations at diurnal and semi-diurnal frequency are not passing unaltered through the Sea of Marmara. The observed spectra at the Bosphorus/Black Sea entrance differed the most from the others as spectral energy was concentrated in the middle of the water column and at lower frequencies (Fig. 2, right). Flow was maximized in the upper portions of the lower layer in a jet-like structure as compared to maximums in the upper portions of the upper layer at other sections. Weak (primarily semidiurnal) tidal oscillations persisted in the bottom of the water column. This suggests that the Bosphorus Strait geometry and/or its baroclinic structure also acts to alter or block higher frequency oscillations.

Analysis of these results has just begun and is ongoing. However, we can conclude that diurnal and higher frequency oscillations are an important component of the variability of the flow in parts of the Turkish Straits system, and that the Straits System acts to significantly affect the transmission of these frequencies.

Fig. 1. Clockwise rotary spectra for representative moorings and depth levels in the Dardanelles Strait. The major tidal frequencies are marked by dotted lines.

Fig. 2. As in Figure 1, but for the Bosphorus Strait.

MASS CONTRIBUTION TO MEDITERRANEAN SEA LEVEL VARIABILITY FOR THE PERIOD 1948-2000

Francisco Calafat ¹*, Marta Marcos ¹ and Damià Gomis ¹

¹ Institut Mediterrani d'Estudis Avançats (CSIC-UIB), Esporles, Spain - kiko.mir@uib.es

Abstract

The mass contribution to Mediterranean Sea level variability is estimated from steric-corrected altimetry and from GRACE observations for the period August 2002 to December 2006. The good agreement between GRACE observations and steric-corrected altimetry supports the quantification of the long-term mass contribution in terms of non-steric sea level in the Mediterranean. For the past decades, total sea level fields are reconstructed using a reduced-space optimal interpolation of altimetry and tide gauge data. The steric component is evaluated from hydrographic observations available for the same period. Results indicate that the mass content has increased at a rate of 0.8 ± 0.2 mm/yr for the period 1948-2000. When the effect of the atmospheric pressure is removed, the trend of the mass component is 1.2 ± 0.3 mm/yr.

Keywords: Sea Level, Geophysics, Global Change

Introduction

In this paper we first use altimetry, GRACE and hydrographic observations spanning the period 2002-2006 to assess the consistency between total sea level and its two components (steric and mass) in the Mediterranean Sea. Fenoglio-Marc et al. [1] and García et al. [2] carried out similar works for the period 2002-2004, but they only focused on the seasonal sea level cycle. Here we consider both intra and inter-annual variability. Other differences with respect to those works are that they use model data (not hydrographic observations) to estimate the steric cycle and that an improved and longer GRACE data set has been made available since then. The good agreement found between GRACE observations and steric-corrected altimetry supports the quantification of the mass contribution in terms of the non-steric sea level in the Mediterranean. Hence, we also evaluate the mass contribution to sea level for the period 1948-2000.

Data sets

The Level-2 Release-04 (RL04) gravity coefficients computed at the Center for Space Research (CSR) and distributed by the GRACE project are used to estimate water mass variations in the Mediterranean Sea between August 2002 and December 2006. A hydrologycal model is used to correct the effect of land waters. The post glacial rebound correction is also applied. To obtain the basin average a smooth averaging kernel is used.

For the period 2002-2006 the Mediterranean mean sea level is computed from Altimetry data while for the period 1948-2000 total sea level fields are reconstructed using a reduced-space optimal interpolation of altimetry and tide gauge data [3]. The steric component is evaluated from hydrographic observations [4]. The errors associated with total sea level and the steric component are evaluated in order to obtain the uncertainty of non-steric sea level.

Results and discussion

Consistency between non-steric sea level and GRACE observations is found for the period August 2002 to December 2006 (Fig.1). The observed mass component from GRACE and the estimated contribution from non-steric sea level have a correlation of 0.75 (significant at the 95% confidence level). The existence of a seasonal cycle in the mass component of Mediterranean mean sea level is not evident and, if it exists, it is not the most energetic signal. The linear trend of the steric-corrected altimetry and that obtained from GRACE are fully consistent: their values are 2.1 ± 0.6 mm/yr and 2.1 ± 0.5 mm/yr, respectively.

The consistency between non-steric sea level and GRACE observations supports that the mass component can be obtained as the non-steric contribution of Mediterranean sea level for a longer period. The overall trends computed for the period 1948-2000 are -0.25 ± 0.04 mm/yr for the steric component and 0.96 ± 0.05 mm/yr for the atmospherically-corrected total sea level. The net mass contribution to sea level trends would then be of the order 1.2 ± 0.3 mm/yr. When the atmospheric component is included the mass component shows a smaller trend: 0.8 ± 0.1 mm/yr. Those values are in agreement with the global mean value obtained by Domingues et al. [5] for the period 1961-2003 (between 0.8 and 1.1 mm/yr).

Fig. 1. Mediterranean mean sea level variability and its components with error bars for the period August 2002 to December 2006: (atmospherically-corrected) total sea level (top), the steric component of mean sea level (middle), and the mass component of sea level (bottom). Black lines show the observed estimates from satellite altimetry (top), the Ishii dataset (middle) and GRACE (bottom), respectively. Grey lines show the estimates obtained by adding or subtracting the other two observational components.

Abstract

Data collected from meteorological stations in the Turkish Straits System around the Marmara Sea are used to assess the performance of atmospheric models in predicting the winds. The Coupled Ocean/Atmosphere Mesoscale Prediction System, COAMPS is applied using different spatial resolutions ranging between 1 km and 27 km to investigate the effect of model spatial grid resolution on accuracy of the computed wind field. The influence of the ocean dynamics on the atmospheric winds is also investigated by comparing wind field predictions from a fully coupled COAMPS with those from the uncoupled (stand -alone atmospheric) COAMPS. Following the examination of the wind products, the importance of using high resolution wind forcing for ocean circulation predictions is evaluated.

Keywords: Marmara Sea, Air-Sea Interactions, Wind/Font, Circulation, Atmospheric Input

The Turkish Straits System (TSS) contains the Dardanelles and the Bosphorus straits that connect the Marmara Sea to the Aegean and the Black Seas, respectively. Fresh, light Black Sea water flows at the surface towards the Aegean Sea while saline, dense Mediterranean water flows deep in the opposite direction resulting in a two-layer stratified flow in both straits. Winds over the region play a major role in generating various features within the TSS system, i.e. blocking of the deep (surface) flow within the straits by Northerly (Southerly) winds; the spread of the Dardanelles outflow plume over the Aegean Sea; and the circulation pattern within the Marmara Sea among the others. Since the winds are the dominant external forcing applied to the ocean models, accurate predictions of twinds by atmospheric models are crucial for accurate predictions of the flow dynamics.

Hourly wind direction and speed data collected from 13 meteorological stations located around the Marmara Sea between May 2008 and June 2009 are used to assess the performance of atmospheric models in predicting winds. The measurements recorded every ten minutes by two Meteo-buoys on the Marmara and Black Seas are also included in the evaluation. The atmospheric models under consideration are the Coupled Ocean/Atmosphere Mesoscale Prediction System, COAMPS [1], and the numerical weather prediction model, COSMO-ME, based on the non-hydrostatic Lokall-Model(LM) [2]. COSMO is the COnsortium for Small scale MOdeling and COSMO-ME is a particular application running on the Southern Europe/Mediterranean Sea domain managed by USAM (Meteorological Service of the Italian AirForce). It has a spatial resolution of 7-km while COAMPS has a coarse operational grid resolution of 27-km. Local configurations of the COAMPS model for grids of 9-km, 3-km and 1-km are also considered.

Fig. 1. Wind speed variation (36-hour averaged) over September and October 2008 at Canakkale and Bandirma meteorological station locations: Measurements (solid), 7-km COSMO model results (dash) and 27-km COAMPS model results (dot).

Fig. 2. Frequency and coherence spectra of wind direction measurements vs. the COAMPS (27-km) and COSMO (7-km) model results for Canakkale and Bandirma meteorological stations.

Both model inter-comparisons (COAMPS vs. COSMO) and model-data comparisons are conducted. Model-data comparisons consider both the raw and filtered time series of wind speed and direction. A more detailed statistical analysis is done by examining the frequency spectra of the modeled and measured wind fields and the coherence between them. The coarser COAMPS model is able to capture the low-frequency (36-hour averaged) wind speed variability as shown in Fig. 1. COAMPS-COSMO comparisons indicate similar wind field predictions (shown in Fig.1) with the exception of wind direction during higher frequency wind events such as the semi-diurnal cycle or the land/sea breeze events as shown in Fig. 2.

SEASONAL VARIABILITY OF PHYSICAL AND CHEMICAL PARAMETERS OF THE NORTHERN AND CENTRAL ADRIATIC SEA DURING 2001

Alessandra Campanelli ¹*, Federica Grilli ¹, Mauro Marini ¹ and Elio Paschini ¹ ¹ ISMAR-CNR L.go Fiera della Pesca, 2. 60125 Ancona, Italy - a.campanelli@ismar.cnr.it

Abstract

During 2001 three oceanographic cruises were carried out in the northern and central Adriatic Sea. Several measurement were situated along multiple transects. In each station physical and chemical parameters were collected in order to study the dynamics of the coastal and off-shore area through the space and the time. The basin showed high nutrient variability during all the year. Nutrient concentrations appeared influenced by river discharge, vertical mixing in the different cruises and uptake from phytoplankton groups. *Keywords: Adriatic Sea, Nutrients, Salinity, River Input*

The Adriatic is a continental basin of the Eastern Mediterranean Sea, located between the Italian peninsula and the Croatian coast; it is elongated in the SE-NW direction. The northern sub-basin is very shallow and gently sloping, with an average bottom depth of about 35 m. River runoff is particularly strong in this area and affects the circulation through buoyancy input and the ecosystem by introducing large amounts of organic matter. the Po river, with an average annual discharge of 1500 m³s⁻¹, accounts for about 50 % of the total northern Adriatic river runoff [1]. The middle Adriatic is a transition zone between northern and southern sub-basins, with the three Jabuka depressions reaching 270 m depth. Two currents dominate the circulation in the Adriatic: the West Adriatic Current (WAC) flows toward southeast along the western (Italian) coast, [2, 3].

The temporal variations of physical and chemical parameters in the Adriatic Sea were observed during three periods (January, June and September 2001) in order to increase the understanding of the area. The CTD (Conductivity-Temperature-Depth) data were collected at all the stations with a SeaBird Electronics SBE 911-plus CTD, equipped with other ancillary sensors. Water samples were obtained by the upcasts with a SeaBird Carousel rosette water sampler. Water samples were collected to analyse nutrient salts and DO (Dissolved Oxygen) with the potentiometric titration method.

Fig. 1. Winter (a) and late spring (b) surface field of: Salinity (black contour, interval 1) and Nitrate (color shading, μ mol l⁻¹). The dots represent the sampling

During the winter cruise (figure 1a) in situ measurements indicated cooler, fresher water to the north and warmer, saltier water to the south of the front located at the southern tip of Istria. Furthermore two months before the cruise the river discharge was about 3 times higher that the mean value (about 5500 m³ s⁻¹). Nutrient concentrations were high along the western boundary and decreased rapidly toward the east forming a strong front along the western side of the Adriatic. The nutrient contribution from the Po plume to the northwestern basin is evident in the high nitrate concentrations (6-8 µmol 1⁻¹) associated with the salinity minimum of the plume. During the late spring cruise (June, figure 1b) the Po plume remained a significant feature in the norther and western Adriatic. Offshore from the mouth of the Po River, the surface layer was characterized by low salinity (30-32) and high temperature (22-23 °C). The Po plume extended much more eastward in late spring than in winter because the vertical mixing is reduced [4, 5]. Low nutrient concentrations were observed in the central basin despite the northern Adriatic shown relatively high nitrate +

nitrite concentrations $(2-4 \ \mu mol \ l^{-1})$. The late summer cruise (September) showed similar patterns of the late spring cruise.

The Adriatic basin showed more nutrient variability during the winter period because of major river discharge during autumn 2000 and vertical mixing. In particular, during spring and summer the nutrient concentrations decreased in most of the basin and this was probably due to uptake from phytoplankton groups under conditions of high available light. This feature was also evidenced by high DO concentrations in these periods respect to winter cruise. The redfield ratios (N/P and Si/P) off-shore were similar to the classic ocean model but with nutrient concentrations slightly higher. The western coast showed high redfield ratios that implied processes of eutrophycation probably due to high river input.

3D MODELLING OF THE BLACK SEA NORTH WESTERN SHELF ECOSYSTEM

A. Capet ^{1*}, M. Gregoire ¹, J. Beckers ¹, P. Joassin ¹, J. Naithani ¹ and L. Vandebulcke ¹ ¹ University of Liège, Liège, Belgium - arthurcapet@gmail.com

Abstract

In the framework of the SESAME European project, a coupled physical-biogeochemical model has been developed to simulate the ecosystem of the Black Sea during the last decades. The biogeochemical model describes the foodweb from bacteria to gelatinous carnivores and explicitly represents processes in the anoxic layer down to the bottom. After validations of the model, equilibrium states from climatologic runs are presented, corresponding to identified key time slices. From them interannual run are studied to compare the interannual variability scales with those between different climatological equilibrium, for the different component of the ecosystem.

Keywords: Black Sea, Models

In the framework of the SESAME European project, a coupled physicalbiogeochemical model has been developed to simulate the ecosystem of the Black Sea during the last decades when eutrophication and invasion by gelatinous organisms seriously affected the stability and dynamics of the system [1]. The biogeochemical model describes the foodweb from bacteria to gelatinous carnivores and explicitly represents processes in the anoxic layer down to the bottom.

For calibration and analyses purposes, the coupled model has first been run in 1D in the central Black Sea [2]. The biogeochemical model involves some hundred parameters which are first calibrated by hand using published values. Then, an identifiability analysis has been performed in order to determine a subset of 15 identifiable parameters. An automatic calibration subroutine has been used to fine tune these parameters. In 1D, the model solution exhibits a complex dynamics with several years of transient adjustment. This complexity is imparted by the explicit modelling of top predators. The model has been calibrated and validated using a large set of data available in the Black Sea TU Ocean Base.

The calibrated biogeochemical model is implemented in a 3D hydrodynamical model of the Black Sea (GHER). A first experiment is driven under climatologic atmospheric, riverine forcings and initials conditions constructed to correspond to three different time-slices: 60-70 (pre-eutrophication phase), 83-90 (severe eutrophication phase), 93-2000 (recovering). This experiment is conducted in order to differentiate the equilibrium states reached by the model for those different forcing sets. Resulting spatial and temporal variations in the annual cycle of the different species, as well as chemicals dynamics will be presented using representations and criticized.

A particular way of representation has been studied to reduce the dimensionality of the data at hands, making use of the Self-Organized Maps technology. We will present the basic principles of this method which automatically recognize self coherent regions in a temporal-multivariate way of speaking, allowing to gather in a single glance the gross annual dynamic of the entire model [3].

Then, inter-annual computations have been initialized from those equilibrium states. Physical dynamics can be accurately criticized in regards with circulation structures and thermo haline annual cycle, using processed sea surface satellite images, circulation features identified in literature and in-situ measurements. This allows us to assess a certain level of confidence attributable to the biological patterns observed in the results. This comes as a complement to what the scarcity of biological data allow us to directly criticize concerning their spatio-temporal correctness [4]. Inter-annual variability is then explored under the light of precedent analysis concerning the different equilibrium states.

During this study, a particular interpolation technique using the software DIVA has been used to reconstruct the 2D and 3D fields for biological data needed for initialisation of the model, and those that are used for visual comparison with the results. This kind of reconstruction, made tricky by the scarcity of data but nonetheless essentials to model study, will be given some minutes for presentation and the obtained results will be presented.

Abstract

During the EMT water inflowing the Adriatic basin were characterised by an anomalous low salinity. After the year 2003 saltier waters associated with the Aegean Sea outflow at higher horizons, were able to enter the Adriatic basin and create the necessary conditions for the deep convection in the Southern Adriatic Pit. The newly dense waters formed profoundly differ from waters of Adriatic origin observed in the region previously being saltier and warmer than in the past. To confirm this, cruises in two specific periods (2003 and 2008) were analysed. Data analysis confirmed the increase in salt and temperature in the abyssal area of the Ionian Sea (Zone A) so as the presence of Adriatic Dense water (ADW) in the northwestern Ionian (Zone C) *Keywords: Eastern Mediterranean, Adriatic Sea, Circulation, Water Convection, Deep Waters*

Using in situ data collected during the last 10 years we investigated the structure and variability of the abyssal water masses of the Eastern Mediterranean Basin (EM). Waters inflowing the Adriatic basin were characterized by an anomalous low salinity over the entire water column and by the absence of the typical salinity maximum associated with inflowing Levantine Intermediate Water (LIW). After the year 2000, saltier waters were able to enter the Adriatic basin and were able to create the necessary conditions for deep convection in the South Adriatic Pit. The dense waters which were formed since then, however, profoundly differ from waters of Adriatic origin observed previously in the region: they are substantially saltier and warmer than in the past. A tendency toward warming and, especially, salinification, seems to be confirmed by the preliminary analysis of very recent data acquired in the area [1], which agrees with the conjecture that very salty intermediate waters flowing toward the Adriatic basin contribute to reinforce the Adriatic source of EMDW. To confirm this tendency, temperature, salinity, and oxygen data sampled during 2008 SESAME cruises in the central (Zone A) and northeastern (Zone C) part of the Ionian basin are compared with the same parameters data obtained during previous years on the METEOR71-3 (2007) and POS298 (2003) cruises (figure 1).

Fig. 1. Deep layer salinity profiles carried out during the 2003 and 2008 cruises in the central Ionian Sea.

The analysis of thermohaline parameters of the 2008 cruises confirms the differences in the EMDW properties for the deep layer (>3000 m) between 2003 and 2008 [2],while no significant changes are observed between the 2007 and 2008 cruises. The analysis of profiles positioned in Zone C (northeastern Ionian), collected during March 2008 cruise, shows clearly the presence of a vein of Adriatic Deep Water in the layer between 1300-1500 m. Oxygen values (figure2), potential temperature and salinity present similar characteristics as those found previously in the Southern Adriatic Pit at ~800m, which seems to outflow almost geostrophically and which may be attributed to the Adriatic Deep Water (ADW).

Fig. 2. Oxygen profiles from CTD casts carried out during the SESAME (2008) cruises in the northwestern zone.

Another branch of water follows the south westerly direction from the Otranto Strait reaching the deepest part of the central Ionian. We observe a general increase of temperature and salinity, hence density, during the period 2003-2008 in the bottom layers of the central Ionian Sea. This could be directly related to the changes in the thermohaline properties of the water mass coming from the Adriatic Sea described above. This trend is confirmed through the time series of temperature and salinity recorded in the Southern Adriatic Pit, which shows an increase of salinity and temperature for both Adriatic Deep Waters (ADW) and LIW between 2003 and 2008 [3]. Starting in 2008, however, this trend seems to have reverted again, as lower intermediate salinity waters are now observed to enter the Adriatic Basin.

Abstract

The HYPerspectral for ADriatic COastal Monitoring project meets requirements for understanding and monitoring the coastal environments. The understanding of the coastal areas dynamics, their processes and significance for the environment, is becoming even more a milestone for any future conservation and protection of these areas. The demand for coastal zones managements has progressively risen due to the increased direct impacts by human activities, which may cause an irreversible damage to the local natural balance. In particular, the project focuses on improving the knowledge of the Albania and Montenegro coastal area by integrating different high resolution spatial and spectral remote sensing technologies. *Keywords: Coastal Waters, Remote Sensing, Adriatic Sea*

Introduction

The HYPAD.COM project takes place at this strategic moment, when the Earth Observation (EO) has become an essential component of the global effort to deal with global challenges.

The purpose of the HYPAD.COM is to promote capacity building in EO, on existing initiatives and sector-specific needs, like GEOSS planned, in order to achieve comprehensive, coordinated and sustained in situ and airborne observations of the coastal area.

The HYPAD.COM activity programme meets the need for timely and quality local scientific information as a basis for decision making, and enhances delivery of benefits to society especially in the following areas, recognized in the GEOSS 10-Year Implementation Plan: "Improving the management and protection of terrestrial, coastal, and marine ecosystems" [1].

In the framework of the HYPAD.COM, the integration of the EO hyperspectral data (airborne and ground-based) has been performed to improve the quality of the information available from EO data as well as to characterize the Albania and Montenegro coastal area and the surrounding lands.

For the purposes of the HYPAD.COM project, the following scientific objectives, for the coastal area, have been identified:

a) the characterization of the coastal water;

b) the detection of the coastal fresh water;

c) the spectral characterization of submerged aquatic vegetation [2].

The aims of the project devoted to characterize the surrounding land are:

d) the spectral characterization of vegetation/land use and land cover;

e) the spectral characterization of the bauxite refinery residues derived from aluminium production [3].

Methodology and results

The CNR (National Research Council) through the mediation of Italian Ministry for the Environment and Territory "Direzione Ambientale Ricerca e Sviluppo" has implemented cooperation with some Italian and foreign research agency for the success of the project. These agencies have shown great interest in and willingness for project activities, collaborating, constructively and proposing suggestions. The Albanian - Montenegrin coastal environments have been selected as study areas in accordance to the local Institutions requests.

On the basis of the scientific objectives and proposes defined in the project, several actions have been taken:

§ Three oceanographic cruises have been realized, in synergy with the Adricosm-star project [4], to spectrally characterize the water constituencies of the coastal waters along the Albanian and Montenegro shorelines. About 90 water column stations were caracterized [5];

§ June 2008, airborne hyperspectral MIVIS survey (53 flightiness) has been deployed on part of the Montenegro and Albanian coast and on the Buna/Bojana river;

§ July 2008 spectral signatures of the main submerged vegetation species were collected on Montenegro coastal with the objectives to map the submerged vegetation extension (e.g. *Posidonia oceanica*) and to analyze the impact of a growing urbanization of the coastline. About 40 sites were caracterized [3];

§ June-July 2008, field CAL/VAL campaigns were conducted along the

surveyed area to define a spectral library of the main land cover units and on the more significant material in order to be applied in a spectral "data base" and to be integrated with the airborne survey.

Conclusions

The HYPAD.COM activities have been carried out within a close and continuing collaboration of the some Italian and foreign research agency. The results of the project have generated strongly interest to continue the scientific research with the involved Institutions.

In front of that, on the Joint Committee of the July 31, 2008 the Ministry of Environment of the Republic of Albania, Institute of Hydrometeorology of Albania e University of Tirana declared their formal declaration of interest to collaborate in the HYPAD.COM project at the Italian Ministry for the Environment and Territory, as the below minute states:

"Hypad.com (HYPerspectral for ADriatic COastal Monitoring).

Members of the Joint Committee agreed that, since involvement of the Albanian Institutions (MoEFWA; Institute of Energy, Water and Environment; Institute of Albanologi Studies) has been important in the definition of the monitoring activities and of the major environmental problems affecting the area, the possibility of involvement (onerous) of the above mentioned Albanian Institutions will be taken into consideration in the proposal of extension of the activities of this project".

Abstract

ROMS and SWAN models are used to simulate and to exploit the Marmara Sea general circulation and the response to windstorms within the framework of the international scientific program "Turkish Straits System (TSS) 08-09". Model results show a general circulation in agreement with previous literature and the data collected as well as a remarkable impact of windstorms with complete reversal of the surface flow and frequent upwelling events.

Keywords: Marmara Sea, Currents, Circulation Models

Between August 2008 and March 2009, the international scientific program "Turkish Straits System (TSS) 08-09" was carried out under the coordination of the NATO Undersea Research Centre (NURC, La Spezia, Italy), jointly with the NRL project "Exchange Processes in Ocean Straits" (EPOS). During September 2008 and February 2009 the NR/V Alliance sampled extensively the Marmara Sea waters with the deployment of several different instruments (e.g., CTDs, moorings, bottom-mounted ADCPs and profilers, surface lagrangian drifters, Wave Raider, meteorological buoy etc.), some of them providing 1 to 6 months time-series of currents, tracers or meteorological conditions.

Several realistic numerical experiments of the Marmara Sea circulation have been carried out in order to understand the ongoing dynamics, providing simulations of the autumn-winter general circulation and the windstorminduced circulation. The core ocean model used is the Regional Ocean Modeling System (ROMS, [1]), run uncoupled or coupled 2-way with the wave model SWAN [2]. The numerical grid (same for both models) covers the entire Marmara Sea, with two open boundaries located a few kilometers up strait in the Bosphorus and Dardanelles straits and a varying horizontal resolution of 500 - 1500 m. CTD data collected during the field trial either in late August 2008 or early February 2009 provide the initial field for the ocean model. Lateral boundary conditions are provided by NRL bottom-mounted ADCPs (momentum fluxes) while available moorings and CTDs provide temperature and salinity profiles in the straits. The non-hydrostatic, highresolution (7 km in the horizontal) numerical weather prediction model COSMO-ME, run at the Italian national meteorological centre of the Italian air force provides surface boundary conditions for both ROMS and SWAN.

The general circulation derived using ROMS is in agreement with the general picture provided by [3], and fairly agrees with the observations collected. A major focus of this modeling exercise is to study the wind driven circulations in the Marmara Sea and model results show complete reversal of the upper layer flow depending on the sector of provenance of the wind storm. Westward (eastward) flow associated with north-easterlies (south-westerlies) also trigger upwelling/downwelling dynamics along the coastline of the Marmara Sea, with relevant storm-induced basin-wide oscillation of the mixed layer depth.

In addition, the 2-way coupled ROMS/SWAN model is used to simulate wave-current interactions in the area. Wave-current interactions are considered using the Mellor's equation for the inclusion of radiation stress and stokes drift in the momentum balance equation [4] and the inclusion of wave breaking as TKE injection as surface boundary condition of the Generic Length Scale turbulence model following [5]. The impact of wave current interactions is eventually assessed using skill scores based on surface lagrangian drifters.

EFFECTS OF THE ADRIATIC-IONIAN BIMODAL OSCILLATING SYSTEM (BIOS) ON THE BIOGEOCHEMISTRY OF THE ADRIATIC SEA

Giuseppe Civitarese ¹*, Miroslav Gacic ¹, Vanessa Cardin ¹ and Gian Luca Eusebi Borzelli ² ¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale-OGS, Trieste, Italy - gcivitarese@ogs.trieste.it ² Telespazio S.p.A., Rome, Italy

Abstract

The Adriatic-Ionian Bimodal Oscillating System (BiOS) is an internal mechanism capable to shape the thermohaline properties and the biogeochemical pool in the Southern Adriatic. The BiOS mechanism determines the upper-layer circulation (anticyclonic or cyclonic) in the Ionian Sea. Biogeochemically, the interfaces (i. e. the nutricline, and the oxygen minimum / nutrient maximum layer) at the border of the gyre in the northern Ionian are upwelled or downwelled depending on the circulation regime. This results in varying of the water characteristics advected northward through the Strait of Otranto, and the dynamics and the trophism of the Adriatic Sea. *Keywords: Adriatic Sea, Ionian Sea, Nutrients*

Recently, the upper-layer circulation in the Ionian Sea has been associated with the deep thermohaline circulation [1] through a negative feedback mechanism [2], here called Adriatic-Ionian Bimodal Oscillating System (BiOS). In few words: the Ionian upper-layer circulation reverses from anticyclonic to cyclonic and viceversa (Fig. 1).

Fig. 1. Anticyclonic (left) and cyclonic (right) circulation modes and the consequent pathways of the major water masses according to the BiOS mechanism.

The anticyclonic circulation allows the modified Atlantic Water (AW) to enter the Adriatic, decreasing the average salinity there. In turn, the Adriatic produces and exports water with progressively lower density. Subsequently, the isopycnal surfaces along the pathway of the Adriatic Deep Water (AdDW) at the flanks of the Ionian deepen, the corresponding sea level increases, gradually weakening the anticyclonic upper-layer circulation and finally inverting the surface pressure gradient and the circulation from anticyclonic to cyclonic [2]. In turn, the cyclonic circulation favours the ingression of salty water of Levatine and/or Cretan origin, now no longer diluted by the presence of the AW. This increases the salinity in the Adriatic, lowering the sea level along the pathway of the exported water at the flanks of the Ionian, inverting the surface pressure gradient and finally re-establishing the upper anticyclonic circulation [2]. Due to the BiOS mechanism, the averaged thermohaline properties in the Southern Adriatic exhibit a quasi-periodic variability at a time-scale of about 10 years. The same behaviour, but with an opposite phase, is reported for the time series of averaged nitrate concentrations during the last 25 years (Fig. 2).

In this case, the decadal variability seems to be associated with the vertical displacement of the interfaces at the border of the Ionian gyre. The sequence of anticyclones and cyclones in the Ionian Sea causes a vertical oscillation of the nutricline and of the oxygen minimum/nutrient maximum layer, determining a significant variations of the biogeochemical averaged concentration of the portion of water column horizontally advected towards the Adriatic through the Strait of Otranto. The comparison of the long-term variations of nutrient concentrations in the Southern Adriatic and in the northeastern Ionian reveals that the two show coherent behaviour. Major differences in concentration values are reported for periods when strong winter convection occurs in the Southern Adriatic [3]. At the re-establishment of the stratification following the winter convective mixing, the nutrient in the enriched surface layer is consumed by the primary producers (phytoplankton). Satellite images clearly show the increase

of biomass immediately after the stratification. Consequently, the nutrient pool is reduced as a function of the intensity and the number of convective events [3]. To conclude, we show that the Ionian upper-layer circulation has a great impact on the major water masses pathway and on the horizons of the biogeochemical interfaces. In turn, the Southern Adriatic represents a sensor for the Ionian circulation and for the state of the thermohaline cell of the Eastern Mediterranean. In this context, the intense activity of OGS and other Italian and Croatian institutions within the recent established Southern Adriatic Interdisciplinary Laboratory for Oceanographic Research (SAILOR) will be further implemented.

IMPACT OF HYDRODYNAMIC CHANGES ON MEDITERRANEAN BIOGEOCHEMICAL BUDGETS (WP1 OF THE MERMEX PROJECT)

Pascal Conan¹, Claude Estournel²* and Louis Prieur³

² Laboratoire d'Aérologie, CNRS Université de Toulouse, Toulouse, France - Claude.Estournel@aero.obs-mip.fr

³ Laboratoire d'Océanographie de Villefranche (LOV), Université Paris VI, CNRS, Villefranche/Mer, France

Abstract

The objectives of the MERMEX project focus on the understanding of the ecosystems response to likely changes in physical, chemical and socio-economical forcing induced by global change and by growing anthropogenic pressure. The objectives of MERMEX workpackage 1 are (i) to assess the budget of nutrients and of some contaminants, (ii) to understand their past and future evolution, and (iii) to understand the specific stoichiometry of inorganic and organic matter in the Mediterranean Sea. *Keywords: Geochemical Cycles, Nutrients, Western Mediterranean*

The questions addressed by the workpackage 1 of MERMEX concern the evolution of biogenic elements and contaminants in the Mediterranean in relation with specific characteristics:

- a marked limitation of primary production by phosphorus,

- budgets of nitrogen and silica showing a deficit but based on non synoptic and sparse data,

- an increasing trend for phosphate and nitrate concentrations in deep water mainly in the western basin,

- an increase of anthropogenic input,

- a recent evolution of the stoichiometry of these imputs.

The strategy chosen to deal with this question is double: first, to establish budgets of nutrients and second, to understand their past and future evolution. This "budget" approach is complexified by the contrasted functioning of the different regions of the Mediterranean, from mesotrophy to ultra oligotrophy. It was then decided to divide the Med Sea in group of regions characterized by similar trophic regimes and to study for each regime a representative region of the group. The approach then consists to do a budget of standing crops of C, N, P in their mineral / organic, dissolved/particulate forms and to characterize their primary fluxes. These informations will then be used to calibrate and validate numerical models which are the only way to integrate the complex interactions between hydrodynamical, and bio-geochemical processes. Following the classification of [1], four typical trophic regimes have been identified: - the regions marked by a bloom in late winter-early spring months, - the "intermittently blooming" zones with erratic regimes alterning intense biomass accumulation and oligotrophic conditions, - the oligotrophic regions with higher and quite constant biomasses in fall-winter and lower and uniform values in late spring-summer, - the coastal regions characterized by a high biomass in winter and a more reduced biomass in spring.

In a first time, we want to implement our strategy on the northwestern Mediterranean representative of the first trophic regime cited above. This region is characterized by a pronounced spring bloom associated to upward transport of intermediate or deep water rich in nutrients. The HYMEREX experiment at the heart of our strategy will be based on three cruises in fall 2012, spring 2013 and fall 2013. These field cruises will be carried out in collaboration with the Hymex program, to have a synoptic view of the meteorological and hydrodynamical conditions in the whole area. Our aim is to reduce the uncertainties on the air-sea fluxes and on the volume and characteristics of dense water formed during winter each year, including the impact on the stocks. composition and quality of organic and mineral matter. For each of these cruises, an array of 280 stations will be visited in less than 35 days (figure 1) at which stocks of nutrients, organic matter, contaminants, biogenic fluxes (production mineralization) will be measured as well as temperature and salinity and meteorological fluxes. Biodiversity will also be considered. The modelling will be initialized from the first array. The boundary conditions will be constrained as often as possible by regular glider lines, and information from autonomous profilers and mooring lines. Specific experiments concerning key biological fluxes (hyperbaric bacterial production, grazing, ...) not in accordance with a high frequency sampling strategy will be carried out in the same time on a second ship devoted to processes studies. Besides this experiment that should allow to improve our hydrodynamic and biogeochemical models, a long-term monitoring of the biogenic elements will be done by the MOOSE project with time series at fixed points, mooring lines, ARGO profilers and gliders equipped with bio sensors allowing to efficiently sample the water column. Finally, we hope to establish dialogue and collaboration with our colleagues of the different countries of the Mediterranean to have similar actions in other typical regions.

SURFACE CURRENT DYNAMICS IN THE NORTH EASTERN ADRIATIC SEA FROM HIGH-FREQUENCY **RADAR OBSERVATIONS AND HIGH-RESOLUTION WIND FIELDS**

Simone Cosoli 1*, Miroslav Gacic 1 and Andrea Mazzoldi 2

¹ Istituto Nazionale di Oceanografia e Geofisica Sperimentale, Trieste, Italy - scosoli@ogs.trieste.it ² Istituto di Scienze Marine - CNR, Venezia, Italy

Abstract

wind influence is stronger (Fig. 1).

The dominant processes governing the circulation in a 40 km x 60 km area off the Italian coast and the Istrian peninsula, Northern Adriatic Sea, are assessed using surface current measurements from high-frequency radars and high resolution wind fields for the period September 2007 - August 2008. Time-averaged currents are weak and reveal a cyclonic circulation pattern with intensification in the northern sector (Fig.1). Vorticity is prevalently positive and related either to current shear or current rotation. The flow in the region is primarily driven by winds, which impart vorticity to the current fields, whereas tidal oscillations within the diurnal and semidiurnal frequency bands have a minor role in the circulation. Keywords: Tides, Remote Sensing, Circulation, Adriatic Sea

High frequency observations of surface currents in the Northeastern Adriatic Sea for the period September 2007 - August 2008 reveal a cyclonic circulation scheme with weaker currents in the southern part of the domain, and an intensification along the Italian coast to the North where water is shallower and

Fig. 1. Time-averaged surface flow pattern in the investigated area (Northern Adriatic Sea) as derived from High-Frequency radar observations for the period August 2007 - August 2008

Tides are weak, and represent a small fraction of the overall flow variance. Highfrequency non tidal oscillations (inertial oscillations; diurnal-period wind-driven currents) have different patterns in time and space. Both inertial motions and non-tidal diurnal-period oscillations increase their contribution during spring and summer seasons, when the water column is stratified (Fig. 2).

An opposite trend in variance distribution characterize these high-frequency motions, with diurnal-period currents having their maximum variance in the Northern part towards the Italian coast and the Trieste Gulf entrance, and inertial oscillations showing their maxima towards the centre of the Northern Adriatic basin.

Current vorticity is prevalently positive and related either to current shear to the North, or to current rotation to the South. Wind stress curl is the major source of surface flow vorticity for time scales longer than the local inertial period. For these time scales wind stress curl is balanced by an increased surface flow divergence.

The dominant wind regimes in the area, namely the bora and the scirocco winds, drive two different current patterns. Bora enhances the coastal jet along the Italian coast and introduces a strong cyclonic recirculation in the southern area. Scirocco on the other hand homogenizes the flow pattern and forms small-scales eddies along the Italian coastline in the Northern sector.

Abstract

The inventory of 137 Cs in the Western Black Sea at 2000 m water depth is presently 3.4 kBq m⁻², not significantly different from that measured in 1988, but about 1 kBq m⁻² was transferred from the surface layer to the depth interval 100-400 m. 12 TBq y⁻¹ of 137 Cs leave the Black Sea in the surface layer through the Bosphorous and only 2 TBq y⁻¹ are brought back in association with the Mediterranean water from the Marmara Sea. The most important mechanism transferring 137 Cs and dissolved contaminants from surface Black Sea to the sub-picnoclyne layer is mixing on the southwestern shelf, at the exit from Bosphorous, between Mediterranean Water and surface water, producing an extra export of some10 TBq y⁻¹ of 137 Cs from the surface layer. *Keywords: Black Sea, Marmara Sea, Radionuclides*

Introduction and objectives

Due to the intense direct Chernobyl fallout and to the delayed input from rivers, the Black Sea has become a point source of radionuclides to the Mediterranean Sea. Some of these, like the long lived ¹³⁷Cs, are still easily detectable in the Black Sea and traceable along their pathway in the North Aegean Sea. The determination of the spatial distribution of ¹³⁷Cs in the system Black – Marmara – N. Aegean Sea can greatly help in elucidating the exchanges of dissolved contaminants among the basins and the role of the Turkish Straits System (TSS) in the contaminants budget of the Black Sea.

Study area

In the Black Sea freshwater input from large rivers (Danube, Dniepr, Dniestr and Don) and precipitation largely exceed loss by evaporation. The densitydriven two-layer exchange flow through the Straits carries the excess of Black Sea Water to the Mediterranean and the saline Mediterranean water first to the Marmara Sea and then to Black Sea. This hydrological balance supports a stable environment, with two main components: colder, fresher, surface waters overlying warmer, more saline deep waters, separated by a permanent pycnocline [1, 2]. In May 2007 seawater samples were collected by IMS-METU in the different water masses of two of the three deep basins of the Marmara and in the Western Black Sea for the characterization of present ¹³⁷Cs vertical profiles and for a first estimate of the fluxes of the radionuclide in the TSS. We also present here the ¹³⁷Cs vertical profiles measured in 2001 in the N. Aegean Sea, to characterize the input of the radionuclide to the TSS in the Mediterranean Water flow (Fig. 1).

Fig. 1. Study area and sampling sites.

Results

In the Black Sea, surface concentrations are about 20 Bq m⁻³ and, decreasing almost exponentially, reach a constant value of 0.7 Bq m⁻³ at a depth of 600 m. Comparing this profile with that obtained in 1988 in a nearby station [3], ¹³⁷Cs concentration below the halocline has significantly increased, while the levels in surface water are less than a half of what expected from physical decay only. The inventories have not significantly changed: 2.9 kBq m⁻² in 1988 (decay corrected to 2007) and 3,4 kBq m⁻² in 2007. The increase at depth below the halocline, in this deep-sea area, compensates the loss at the surface. In the Marmara Sea surface concentrations are about 15 Bq m⁻³, decreasing to about 4

Bq m⁻³ in the underlying Mediterranean water. The ¹³⁷Cs concentration in the Mediterranean Water entering the Dardanelles was assumed to be 3.5 Bq m⁻³, mean value of the ¹³⁷Cs concentrations in the depth interval 50-300 of the N. Aegean Sea, corrected for physical decay to 2007. Based on ¹³⁷Cs concentrations in the different water masses and on volume fluxes estimated by Besiktepe et al. [2] we have estimated the fluxes of the radionuclide in the Turkish Straits System (Fig. 2).

Fig. 2. Mean annual fluxes of ¹³⁷Cs (10¹² Bq y⁻¹) in the TSS.

Conclusions

In the Western Black Sea, at 2000 m water depth, about 1 kBq m⁻² of 137 Cs was transferred from the surface layer to 100-400 m in the period 1988 - 2007. Presently about 12 TBq y⁻¹ of 137 Cs leave the Black Sea in the surface layer through the Bosphorous and only 2 TBq y⁻¹ are brought back with the Mediterranean water from the Marmara Sea, resulting in a net annual loss of 10 TBq y⁻¹. The inflow of Mediterranean water alone does not explain the increase of 137 Cs concentration and inventory at intermediate depth in the Western Black Sea. The most important mechanism transferring 137 Cs and dissolved contaminants from surface water to the sub-picnoclyne layer appears to be the mixing on the southwestern shelf, at the exit from Bosphorous, between inflowing Mediterranean Water and Black Sea surface water. This process produces an extra export of some10 TBq y⁻¹ of 137 Cs from the surface layer. It is the advection of this water towards the Black Sea deeper layer (200-600 m) that maintained the inventory constant with time.

Aknowledgements

A FIVE-YEAR BUDGET OF FINE SEDIMENT IN THE GULF OF LIONS: IMPORTANCE OF INTENSE EVENTS (FLOODS, STORMS AND DENSE WATER CASCADING)

C. Estournel¹*, C. Ulses¹, X. Durrieu De Madron², P. Puig³ and P. Marsaleix¹ ¹ Laboratoire d'Aérologie, CNRS, University of Toulouse, Toulouse, France - claude.estournel@aero.obs-mip.fr ² CEFREM, CNRS and University of Perpignan, Perpignan, France

Abstract

A sediment transport model has been applied to the Gulf of Lions to estimate the budget of fine particles over the period running from December 2003 to December 2008. The consequences of the succession of intense events are examined in terms of sedimentation and resuspension on the different parts of the shelf, and export toward the slope and the deep basin. *Keywords: Coastal Models, Continental Shelf, Sediment Transport, Western Mediterranean*

A modelling approach [1] was used to study during a 6-month period in 2003-2004 the effect of marine storms and high rivers discharge on the fate of fine sediment in the Gulf of Lions. This study was extended to a period of 5 years including a variety of hydrologic and hydrodynamic conditions characteristic of the region including an exceptional flood of the different rivers of the Gulf, two severe winters and a few storms associated to moderate to high waves. Thanks to the monitoring of currents, temperature and turbidity performed on the Gulf of Lions slope during several crucial periods [2, 3], the model was first calibrated and validated. The main transport events are satisfactorily simulated. As both velocity and suspended matter concentration are well represented at the moorings localized in the canyon known as the main conduit from the shelf to the slope, the export given by the model is considered as robust. The duration of the simulation (5 yrs) allows to better understand the different mechanisms affecting the fate of fine particles. First the role of the Rhone prodelta on the storage of the river-borne particles, the effect of storms to transport sediment from east to west and the dense water cascading flushing the matter in the canyons of the western part of the Gulf. The role of bioturbation to renew the stock of fine particles in the surface sediment after a storm is also shown. The model is used to integrate the effect of these different mechanisms and to estimate the time constants associated to the transport along the river mouth, shelf, slope and deep sea continuum. A sediment budget of the different parts of the shelf and slope is shown on Figure 1.

Fig. 1. Sediment budget of the December 2003-December 2008 period in meter. Positive value correspond to deposition, negative values to erosion. White isocontours indicate the 200, 1000 and 2000m isobaths.

Dark colors indicate mean erosion, light colors indicate accumulation. The Rhône prodelta accumulates a large part of the continental particulate input to the Gulf of Lion. Erosion is mainly confined on the inner shelf but the Cap de Creus canyon was also eroded due to the strong currents associated to the dense water cascading of winters 2005 and 2006. The exportation off the Gulf of Lion shelf

has been estimated to lie between 20 and 30 Millions of tons in 5 years. The region of the Cap de Creus is the main pathway for this export. The role of the Cap de Creus canyon is particularly important as it is able to stock after a storm large amounts of matter which can be later flushed by dense water cascading. The affinity of heavy metals with fine particles allows us to give a first estimation of the remobilization of these contaminants by intense events.

WATER MASS STRUCTURE AND ASSOCIATED PROCESSES IN THE TYRRHENIAN SEA (SOUTHERN SECTOR) BY MEANS OF IN SITU DATA COLLECTED DURING VECTOR-TM CRUISES

Pierpaolo Falco 1* and Enrico Zambianchi 1

¹ Dipartimento di Scienze per l'Ambiente, Università degli Studi di Napoli "Parthenope" Centro Direzionale, Isola C4 80143 Napoli,

Italy - pierpaolo.falco@uniparthenope.it

Abstract

In this work we will present the results obtained from the analysis of hydrological data collected during 5 oceanographic cruises carried out in the southern sector of the Tyrrhenian Sea. Details regarding the vertical structure and associated processes of the water column are presented, together with information regarding deep current and temperature data obtained from a mooring located approximately in the centre of the southern Tyrrhenian basin

Keywords: Tyrrhenian Se, Hydrology, Deep Waters, Deep Sea Processes

In the framework of VECTOR (VulnErability of the Italian coastal area and marine Ecosystems to Climatic changes and Their rOle in the Mediterranean caRbon cycles) project, starting at the end of November 2006, six oceanographic cruises were carried out in the area, centered on the so-called VTM station (see Fig.1, which also shows the CTD stations regularly sampled during the cruises as well as the position of the mooring), selected as a test site to study the seasonal and interannual variability of the intermediate and deep hydrology and dynamics of the Tyrrhenian Sea. The VTM point depth is approximately 3450 m, its coordinates are $39^{\circ}30'$ N, $13^{\circ}30'$ E, approximately 90 nautical miles off the Italian coasts. The oceanographic cruises were carried out in different seasons even if three of the six were conducted in a winter month. Thus, in terms of interannual variability, information could be derived only for the winter season. The remaining three campaigns were in Fall (late November 2006), early and late Spring (April 2007 and first third of June 2008 respectively).

Fig. 1. Map of the stations sampled during VECTOR-TM cruises. Diamonds indicate CTD stations positions, whereas the triangle is the mooring

Moreover, on April 2007, a mooring was deployed very close (less than 1 nautical mile) to the point VECTOR-TM and worked up to January 2009. Current measurements at the depths of 1000, 1600 and 2200 meters, collected by means of Aanderaa RCM-9 currentmeters, are available for the period June 2007 –December 2007, whereas a yearly temperature time series (February 2008 – January 2009) at a depth of about 3430 meters is available too.

Information derived from this composite data set addressed three main issues: vertical structure of the investigated transect; thermoaline processes along the vertical, especially in the farthest offshore stations of the transect; intermediate and deep current patterns obtained from mooring time series.

The analysis of the collected CTD data allows identifying the three major water masses present in the basin: Atlantic Water (AW), Levantine Intermediate Water (LIW) and Tyrrhenian Deep Water (TDW). In particular, the vertical distribution of temperature and salinity of the upper layer, together with the relative geostrophic velocity field, pointed out that the overall circulation is broadly anticyclonic, as expected. If looked at from the perspective of long term change the data reveal several points of interest: for instance, bottom temperature and salinity values result slightly higher than in the past [1]; at the same time, the observed salinity maximum relative to the LIW is higher than in historical data (Fig. 2).

Fig. 2. Theta-S diagrams for the cruises VECTOR-TM 2 (a) and 6 (b). The two squares indicate the range of LIW and TDW as defined in [2].

The central Tyrrhenian is notoriously an area where double diffusive processes can be observed [2]. Thermohaline staircase structures have been found in all cruises, and characterized in terms of a number of parameters classically utilized for this purpose [3]. The stability of double diffusive structures in space and time (e.g., in terms of depth, width, gradient) is remarkable. Their associated temperature and salinity fluxes result stronger than in the past, and would deserve further investigations, prolonged in time.

Current data obtained from the mooring shows a relative strong W-NW flow with velocity values up to 10 cm/s at 1000 m whereas, as expected, the velocity slows down to few cm/s at deeper depths where the remaing two currentmeter were located. The direction is less stable with respect to the 1000 m currentmeter data but the net displacement is northwestward as well. Also, a diurnal tide signal can be observed from the spectral analysis of the deepest currentmeters whereas it does not appear in the 1000 m depth current measurement.

RETRIEVING OCEAN SALINITY FROM SMOS MICROWAVE RADIOMETRIC MEASUREMENTS

Jordi Font 1*

¹ Institut de Ciències del Mar CSIC, Barcelona, Spain - jfont@icm.csic.es

Abstract

SMOS (Soil Moisture and Ocean Salinity) is an Earth observation satellite from the European Space Agency launched in November 2009. It is the first satellite mission addressing the challenge of measuring sea surface salinity, never attempted before due to its technical complexity. It uses a microwave interferometric radiometer with aperture synthesis that generates brightness temperature images at 1.4 GHz, from which both geophysical variables are derived using their influence on the dielectric constant of the emitting body, land or ocean. This paper presents the principles of operation of the instrument, the algorithmic approach implemented for the retrieval of salinity from the observations, and the limitations for the use of SMOS products in the Mediterranean Sea. *Keywords: Salinity, Remote Sensing, Surface Waters, Open Sea*

In 1999 the European Space Agency (ESA) selected the proposal of a mission to provide for the first time a global and continuous coverage of Soil Moisture and Ocean Salinity with resolution and accuracy adequate for climatic studies and large scale oceanography, as both variables play a key role in the control of the Earth's water cycle and as a consequence in the understanding of the possible climate evolution in the present context of global warming [1]. SMOS (http://www.esa.int/esaLP/LPsmos.html) was launched on November 2, 2009 and is expected to become operational by May 2010.

The measurement principle

All bodies emit electromagnetic radiation in a large range of wavelengths. At low frequencies, including microwaves, the brightness temperature of the body (T_B , the quantity to be measured by a radiometer, and related to the emitted power) is proportional to its physical temperature. The proportionality coefficient, the emissivity, is a function, among other variables, of the dielectric constant and as a consequence of the conductivity, and hence salinity when the emitting body is seawater. For SMOS a frequency of 1.4 GHz was selected, as it is close to the maximum sensitivity of T_B to changes in salinity as well as minimises the impact of other parameters influencing it. In addition, this is a frequency band where human made emissions are forbidden, so the risk of interferences should not be an issue. At this frequency the penetration of the radiation, and then the thickness of the emitting surface layer, is around 1 cm.

The fundamentals of salinity and soil moisture determination by microwave radiometry were sufficiently known, but no satellite mission had been attempted so far to measure these variables. The main reason was that to achieve a reasonable spatial resolution at this low frequency very large scanning antennas were needed, something that appeared not feasible on board a satellite. The solution implemented in SMOS is the use of a large number of small fully polarimetric antennas (up to 69, 20 cm diameter) deployed along three 4 m arms forming a Y shape. Instead of using the T_B recorded by the individual antennas, SMOS takes the correlation of the polarised signals from all pairs of antennas to reconstruct a unique T_B image through a complex process based on interferometry [2]. The result, in the selected configuration (758 km height, antenna plane 32.5° from horizontal), is a curved-hexagonal field of view, almost 1000 km wide, formed by pixels from 30 to 100 km, with varying incidence angle and radiometric resolution.

Fig. 1. The 69 antennas along the SMOS arms (by P. Carril for ESA)

Retrieving salinity values

The approach to determine the salinity of the ocean surface imaged at each SMOS overpass is based on a convergence loop that compares the measured T_B to the T_B theoretically emitted by the surface following a forward model of the ocean emission taking into account the seawater conditions. During the convergence the sea surface salinity (SSS) value is modified from a first guess until reaching an optimal fit with the measured TB value. The geometrical optics theory provides a model of the flat sea emission, which depends on the temperature, salinity, angle of observation, frequency and polarisation state of the radiation. On top of this we have to introduce the effect of the sea roughness, as the topography of the emitting surface has a strong impact on the viewing geometry and then on the TB measured by the radiometer. Further modifications are needed before comparing modelled and measured TB, as the emitted radiation is modified in its path from the surface to the satellite (attenuation by the atmosphere, polarisation mixing in the ionosphere, ...), while it is necessary to take into account other sources of radiation at the same frequency that can also reach the radiometer (emission by the atmosphere, galactic radiation scattered on the surface, ...). The result is a quite complex algorithm implemented in the SMOS salinity processor [3].

Even the multiangular measurement characteristics allow for a redundant determination of SSS, the noise and other possible errors due to the instrument performance limitations, image reconstruction process, errors on external parameters needed to estimate the sea surface state (provided by numerical weather forecasts), and incomplete forward model formulation are expected to result in an accuracy in retrieved salinity around 1.5. To reduce this noise and reach the mission objectives, further processing is planned to generate global salinity maps by integrating several SMOS orbits in a temporal window of 10-30 days and spatial resolution of 100-200 km, then providing a product similar to present climatologies but including the temporal evolution. The goal is to achieve salinity accuracy close to 0.1.

These spatio-temporal characteristics of the SMOS observations, together with the fact that strong contamination from land radiation is expected in the first 100-200 km from coast, makes the use of these products in the Mediterranean Sea a real challenge. Some validation activities are planned within the Mediterranean Operational Oceanography Network (MOON, http://www.moon-oceanforecasting.eu/) to explore this limitation.

The development of SMOS has been a collective effort coordinated by ESA of many scientists and technologists as well as industrial companies from several countries, especially Spain and France. This paper is a contribution to the SMOS Barcelona Expert Centre and project ESP2007-65667-C04 funded by the Spanish Ministry of Science and Innovation.

SURFACE CIRCULATION IN THE MARMARA SEA

Riccardo Gerin ¹*, Pierre-Marie Poulain ¹, Sukru Besiktepe ² and Pietro Zanasca ² ¹ OGS-Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Trieste, Italy - rgerin@inogs.it ² NATO Undersea Research Centre, La Spezia, Italy

Abstract

We study the surface circulation of the Marmara Sea over about one year using CODE drifters. The pseudo-Eulerian statistics were computed using the whole dataset and in terms of deployment episodes and major wind regimes. Keywords: Circulation Experiments, Marmara Sea, Surface Waters

The Marmara Sea is a small (70 km x 250 km) semi-enclosed sea connecting the Mediterranean to the Aegean (through the Dardanelles Strait) and to the Black Sea (through the Bosphorus Strait). It has a complex topography characterized by three deep sub-basins each greater than 1000m in depth separated by deep sills and is connected to the straits through canyons. Here, complex processes of two-way exchange flows, jets, eddies and gyres occur [1].

As part of the Turkish Straits System (TSS) experiment, the surface circulation dynamics of the neighboring Black, Marmara and Aegean Seas was studied at scales from inertial/tidal to seasonal using low-cost CODE Lagrangian drifters [2] over about a year (from September 2008 to May 2009). Particular focus was given to the Marmara Sea that was seeded in two seasonal episodes (September 2008 and February 2009). About 30 drifters were deployed in key locations to maximize the geographical coverage and mainly in small (1 nautical mile) clusters of three drifters.

In addition to the standard positioning and data telemetry (SST, battery) provided by the Argos Data Collection and Location System (DCLS) onboard polar-orbiting NOAA satellites (with 300-1000 m position accuracy and about every 100 min), the drifters were equipped with GPS receivers to have a better determination of their position (with less than 10 m of uncertainty) and more frequently (every 30 min).

On the whole, the drifters sampled adequately the Marmara Sea (Fig.1), but the southern part was covered by drifters mainly during the first experiment (September deployments) and the northern part mainly during the second one (February deployments). The lifetime of the drifters in the Marmara Sea is very low due to the recovery by seafarers and stranding (it span from a few days to 50 days) and the mean half lifetime is only 13 days.

The combined raw Argos and GPS positions were edited for outliers and spikes using statistical and manual techniques [3] and were interpolated at regular 2hours intervals. Surface velocity were calculated by central finite differencing the interpolated positions.

The Pseudo-Eulerian statistics (mean flow, variance ellipses, MKE and EKE) were calculated [4, 5] using a spatial averaging scale of $0.1^{\circ} \times 0.1^{\circ}$ overlapped bins for the whole dataset, for the two deployment episodes and for different wind regimes.

The map of the mean surface flow using the whole dataset (Fig. 2) shows two eddies located in the northern part of the sea which extend for about 30 km and reach the middle of the Marmara Sea (the western feature is anticyclonic and the eastern one is cyclonic). South of these large features, a flow of about 20 cm/s joins the Bosphorus to the Dardanelles and another cyclonic eddy is evident in the southeastern area of the Marmara Sea.

The TSS drifter data were included in the MedSVP (Mediterranean Surface Velocity Program) database (http://nettuno.ogs.trieste.it/sire/medsvp/) and will be used to deepen our understanding of the surface dynamics of the Mediterranean and Black Seas.

Fig. 1. Drifter spaghetti diagram in the Marmara Sea.

Fig. 2. Mean surface circulation in the Marmara Sea. The mean flow arrows are centred at the centre of mass of the observations in each bin. Data are grouped into $0.1^{\circ} \times 0.1^{\circ}$ bins overlapped by 50%. Results for bins with less than 5 observations are not plotted.

ASSESMENT OF POST-TRANSIENT CHANGES IN LEVANTINE BASIN DEEP WATERS

Isaac Gertman¹*, Barak Herut¹ and Nurit Kress¹

¹ Israel Oceanographic & Limnological Research, Haifa, Israel - isaac@ocean.org.il

Abstract

Large deep water (DW) renewal in the Levantine Basin (LB) by dense water from the Cretan Basin started at about 1989 after massive advection of salty Levantine Surface Water in the Aegean Sea. An apogee of the DW outflow to the LB was observed in 1993 after the abnormally cold winters of 1992-1993. A relatively salty and warm water propagated above the sea bottom from the Cretan Passage with a rate of about 280 km/year. The DW renewal was first recorded near the south eastern continental slope of the LB in 1996. During 2001, the LB DW was quite homogeneous east of 25E. According to observations during 2008, a new DW mass spreads eastwards in the LB. This new water, originating from the Adriatic Sea, has higher potential density than the Cretan origin DW and the pre 1989 Adriatic DW.

Keywords: Deep Waters, Levantine Basin

A comprehensive analysis of Levantine Basin deep water evolution during the Eastern Mediterranean Transient (EMT) [1] brought a vivid picture of Cretan dense water cascading through the Cretan Arc straits and spreading in the Eastern Mediterranean intermediate and particularly bottom layers. Advection of abnormally saline Levantine Surface Water in the Aegean Sea during 1989-1990 [2] followed by extremely cold winters 1992-1993 [3] forced the formation of deep water with potential (relative 2000 db) density anomaly (σ_2) of about 37.83 kg/m³ [1]. The excess over the pre EMT bottom water density was just 0.03 kg/m³. However it was enough to generate a wide spreading of newly formed water. In 1995, three years after the apogee of dense water outflow from the Cretan Basin, the Levantine Deep Water below 2000 m had a stable inversion layer both in salinity and potential temperature. According to a long term series of Israeli observations on station h5 located near the continental slope of the south-eastern Mediterranean shelf (33.0°N, 34.5°E) the first evidence of such inversion was found in 1996. A coarse estimation of propagation rate of dense water from Cretan Passage to the south-eastern continental slope was about 280 km per year. Before the EMT influence, the h5 station's water at depth of 1400 m had salinity 38.68±0.02 with a negative vertical gradient of about 0.005 per 100 meters. Potential temperature was 13.37±0.02°C with a decrease rate of 0.015°C per 100 meters. During the period 1996 - 2002, salinity and potential temperature increased monotonically reaching 38.77, 13.59°C and changing the vertical gradients signs.

Relatively regular observations in the framework of Israel's national project "Haifa Section" from 2002 to 2009 show fluctuations in salinity and potential temperature with ranges of 0.02 and 0.02°C respectively. Observations from R/V "Meteor" during 2001 [1] revealed quite homogeneous water for regions east of 25°E and deeper than 2000 m (38.82 ± 0.02 , $13.71\pm0.02°C$). However on the most western stations an intrusion of new water was already observed. This water was slightly less saline (38.78) and colder (13.56°C) than the water which originated from Cretan Basin. In the field of potential density relative to 2000 db it is possible to see that the new deep water is denser by about 0.005 kg/m³ than the relict water from the previous EMT renewal.

Further eastward propagation of the new water, which Roether et al. [1] defined as having Adriatic origin, was observed in summer 2008 during the R/V Shikmona cruise carried out in the framework of EU funded project SESAME (http://www.sesame-ip.eu). The western boundary of the Cretan origin water was shifted to about 27.5° E (Fig). The boundary is clearly observed in the salinity field (Fig) as well as in fields of potential temperature and dissolved oxygen. The Cretan origin deep water were disconnected from their origin in the Aegean Sea and became, due to mixing, less salty and colder (38.79, 13.63°C) than they were during 2001. The Adriatic origin water did not change its parameters compared to observation from 2001. Apparently this water mass had a permanent feeding from the Otranto strait. Differences in potential density between the Adriatic and Cretan water masses remained the same as in 2001 (about 0.005 kg/m³). The eastward propagation rate of Adriatic origin water was seven times slower than the propagation of the Cretan origin water. This seems to be connected to the smaller difference in potential density.

Abstract

without in situ confirmation.

During the summer of 2009, 6 Lagrangian drifters were launched in the South eastern Levantine basin, 3 of them near the Israeli coast. The drifters moved northward along the shelf and turned toward the deep sea off Haifa Bay. One of the drifters was trapped in a stationary meander for a week, later it moved in a trajectory that is interpreted as a detachment of the meander to an anticyclonic eddy. This eddy moved, within 4 days, northwest to a location where the Shikmona eddy was previously observed. Over the next 30 days the drifter demonstrated a stationary eddy position and then exited the eddy area. Satellite observations of high chlorophyll-a (Chl-a) concentration correspond to the geographical position of the meander and the eddy. Operational model forecasts in the area fail to generate the observed phenomena. *Keywords: Levantine Basin, Circulation*

The south eastern circulation in the Levantine basin is generally characterized by a large scale cyclonic circulation. Development of a north bound jet current along the eastern continental slope is frequently observed [1]. Another energetic feature of the circulation is the anticyclonic Shikmona eddy observed generally in the vicinity of 33.8°N, 33.8°E [2]. The formation of the Shikmona eddy was attributed either to meandering of the Mid Mediterranean Jet in connection to dynamic instability near the Eratosthenes Seamount [3] or to meandering of the alongshore current [4]. The later mechanism was derived from SST analysis

NEMED is an observational program, led by OGS [5], to quantify the circulation and eddy variability in the Eastern Mediterranean, with major attention to the eastern and northern regions of the Levantine sub-basin, using among others, low-cost satellite-tracked drifters in the vicinity of Cyprus and Israel. The first series of SVP drifters included 3 drifters which were launched on the Israeli continental slope near Ashdod by IOLR and 3 drifters which were launched on the line connecting Limasol and Port Said by the University of Cyprus. The continental slope drifters were carried north by the alongslope jet current with an estimated velocity of 20-30 cm/s. Their trajectories deviated westward south of Haifa Bay. Two drifters outlined a meander reaching about 70 km west of the shore and continued along the Lebanese and Syrian coast (Fig 1a). The third drifter was trapped in the meander for a week and then travelled, within 4 days, northwest in a spiraling trajectory (Fig 1b). Afterwards it outlined the Shikmona anticyclonic eddy centered at 34.2°E, 33.6°N with diameter of about 50 km and remained there for 30 days (Fig 1c). One of the drifters launched south of Cyprus was also trapped by the eddy in a larger orbit (80 km diameter) for two weeks.

Fig. 1. Stages in the evolution of Shikmona Eddy from meander. Lines: Lagrangian drifters trajectories. Background: concentration of Chl-a (lighter shades represent higher concentrations).

Remote satellite observation of Chl-a provided by CYCOFOS [6] showed local concentration maximum in the center of the meander and later in the center of

the eddy, corresponding to the trajectory of the trapped drifter in time and space. During the 30 day period Chl-a concentration gradually decreased until it was no longer discernable, around this time the drifter exited the eddy area. SST maps, unlike Chl-a, showed only a weak signal of the eddy. Model forecast from the same period run by IOLR did not reproduce the phenomena described above and showed the alongshore jet with no meandering.

M₂ TIDAL DYNAMICS IN ALGECIRAS BAY AND ITS RELATION TO THE HYDRODYNAMICAL REGIME OF THE STRAIT OF GIBRALTAR: NUMERICAL 3D MODEL RESULTS

C. J. Gonzalez^{1*}, L. López¹, Ó. Álvarez¹, M. Bruno¹ and R. Mañanes¹

¹ University of Cadiz. Department of Applied Physics, Puerto Real, Cadiz, Spain - carlosjose.gonzalez@uca.es

Abstract

A simulation of the M₂ tidal dynamics in Algeciras Bay (South of Spain) was conducted by use of a 3D hydrodynamical model and complemented with experimental data, focusing on the influence of the general hydrodynamical regime of the Strait of Gibraltar over the bay dynamics. The semidiurnal, mesotidal regime present in the strait, together with the strong density-stratification of the water column, was found to have important consequences for the particular tidal dynamics of Algeciras Bay. Firstly, model results showed the occurrence of a cross-current system between the Atlantic and Mediterranean water layers inside the bay. Secondly, the 3D hydrodynamical model was able to simulate accurately the so-called baroclinic internal wave, generated by hydraulic jump over Camarinal Sill, as well as its propagation into Algeciras Bay. *Keywords: Tides, Models, Strait Of Gibraltar*

Study site

Algeciras Bay (South coast of Spain) constitutes a physical environment of special characteristics, due to its morpho-bathymetric configuration and geographical location, close to the eastern boundary of the Strait of Gibraltar. The interaction between the mesotidal, predominantly semidiurnal tidal regime of the Strait of Gibraltar with the water stratification, due to the presence of Atlantic water at the upper layer and Mediterranean water (more salty and cold) at the lower one, has important hydrodynamical consequences, as the generation of the so-called baroclinic internal wave over Camarinal Sill and effects on the vertical profiles of the velocity of currents. Because of its wide connection to the Strait, the tidal hydrodynamics of Algeciras Bay is expected to be submitted to this peculiar processes, so the aim of this study was to conduct a detailed research in that respect by analyzing both empirical and numerical 3D model data, comparing them and setting the main characteristics of the tidal dynamics in this environment.

The Model

The three-dimensional, nonlinear, high-resolution, finite-difference, sigmacoordinated UCA 3D hydrodynamical model is based on the numerical solving of 3D equations of motion (assuming the hydrostatic simplification). The system is coupled to a two-dimensional, depth-averaged scheme [1] by the splitting technique [2]. For the modeling of the M_2 tidal hydrodynamics in the Strait of Gibraltar and Algeciras Bay, a calculation domain was chosen extending from the western Strait boundary to the Alboran Sea. The model Arakawa-C staggered grid had a horizontal resolution of 500 m and 50 vertical sigma-levels. The system was forced by a single M_2 tidal wave and the zero-frequency constituent Z_0 ; initial conditions of free-surface elevation and current velocity (amplitudes and phases), as well as those of salinity and temperature, were obtained from the Experiment "Strait 94-96" and previous works by [3] and [4].

Results

Modeled time-spatial fields of the M_2 harmonic parameters, obtained by conventional harmonic analysis [5], were compared with available experimental values at 40 different locations. The root mean squares of errors were 4.0 cm and 4.4° for the amplitude and phase of elevation and 18.2 cm s⁻¹ and 18.3° for those of depth-averaged current velocity. Focusing on the Algeciras Bay area, model results show a little spatial variation of M_2 elevation harmonic parameters, with amplitudes and phases around 31 cm 47° Greenwich. Modeled depth-averaged M_2 current ellipses present highest semimajor axes by the coastal margins (until 40 cm s⁻¹), while they do not overcome 10 cm s⁻¹ through the deeper central canyon of the Bay. A more detailed analysis of vertical velocity profiles revealed that the latter is due to a system of tidal crosscurrents between the Atlantic and Mediterranean water layers inside Algeciras Bay, being a phase-lag of near 180° between the current ellipses of both layers. Comparisons with experimental ADCP data through ship transects in the Bay area show a remarkable qualitative and quantitative correlation in that respect.

In relation to the time-spatial propagation of the baroclinic internal wave, Fig. 1 (top) shows an example of model spatial field of free-surface elevation together with remote-sensing satellite image at the corresponding tidal stage. It can be appreciated a significant correspondence between them, as well as the penetration of the eastwards internal wave front into Algeciras Bay. The wave parameters, estimated from model and satellite fields, are: period: 22 minutes; wavelength: 1.8 km; wave celerity: 4.9 km/h; the amplitudes of oscillations are of the order of 1 cm. The spectral density distribution of free-surface elevation

from a CTD cast on the inner Bay (Fig. 1, bottom) shows a marked peak by period values close to the calculated from model results.

Fig. 1. Top: an example of ASAR image (left) and modeled field of free-surface elevation at analogue tidal stage (right). Bottom: spectral density distribution of free-surface elevation from a CTD cast inside Algeciras Bay, with periods up to 2 hours removed.

Abstract

In March 2009, two gliders began occupying a hydrographic endurance line for measurements of temperature, salinity, dissolved oxygen, optical backscatter, and fluorescence in the Levantine Sea south of Cyprus in a butterfly pattern over the Eratosthenes Seamount. The line will extend in space and time an historical one. Comparison with past hydrographic cruise data shows similarities. In particular, a large anticyclonic eddy, the Cyprus Eddy, over the Eratosthenes Seamount dominates, with traces of Atlantic Water around the periphery. This eddy was investigated intensively by a fleet of gliders from November 2009 to January 2010. Keywords: Hydrography, Levantine Basin

In March 2009, two gliders began occupying an endurance line for measurements of temperature, salinity, dissolved oxygen, optical backscatter, and fluorescence in the Levantine Sea south of Cyprus. The transects follow a butterfly pattern over the Eratosthenes Seamount, extending to a maximum depth of 1000 m. The operational transects represent the first in a planned time series for the next several years to be carried out by the Oceanography Center of the University of Cyprus (OC-UCY). Following the 4th EGO Meeting and Glider School in Larnaca in November 2009, a joint project, "EYE of the Levantine," was carried out in which 6 gliders were deployed to investigate the Cyprus warm core eddy observed earlier in the year by both glider and shipboard CTD. In December 2009, the TARA Oceans vessel was involved as well with CTD and water samples and the deployment of 4 surface drifters and 2 profiling floats in and around the eddy. Near the end of the experiment, the eddy was sampled again with shipboard CTD grid carried out by the Maria S. Merian in mid-January 2010. At this time, only one of the original gliders continued to collect data while beginning the second round of its endurance line. which should also pass through the eddy. About 2000 profiles down to 1000 m and 1000 profiles down to 200 m have been collected by the fleet of gliders including measurements of not only temperature and salinity, but also fluorescence (Chl a, CDOM) and backscatters (at 470, 532, 660, 700, and 880 nm).

Fig. 1. Map of glider tracks with bathymetry and depth-averaged velocity centered over each dive from 23 November 2009 to 18 January 2010. One of the transects to be shown later is highlighted by a thick grey line.

Since the POEM cruises of the 1980s [1], the general vertical and horizontal distributions of the water masses of the region have been known: the Levantine Surface and Intermediate Water (LSW and LIW) masses sandwiching the Atlantic Water (AW), with the Eastern Mediterranean Deep Water (EMDW) at the deepest observed levels. The variability of the AW pathway, the eddy structures, and absolute transport are all to be addressed by the operational "section series," but in this paper, we present the results of the even more intensive sampling of an eddy using a fleet of gliders which provide a larger-scale

synoptic view not possible with a single platform of any kind. The dominant feature of the data set is the anticvclonic (warm, salty core) eddy known as the Cyprus Eddy [2] near the Eratosthenes Seamount (Fig. 1). During the experiment the eddy had a radius of about 40 km and consisted of a core of LIW extending down to 500 m. Currents averaged over the 1000 m dives peaked at the edge with magnitudes of 0.30 m s⁻¹. During the experiment, the eddy shifted about 10 km to the east. The slightly fresher AW is found just below the thermocline, most often around the periphery of the Cyprus Eddy (Fig. 2). Dissolved oxygen, optical scattering, and chlorophyll fluorescence typically show maximum values also in the layer just below the thermocline

Fig. 2. Vertical section from North to South of a) salinity, b) potential temperature (deg C), and c) dissolved oxygen along transect highlighted in Fig. 1, from 24 November 2009 to 02 December, 2009.

Remotely-observed sea level anomaly (AVISO) products showed similar surface signals, at coarser resolution, as did drifter tracks. Operational forecasts were not as successful in predicting the eddy presence: OC-UCY forecasted a similar eddy, but in a slightly different location and time. Future work includes the assimilation of glider profiles into the operational forecasts at OC-UCY, and further comparison with satellite altimetry, remotely-sensed sea surface temperature and ocean color.

IMPACT OF THE EASTERN MEDITERRANEAN TRANSIENT (EMT) ON THE NORTHWESTERN **MEDITERRANEAN SEA (NWMS): THE CASE OF THE EXCEPTIONAL 2004-05 CONVECTION EVENT**

Marine Herrmann¹*, Jonathan Beuvier², Florence Sevault¹ and Samuel Somot¹

¹ Centre National de Recherches Météorologiques, Toulouse, France - marine.herrmann@m4x.org ² ENSTA/UME, Palaiseau, France

Abstract

Spectacular convection occurred in the NWMS during 2004-05: the convection area was exceptionally large, and Western Mediterranean Deep Water (WMDW) formed this winter was warmer and saltier than usually. We perform numerical oceanic simulations to assess the respective contributions of oceanic and atmospheric conditions to this event. Our results suggest that WMDW characteristics are mainly related to the NWMS heat and salt contents before the convection. The increase of those characteristics in 2004-05 is due to an increase of those contents, due to the absence of strong convection during the 90's. Convection intensity is related both to the winter atmospheric conditions and to the autumn NWMS stratification. The EMT modified this stratification in autumn 2004, potentially doubling the volume of WMDW formed.

Keywords: Deep Waters, Gulf Of Lions, Western Mediterranean, Water Convection, Air-Sea Interactions

Open ocean deep convection takes place in a few regions of the world ocean, among which the NWMS [1]. In this region, the combination of cyclonic circulation and strong winter surface buoyancy losses associated to northern wind events (Mistral, Tramontane) induces deep convection events, at the origin of the formation of WMDW. During winter 2004-05, an exceptionally strong convection event was observed by several experimentators [2, 3, 4]: it covered an area much larger than usually, and the WMDW formed this winter was significantly saltier and warmer than the values reported in the literature.

Two major explanations for the exceptional characteristics of this convection event (intensity and WMDW characteristics) were proposed by those authors: the first one relates the exceptional intensity of this convection event, as well as the change of the characteristics of the WMDW formed this winter to the atmospheric conditions. The second one relates them to the effect of the EMT on the Ligurian Intermediate Water (LIW), hence on the oceanic conditions. To determine which element played a role in this event, and how, we performed several numerical simulations.

First we performed a realistic numerical simulation of the Mediterranean oceanic circulation during the 1958-2006 period. The long term analysis of this simulation was performed by [5], who validated the long-term evolution of the temperature and salinity in the basin and showed that the model is able to reproduce correctly the EMT. This control simulation is able to reproduce very realistically the 2004-05 NWMS convection event, in terms of chronology, intensity and WMDW characteristics.

We also performed sensitivity simulations, in order to assess the contributions of the oceanic and atmospheric conditions to this convection event. The results show that, for given atmospheric conditions, the temperature and salinity of the WMDW are linearly related to respectively the heat and salt contents of the NWMS just before the convection event (Fig. 1). They suggest that the change of WMDW characteristics observed in 2004-05 was related to an increase of those heat and salt contents during the last decade. The model suggests that this increase was not due to the EMT, but to the absence of deep convection during the 90's enabling salt and heat to accumulate in the LIW. This absence of strong convection was related to the weakness of the winter buoyancy loss during this period. WMDW characteristics are therefore not influenced by the atmospheric conditions during its formation, but by the evolution on those conditions on the long term. The EMT induced a deepening of the LIW in the Western basin, observed by [6] and reproduced by the model, that resulted in a decrease of the stratification of the water column compared to what could have been the case without the EMT. Our results show that, for given atmospheric conditions, the intensity of deep convection in terms of WMDW formed is linearly related to the stratification of the water column just before the convection event. Moreover, in 2004-05, convection reaches the bottom in all the simulations, whatever the pre-convection stratification. It therefore appears that the strong atmospheric conditions during winter 2004-05 were responsible for the intensity of the convection this year, but that the EMT accentuated this intensity by weakening the stratification, and potentially doubled the volume of WMDW formed.

Abstract

La connaissance de la qualité de l'eau est une composante essentielle dans la gestion intégrée du littoral. L'aspect biologique de cette composante est sans aucun doute le plus difficile à prendre en compte, du fait de la complexité des mécanismes gouvernant la production primaire en milieu côtier. Les propriétés optiques des algues, des substances organiques dissoutes et des particules non organiques en suspension peuvent considérablement affecter la couleur de l'eau de mer. Inversement, des mesures précises de la couleur de l'eau et de sa réflectance spectrale permettent d'estimer la concentration de ses composants en utilisant des modèles mathématiques appropriés.

Keywords: Coastal Models, Phytoplankton, Remote Sensing, Pollution, Ocean Colours

Introduction

L'objectif général de ce travail est la caractérisation de la couleur de l'eau de la baie d'Alger à partir des données satellites. L'application permet de quantifier la concentration de la chlorophylle et celle du phytoplancton, qui ont un effet sur la «couleur de l'eau de mer », à partir de mesures satellites [1]. Dans ce contexte, la démarche suivie se base sur le concept de mesures in situ et l'interpolation des résultats trouvés par similitudes ou par des modèles mathématiques. Une corrélation importante entre le compte numérique du premier canal du satellite Landsat TM et la concentration en matières en suspension a été également réalisée [2]. Les bandes spectrales Thematic Mapper étaient utilisées davantage pour corréler avec les propriétés spectrales de l'eau et sa teneur en matière organique ou encore pour la caractérisation de la couleur, la salinité et la concentration en chlorophylle de l'eau de mer. D'autres chercheurs ont montré par l'utilisation des techniques optiques la possibilité d'établir des cartes de chlorophylle a, matières en suspension totales ou carbone organique dissous [3]. En s'inspirant des différentes approches développées et des caractéristiques des satellites Spot et Seawifs, nous avons essayé de mettre en évidence l'utilisation de la télédétection afin de trouver des relations entre les paramètres optiques et les descripteurs de la qualité de l'eau. Il devient donc nécessaire de s'appuyer sur des modèles de réflectance que l'on inverse pour déterminer la teneur de l'eau en ses différents éléments [4]. Nous présentons dans cet article: (a) les mesures physicochimiques des différentes qualités d'eaux ; (b) les résultats des réflectances obtenues à partir des données numériques des satellites et (c) la modélisation des paramètres physico-chimiques, la chlorophylle et le phytoplancton marin dans les profondeurs de la baie d'Alger dans chaque bande spectrale du satellite.

Analyse de l'eau de mer et extraction de la réflectance

Nous avons utilisé l'image satellite SeaWiFS (Sea-Viewing Wide Field-of-view Sensor) pour fournir des données sur les propriétés bio-optiques de l'eau et des principaux paramètres biologiques, notamment la chlorophylle a à la surface de l'eau de mer. Pour extraire la réflectance de chaque pixel de l'image, on transforme l'image compte numérique (CN) en image Luminance.

Resultats et discussion

- Variation des mesures *in situ* et les indicateurs organoleptiques. La distribution spatiale de la chlorophylle *a* et des phéopigments dans la baie d'Alger montrent une grande similitude pendant les périodes de prélèvement. Nous avons pour chaque campagne deux zones distinctes de concentration en chlorophylle *a* et phéopigments. En absence d'activité biologique, la concentration d'oxygène dissous tend vers la saturation de l'eau, qui est en fonction de la température et de la salinité (à pression atmosphérique normale) [1], [5]. Les faibles teneurs de l'oxygène dissous dans l'eau de mer à proximité des rejets sont préoccupantes, et montrent une consommation excessive de l'oxygène qui a des conséquences très graves et fatales sur la vie aquatique en entraînant un phénomène d'eutrophisation du littoral (des pullulations d'algues vertes *Ulva Enteromorpha* ou de phytoplancton *bloom*).

- Analyse des réflectances. La distribution de la teneur en chlorophylle dans l'eau de mer est mise en relation avec la turbidité ; ceci peut expliquer les taux de liaison trouvés sur les canaux visibles Spot et Seawifs étant donné que les eaux où domine le phytoplancton présentent un maximum de réflectance dans le jaune vers 565 nm [5]. Il y a donc une réflexion considérable dans ce domaine spectral qui justifie que les canaux visibles peuvent servir pour étudier la couleur de l'eau de mer et pour en déduire la concentration en sédiments et la concentration en chlorophylle a.

- Spatialisation des paramètres et images satellites. En utilisant le logiciel PCSATWIN d'images satellites, nous avons transformé l'image réflectance en une image qui permet d'estimer dans certaines mesures la concentration de la chlorophylle et celle des espèces phytoplanctoniques dominantes dans la région. En réalité, la couleur de l'eau de mer, qui est l'un des descripteurs organoleptiques évident, reste toujours un facteur important de différenciation qui renseigne sur la lueur de l'eau, sur sa qualité, et qui peut servir comme un indicateur de sa transparence [5].

Conclusion

La modélisation a rendu réalisable la détermination de la couleur de l'eau et de la chlorophylle à partir des satellites. La spatialisation des valeurs mesurées sur le terrain facilite en effet le suivi environnemental de la qualité des eaux et les interventions sur le milieu. Une surveillance directe des populations phytoplanctoniques, couplée avec l'utilisation de capteurs satellitaires et le Système d'Information Géographique, peut améliorer grandement notre connaissance de l'état des eaux côtières et établir une carte de la couleur de l'eau et de la biomasse phytoplanctonique.

INVESTIGATION OF THE MEDITERRANEAN-BLACK SEA COUPLING USING MULTI-SCALE MODELS OF THE TURKISH STRAIT SYSTEM

Sinan Husrevoglu¹*, Emin Ozsoy¹, Adil Sozer¹ and Ozgur Gurses¹

¹ Institute of Marine Sciences - Middle East Technical University, Mersin, Turkey - sinan@ims.metu.edu.tr

Abstract

A multi-scale, high-resolution ocean-ecosystem numerical model suite is implemented for the Turkish Strait System (TSS) to study the dynamics of the coupling between the Black Sea and the Mediterranean, specifically to assess the role of TSS on the behaviour of the coupled ecosystems, to understand the relative importance of remote and local forcing mechanisms on the exchange flows and mixing in the TSS, and to quantify the two-way transport of materials through the TSS. Since the problem of coupling between the adjacent basins of the Black and Mediterranean basins is truly a complex one, an assembly approach is used. Various levels of models are used, producing simulations corresponding to different levels of approximation in order to enable feedbacks on the effects of resolution, model parameterizations, and setup between these levels. *Keywords: Models, Bosphorus, Dardanelles, Marmara Sea, Black Sea*

The TSS is much like a fiord system, characterized by two-laver exchange flow with a strong pycnocline maintained by density and sea level gradients between the Black Sea and the Aegean Sea, and controlled by hydraulic constraints in the straits and exit regions. The depth of the interface undergoes high temporal and spatial variability inside the straits and their exit regions, but has a relatively stable depth at about 25m in the Marmara Sea proper, occasionally exceeding this depth under conditions of extreme surface mixing. The Marmara Sea is a small, enclosed body of water with complex topography, comprised of three deep basins of depth greater than 1000m each, separated by deep sills of 600-700m in depth, adjoining a wide continental shelf of 100m depth occupying the southern half of the basin, which then connect to the straits through canyons extending out from them. Horizontal re-circulating flows under constraints of a highly irregular coast in the confined geometry of the Marmara Sea induce horizontal shears and inhomogeneity. The surface exit flows from straits into the Marmara and Aegean basins are in the form of buoyant turbulent jets. The relatively fresh surface water (S = 18) entering from the Black Sea is modified to reach higher salinities (S = 22-30) within the upper layer of the Marmara Sea, separated from the underlying salty Mediterranean water (S = 38.5). The wider Marmara Sea acts as a buffer zone, or a 'stilling basin' between the two larger basins. The shallowness of the upper layer makes its response to winds and other driving forces extremely rapid.

Due to the lack of sufficient computational resources to handle the required finescale spatial resolution, present ocean numerical models implemented for the coupled Mediterranean – Black Sea system can neither correctly simulate the stratified exchange flow between these basins through the Turkish Straits nor the compounded effects of such exchange on the energetics, stratification, and sea level in these adjacent seas. Extremes in cross-shelf interaction, such as dense water cascading, surface jets, hydraulically controlled, super-critical, nonlinear, non-hydrostatic, layered and occasionally blocked flows occur in the region of the straits, in response to remote forcing from the adjacent seas and the complex topography with very fine details.

In parallel with advances in computer technology, ocean general circulation numerical models (OGCM) have become widely used tools to estimate the consequences of physical, chemical, and biological processes in the ocean and to evaluate the ocean response to atmospheric forcing under realistic and extreme scenarios.

Modeling the Turkish Straits System (TSS) and its role in coupling the adjacent seas is a grand challenge. Features described above make it a formidable problem to forecast currrents and circulation in the Turkish Straits System. Traditional ocean models with simplified physics and topographical representation are often unable to comprehensively capture the features and multiple space-time scales that are involved. A true and full coupling considering the entire system of adjacent Mediterranean and Black Sea basins is in fact far beyond reach for most of the present day ocean models. Therefore, a multi-scale, three-level, hierachical numerical model suite is designed and executed in an attempt to realistically represent the challenging physical and biogeochemical dynamics of the TSS.

For the first level, a barotropic unstructured grid model (MOG2D) is set up covering the Mediterranean and the Black Sea together to predict water levels and net transport through the straits. On the second level, a laterally integrated (x-z) time dependent model solving two-dimensional vorticity equation is adapted for the Bosphorus and is initialized with a lock-exchange situation,

specifying property contrasts between adjacent seas. The third level consists of three-dimensional models of the Bosphorus and Dardanelles Straits driven by net through-flow, boundary conditions specified in the adjacent Aegean and Black Seas and a three-dimensional model of Marmara Sea alone, excluding the straits and attempting to simulate Marmara Sea circulation based on strait exit boundary conditions. The third level models are all based on the Regional Ocean Modeling System (ROMS) [1]. The Fennel ecosystem components [2] are implemented as well in the three-dimensional ROMS models of the Bosphorus, Dardanelles Straits and the Marmara Sea.

Control runs with the Bosphorus model show that major features of the observed currents are successfully reproduced by the model (Figure 1). Following the set-up and testing phase, the control runs established from hindcasts produced by the dynamical and coupled ecosystem models of the TSS are validated with available data and fine-tuned before advancing to forecast, and potentially operational modes of simulation.

Abstract

Recent studies suggest that the dynamics in the upper layers of the ocean can be modeled with an effective version of the Surface Quasi-Geostrophic (eSQG) equations. The validity of this approach implies that the 3D velocity field can be reconstructed for the firsts 300-500 m from a Sea Surface Temperature (SST) snapshot. Then, the main objectives of this study are to investigate the applicability of the eSQG approach in the Mediterranean sea and to determine if the eSQG approach can be used to reconstruct vertical velocities from real infrared satellite data. To this end we will focus on the comparison of satellite derived fields with in situ measurements.

Keywords: Western Mediterranean, Remote Sensing, Mesoscale Phenomena, Instruments And Techniques, Currents

An important problem in oceanography is the estimation of the synoptic 3D velocity field, which is currently available only from expensive and labourintensive in situ measurements. Altimeters measurements allow us to reconstruct the 2D velocity field of the ocean's surface with resolutions of the order of 100-150 km. However, high resolution satellite observations in the visible and infrared parts of the spectrum have shown an ocean very active at scales between 10 and 100 km. Although Sea Surface Temperature (SST) observations in the infrared spectrum provide a qualitative picture of the ocean dynamics at these scales, it is very diffiult to extract surface velocities from them and it is impossible to access vertical velocities.

Recent advances in our understanding of the dynamics of the upper layers of the ocean suggest that these can be modeled with an effective version of the Surface Quasi-Geostrophic (eSQG) equations [1]. The validity of this approach implies that, in situations for which the SST anomaly is representative of the density anomaly below the mixed layer, the stream function and density anomaly can be reconstructed for the firsts 300-500 m with resolutions of 10 km from a single SST image as

$$\hat{\psi}(\vec{k},z) = \frac{g\alpha}{\rho_0 f_0 n_T} \frac{\hat{T}_s(\vec{k})}{k} \exp(n_0 k z)$$

and

$$\hat{b}(\vec{k},z) = -\frac{g\alpha}{\rho_0}\hat{T}_s(\vec{k})\exp(n_0kz)$$

Here $\hat{}$ stands for the horizontal Fourier, k is the wave-vector modulus, fo is the Coriolis frequency, g the gravity constant, α the thermal expansion coefficient, no is a "mean" Brunt-Väissälä and nT an "effective" Brunt-Väissälä frequency that takes into account the contribution of the interior PV and the partial compensation of thermal fronts by salinity [1,2]. n₀ is usually derived from existing observations of the large-scale density field while n_T is usually estimated comparing surface fields with independent observations [2,3]. Furthermore, as it has been shown by [1, 4], vertical velocities can be diagnosed as

$$\hat{w}(\vec{k},z) = -\frac{1}{n_T^2} \left[\widehat{J(\psi_s,b_s)}\exp(n_0kz) + \widehat{J(\psi,b)}\right],$$

which is an alternative to the classical Omega equation.

The Mediterranean is an area that could benefit significantly from the use of infrared SST imagery to study the surface circulation at scales below 100 km. On one side, the percentage of pixels without clouds is quite high. On the other side, an important part of the mesoscale dynamics is not readily observable with existing altimeters since the Rossby radius of deformation is of 10-15 km.

As in [5], we have started our study analyzing in situ and satellite data from the Omega campaign. The data analyzed corresponds to the three consecutive samplings of the northern part of the Western Alboran Gyre carried on between October 1 - October 11, 1996 (see the figure). They consisted on temperature and salinity measurements obtained from an undulating CTD and velocities from a ship mounted ADCP. On the other side, satellite data consisted on nighttime infrared measurements from the AVHRR sensor on the NOAA-14 satellite provided by MeteoFrance.

Fig. 1. Left: Brightness Temperature corresponding to October 8, 1996 with the derived surface velocities and the ship track between October 6 and October 9 superimposed. Right: scatter plot between surface velocities measured by the ADCP instrument and geostrophic velocities estimated from satellite data.

To estimate the velocity field using the above equations we need to reduce the noise level of satellite images. Therefore, we used Brightness Temperatures (BT) from channel 4 of the AVHRR instrument instead of SST and we further reduced the noise level using a wavelet-based denoising method. Then, the resulting geostrophic surface velocities (see the example in the figure) were linearly interpolated in time and space to the positions of real velocities observed by the ADCP. Preliminary results (see the figure) revealed a relatively good coincidence between both fields with a linear correlation of 0.8. In this case the "effective" Brunt-Väisälä frequency, n_T, was set to match the kinetic energy of ADCP velocities. The ability to reconstruct vertical velocities is under study.

VOLUME FLUX VARIABILITY IN THE BOSPHORUS STRAIT

E. Jarosz^{1*}, W. J. Teague¹, J. W. Book¹, S. Besiktepe², M. Kodioglu³, M. Hulbert¹ and A. Quaid¹

Abstract

Recently collected time series of currents, salinity, and temperature were used to estimate volume transports along sections located across the northern and southern ends of the Bosphorus Strait. The volume fluxes in upper and lower layers display high variability that is especially distinct in the upper layer and is coherent with the water level difference between the ends of the strait and along-strait wind stress.

Keywords: Bosphorus, Water Transport, Currents

The Bosphorus (Istanbul) Strait is a part of the Turkish Straits System (TSS) that also includes the Sea of Marmara and further towards the south the Dardanelles (Çanakkale) Strait. The TSS is the only connection between the Black and Aegean/Mediterranean Seas, and plays a paramount role in water mass exchange between these basins. It has been established for centuries that due to the density contrast in the adjacent basins, the basic exchange flow in the Bosphorus Strait is characterized by Black Sea brackish waters flowing southward in a surface layer, and salty waters from the Sea of Marmara moving northward below (Marsigli, 1681; Ünlüata et al., 1990; Latif et al., 1991; Gregg and Özsoy, 2002). Furthermore, this two-layer exchange is modified by the atmospheric forcing and variability of the water levels in the Black and Marmara Seas.

The United States Naval Research Laboratory (NRL) and the NATO Undersea Research Center (NURC) in collaboration with the Turkish Navy Office of Navigation, Hydrography and Oceanography deployed two mooring sections (Black Sea and Marmara Sea entrances) in the Bosphorus Strait as a part of the TSS08 (NURC project) and EPOS (NRL project) programs in September 2008. Each section was configured with: two BARNY moorings (ADCP, wave/tide gauge, temperature, and conductivity sensors) and one line mooring with seven pressure, temperature, and conductivity sensors (T/C sensors). All moorings were recovered at the beginning of February 2009. Full high quality time series were returned from the BARNY moorings. Unfortunately, both line moorings were partially damaged; hence, the data return was limited.

Fig. 1. Volume transports (km3/year) in the Bosphorus Strait: upper layers – dashed line; lower layers – continuous line, and net volume flux – dotted line.

The available data were then used to estimate volume transports in the upper and lower layers in the Bosphorus Strait. Times series of transport (upper, lower, and net) for both ends of the strait are shown in Figure 1. Time series means (September 2, 2008 – February 3, 2009) are 401 km³/year, 286 km³/year, and 115 km³/year for the upper layer, lower layer, and net transports, respectively, along the southern entrance section, and 361 km³/year, 222 km³/year, and 139 km³/year for the upper layer, lower layer, and net transport, respectively, along the northern entrance section. Additionally, at both locations, the volume transport shows high variability. This variability is generally more distinct for the volume flux of the upper layer. The fluctuations there could be twice as large as their respective mean values. Results from multiple and partial coherence analyses indicate that the variability of the upper layer transport is primarily highly coherent with the water level difference between the Black and Marmara Seas, secondarily with the local along-strait wind stress, and thirdly with the atmospheric pressure. The atmospheric forcing and water level difference can easily account for at least 70% of the variance of the upper layer volume transport in the Bosphorus Strait.

WESTERN MEDITERRANEAN WAVE CLIMATE CHANGE SCENARIOS FOR THE XXIST CENTURY

G. Jordà¹, M. Marcos¹, D. Gomis^{1*}, F. M. Calafat¹ and M. Gómez²

¹ Institut Mediterrani d'Estudis Avançats (CSIC-UIB), Esporles, Spain - damia.gomis@uib.cat ² Puertos del Estado, Madrid, Spain

Abstract

Future wave climate in the Western Mediterranean under different emission scenarios will be presented and compared to present day climate. The results are obtained with a 1/6° wave model forced by 6-hours winds generated by a dynamical downscalling over the Mediterranean with 50km resolution. Changes in the seasonal cycle, dominant patterns and extreme events will be assessed. Keywords: Waves, Models

The knowledge of surface wave climate is of great importance to the design of offshore structures, coastal environment protection and the planning of operations at sea, among other maritime activities. Therefore, the identification of changes in the wave climate produced by future emission scenarios is crucial for the long term management of those activities. In this contribution, we present a consistent and homogeneous dataset of past and future wave climate in the Western Mediterranean. The dataset is based on the results of a numerical model and consists on a reanalysis of past climate (1960-2000). three runs of future climate (2000-2100) under different emission scenarios (B1, A1B and A2) and a complementary control run of present climate assuming only present emissions (with no data assimilation in the atmospheric forcing). The WAM model [1] has been implemented in the Western Mediterranean with a 1/6° resolution. The wave model is forced with 6-hours winds provided by the ARPEGE climate model that provides information over a variable resolution grid (~50km resolution over the Mediterranean [2]).

The reanalysis simulation results are compared with wave buoy measurements showing a good agreement in terms of mean values and correlation (Table 1). The changes in the wave climate will be assessed through different diagnostics. First we will look at the evolution of the seasonal cycle of SWH (Significant Wave Height) and Tm (Mean Period). Preliminary results suggest a reduction of the winter mean SWH that ranges from 10% in the B1 scenario to 50 % in the A2 scenario at the end of the XXIst century. This will be accompanied by a reduction of 5-10% in Tm for the same period.

Tab. 1. Comparison of modelled and buoy measurements of wind and wave pameters. The average values at three different observing sites are presented

	Buoy Mean	Buoy STD	Model Mean	Model STD	Correlation model-obs		
Wind speed	6.3 m/s	4.1 m/s	5.9 m/s	3.3 m/s	0.84		
SWH	1.1 m	0.85 m	0.89 m	0.69 m	0.92		
Tm	4.1 s	0.9 s	3.5 s	0.9 s	0.82		

In a second step, the good agreement of the reanalysis dataset with observations supports a characterization of the present day climate in terms of dominant patterns (EOF analysis) of SWH. Then, future changes could be assessed projecting the results of future climate runs on the present day EOFs. In our presentation, we will show the main changes of wave climate relating them to changes in the wind climate.

Finally, extreme wave events will be characterized in terms of their occurrence number, duration and intensity, both for the present-day climate and for the future climate. First results (Table 2) suggest that the number of wave storms and their intensity will decrease by the end of the XXIst century due to the weakening of winds and cyclone activity over the Western Mediterranean.

Tab. 2. Changes in the extreme events characteristics in under different emission scenarios for a point located to the south-west of Mallorca Island

Variable	Scenario	1960-2000	2060-2100
SWH 99.5 Percentile	B1	4.5 m	4.2 m
SWH 99.5 Percentile	A1B	4.5 m	3.8 m
SWH 99.5 Percentile	A2	4.5 m	4.1 m
$N^{\rm o}$ days/year with SWH >4.5 m	B1	9.8	7.6
$N^{\rm o}$ days/year with SWH >4.5 m	A1B	9.8	6.0
N° days/year with SWH >4.5 m	A2	9.8	7.3

SEA SURFACE TEMPERATURE ANOMALIES IN THE SOUTH EASTERN MEDITERRANEAN SEA

Salama M. Kamel¹, Ibraim A. Mayza¹ and Mohamed A. Said¹*

¹ National Institute of Oceanography & Fisheries, Qayet-Bey, Alexandria, Egypt - masaid@yahoo.com

Abstract

The hydrographic data of 61 years were used to study the regular formation of the sea surface temperature anomalies (SSTA) in the South Eastern Mediterranean Sea.

Time distribution of SSTA values display both positive and negative cycles which are nearly associated with the 11 year cycle of sunspots activities. Normal SSTA band occupies only 21.41%, while the positive and negative bands occupy 32.90% and 45.69%. *Keywords: Eastern Mediterranean, Temperature*

The relationship between sea surface temperature (SST) and atmospheric variables is very important for the formation of the intermediate and deep waters [1-2]. The area of study lies between 30 - 33°N and 25 - 34°E. The vertical mean temperature of the upper 10 m layer is considered as sea surface temperature to reduce the diurnal variations. The monthly mean sea surface temperature (T) is calculated for each 1° grid (18 grids, Fig. 1) for every month in the period from April 1948 to August 2008 using the available historical data.

The mean monthly Sea surface temperature is obtained from the Climatological Atlas [3]. The deviation from the mean is computed and considered as monthly SSTA for every grid. The mean monthly positive and negative SSTA through the investigated period are determined, from which the SSTA amplitudes are calculated. The regular formation and evaluation of the SSTA will be studied.

Fig. 1. Mean annual variation of SSTA of the South Eastern Mediterranean Sea.

Spatial and temporal distribution of SSTA

The normal, positive and negative SSTA bands occupy 21.41, 32.90% and 45.69% of the investigated period (Table 1). The negative SSTA is developed in January, June and November. As for positive SSTA, there are one active periods from May to August. The maximum SSTA amplitude occurs in June, which coincided with negative and earlier than positive anomalies. The active period of the SSTA amplitude is extended between May and November.

Tab.	1.	The	percentage o	f occurrence	of	SSTA	bands
------	----	-----	--------------	--------------	----	------	-------

17 75%
11.1270
18.02%
9.92%
21.41%
8.62%
12.79%
11.49%

The high amplitude lies close to land with inverse relation to the shelf width. The low amplitude is centered off the Nile Delta characterized by very wide continental shelf.

The positive SSTA is high in the west and centre decreasing seaward. In the north-east there is an area of high positive anomaly. There are two areas of low positive anomaly coincide with Mersa Matruh and Dammetta anticyclonic

gyres [4-5].

The Interannual variability of the anticyclones is the reason of the presence of negative active areas. This conclusion is coinciding with the results of [6-7].

TRANSMISSOMETRY AND LISST MEASUREMENTS DURING SESAME-IP CRUISE IN THE EASTERN MEDITERRANEAN (MARCH-APRIL 2008)

Aristomenis Karageorgis 1*

¹ Hellenic Centre for Marine Research, Anavissos, Greece - ak@ath.hcmr.gr

Abstract

Light transmission, fluorescence, *in-situ* particle size, and particulate matter concentration were measured during March-April 2008 in 20 stations over the Eastern Mediterranean Sea, as part of the SESAME Project. We present a preliminary assessment of the similarities and differences of the Ionian, Levantine, north Aegean and south Aegean Seas, focusing on the properties of the supended particles and their spatial distribution patterns.

Keywords: Eastern Mediterranean, Sampling Methods

Introduction

The use of transmissometers is well-known for the study of particle dynamics in the ocean for many decades [1, 2]. However, information regarding *in-situ* particle size spectra, mean grain size, and volume concentration of particles in suspension up to 3000 m depth, can be measured only recently with LISST-Deep (Laser In Situ Scattering and Transmissometry; Sequoia Scientific, Inc. [3]), the only commercially available instrument with such specifications. In the framework of SESAME Integrated Project (Southern European Seas: Assessing and Modelling Ecosystem Changes), a multidisciplinary oceanographic cruise took place in the Eastern Mediterranean, collecting data, among others, on light transmission, fluorescence, particulate matter concentration, and *in-situ* particle size distributions. The aim of this work is to contribute to a better understanding of particle dynamics in different sectors of the Eastern Mediterranean, i.e. the Ionian, Levantine, north Aegean, and south Aegean Seas, and to provide for the first time information on suspended particle size distributions.

Fig. 1. Sampling stations location map.

Materials and Methods

During the cruise 20 stations were occupied on board the R/V Aegaeo (Fig. 1). Standard CTD measurements were obtained with a Sea-Bird Electronics 11*plus* CTD deck unit interfaced with a Sea-Bird Electronics 9*plus* unit attached to a General Oceanics rosette with 24 Niskin bottles. Light transmission (subsequently converted to beam attenuation coefficient *c*, in m⁻¹) was measured by two 25-cm path-length transmissometers emitting at 470 nm (Chelsea Alphatracka MKII) and 660 nm (Wetlabs C-Star), fluorescence by a fluorimeter (Chelsea Aquatracka III), and particle-size with the autonomous LISST-Deep. All sensors were attached to the lower part of the rosette frame and results refer to the downcasts [4]. The particulate matter concentration (PMC) was determined by on board water filtration of 1 to 10 litres of seawater passed through pre-weighed polycarbonate membrane filters with pore size 0.4 µm; filters were dried and re-weighed upon return to the laboratory (163 samples).

Results and Discussion

Ionian Sea: Beam *c* values vary from 0.384 to 0.503 m⁻¹ (mean 0.401 m⁻¹) with noticeable higher values in the upper 150 m. The highest value is recorded near the surface of the westernmost station; however, there is a slight increasing trend towards the east. Fluorescence shows a very clear high concentration zone between 60 and 110 m depth, with maxima at 80 m. This pattern is consistent at all Ionian Sea stations. PMC range is 0.03-0.30 mg l⁻¹ (mean 0.12 mg l⁻¹), with relatively higher values appearing at the upper 0-200 m (mean 0.16 mg l⁻¹), demonstrating the general scarcity of suspended particles in the Ionian Sea [5]. Median particle diameter D_{50} measured in 3

stations with LISST varied from 40 to 160 µm, but without any consistent pattern over depth. Records were generally noisy and with a lot of spikes, making the interpretation rather difficult, whereas the distribution of particle volume concentration (VC, in µl l-1) looks more reasonable. Levantine Sea: Only 3 stations were occupied south of Crete. Beam c values vary from 0.406 to 0.521 m⁻¹ (mean 0.422 m⁻¹) and they are observed clearly in the zone between the surface and 100 m depth. Fluorescence exhibits maxima around 80 m, with a decreasing trend offshore. PMC (0.06-0.43 mg l⁻¹) shows slightly higher values, similarly to beam c, because of the proximity of the stations to the land D_{50} measured in 2 stations shows a similar behaviour as the previous. Summarizing, the general picture of the Ionian Sea and the Levantine Sea is fairly similar. North Aegean Sea: 4 stations occupied. Beam c values vary from 0.424 to 0.837 m⁻¹ (mean 0.479 m⁻¹). In this area characteristic surface, intermediate, as well as bottom nepheloid layers are observed, demonstrating generally a more turbid environment. Fluorescence values show maxima at 50 m depth and an increasing trend from the north to the south. PMC range is 0.05-0.85 mg l⁻¹ (mean 0.20 mg l⁻¹), with higher values appearing clearly at the upper 100 m. LISST measurements are characterized by high variability over depth (D50 30-150 µm). South Aegean Sea: Beam c values vary from 0.409 to 0.578 m⁻¹ (mean 0.444 m⁻¹), with pronounced surface nepheloid layers extending to 150 m depth. Fluorescence maxima appear between 50 and 100 m and decrease toward the open sea (southwards). PMC range is 0.04-0.63 mg l⁻¹ (mean 0.22 mg l⁻¹). Similarly to the north Aegean, LISST measurements are not satisfactory.

Conclusions

The Ionian and the Levantine Sea are characterized by extremely particle-free waters throughout the water column, followed by the south Aegean Sea. The north Aegean Sea shows more turbid waters due to rivers inputs. Fluorescence maxima are pronounced but they are observed at different depths. Particle size measurements obtained with LISST are questionable, since they show high fluctuations over depth and also very high D_{50} , which is not expected at such depths. However, the presence of marine snow composed of large aggregates could provide an explanation for the large size classes. On the other hand, the high frequency variability in D_{50} is mostly due to the influence of noise on the measurements because the signal is very low. The main issue is that there are hardly any particles in the water; the volume concentrations from the LISST are well below 1 µl l-1 in most cases, and PMC data support this. So this is really pushing the technology to the extreme limits of what is measurable, in terms of light scattering. The overall behaviour of the instrument and its measurements needs careful re-evaluation. Most probably problems arise from the very low PMCs observed in the Eastern Mediterranean.

IMPACT OF WINTER COOLING ON THE VARIABILITY OF THERMOHALINE CHRACTERISTICS OF ACTIVE LAYER IN THE BLACK SEA

Alexander S. Kazmin¹, Andrei G. Zatsepin^{1*} and Vladimir B. Piotukh¹

¹ P.P. Shirshov Institute of Oceanology Russian Academy of Sciences, Moscow, Russia - zatsepin@ocean.ru

Abstract

The influence of the winter atmospheric forcing on the inter-annual variability of the Black Sea active layer's thermohaline structure during 1982-2008 is investigated. A high correlation between the variability of the winter-mean sea surface temperature/air temperature and thermohaline characteristics of the active layer during the following warm season was found. It is shown that winter atmospheric forcing significantly affects the variability of both temperature and salinity and density up to 150-200 m depth. *Keywords: Black Sea, Air-Sea Interactions, Hydrography*

The response of the marine environment to the long-term variability of the atmospheric forcing is a problem associated with the influence of the climate change on the ecosystem. It is especially important for the Black Sea since its ecosystem is very sensitive to the variability of the thermohaline structure [1, 2]. This variability on scales from synoptic to seasonal is reasonably well established [3, 4]. However, information on the longer-term variability and its connection with the large-scale atmospheric forcing is limited and refers mainly to the sea surface temperature (SST). The first attempts to associate the long-term variability of SST in the Black Sea with the large-scale atmospheric forcing are presented in [5, 6]. The goal of the present study is to investigate the influence of the winter atmospheric forcing on the inter-annual variability of the Black Sea thermohaline structure during 1982-2008. The results are based on a combined analysis of ship hydrological measurements, satellite measurements of the SST and NCEP/NCAR reanalysis data for the surface air temperature (SAT). The preliminary results of our findings may be briefly summarized as follows:

(1) the integral indicators of winter atmospheric forcing are SST (averaged for January to March) or SAT (averaged for December to February). SST and SAT are highly inter-correlated (R=0.92) which means that significantly longer time series of SAT may be used for analysis;

(2) the thermal climatic signal in the active layer is positively correlated with SST and SAT, reaches its maximum at 40-60 m and monotonously falls down with depth. The salinity and density variability is more complicated. They are negatively correlated with SST/SAT up to 80-100 m and change the sign of correlation to opposite at the level of the permanent thermocline. Inter-annual variability of the thermohaline characteristics becomes negligible at the depth of 150-200 m;

(3) an integral indicator of the long-term variability in the active layer of the Black Sea is the mean temperature of the cold intermediate layer (CIL). The CIL mean temperature decreased during 1982-96 and increased for about 0.9 deg.C in 1997-2002, which is consistent with the major climatic events described in [5, 6];

(4) we find out that the heat content deficit in the CIL is spatially inhomogeneous: it is about twice as thicker in the area of the continental slope compared to the deep area due to the specific water circulation;

(5) a statistically significant correlation between the CIL temperature and winter SST/SAT existed for two years. It means that the influence of winter cooling on a given specific year may be traced in the CIL characteristics during at least the two following years.

This work was funded in the frame of bilateral the Russian–Turkish project 'Response of Black and Aegean Seas to climatic variations' (Russian Foundation for Basic Research grant #09-05-91221-CT a) and EU international project "SESAME".

⁴ Institute of Marine Sciences, Technical University of Middle East, Erdemli, Turkey

Abstract

In this work, an estimation of vertical eddy diffusivities and dissipation rates for the SESAME cruises is conducted. The method is based on tracing the 'genuine' overturn limits within potential density CTD profiles. The respective algorithm is applied on CTD data of the broader area encompassing the Greek Seas, the Black Sea, the Turkish Straits and Marmara Sea, acquired at 2 seasons (Winter and Summer 2008).

Keywords: Coastal Processes, Aegean Sea, Black Sea, Marmara Sea, Vertical Profile

The identification and vertical extent estimation of 'genuine' vertical overturns has already been used in literature [1, 2, 3] for assessing vertical eddy diffusivities and dissipation rates. Overturns are 'unstable' potential density (p. d) structures, in which heavier water masses temporarily overly lighter ones. Instability will cause the water parcels to move towards restoring a stable, increasing monotonically with depth, p.d profile (when all motions are 'included' within the overturn limits the overturns are referred to in literature as 'complete').

An algorithm has been developed, for tracing all possible complete overturns (by estimating their exact boundary limits) that are (in the form of onedimensional snapshots) part of a CTD measured p.d profile. The algorithm further sorts the traced overturns as 'genuine' or 'artificial', according to the Galbraith and Kelley method [1]. This method disqualifies overturns that are result either of instrumental noise, (being characterized by small on the average populations of spatially subsequent and kinematically correlated particles), or instrumental errors (being characterized by 'non-linear' T-S relation of their water masses). As a final step the algorithm estimates value pairs of vertical eddy diffusivities and dissipation rates, one value pair per overturn, according to turbulent scale analysis.

The algorithm was applied on the available SESAME 1 (Winter 2008) and SESAME2 (Summer - Fall 2008) CTD cruises for the Aegean Sea, the Cretan Sea, the Southern Ionian Sea, the Marmara Sea and the Black Sea, thus enabling both spatial and temporal variation studies. Stations that presented considerable number of overturning events were 'pooled together' in transects, for studying the vertical distribution of 'eddy diffusivities' and correlating turbulent events with local dynamic conditions, if and when possible (Figures 1 and 2).

Fig. 1. Vertical distribution of eddy diffusivities (circles) along a transect (drawn in the inlay) in the Sea of Marmara, Turkey, in October 2008 (during the SESAME2-WP3 cruise). The circle sizes are analogous to the log (diffusivities). Overlaid is the vertical potential density (sth) and inlaid the horizontal sth distribution at 70 m.

Fig. 2. Vertical distribution of eddy diffusivities (circles) along a transect (transect line is drawn in the inlay) in the North Aegean Sea, North off Lemnos islan, Greece, in April 2008 (during the SESAME1-WP3 cruise). The circle sizes are analogous to the log(diffusivities). Overlaid is the vertical potential density (sth) and inlaid the horizontal sth distribution at 10 m.

Histograms of overturns' frequency of occurence versus eddy diffusivities and dissipation rates showed peaks of highest frequency at 10⁻⁴ to 10⁻⁵ m²/sec and 10⁻⁶ to 10⁻⁷ m²/sec³ for eddy diffusivity and dissipation rates respectively. Higher diffusivity values were observed in North Aegean, where surface Black Sea Water intermingles with subsurface Levantine Water. Higher diffusivity values were also observed in the proximity of the Turkish Straits (Dardanelles, Bosphorus). Most overturns were observed above the thermocline, however intermediate depth (200m to 300m or more) depth overturns were occasionally observed in almost all the study Seas. High resolution CTD data, comprising a dense horizontal grid, prove essential for future vertical diffusion studies. The method however is also valuable for historical diffusion studies.

THE STATUS OF THE DEEP HYDROGRAPHY AND EDDY FIELD DURING 2006-2009 AT THE SOUTHEAST IONIAN TENTATIVE NEUTRINO-TELESCOPE SITE

Harilaos Kontoyiannis¹*

¹ Hellenic Centre for Marine Research, Anavyssos/Athens, Greece - hk@ath.hcmr.gr

Abstract

The deep neutrino-telescope site (NESTOR) in the southeast Ionian Sea is located offshore from the southwest end of the mainland of Greece in the deepest area of the Mediterranean with depths reaching 5.2 km. Among various multidisciplinary observational tasks in the period 2006-2009, long current-meter moorings were deployed and several west-east, normal-to-local-bathymetry hydrographic sections were conducted with main goal to monitor the physical water characteristics and flow conditions. The sections cut through a deep vein at ~3200 m of Cretan water in the southeast Ionian. A weakening in the presence of Cretan water and a tendency for offshore migration of the vein core is observed from 2006 to 2009, while the flow field at depths greater than ~3.5 km is dominated by a cyclonic eddy locked on the local bathymetry.

Keywords: Deep Sea Basins, Ionian Sea, Circulation

Introduction

The role of Physical Oceanography in the development of the appropriate infrastructure for the operation of underwater deep-facilities of neutrino telescopes in the Mediterranean has been to provide the description of the physical water characteristics and flow conditions along with their variability at the selected sites. One tentative site is located in the southeast Ionian Sea offshore from the south-west tip of Peloponissos/ Greece with depths of 4-5 km. This area is not far from the Cretan Straits, where the Cretan water masses outflow into the deep Eastern Mediterranean (Ionian and Levantine Seas). Thus, the involvement of Physical Oceanography in the effort of developing the Mediterranean neutrino telescopes is directly related to the deep thermohaline circulation, spreading and transformation of water mass properties originally generated at their formation regions.

Field Work

Intense observational work has been carried out in the period 2006-2009. A basic effort has been put to monitor the hydrographic conditions along a westeast section on a yearly basis, while additional CTD stations in the near vicinity have allowed to construct maps of dynamic topography showing the localized sub-mesoscale circulation structures. In parallel, long current meter moorings at two sites with bottom depths 4.5 km and 5.2 km have been maintained providing direct current measurements at four levels of the water column (Fig. 1). Unfortunately, in the period 2006-2009 there was no larger-scale hydrographic survey to map the particular meso-scale or sub-basin scale structure(s) in which the transect observations were/are embedded.

Fig. 1. Time series of deep currents at positions NESTOR_5.2 (36° 32,709' N - 21° 07.231' E) and NESTOR_4.5 (36° 32.822'N - 21° 29.064'E)

Results

A deep vein-like structure with a core at ~3200 m is identified in the transect to the west of Peloponissos. The local salinity maxima at its core indicate a Cretan origin. Below ~3200 m, there exist water masses of recent Adriatic origin, whereas at ~5.2 km there is a low-oxygen, isolated, old Adriatic water mass. Apart from the typical properties of temperature, salinity and dissolved oxygen used to identify and describe these structures, water transparency is also measured in the transects due to its importance in detecting neutrinos. The Adriatic and Cretan water masses do carry a transparency signal, characterizing their origin, with decreasing/increasing transparencies in the Adriatic/Cretan water mass. The core of the Cretan water at ~3200 m is shifting towards the west by ~30 km. In 2009 it loses the vein-like structure in salinity but it consistently preserves its higher transparency core signal in the entire observational period. The overall salinity is decreasing from 2006 to 2009. The

deep flow field at depths of 4.5 km and 5 km is characterized by extremely weak velocities with mean speeds near ~2 cm/sec. A cyclonic eddy locked on the local bathymetry appears to exist at depths from ~3.5 km to the bottom in 2006 and 2008. In May 2009, however, its vertical extent is decreased to depths greater than ~4 km.

Abstract

Recent advances in both observations and modelling have allowed the better understanding of the factors that influence the transport pathways of waters of Black Sea origin and their influence on the Aegean Sea physics and ecosystem over a range of spatial and temporal scales. This study elucidates the related dynamics, focusing on the influence of the biophysical properties of the Dardanelles outflow, atmospheric forcing and the complex topography of the receiving basin on (a) the seasonal and inter-annual variability of observed surface Chlorophyll-a spatial patterns; and (b) long term changes in Sea Surface Temperature and the associated variability in the North Aegean contribution of Eastern Mediterranean dense waters.

Keywords: Continental Shelf, Aegean Sea, Black Sea, Circulation Models, Chlorophyll-a

The outflow of waters of Black Sea origin (BSW) in the Aegean Sea through the Dardanelles Strait is a key mechanism in the coupling of the Mediterranean and Black seas. The low-salinity, nutrient-rich BSW are a key factor in increased biotic productivity for the North Aegean, sustaining one of the most significant fish stocks in the Eastern Mediterranean. They also may influence long term changes in the properties of deep water masses, as they may alter the pre-conditioning for dense water formation.

An international effort has recently focused on the coupling of the two basins, recognizing the key role of the flow exchanges in the Northern Aegean and the Southern Black seas through the Turkish Straits System (TSS: Dardanelles Strait, Sea of Marmara, Bosporous Strait). This effort is a unique collaboration of projects funded by the European Union (SESAME project), the NATO Undersea Research Center (TSS 2008-2009 Sea Trials), the U.S. Naval Research Laboratory (NRL-Stennis Space Center) and the U.S. Office of Naval Research. The coordinated observational and modeling effort is a true breakthrough for the oceanography of this complex region, toward the better understanding of the biophysical dynamics of the coupled Mediterranean and Black Sea system.

This presentation will focus on modeling results, with appropriate examples and references to abstracts that present the analysis of recent observations. Satellite and drifter observations will be employed for model evaluation. In particular, results from two hydrodynamic models (based on the Princeton Ocean Model, POM; and the Hybrid Coordinate Ocean Model, HYCOM) and a coupled hydrodynamic/biogeochemical model (based on POM and the European Regional Seas Ecosystem Model, ERSEM) will be presented. The seasonal variability of BSW pathways will be revealed and the long term (1985-2007) interannual variability of the North Aegean water mass characteristics will be examined and compared against the effects of vertical (atmospheric forcing) and lateral (buoyancy input) fluxes, in an attempt to assess the productivity variability in the N. Aegean over the last decades and identify any possible climatic trends. High frequency/high resolution atmospheric forcing has been used for the 2002-2007 period from the POSEIDON operational atmospheric model [1]. The atmospheric forcing for the 1985-2000 period is based on the ECMWF ERA40 reanalysis [2]. The modelled major events of low Sea Surface Temperature (SST) are in agreement with satellite derived SST and the associated increased dense water formation in the N. Aegean can be connected to the Eastern Mediterranean Transient (EMT, [3,4,5]). This phenomenon of massive dense water formation in the N. Aegean has been attributed to the local atmospheric forcing variability triggering significant buoyancy loss through evaporation, combined to an increased salinity preconditioning induced by a decrease of BSW inflow and/or the increased inflow of Levantine more saline waters [6]. However, the impact of BSW on the preconditioning phase remains unclear.

We also explore and assess the major variables that influence the surface phytoplankton biomass. Temperature, Salinity, Sea Surface Height and Mixed Layer Depth from the two different hydrodynamic models and productivity parameters from the biophysical model have been employed in Generalised Additive Models (GAMs: a flexible regression technique that can model nonlinearities using nonparametric smoothers), to study the contribution of these various physical and ecological factors in the variability of satellite derived Chlorophyll-a, a proxy for BSW influence. The remotely sensed surface Chl-a data were derived from the SeaWiFS sensor, for the period of 2002-2006. Monthly averaged time-series were created from the parameter matrix of both SeaWiFS and the numerical models. The analysis was performed for the whole Northern Aegean Sea and for subdomains in the open sea and over different shelf areas, including regions under the immediate influence of both small (rivers) and large (Dardanelles) buoyant outflows, which provide inputs of high Chl-a content. The GAMs analysis showed that the combined effects of the variables used, explained >80% of the surface Chlorophyll variation. Also it was found that depending on the subarea, the Chl-a was primarily controlled physically rather than chemically (nutrient related) and vice versa. As a general rule, higher Chl-a values were associated with lower temperature and salinity values, increasing phosphate and declining nitrate trends. The negative correlation with nitrate indicates that generally the study area is a phosphate limited one. Finally, the influence of cold, nutrient rich, and less saline waters of the Black Sea and/or riverine origin on the observed chl-a patterns, is evident in almost every subarea.

INVESTIGATING THE CIRCULATION IMPACTS OF THE DARDANELLES FLOW EXCHANGE WITH THE NORTH AEGEAN HYBRID COORDINATE OCEAN MODEL

Villy Kourafalou ¹*, Ioannis Androulidakis ² and Ioannis Krestenitis ² ¹ University of Miami, Miami, FL, U.S.A. - vkourafalou@rsmas.miami.edu ² Arisotle University of Thessaloniki, Thessaloniki, Greece

Abstract

The outflow of low salinity, eutrophic and cool waters of Black Sea origin (BSW) through the Dardanelles Strait is the strongest buoyant input for the North Aegean Sea. This outflow affects significantly the physical and biological characteristics of the basin, with implications for water mass characteristics and the circulation and biotic production around remote coastal ecosystems. This study focuses on the understanding of the processes that influence the initial ballooning of the Dardanelles outflow and the subsequent transport and fate of BSW through the Northern Aegean Sea. The Hybrid Coordinate Ocean Model (HYCOM) is employed in a methodology to parameterize and simulate the coupling of the Aegean and Black Seas through the Dardanelles Strait. *Keywords: Aegean Sea, Black Sea, Circulation Models, Coastal Processes, Coastal Engineering*

The Dardanelles outflow contains waters of Black Sea origin (BSW) that are generally cooler and with higher nutrient content than the oligotrophic Aegean Sea [1]. This allows the outflow to be detected in Sea Surface Temperature (SST) and ocean color imagery. The BSW is also fresher and responsible for the overall lower salinities in the northern Aegean, where the frontal areas are related to the spreading of BSW above the saltier modified Levantine Intermediate Water (LIW); [2,3,4]. The evolution of BSW through the North Aegean Sea resembles that of a buoyant plume, under the influence of atmospheric forcing and further modified by the complex topography. This outflow affects significantly the physical and biological characteristics of the basin, with implications for the circulation and biotic production around remote Aegean coastal ecosystems.

Lagrangian observations [5] have revealed the complexity of the BSW pathways and the modification of flows through interaction with narrow passages and straits, around islands, along the rim of shelf/coastal areas and deep sub-basins. It is the complexity of topography that motivated the employment of the Hybrid Coordinate Ocean Model [6] on the North Aegean (NAEG-HYCOM), to allow suitable transitions of the vertical coordinate system from isopycnal in the deep regions to bottom-following (sigma) and cartesian (z-level) in the shelf and coastal areas.

The NAEG-HYCOM has 1/50° horizontal resolution and 20 hybrid layers in the vertical. The model has been nested within a basin scale, data assimilative model for the Mediterranean Sea (resolution of 1/25°). This study is part of a unique collaboration of projects funded by the European Union (SESAME project), the NATO Undersea Research Center (TSS 2008-2009 Sea Trials), the U.S. Naval Research Laboratory (NRL-Stennis Space Center) and the U.S. Office of Naval Research. The coordinated observational and modeling effort is a true breakthrough for the oceanography of this complex region, toward the better understanding of the biophysical dynamics of the coupled Mediterranean and Black Sea system.

Two types of experiments have been executed in order to elucidate the development and evolution of the Dardanelles buoyant plume, expressed by the initial tendency for ballooning of the outflow and the subsequent formation and variability of the associated rim current. Theory and observations have been employed to evaluate the model results. Several process oriented experiments have isolated and examined each of the distinct physical aspects that affect the North Aegean Sea circulation and mass characteristics. Realistic experiments covering the 2002-2008 period have focused on the interaction of the circulation forcing mechanisms in determining the seasonal and inter-annual variability of the BSW pathways. Sensitivity to the spatial resolution of the atmospheric forcing is revealed through twin experiments with two high-frequency operational atmospheric products, namely the fine scale (1/10 degree) POSEIDON/SKYRON [7] and the coarse scale (1 degree) Navy Operational Global Atmospheric Prediction System (NOGAPS, [8]).

We employ comparisons of the NAEG-HYCOM model and in-situ observations and satellite images to evaluate the river parameterization procedure, the requirements in atmospheric forcing fields and the impact of the parameterization of the coupling between the North Aegean and Black seas through the BSW outflow at Dardanelles. The BSW bulge balooning and several outflow parameters are compared to the findings of [9]. The parameterization of the Dardanelles outflow follows approaches ranging from a river-like buoyant discharge to a two-layer inflow-outflow system, to coupling with an unstructured grid model of the Turkish Straits System (Dardanelles Strait-Sea of Marmara-Bosphorous Strait), suitable to employ updated time series of measured flow properties.

Abstract

The state of the art of the oceanographic properties in 2008 of the Ionian Sea is derived from the data sets collected during two campaigns in the framework of the SESAME project. The physical characteristics of the main water masses present in the basin and their seasonal differences are described. The long-term changes in the deep water in the central Ionain Sea are traced by the use of the ¹³⁷Cs content and associated with a change of the thermohaline properties in the last two decades. *Keywords: Ionian Sea, Density, Salinity, Temperature*

Surface dynamical features characteristic of the Ionian Sea area are described by means of satellite altimetric imagery (absolute dynamic topography; http:// www.aviso.oceanobs.com/en/data/product-information/duacs/index.html). They are compared to the subsurface current field measured by a vessel-mounted Acoustic Doppler Current Profiler along the track of the research vessel. The Ionian basin is characterised by the overall anti-cyclonic surface circulation at surface, within which a number of sub-basin and meso-scale gyres and eddies, both clock-wise and anti-clockwise are imbedded. The most persistent is the Pelops anti-cyclonic gyre. These structures influence the distribution and the pathways of the surface and intermediate water masses (Ionian Surface Water, Atlantic Water, and Levantine Intermediate Water, in particular). During winter the upper layer is relatively well mixed. The Atlantic Water (salinity 38.4) is confined to the western portion of the W-E section from the surface down to 100 m (Fig. 1). Levantine Intermediate Water (salinity > 38.9) spreads westward from the eastern Ionian in the layer 150-500 m.

Fig. 1. Vertical distribution of salinity along the W-E section in winter 2008. A rectangular area in the inserted map indicates the central Ionian station.

Fig. 2. Vertical distribution of salinity along the W-E section in summer 2008. A rectangular area in the inserted map indicates the central Ionian station.

In summer (Fig. 2), stratification in the upper layer and the sub-basin scale eddies influence the recirculation of the Atlantic Water (minimum salinity < 38 in the 30-50 m layer below the surface), while the Levantine Intermediate Water is down-welled by the Pelops anticyclone. Below the Transitional Mediterranean Water (characterized by an oxygen minimum at around 1000 m) the deepest zones to the west and in the central Ionian are filled with the dense

waters (Eastern Mediterranean Deep Water, EMDW) of Adriatic origin (salinity 38.74), while to the east less saline dense waters reside. The most recent EMDW (of Adriatic origin) has higher salinity and temperature values. The present state is compared to changes in the central Ionian Sea during the last two decades [1], and illustrated also by the uplifting of the old bottom waters (detected by means of the ¹³⁷Cs content).

TWO DIFFERENTS NORTHERN ADRIATIC WINTER OCEANOGRAPHIC TYPES

Romina Kraus¹*, Tamara Djakovac¹, Robert Precali¹ and Nastjenjka Supic¹

¹ Ruder Boškovic Institute, Center for Marine Research, 52210, Rovinj, Croatia - kraus@cim.irb.hr

Abstract

It has been observed that two types (A and B) of winter oceanographic conditions can occur in the northern Adriatic. The difference between the eastern and western parts bottom layer density distinguishes the two winter types. We intend to present a precise definition of the two types and introduce a third winter type (C). A and B types differ in hydrographic (temperature and salinity), dynamic (geostrophic currents distributions), chemical (total inorganic nitrogen and phosphorous) and biological (phytoplankton) parameters.

Keywords: Adriatic Sea, Circulation, Nutrients, Phytoplankton, Po Delta

Introduction

The northern part of the Adriatic is under the influence of the Po River, one of the largest Mediterranean rivers. Spreading of the Po River waters highly influences oceanographic processes in this region. Depending on circulation patterns, Po River waters are drawn into the northern Adriatic region or are diverted southwards (Figure 1). According to Supic and Vilibic [1], who described winter hydrographic conditions in the northern Adriatic for the 1966-2000 period, two basic hydrographic February conditions (A and B) can occur in the region. The A type occurs when bottom density is higher in the eastern part than in the western one of the northern Adriatic and the B type is when it is just the opposite. A detailed analysis of the two types was needed.

Fig. 1. Northern Adriatic map and schematics of two circulation types in its surface layer. The "open" circulation pattern (solid arrows) favors the inflow of southern Adriatic waters, and the "closed" circulation pattern (open arrows) spreads the Po River waters towards the east.

Methods

Sampling strategy, parameters determination and calculation

Hydrographic (temperature, salinity and density), dynamic (geostrophic currents relative to 30 m depth between each two neighboring stations), chemical (total inorganic nitrogen and phosphorous) and biological (microphytoplankton) samples were collected in February at six stations between the Po River delta (Italy) and Rovinj (Croatia) (Figure 1) in the 1981-2007 period. The parameters were determined by standard oceanographic methods.

Type determination

The A or B type occurs when average 30 m sigma-t value at western stations

SJ108 and SJ101 (Table 1) is at least 0.1 lower or higher than at eastern SJ107, respectively. The special C type occurs when the difference is less than 0.1.

Results

In type A winters temperature, nutrient concentrations and phytoplankton abundance at the entire Po River delta - Rovinj transect were generally higher than in type B winters, while salinity and density were lower (Table 1). The difference in phytoplankton abundances between A and B types for the eastern part of the transect was especially pronounced (Table 1).

Tab. 1. Bottom density of the western (W) and eastern (E) northern Adriatic (bottom ρ), the corresponding winter type, surface geostrophic currents relative to 30 m between SJ105 and SJ107 (v; + means flow towards north, and - means flow towards south), intensity of the Po River flow during January and February compared to long-term means (Po flow) and water column averages for temperature (T), salinity (S), density (ρ), orthophosphate (P), total inorganic nitrogen (N; nitrite, nitrate and ammonium) and phytoplankton (phyto; 20-200µm)

In winters of A type (except in 2007, when currents were very weak) there was a geostrophic flow towards south between stations SJ105 and SJ107, indicating the presence of a large anticyclonic gyre off the Po River delta and spreading of Po waters towards east (Table 1, Figure 1). On the contrary, in winters of B type a geostrophic flow towards north between stations SJ105 and SJ107 was observed. Results of an analysis of winter circulation fields (in preparation) show that the distribution of surface geostrophic currents in winter strongly depends on bottom density distribution. Winter types occur independently of the Po River input (Table 1). Values obtained for all parameters during C type winters are generally between values characteristic for A and B type ones.

Conclusion

Results strongly indicate that in A type winters Po River waters spread over the northern Adriatic, distributing fresh nutrient rich waters towards east and favoring phytoplankton blooms over a large area. In winters of B type, these waters are restricted to the western area. C type winters are more vague and cannot be described as precisely as A and B type winters.

Abstract

Using traditional and modern observational methods, the investigations of short-term variability of hydrophysical structure and water dynamics in the Black Sea over the shelf and upper part of continental slope near Gelendzhik were carried out during 3 years (2006-2008). The methods include: a) an analysis of satellite images (sea surface temperature and color); b) sea-going transects at shelf-deep sea area with frequent CTD-profiling; c) quasi-instantaneous surveys (snapshots) with measurements of velocity field by means of towed ADCP. The activities were fulfilled predominantly in autumn season under the conditions of well-developed mesoscale water circulation in north-eastern part of Black Sea and non-stationary wind forcing. *Keywords: Black Sea, Continental Shelf, Coastal Processes, Continental Slope*

Sub-mesoscale (1-10 km) and short-term (1-100 hours) variability of the hydrophysical structure and fluid dynamics at the narrow Black Sea shelf depends on a number of factors: wind forcing, fresh water runoff, fluid dynamics over the continental slope and deep part of the sea, coast relief and bottom topography. The influence of the mentioned factors on the shelf fluid dynamics and cross-shelf exchange processes (that are responsible for shelf water renewal and self-purification from natural and anthropogenic pollution) is not well studied. In this paper we present the results of an investigation on the Black Sea shelf fluid dynamics over the influence of water dynamics over the continental slope and deep sea as well as coast relief and bottom topography.

The study was fulfilled in Gelendzhik area at autumn seasons of 2006-2009. Following data, methods and equipment were used:

1) NOAA, MODIS-AQUA and MODIS-TERRA satellite information

- (sea surface temperature, chlorophyll "a", water leaving radiance);
- 2) cross-shelf CTD sections;
- 3) towed ADCP surveys with sub-mesoscale resolution;
- 4) bottom mounted ADCP measurements at selected stations.

mechanisms of sub-mesoscale eddy formation were revealed. The first was the shear instability of the along-shore current. The second was observed only in case of strong external circulation (when along-shore current velocity over the shelf edge exceeded 40-50 cm/s) and consisted in periodic eddy formation in the concave forms of the coast relief, their detachment from the shore and inclusion to the along-shore current. Some eddies grow up rapidly and transform to mesoscale (geostrophic balanced) eddies, that play an important role in cross-shelf water exchange and influence on the ecosystem of Black Sea coastal zone [1].

Fig. 1. Anticyclonic sub-mesoscale eddy over the Black Sea shelf, revealed during a towed ADCP survey.

A well-pronounced short-term and sub-mesoscale variability of the fluid dynamics over the shelf and upper continental slope was revealed. Particularly the dynamical variability was characterized by an inconstancy of the alongshore and cross-shore velocity components accompanied by intensive cross-shelf water exchange. The general origin of the observed variability was related to the formation and along-shore transfer of sub-mesoscale eddies with diameter about 5-10 km (Fig. 1).

These eddies were ageostrophic and their life-time normally did not exceed a few days. The main energy source of sub-mesoscale eddy formation was the external circulation – currents over the continental slope. Two basic physical

MODELLING IN A PERPETUAL MODE THE MEDITERRANEAN CIRCULATION USING ATMOSPHERIC FIELDS AT DIFFERENT SPACE-TIME RESOLUTIONS

Abstract

This paper presents a sensitivity study in regional air-sea numerical modelling. The NEMO-MED12 ocean model is driven by different forcing fields coming from the WRF atmospheric model. We examine here the modifications in the thermohaline circulation and in the small scale ocean response especially under intense meteorological events, when varying the temporal resolution or the spatial resolution of the atmospheric forcing.

Keywords: Models, Atmospheric Input, Air-Sea Interactions, Gulf Of Lions

The Mediterranean Sea circulation with its complex patterns is sensitive to the regional climate [1] and to local extreme meteorological events that frequently occurred over the region. In the framework of the MORCE-MED project, a two-way ocean-atmosphere coupling is developed between the WRF atmospheric model [2] and the NEMO-MED12 ocean model [3]. The future ocean-atmosphere coupled system is part of the future regional numerical platform including also the modelling of the continental superficial layers, atmospheric chemistry and marine biogeochemistry. The whole regional coupled model aims to study the impacts of the climate change over the Mediterranean basin. Before applying the full two-way interactive coupling between the two regional models, the forcing mode is considered through a sensitivity study.

The downscaling of the NCEP reanalyses over the full Mediterranean basin with a 20-km resolution has been done with WRF between August 1998 and July 1999. The WRF model is able to well represent the Mediterranean climate and annual heat and freshwater budgets (Fig. 1), and with a good representation of extreme meteorological events such as strong local winds or heavy precipitation.

Fig. 1. (a) Heat and (b) freshwater budgets over the Mediterranean [HB (W/m^2) = SW (short-wave radiation -LW (long-wave radiation) -H (sensible heat flux) -LE (latent heat flux); FWB (mm/year)= E (evaporation) -P (precipitation)] according to the daily-averaged WRF simulation fields at 20-km resolution between the 1-Aug-1998 and the 31-July-1999.

The daily atmospheric fields obtained are then used to drive the MED12 ocean model (6-8 km resolution) in a perpetual mode during a spin-up of 8 years. Then, four experiments are done for a period of 4 years. The first

experiment (or control experiment CTL) is the continuity of the spin-up. In the second experiment (ZOOMGOL), a finer spatial resolution is applied over the Gulf of Lions area in order to better represent atmospheric mesocale patterns, in particular the channelling of the mistral and tramontane. In the third experiment (3HFREQ), a higher temporal resolution is used, i. e. the frequency of the forcing is 3 hours, allowing a good representation of the diurnal cycle and of the extreme air-sea exchanges during severe meteorological events. Finally, the fourth simulation (HIGHRES) combines the high temporal frequency and the zoomed forcing fields over the Gulf of Lions.

Even if few differences are found between the four MED12 experiments at the basin scale, the local effects of increasing the space-time resolution are significant. The better representation of the mistral/tramontane channelling and acceleration in the zoom modifies the ocean response over the Western basin. Some convective chimneys persist in the Gulf of Lions a few days later than in the control experiment (Fig. 2). The diurnal cycle limits in some extent the surface seasonal warming/cooling, and modifies also the deep convection (Fig. 2); The intense and short-range peaks in the precipitation rate or in the wind stress locally modify the ocean freshening and/or cooling. This results confirm the conclusions already discussed using a 1D ocean model [4].

MONTHLY AND SEASONAL OSCILLATIONS OF THE EASTERN ADRIATIC CURRENT

N. Leder ¹*, N. Domijan ¹, Z. Grzetic ¹, H. Mihanovic ¹ and M. Mlinar ¹ ¹ Hydrographic Institute of the Republic of Croatia, Split, Croatia - nenad.leder@hhi.hr

Abstract

Long-term ADCP measurements were carried out between November 2007 and December 2008 along the Croatian internal and territorial waters. Preliminary results of monthly and seasonal oscillations of the Eastern Adriatic Current are presented. *Keywords: Adriatic Sea, Currents, Circulation*

Introduction

The Eastern Adriatic Current (EAC) is a branch of the general Adriatic cyclonic circulation along the eastern part of the Adriatic Sea with predominant NW direction. It is well known that EAC varies seasonally, being strongest in winter and weakest in summer [1]. In 2007 the scientific and research program – "The Adriatic Sea Monitoring Program" was implemented. Part of this program consisted on current measurements along the Croatian internal and territorial waters, during a year long period. The measurements started in November 2007 and finished in December 2008. They represent a novel contribution to Croatian physical oceanography, incorporating the greatest number of stations up to date, as well as providing the longest time-series available.

Materials and methods

During the first 6 months current measurements were performed at 20 current meter stations: S01 to S20 (Fig. 1), and in the next 6 months at other 20 current meter stations: S01 to S05, S08 to S14, S16, S18, S20 and S21 to S25 (not shown in Fig. 1). For the first time a large number of long current time-series (forty time series with six-months of measurements) was obtained simultaneously by using ADCP current meters with a sampling interval of 15 minutes and 2 m vertical resolution. Basic statistical analysis of current flow and spectral analysis of current field were obtained through calculation of the monthly current vectors.

Results and discussion

The spectral analysis of currents showed that energy distribution, depending on the frequency, differed at all stations in both measurement periods. This leads to the conclusion that acting forces in individual sea areas occur with completely different intensities. In the current spectra, gradient currents most frequently have maximum energies, while wind and tidal oscillation energies are somewhat weaker. Some other phenomena and processes, such as fundamental Adriatic seiches and inertial oscillations [2], were also observed in the current spectra. The analysis of measurements shows a general NW circulation (Fig. 1) along the Croatian Adriatic coast – the well known Eastern Adriatic Current (EAC). The resulting circulation may be explained as a modification of the long-periodic gradient currents through the permanent influence of tidal oscillations and wind, while seiches and inertial oscillations are transient. The maximum current speeds were within a range of 55 to 80 cm/s in the surface layer, and from 20 to 30 cm/s in the bottom layer (depending on the station's depth). The absolute current speed maximum of 102 cm/s was measured at station S03 near Rt Kameniak cape, which is very close to the extreme current speeds recorded in the Adriatic Sea. Mean monthly current speeds were mostly between 5 and 15 cm/s, and usually below 5 cm/s in the bottom layer. Very intense current oscillations were recorded at the seasonal and monthly period at all stations. Generally, that circulation is stronger in the autumn and winter (cold seasons) than during the spring and summer (warm seasons), but there are also exceptions to this general rule. The strongest circulation was observed in February (Fig. 1), and the weakest in August, which matches the present understanding of seasonal sea current oscillations along the eastern Adriatic coast [1]. In February 2008, the circulation matched with the already well-known NW circulation along this coast (Fig. 1). The dominant NW circulation was deformed in some sea areas by the direction of the shore or channel. The circulation was barotropic, which is typical for the winter season. The strongest surface circulation was recorded at S03 (Rt Kamenjak cape) and S11 (open sea in front of the Šibenik archipelago), where the mean monthly current vector was around 12.5 cm/s and the stability factor around 70%. Bottom circulation was significantly weaker, mostly under 5 cm/s. It is important to stress that the circulation at S01 and S02 was in an opposite direction, so that it may be assumed that there was a cyclonic eddy in the northernmost part of the Adriatic [3]. Generally speaking, the weakest circulation was recorded in August 2008, when the mean speeds of the surface monthly current vectors were under 5 cm/s, and those at the bottom were under 2 cm/s. The circulation was baroclinic due to the presence of the strong pycnocline. It appears that in August 2008 two eddies were present in the

northern Adriatic: a cyclonic eddy north of the Po-Rovinj joining line and an anticyclonic eddy south of the same line, with the presence of the Istrian Coastal Countercurrent (ICCC) south-west of Rovinj [3].

Fig. 1. Monthly mean currents for February 2008 for the subsurface (gray) and near-bottom (black) layer, in the northern Adriatic (top) and middle and south Adriatic (bottom).

EVOLUTION OF SURFACE WAVE SPECTRA IN EXTREME SEA STATES ALONG THE EASTERN ADRIATIC OPEN SEA AND CHANNEL AREAS

N. Leder ¹*, V. Androcec ², S. Cupic ¹, N. Domijan ¹ and G. Loncar ² ¹ Hydrographic Institute of the Republic of Croatia, Split, Croatia - nenad.leder@hhi.hr

Abstract

Measurements of the wind-generated surface waves along the eastern part of the Adriatic Sea in coastal areas are rare; most earlier measurements have been carried out in the open sea. As a part of the scientific and research program – "The Adriatic Sea Monitoring Program", long-term wave measurements were carried out between November 2007 and December 2008 at two stations: in the open sea north area (V1) and in the channel area of the middle Adriatic (V2). Spectral characteristics of waves in extreme sea states are presented and compared.

Keywords: Adriatic Sea, Waves

Introduction

The process of formation and development of surface waves may be considered as a function of three basic variables: wind direction and speed, fetch over which the wind blows and duration of wind of a particular direction. Occurrence of a fully developed model of wind waves is unusual in the Adriatic, which is a semienclosed sea of limited fetches. However, instrumental measurements and visual onboard observations of surface wave elements show that during strong gale force winds of longer fetches (SE, W, SW and NE) wave models of respectable dimensions may be developed in the Adriatic Sea. Absolute maximum of wave height H_{max} =10.8 m was measured in the north (V1) and extreme expected value of Adriatic wave height is about 14 m [1].

Materials and methods

Wind generated surface waves were measured at V1 (φ =44°44.5' N; λ =3°10.2' E) in the open part of the north Adriatic and in the Bracki Channel area of the middle Adriatic at V2 (φ =43°29.3' N; λ =16°27.9' E; Fig.1).

Fig. 1. Location of waverider stations: V1 in the open part of the north Adriatic and V2 in the Bracki channel.

This was undertaken in the time interval from 11.2007 to 12.2008, by using Datawell waveriders with all its components. For the analysis and description of extreme sea states maximum recorded wave height H_{max} and significant wave height $H_{1/3}$ and associated wave spectra will be presented.

Results and discussion

The measurement results show that much larger waves appear in the northern Adriatic compared to the middle Adriatic channel area. This is attributed to a significantly larger fetch of predominant winds in the north (Fig. 1). The maximum wave height of 7.27 m, which corresponds to significant wave height of 4.22 m, was measured at V1 on 10.12.2008. At V2, significantly smaller values were measured, with a maximum wave height of 2.84 m (3.12.2007), which corresponds to significant wave height of 0.92 m. The spectral characteristics of extreme surface waves at V1 are very similar to the observed wave spectra for the open sea [2, 3]. Fig. 2 shows the density spectrum of energy of surface waves for strong and gale southeasterly wind (Scirocco) in V1 on 10.12.2008 when the maximum measured wave height was 7.27 m. It is clear that the maximum density spectrum of energy S(f)=42.52 m^2/Hz corresponds to wave period of 9.1 s, matching the significant wave height H_{1/3}=3.75 m. The figure also shows the evolution of the spectrum for the period of increase of energy up to maximum (Fig. 2a) and for the period of decrease of energy (Fig. 2b). During the period of increasing wind speed, an increase of wave spectral energy density and its maximum were observed. Simultaneously, the maximum of the spectrum moves toward the lower frequencies. During decreasing wind speed, S(f) decreased and the maximum in spectrum moved slightly toward the lower frequencies. At V2, wave spectra evolution during strong Scirocco differs

significantly from open sea (Figs. 2c, 2d). The difference is observed for the period of decreasing wind speed and wave energy, when the maximum in spectrum is shifted in time toward the higher frequencies (Fig. 2d). It can be concluded that in enclosed seas of very small fetches (Bracki Channel), the evolution of surface wave spectra in extreme wave conditions is considerably different than in open sea area. The wave spectra evolution for the open Adriatic is very well known [1], while for the channel area it is presented here for the first time. The occurrence of extreme sea states in this channel area is not possible, as confirmed by these results, although this time-series of measurement is not representative. Fetch is the major limiting factor in sea state development in the channel area.

Abstract

A comprehensive analysis of hydrological, current-meter and meteorological data was performed in the northern Ligurian sea to describe the coastal dynamic near the Portofino cape and its relation with the general cyclonic circulation during summer 2004. Current-meter data was acquired in two coastal sites: the Portofino Cape and the marine area of Arenzano. The hydrological parameters around the cape suggested the presence of two different water masses. The first, located in the lee of the cape, is influenced by local effects, while the second, offshore the cape, is correlated to the general circulation of the Ligurian Sea. The prevalent southern direction of the current in Portofino indicates the presence of a local anticyclonic circulation, associated to the presence of the cape.

Keywords: Currents, Hydrology, Ligurian Sea

A current analysis has been performed in two coastal locations of the Northern Ligurian sea, situated respectively in the eastern and western side of the Gulf of Genova: the Portofino Cape, characterized by a unusual squared-shape of the coast, and the coastal area offshore Arenzano. A very narrow shelf with a very steep slope is typical of the Portofino location, while Arenzano presents a gently sloping bathymetry and a fairly straight coast.

Between July and August 2004, current-meter measures were acquired in the lee side of the cape on a bottom of 30 metres, using a new technology named SEPTR [1]. A hydrological survey was also conducted in the same area in August, using a CTD probe on 36 stations around the cape. In the maritime coastal area of Arenzano an ADCP mooring was placed at 30 m of depth, on a bottom of 50 m. Satellite wind data was acquired by QuikScat for the summer 2004, and compared with the local winds four stations along the Ligurian coast. The aim of this work is to provide a coastal dynamics circulation scheme around the Portofino cape, with particular attention to its interaction with the general cyclonic circulation, and to describe the role of the meteorological and the topographic forcings.

Fig. 1. Five time series are presented: (top) wind stress in Genova (unit 10^{-2} Pa); (second and third) Arenzano currents at 15 m and 23 m respectively; (forth and fifth) Portofino currents at 15 m and 23 m respectively (units: cm/s).

The direct current measures on the lee side of the cape suggest a local recirculation with a prevalent southern current direction almost perpendicular to the coast. On the other hand the main local current direction in Arenzano is south-west, following the isobaths of the continental shelf [2]. The comparison between Arenzano and Portofino currents shows the maximum correlation of 0.53 for a time lag about 9-10 hours: the Portofino current anticipates the Arenzano one. The ADCP data shows shorter time scale phenomena (few days) in both locations, mainly forced by meteorological events. The study of the baroclinic component of the Portofino currents indicates an important role played by both the wind and the bottom stress. A preliminary meteorological analysis suggests to consider the wind at Genova location, which is prevalently directed towards north-west, with the main intensity-current picks well correlated to all the other wind locations. Comparing the low-frequency current fluctuations of Portofino (15-24 metres deep), of Arenzano (15-23 metres deep) and the Genova wind stress, it is possible to reveal a common time variability between July and August 2004 (Figure 1). The singular topography of the Portofino Cape plays a significant role in the response of the coastal waters to wind forcing and to the general circulation of the Ligurian Sea, determining a small-scale, anti-cyclonic eddy on the western side of the Portofino Cape, according to previous numerical study [3].

EVOLUTION OF THE WESTERN MEDITERRANEAN THERMOHALINE ANOMALY AS OBSERVED NEARBY BALEARIC ISLANDS (2005-2009)

José Luis López-Jurado ¹*, Cesar Gonzalez-Pola ² and Pedro Velez-Belchi ³ ¹ Instituto Español de Oceanografía. Centro Oceanográfico de Baleares - lopez.jurado@ba.ieo.es ² Instituto Español de Oceanografía, Centro Oceanografico de Gijon, Spain ³ Instituto Español de Oceanografía, Centro Oceanografico de Canarias, Spain.

Abstract

The complex thermohaline structure observed in the Western Mediterranean after the severe winter of 2004-05 is still present in the summer of 2009 at the Balearic Islands. The processes that caused the anomaly are now well identified, as well as the different newly formed water masses. The evolution of the anomaly during the period involves a progressive homogenization of the deep waters masking the layered structure. The final product is a warmer and saltier water type that apparently has incorporated deep waters formed in subsequent winters but not from other intense cascading episodes. On the other hand, Levantine Intermediate waters observed at the north of the Balearic Channels does not present robust trends since mid-90's. *Keywords: Western Mediterranean, Balear Sea, Deep Waters*

The Mediterranean Sea has been immersed in a process of warming and saltincrease at least since the mid 20th century. Anthropogenic global warming and damming of the major rivers have been postulated as the causes of the process. The severe winter of 2004-05 caused the highest heat-loss at the area of deep water formation in the western Mediterranean, triggering the production of immense amounts of cold dense waters that quickly spread along the whole basin creating a complex structure [1]. The new structure was satisfactorily explained as a combination of cascading of very cold and quite fresh waters along the shelf-slope plus the production of saline and warm deep waters at the open ocean.

The trace of the anomaly is clearly visible as a sting-like signature on the TS diagram (Fig 1). Three source waters contribute to it, the coldest mode corresponds to the cascading and the high-saline warm mode of the curve corresponds to the open ocean convection. Both lay below the older deep waters at the end of the straight TS line [2]. The detailed monitoring has shown that the anomaly is extended along the whole basin [3] and persists up to now. The characteristics have evolved towards an homogenization of the layered structure ending with a DW modal water much warmer and saltier than before, with a little contribution of extra cascading waters and intermittent incorporation of open water convection waters, as in winter 2006.

On the other hand, Levantine Intermediate Water properties have been monitored since 1996 at the north of the Balearic Channels. This water mass shows strong interannual variability but not a clear trend during that period, therefore it is not apparently a strong effect caused by the Eastern Mediterranean Transient, at this location.

NORTH ADRIATIC WINDS AND THE RESIDUAL CURRENTS IN THE INLETS OF THE VENICE LAGOON

Isaac Mancero-Mosquera ^{1*}, Miroslav Gacic ¹ and Andrea Mazzoldi ²

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale. Trieste, Italy. - imancero@ogs.trieste.it

² Istituto di Scienze Marine - CNR. Venice, Italy.

Abstract

The principal components of the wind measured in front of the Venice lagoon are related to the variability of the residual flow in the inlets connecting the lagoon with the Adriatic sea. Lido and Chioggia inlets have an exponential response to the Principal component of the wind (PC1); while the second component (PC2) affects only the Chioggia inlet in a linear way. Thus, during Bora events (detected mainly in PC1 series), the inflow through Lido channel is reinforced as well as the outflowing in Chioggia. On the other hand, Sirocco events (detected in the PC2 series) slow down the outflowing in Chioggia.

Keywords: Adriatic Sea, Currents, Time Series, Wind/Font

Introduction.

Current velocities are monitored in the three inlets, i.e., Lido, Malamocco and Chioggia, connecting the Venice lagoon with the Adriatic Sea. They are relatively narrow and shallow thus making the flow highly polarized along the channel axis, and barotropic. Therefore, analyses carried out on the vertical averages of along-channel components (obtained via Principal Component analysis) can be considered fairly accurate. It is well documented [1] that the astronomic tides account for most of the energy of the current flow, so that more than 90% of the energy can be removed via Harmonic Analysis. Still, an important portion of energy coming from the open sea and atmospheric forcing is evident in the non-tidal component. A quantification of the wind effect on the current velocities is attempted by removing the energy of seiche oscillations and decomposing the wind into its principal components.

Adriatic Seiches and Wind Decomposition

A translation-invariant Wavelet transform was applied to the de-tided verticallyaveraged current series in order to decompose the variance on a scale-by-scale basis. It was found that the main portion of energy was in the scales containing the main Adriatic seiche modes of 11 and 22 hours. An additional free oscillation with periodicity of 4.87 hours was also detected. Seiche signals were removed by fitting the corresponding wavelet scales to the de-tided time series. The 88% of non tidal variability in Lido, 92% in Malamocco and 85% in Chioggia were thus removed, leaving the residual time series ready for comparison with the wind vector time series.

Winds were decomposed by Principal Component Analysis. The main axis of variance (PC1) is aligned with the strongest wind in the area, i.e., Bora; while the second component (PC2) is aligned mostly with the Sirocco direction of blowing. Since the principal components are independent up to 2nd order statistics [2], correlations were computed separately between the wind components and the residual currents time series.

Fig. 1. Exponential response of residual currents in Lido (lower side) and Chioggia (upper side) to PC1 wind velocity classes. Dashed lines show the model fitted to the data. The negative region in PC1 is where actual Bora events are detected. Positive currents mean outflowing from the lagoon.

Results

Overall linear correlation between residual currents is low, on the order of 0,4 in magnitude; but they increase until 0,7 in absolute values during specific events of Bora and Sirocco blowing. The connection is specifically stronger between PC1 and Lido as well as PC1 and Chioggia, but in opposite sense: a Bora event would lead to a stronger inflow of water through the northern Lido channel but reinforcing the out flowing through Chioggia channel in the southern part of the lagoon, with Malamocco showing no significant response at all. Chioggia inlet flow shows also a response to PC2 winds, especially during Sirocco event which slows down the residual out flowing in the inlet. A partition of wind components were done, defining a calm state between -3m/s and 3m/s. Other partition limits being +/-5m/s, +/-10m/s, +/-15m/s and +/-20 m/s. Thus, the effect of PC1 is studied while forcing a calm state on PC2; conversely, PC1 is conditioned to the calm state to study the PC2 effects. It has been found that the flow of Lido and Chioggia inlets has an exponential response to the PC1 wind velocity classes with exponential rates of b = -0,1 following the model Y = A.exp(b.PC1) where A is -0,021 for Lido and 0,033 for Chioggia (Fig. 1). Likewise, the response of Chioggia to PC2 wind velocity classes has a linear fashion Y = a.PC2 + b with a = -0,0036 and b = 0,03844 (Fig. 2). The explained variance is over 96% in each case.

Fig. 2. Linear response of Chioggia residual flow to PC2 wind velocity classes. Dashed line shows the model fitted to data. Lido and Malamocco show no response until PC2 reaches a 15m/s or higher velocity, when the residual flow in Chioggia inlet change its sign. The positive region in PC2 is where actual Sirocco events are detected.

STORM SURGE VARIATIONS IN THE MEDITERRANEAN SEA UNDER CLIMATE CHANGE SCENARIOS

M. Marcos¹, G. Jordà¹, D. Gomis^{1*}, F. M. Calafat¹ and E. Alvarez - Fanjul² IMEDEA (CSIC-UIB), Esporles, Spain - damia.gomis@uib.es ² Puertos del Estado, Madrid, Spain

Abstract

A 2D ocean numerical model covering the Mediterranean Sea and the NE Atlantic sector has been forced by atmospheric pressure and wind fields generated by dynamical downscaling over the European region that follow three climate change scenarios (A2, A1B and B1). The variability of the obtained atmospherically-induced sea level has been compared among scenarios and with a re-analysis of the period 1960-2000 carried out with the same numerical model. The analysis presented here focuses on the changes in the decadal variability of mean sea level and in sea level extremes projected for the 21st century Keywords: Air-Sea Interactions, Sea Level

Sea level is an important parameter for coastal habitats and infrastructures and has been recognized as a key indicator of global climate change. During the last vears there has been a growing interest among the scientific community in understanding sea level changes, given the impact that sea level rise may have in coastal and highly populated areas. Global sea level rise during the 20th century has been estimated in 1.8 mm/yr [1], while in the Mediterranean coastal sea level derived from the longest tide gauges indicates a rate of sea level rise of 1.1-1.3 mm/yr [2]. In a world with a higher mean sea level, high waters caused by storm surges will have increasing hazardous impacts on coastal areas. However, while projections of climate models mostly agree and predict a continuous increase in mean sea level in many parts of the globe during the 21st century, no consensus has been reached in respect to the changes in storminess [1]. This work aims at obtaining regional projections of storm surges in the Mediterranean Sea and the adjacent NE Atlantic area for the 21st century under different climate change scenarios on the basis of regional atmospheric and oceanic numerical models. Extreme sea level events are commonly driven by the combination of tidal elevation and storm surges. However, the non-linear interaction between tides and surges in the Mediterranean is negligible and can thus be ignored [3] Therefore we will concern ourselves only with the storm surges component. High frequency (6h) atmospheric pressure and wind fields are obtained as the output of a global atmospheric model with variable-resolution (50 km over the Mediterranean [4]). The atmospheric model is run for the period 2000-2100 forced by greenhouse gases (GHG) and aerosols concentrations following the A2, A1B and B1 SRES scenarios. Two more runs have been carried out for the period 1960-2000. One was forced by observed GHG and aerosols concentrations (the control run). The second is a dynamical downscaling of ERA-40 reanalysis fields. The atmospheric fields are used to force the oceanic barotropic model HAMSOM over the area 30°N to 47°N and 12°W to 35°E, which covers the Mediterranean Sea and the NE Atlantic adjacent sector with a spatial resolution of 1/4°x1/6°. Mean values and decadal variability of atmospherically-induced sea level will be examined and compared between the different runs for the 21st century and with the results obtained for the 20th century. The hourly outputs will be used to explore the changes in the magnitude and frequency of extreme sea level events under climate change scenarios.

THE SST MULTI-DECADAL VARIABILITY IN THE ATLANTIC-MEDITERRANEAN REGION

Salvatore Marullo ¹*, Vincenzo Artale ¹ and Rosalia Santoleri ² ¹ ENEA - CR Frascati (Italy) - salvatore.marullo@enea.it ² CNR-ISAC, Roma (Italy)

Abstract

The multi-decadal variability of the Mediterranean Sea Surface Temperature (SST) field is analyzed using different datasets. The analysis of the Mediterranean SST revealed the presence of an evident oscillation of about 70 years. The same oscillation was found only in the North Atlantic Ocean and corresponds to Atlantic Multidecadal Oscillation (AMO). Singular Spectral Analysis and MTM applied to Mediterranean and Atlantic quantitatively confirmed the importance of this oscillation. The analysis of the correlation between SST and NAOI (North Atlantic Oscillation Index) suggests the importance of the external atmospheric forcing for most of the last 150 years.

Keywords: Temperature, Surface Waters, Open Sea, Global Change

Data and Methods

In this work we used the Extended Reconstructed SST (ERSST.v3) dataset (1854-present, monthly, 2 deg spatial resolution) [1] and the Hadley Centre Sea Ice and Sea Surface Temperature (HadISST) dataset (1870-present, monthly, 1 deg spatial resolution) [2] and we analyzed the consistency between the two datasets. At global level, when yearly averages are considered, seasonal or spatial discrepancies between ERSST.v3 and HadISST tend to compensate and the two datasets exhibit similar behaviors. The relatively high abundance of data in the Mediterranean Sea, allow us to produce a new estimate (MArtaS) of the mean monthly sea surface temperature of the Mediterranean Sea using only ICOADS (International Comprehensive Ocean-Atmosphere Data Set) SSTs. MArtaS (Marullo-ARTAle-Santoleri) is based on a simple space average of the available monthly data introducing a correction factor F that takes into account the presence of data voids for each specific month of the year. In spite of its crudeness MArtaS, that is not based on interpolated data, follow quite closely the other two series with differences that rarely exceed 0.1°C. The agreement between the two interpolated SST series (ERSST.v3, HadISST) and the non interpolated one (MArtaS) suggests that dumping or other possible distortions due to the interpolation are not dominant in the Mediterranean basin when yearly averages are used. On the contrary, when monthly means are used, the difference between two interpolated data sets became larger exhibiting a marked annual cycle with an amplitude of about 0.8 °C.

Spectral Analysis, Correlations and NAOI

In order to obtain the signal to noise separation we computed the eigenvalues spectrum of the SST time series using Singular Spectral Analysis (SSA). The first two leading EOFs, that explain about 40% of the total variance and capture the low frequency variability of the SST, have approximately the same amplitude (considering the range of error bars) and are in quadrature. This fact could be interpreted as the occurrence of a ghost limit cycle related to a physical oscillation of the dynamical system that has generated the SST time series [3]. The low frequency variability of the Mediterranean was also investigated applying the Multi Taper Method (MTM) to the de-trended yearly SST. The Multitaper method is a technique developed by D.J. Thomson [4] to estimate the power spectrum of a stationary ergodic finitevariance random process. This method provides useful tools for the spectral estimation of a relatively short time series whose spectrum may contain both broadband and line components. The F-test criterion for harmonic signals yields 6 peaks at the 99% confidence level and 10 peaks at the 95% confidence level that can eventually be associated to some harmonic, phasecoherent oscillation. Peaks at 73, 6.3, and 2.8 years exceed the 99% confidence level in the harmonic test and correspond to significant spectral bands in the power spectrum. The higher frequency peaks are very close to the preferred scale of variability of the ENSO's quasi-biennial and low-frequency modes while the lower frequency one is very similar to the AMO (Atlantic Multidecadal Oscillation). Similar peaks are also observed in the North Atlantic ocean. The evidence that both North Atlantic ocean and Mediterranean Sea exhibit the same multi-decadal climate cycle suggests the occurrence of a common external forcing, likely of atmospheric origin, probably coupled with some internal oscillation[5]. Correlation analysis between NAOI [6] and SST in the Mediterranean and Atlantic Ocean reveals that NAOI is significantly (90%) negatively correlated with SST only in the Eastern Mediterranean Sea (only during Winter), and in the two centers of the NAOI (during the four seasons): The tropical Atlantic and the sub-polar gyre area.

HIGH RESOLUTION GLIDER MEASUREMENTS AROUND THE VERCELLI SEAMOUNT (TYRRHENIAN SEA) IN MAY 2009

E. Mauri ^{1*}, G. Bolzon ¹, A. Bubbi ¹, F. Brunetti ¹, R. Gerin ¹, N. Medeot ¹, R. Nair ¹, S. Salon ¹ and P. Poulain ¹ ¹ Istituto Nazionale di Oceanografia e Geofisica Sperimentale (OGS), Trieste, Italy - emauri@inogs.it

Abstract

Physical and bio-chemical characteristics of the upper water column in the vicinity of the Vercelli Seamount were studied from the 23rd to the 30th of May 2009 using a Slocum shallow battery-powered glider. In addition to mesoscale and sub-mesoscale structures crossed by the glider, the near-surface water properties changed abruptly on the 27th of May under the influence of a cold near-surface plume originating from the Strait of Bonifacio and triggered by Mistral winds. *Keywords: Tyrrhenian Se, Surface Waters*

Introduction

The "Tyrrhenian Seamounts Ecosystems: an Integrated Study" (TySEc) experiment took place in the Tyrrhenian Sea in late Spring 2009 with the aim of studying the geomorphologic characteristics and the hydrodynamics of the area over and around a seamount. Seamounts are sites of high productivity with coexisting biocenosis in a relative limited space, moreover they represent 'stopping stations' in the benthonic dispersion processes. Their importance on the ecology of the marine environment and of their high level of vulnerability to the global climate change represents an interesting subject in different international projects.

As part of the TySEc experiment, the "Trieste-1" glider was operated in an area of roughly 750 km² over the Vercelli Seamount (Figure 1) for a period of about 8 days (from the 23rd to the 31st of May). The seamount is located in the northern Tyrrhenian Sea, (41°05' N / 10°53' E), and its summit reaches 55 m below the sea surface. The glider was configured to provide oceanographic data during the ascending phase of the saw-tooth path, every 0.75 km. During the entire campaign 300 profiles between 4 and 180 m depth were acquired, providing temperature, salinity, oxygen, fluorescence, and turbidity data.

Fig. 1. Details of the glider track overlaid on the bathymetry showing the Vercelli Sea mount.

Results

A shallow (5-10 m deep) mixed-layer with maximum temperature of 23° C was present until the 27^{th} of May, when the temperature at the surface abruptly decreased to 21° C and the mixed layer deepened to over 15 m (Figure 2). Satellite sea surface temperature images and sea level anomaly maps reveal that this change corresponds to the expansion/intrusion of a relatively cold near-surface plume originating from the Strait of Bonifacio (between Corsica and Sardinia). Due to sustained Mistral winds, there is an increase of the double gyre structure associated with the plume. In particular, the southern anticyclonic gyre strengthen on the 27^{th} of May, advecting cold water which reaches the study area.

Fig. 2. Contour plot of the temperature (°C) along the glider track between 4 and 20 m.

The salinity which was essentially minimal (around 37.7) near the surface before the 27th of May, increases to 38.0-38.1 in the surface mixed layer, while a layer with minimum salinity develops near the base of the mixed layer (10-20 m). Contemporarily the dissolved oxygen maximum deepens from the surface to the base of the mixed layer (10-20 m). In addition to the above evolution of the water mass properties, high frequency (with periods of 0.5 day or less) variations are ubiquitous and are mostly apparent near the base of the mixed layer. They correspond to mesoscale and sub-mesoscale structures crossed by the glider and to tidal/internal waves. Below the mixed layer, the salinity and oxygen distributions show correlated structures (high salinity corresponding to low oxygen) all the way down to 180 m. A sub-surface maximum in chlorophyll concentration and turbidity is also seen between 60 and 80 m. Apparently the Vercelli Seamount has little effect on the water properties measured by the glider.

The "Trieste-1" glider is involved in the DORII project (Development of Remote Instrumentation Infrastructure) whose objective is the integration of observations and model simulations in the Grid. DORII e-Infrastructure is based on the concept of instrument element, that virtualized an instrument within the Grid. More generally, a computational Grid is a hardware and software infrastructure that provides dependable, consistent, pervasive, and inexpensive access to high-end computational capabilities [1].

MULTI-SENSOR SATELLITE TIME SERIES OF OPTICAL PROPERTIES AND CHLOROPHYLL A CONCENTRATION IN THE ADRIATIC SEA

F. Mélin¹*, J. Berthon¹, M. Clerici¹, D. D'alimonte², V. Vantrepotte¹ and G. Zibordi¹

Abstract

Advanced remote sensing techniques and algorithms are combined to produce and analyse an improved 12-year multi-sensor time series of bio-optical properties for the Adriatic Sea. First, a multi-sensor series of normalized water-leaving radiance is created with an optically-based merging technique applied to SeaWiFS and MODIS data. Then, two empirical algorithms, embedded in a dynamic algorithm selection scheme, serve to compute the concentration of chlorophyll a (Chla), and distributions of inherent optical properties are obtained with a semi-analytical bio-optical model.

Keywords: Adriatic Sea, Ocean Colours, Remote Sensing, Chlorophyll-a

Introduction

The potential of satellite ocean colour for monitoring and studying marine ecosystems could be better exploited in coastal and marginal seas if the uncertainties associated with satellite products could be reduced. Moreover, the creation of a long-term satellite data record needs to address the combination of satellite products derived from different space missions. This work aims at generating and presenting a time series of improved qualityassessed bio-optical products for the Adriatic Sea using advanced remote sensing techniques and specific algorithms.

Satellite Data Merging

Building on previous work [1, 2], an optically-based technique is proposed to merge L_{WN} from SeaWiFS and MODIS by averaging sensor-specific values after wavelength differences are corrected by a band-shift correction scheme. The resulting 12-year series of L_{WN} serves to generate derived products of optically signifiant constituents. Field measurements collected at the Acqua Alta Oceanographic Tower (AAOT) located in the North Adriatic [3] provide a unique data set for validation of the merged L_{WN} . Uncertainty estimates decrease from 28% at 412 nm to 10% between 490 and 555 nm.

Development of Derived Products

A single empirical algorithm for calculating Chla is unlikely to produce a data set with a consistent level of uncertainty across the optical diversity of the Adriatic basin. The approach adopted here, based on the novelty detection technique [4], is to distinguish two dominant water types, representing offshore waters (Class 1) and coastal regions (Class 2), and dynamically blend the outputs from the associated algorithms [5, 6] according to the probability of the input L_{WN} of belonging to a specific optical class. The optical classes are defined by bio-optical datasets made of globally-distributed measurements representative of offshore clear waters and the data collected at AAOT. The Chla dataset is completed by inherent optical properties obtained with a semi-analytical algorithm [7]. Uncertainties for these optically significant constituents are estimated with field data collected at the AAOT site. For instance, the RMS difference computed for log-transformed Chla amounts to 0.15.

Applications

A 12-year budget shows that 66% and 8% of the basin are classified as Class 1 and 2, respectively. Most of the points that are left un-classified have optical properties located along the gradient (in optical space) between Classes 1 and 2. The areas classified as Class 2 are mostly located in the northwest Adriatic and along the Italian coast. Average values for north, central, and south Adriatic are, respectively, 0.58, 0.21 and 0.18 mg m⁻³ for Chla, 0.023, 0.013 and 0.012 m⁻¹ for phytoplankton absorption at 443 nm, 0.074, 0.040 and 0.035 m⁻¹ for absorption due to chromophoric dissolved organic matter and non-pigmented particles at 443 nm, and 0.0054, 0.0029 and 0.0026 m⁻¹ for particle backscattering at 555 nm. Finally, the temporal variability of the time series is analysed with statistical techniques distinguishing seasonal and trend components [8]. A significant amount of interannual variations are found, particularly in the North and Central Adriatic, with Chla values that tend to be higher at the beginning of the data record.

Conclusion

The Adriatic basin displays a significant diversity in optical water types, and has thus served as a testbed for new approaches. Combining these led to the definition of a multi-sensor 12-year record for optically significant

constituents, particularly a much-improved time series of Chla. The applicability of this framework to other European seas depends on several factors, including the optical properties associated with the considered region, and the in situ data available to statistically model these properties, and the uncertainties associated with the primary ocean colour product that is L_{WN}.

SUBSURFACE (350 M) CIRCULATION IN THE MEDITERRANEAN SEA BASED ON ARGO DATA

Milena Menna^{1*} and Pierre Marie Poulain¹

¹ Istituto nazionale di Oceanografia e di Geofisica Sperimentale- OGS, Sgonico (TS), italy - mmenna@ogs.trieste.it

Abstract

The trajectories of 38 Argo floats, deployed in the Mediterranean Sea between October 2003 and September 2009, are used to create a dataset of velocities at 350 m and to study the subsurface circulation in regions with good data coverage. The float subsurface velocities and the pseudo-Eulerian statistics computed from them show typical circulation pathways, which can be related to the motion of the Levantine Intermediate Water.

Keywords: Intermediate Waters, Currents, Eastern Mediterranean, Western Mediterranean

Among all the floats deployed in the Mediterranean Sea, we have selected 38 instruments according to their cycle characteristics. They were deployed as part of the MFSTEP project in 2003 and are referred to as MedArgo floats. Each float descents from the surface to a programmed parking depth of 350 m, where it remains for about 4 days before reaching the profile depth, that is generally 700 m but extends to 2000 m every ten cycles. At the end of each cycle the float remains for about 6 hours at the sea surface, where it is localised by, and transmit the data to, the Argos satellite system [1].

The Argos positions were used to determine the subsurface currents through three different steps: the first provides rough estimates of subsurface velocities (V_{old}) [2]; the second produces the best surface displacement [3]; the third provides the subsurface displacement (V₃₅₀) that involves the use of the average vertical speed of the float and an approximation of current shear in the upper water column [4]. From the comparison between V_{old} and V₃₅₀ and the results of the statistical analysis computed on V₃₅₀, we select only the best estimates of velocities (variance explained/total variance > 0.8) to produce the final dataset V₃₅₀^{end} (Fig.1) [4].

The V₃₅₀^{end} velocities reach the maximum values of ~ 33 cm/s east of the Balearic Islands and in the Ierapetra Eddy; high speeds (larger then 20 cm/s) are also found in the north and central regions of the Liguro-Provençal-Catalan basin and in some eddies of the Eastern basin, whereas the Liguro-Provençal, Algerian and Libyan-Egyptian Currents are characterised by maximum speeds of 15 cm/s.

The pseudo-Eulerian statistics, computed with V₃₅₀^{end}, show typical circulation pathways related to Mediterranean subsurface currents and to the motion of the Levantine Intermediate Water. In the Western Mediterranean basin, the velocity field reveals the characteristic cyclonic paths in the Tyrrhenian, Liguro-Provençal and Algerian sub-basins, as well as the Algerian and Liguro-Provençal-Catalan currents, where it reaches the maximum intensities (12-14 cm/s). In the southern Ionian Sea, the float velocities show a dominant anticyclonic circulation between 32°-36° N and 16°-20.5° E, in which the southern limb corresponds to a north-westward flow located on the African continental slope. The rest of Eastern Basin is dominated by mesoscale and subbasin scale circulation eddies, with maximum values of mean velocity (~ 12 cm/s) located south of Crete (Ierapetra eddy) and south of Cyprus. All over the Mediterranean Sea the EKE has strong gradients compared to MKE.

In the regions with significant bathymetry gradients, that is mostly along the continental shelf slope, subsurface currents are driven by topography and the along-isobath components of velocity have values larger then the across-isobath components. Speeds have mean values of \sim 5 cm/s and reach 20-27 cm/s east of the Balearic Islands, in the Cretan Passage and in the southern entrance of Tyrrhenian Sea.

ON THE EXTERNAL SEA LEVEL FORCING OF METEOTSUNAMIS AT THE BALEARIC ISLANDS

Sebastian Monserrat^{1*} and Marta Marcos² ¹ Universitat de les Illes Balears, Mallorca, Spain - s.monserrat@uib.es ² Institut Mediterrani d'Estudis Avançats IMEDEA (UIB-CSIC), Mallorca, Spain

Abstract

High frequency sea level observations at four coastal sites are used to examine the external forcing causing significant seiches (meteotsunamis) in certain harbours at the Balearic Islands. Forcing characteristics estimated for different events are different, while for the same events are similar, even for sites located far away from each other. Spectacular similarities are found for two specific sites, Ciutadella (Menorca Island) and Cala Ratjada (Mallorca Island). *Keywords: Mesoscale Phenomena, Coastal Engineering*

High frequency sea level oscillations in bays and harbours, known as seiches, may reach significant amplitudes depending on the external forcing in the open sea and the local topographic response. When resonance occurs, the phenomenon may pose important risks to the infrastructures as well as to the commercial or fishing activities and sometimes even threatening to human lives. When the external forcing responsible of such amplification consists of long waves generated by an atmospheric origin they are referred to as meteotsunamis. Meteotsunamis are similar to ordinary tsunami waves and can produce similar damages at the coast, although the catastrophic effects related to this type of waves are normally observed only in specific bays and inlets. One of the places where meteotsunamis with the largest sea level amplitudes are reported is Ciutadella Harbour, a natural elongated and shallow inlet located in the western coast of Menorca Island (NW Mediterranean, see Figure 1).

Fig. 1. Map of the area and location of the stations.

The phenomenon is locally known as "rissaga" and occurs every year mostly in late spring and summer. Ciutadella seiche has a period of approximately 10.5 minutes and typical background amplitude of few centimetres. Typical rissaga events have amplitude of around 1 m, but they may reach up to 4-5 m through to crest in an average water depth of 5 m in singular episodes. In this paper we analyze a recent set of sea level measurements recorded around de Balearic Islands (Mallorca and Menorca) to characterize large amplitude seiche oscillations at four tide gauge locations (Figure 1). The effects of the local topography and bathymetry are isolated at each site by computing the background spectral content of the sea level oscillations in absence of forcing, that is, for time periods with very small amplitudes inside the inlets. Background spectra strongly vary from one site to another but are approximately independent of time. Then, the average of several background

episodes may be considered as a good proxy for the local resonant response of the given site. The frequency response of the forcing for each episode has been computed as the spectral ratio of the energy content of a seiche event and the background spectra [1]. The more constant is the background spectra for a tide gauge site, the more liable and accurate is the characterization of the external forcing. For all the episodes, the energy content for the external forcing is concentrated in periods between 5 and 50 min at the four sites. Different forcings are found among sites and events, the latter due not only to the amplitude of the incoming waves but also to the inlet orientation and other parameters. It is found that external sea level forcing at CIU and CRA are very similar, although the responses of both inlets differ significantly. The forcing is almost the same for signals with frequencies lower than 30 min⁻¹. For higher frequencies, changes in the travelling atmospheric pressure from Mallorca to Menorca seem to play a major role in the generated sea level oscillations and the obtained sea level forcing is somewhat less coherent, although the magnitude of the energy content is always comparable between the two sites.

Fig. 2. One example of the spectral ratios ("source functions") of daily spectra for the rissaga event of 21-24 June 2007. Black line is the average of the spectral ratio at CIU and CRA.

Therefore, sea level oscillations in CRA could be used as an indication of an incoming rissaga event in CIU and should be used as part of an eventual rissaga warning system designed to mitigate the possible damages inside CIU harbour, maybe as part of the Mediterranean Tsunami Warning System ICG/NEAMTWS.

SPECTRAL SIGNATURES OF PIGMENTS IN THE KAŠTELA BAY

M. Morovic ¹*, M. Kiševic ², A. Smailbegovic ³, V. Flander Putrle ⁴, R. Andricevic ² and B. Grbec ¹ ¹ Institute of Oceanography and Fisheries, Split, Croatia - morovic@izor.hr ² Faculty of civil engineering and architecture, Split, Croatia ³ Charleston College, Charleston, USA ⁴ Marine Biology Institute, Piran, Slovenia

Abstract

Several cruises were performed in the middle Adriatic coastal area (Kaštela Bay) in late spring and early fall 2009 with an hyperspectral sensor and an in-situ optical profiler, accompanied with other oceanographic measurements and measurements of in-situ pigments. Spectral surface signatures revealed a difference between the two optical methods. *Keywords: Adriatic Sea, Ocean Colours, Pigments*

Two kinds of optical measurements were performed at 8 stations in the Croatian Adriatic coast (Figure 1) during three cruises in May and October 2009. Multispectral in-situ irradiances and radiances were measured with a Biospherical optical profiler PRR800 at 14 wavebands (340; 380; 412; 443; 465; 490; 510; 532; 555; 589; 625; 665; 683 and 710nm).

A hyperspectral sensor (ASD FieldSpec® 3 VNIR spectrometer) measured every 3 µm within the range 350-1050nm and was used from the ship, at about two meters above the water surface. A SeaBird CTD profiler measured temperature, salinity and transmission. The measurements were accompanied with the analysis of pigments.

Fig. 1. Location of Kaštela Bay and stations in the eastern Adriatic

During two measurements qualitative and quantitative analyses of 17 different pigments were determined using a reverse-phase HPLC (High Performance Liquid Chromatography) method [1] from water samples filtered through Whatman GF/F filters and frozen until analyzed at -80° C.

The vertical structure of the water column during the cruises was stratified on 26-27 May, with thermocline developed to 7m. In mid October, the thermal structure was homogenous with 20° C temperature reaching the deepest part of the bay (35m). The environment was rather turbid during both measuring periods with transparencies between 11-12m in May and 6-10m in October.

After calculating optically weighted pigments for the surface layer, the spectral absorption curves were reproduced for the main pigments groups. Absorption spectra were digitized and with the use of spectral absorption data available in the literature [2], were normalized to pigment content to yield estimates of specific absorption curves, which were compared to calculated attenuation coefficients and reflectances.

Different in-situ pigment groups have had lesser influence to overall spectral

reflectance curves because of the presence of dominant Chlorophyll type pigments.

Spectral reflectance curves have shown typically one peak in the visible spectrum between 490nm and 555nm, but at some stations, they were sometimes different for the two methods. However, examining the first differences, typically in both methods a distinct peak appeared between 555nm and 589nm (Figure 2). Higher order differences revealed some identical peaks, pointing to the similarity between the two methods.

Fig. 2. Reflectances and first differences at some stations in the Kaštela Bay form optical profiler (full line) and from hyperspectral scanner (dashed line).

Additional analyses have explained to some extent the initial differences between reflectance spectra.

Vertical structures of optically active substances have had higher impact to profiler measurements, while the differences to the measurements from the air could have been caused by the higher sensitivity of the latter to particular conditions at the sea surface. In spite of the difficulties in distinguishing the water column impact and the bottom reflectance in the shallow region, the analysis has shown the potential for mapping of different coastal water types with both methods.

Abstract

The MEDUZA cruises in the south Adriatic Sea have acquired a number of oceanographic data in the deep South Adriatic Pit in summer 2003. Temperature, salinity and dissolved oxygen concentrations, together with transmission, pigments and optical parameters, were measured by two multiprobes in 6-h intervals during several days. Strong quasi-diurnal fluctuations of isothermal depths were observed, being in phase with local sea level, thus indicating internal waves as important phenomenon during this cruise. *Keywords: Adriatic Sea, Temperature, Circulation Models, Stratification*

Although the general oceanography of the South Adriatic Pit is well studied in the past, the lack of high-resolution measurements prevented the investigations of a variety of processes that occur on the hourly timescales. Measurements in the frame of MEDUZA experiment tried to overpass that problem, at least over a local scale, as a large amount of data has been acquired at a single station (Figure 1) in short time intervals (approximately every 6 hours) between 23 and 28 July 2003. The deep sea CTD (Idronaut) multiprobe sampled the whole water column (1200m) once a day, while other measurements were performed with SBE25 multiprobe, reaching a maximum depth of 300m.

Fig. 1. Location of measurement station in the South Adriatic Pit

The cruise started with calm and clear weather, but at the fourth day strong SE wind and high waves prevented measurements for 36 hours, after which the fair conditions continued. Summer conditions in July 2003 were extremely warm and dry [1] with anomalously high air temperatures and low precipitation and runoff discharges. Surface sea temperatures were exceptionally high, reaching 27°C. Salinity was generally high in the whole water column. Thermocline was strongly developed at several tens of meters as expected. Below the thermocline, isothermal layers fluctuated unexpectedly strongly (10 m or even more) between the measurements (Figure 2).

As lower salinity waters have resided above the thermocline, the pycnocline was strengthened by the haline effect. The fluctuations of the pycnocline have a clear resemblance to the internal waves. The type of internal waves is hard to obtain as the measurements were too short, sparely for capturing such waves. However, the sea level fluctuations observed at the Bari and Dubrovnik tide gauges were in phase with the fluctuations. Also, high vertical oscillations in thermal structure were observed especially in deep layers (up to 120 m), pointing to the internal tides as a process that generated the oscillations.

The observed fluctuations were strong in the deep layers and attenuated

towards the surface. Previously, strong isopycnal oscillations on diurnal and

semi-diurnal periods has been found along the South Adriatic Pit northwest perimeter [2], being resonantly amplified by the topography [3]. However,

Fig. 2. Vertical oscillation of isotherms

These vertical fluctuations in the water column impacted a variety of properties from temperature and light transmission to chlorophyll maximum. Changes in optical parameters are known to be caused by depth rearrangement of phytoplankton throughout the day, but the physical processes may be quite important as well. This also applies to the observed daily vertical migration of zooplankton species found to be also remarkable [4], some of these presumably related to physical processes too.

ASPECTS OF THE SURFACE TYRRHENIAN SEA SUMMER CIRCULATION

Ernesto Napolitano^{1*}, Roberto Iacono¹, Salvatore Marullo¹ and Vincenzo Artale¹ ¹ ENEA CR-Casaccia, Rome, Italy - ernesto.napolitano@enea.it

Abstract

A preliminary assessment of the Tyrrhenian Sea surface circulation of summer 2009 is given, based on the results of an operational ocean model, recently developed at ENEA. The numerical simulations reveal a complex circulation structure in the eastern part of the basin, that organizes around several well-defined quasi-permanent gyres. Comparison with altimeter data shows that these gyres are robust features of the summer circulation.

Keywords: Tyrrhenian Se, Models

Introduction

The Tyrrhenian Sea (TS), the main Italian sea, is a deep basin, with complex bathymetry, whose circulation is not yet fully understood. Although local wind forcing certainly plays an important role, the basin dynamics is also affected by the exchanges occurring at the three openings (Sardinia and Sicily Straits, Corsica Channel). In this work, we focus, in particular, on the role of the inflow of Atlantic water (AW) on the surface circulation of the basin. The main tool used is a high-resolution (1/48°, 40 sigma levels) operational model of the TS circulation, developed in the context of the PRIMI Project. This model takes initial and boundary data from MFS [1], and is forced by surface fluxes obtained from ECMWF data.

Results

Figure 1 shows the average 2009 summer surface (at 75 m depth) velocity field resulting from the analyses produced by the operational system, where some well-defined cyclonic and anticyclonic structures have been numbered from 1 to 6. Together with some established patterns, such as the Bonifacio cyclone-antyciclone system, the figure shows some interesting aspects of the circulation that have apparently not been stressed in previous descriptions. The first is the fact that the northward stream of AW entering the basin (known from previous numerical studies, e.g., [2]) bifurcates at about 41° N, with a branch recirculating southward around a very wide cyclonic region (6), and another one circling around the Bonifacio gyre and finally leaving the basin through the Corsica Strait. Contrary to previous descriptions (see, e.g., the classical works [3]), there is no northward AW flow along the Italian coast.

To the east of 6, there is a wide anticyclonic cell that occupies the whole eastern part of the TS, meandering around several well-defined eddies, the cyclone-anticyclone couples 1-2 and 4-5, and the anticyclonic area 3. These structures are present, with some variability, over the whole season. Although recent work suggests a complicated dynamics in the area, this is the first time that such a detailed structure of the circulation has been highlighted. We also note that the anticyclonic structure 1 may be related to the gyres recently described in [4].

Fig. 1. Velocity field at 75 m produced by the operational model (2009 summer average)

The circulation in the eastern TS is probably mostly determined by the interaction between the local wind stress (that is typically anticyclonic in summer) and the complex topography. However, the fact that the western boundary of the anticyclonic cell is adjacent to the northward AW stream that flows through the central part of the basin suggests that this stream may also contribute to the eastern circulation, and to the associated vortical structures, through exchanges of momentum and vorticity.

It is natural to wonder whether the structures simulated by the model during 2009 are robust features of the summer circulation. To give a first answer to this question, we have analysed the SALTO-DUACS altimeter data provided by AVISO (http://www.aviso.oceanobs.com/duacs/), and we show in Figure 2 the summer average of the absolute dynamic topography over the whole period 1993-2008. The comparison seems excellent, since all the main structures appearing in the numerical results have their counterpart in the altimeter map, with close shapes and positions.

Fig. 2. Absolute dynamic topography by AVISO (1993-2008 summer average)

THERMOHALINE CHARACTERISTICS OF THE MEDITERRANEAN DEDUCED FROM ARGO DATA IN 2000-2009 (STATISTICAL ANALYSIS)

Giulio Notarstefano ¹* and Pierre-Marie Poulain ¹

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale- OGS- Trieste, Italy - gnotarstefano@ogs.trieste.it

Abstract

Since 2000, numerous Argo floats have been deployed in the Mediterranean Sea under various programs and by different institutions/countries. Different cycling and sampling characteristics have been chosen to monitor this marginal sea, including cycles of 5 to 10 days, parking depths at 350 m and maximum profiling depths between 700 and 2000 m. This work contains the description of the thermohaline variability obtained using all the historical Argo data in the Mediterranean. The intrinsic variability of the temperature and salinity is described for most of the Mediterranean sub-basins by means of monthly statistics. The temporal decorrelation scales of temperature and salinity following floats are also estimated. *Keywords: Temperature, Salinity*

Data and methods

In total, 88 Argo floats have been operated in the Mediterranean Sea between December 2000 and June 2009 (more than 7700 CTD profiles), out of which 27 correspond to the MFSTEP project [1]. The maximum density of floats was obtained in May 2006 with 31 floats running simultaneously. The following sub-basins were relatively well sampled by the floats: Catalan, Algerian, Ligurian, Tyrrhenian, Ionian, Cretan and Levantine. The Alboran and Aegean seas and the Sicily Channel area have limited Argo data. No data are available in the Adriatic Sea.

Thermohaline characteristics in the Mediterranean sub-basins

The following statistics have been calculated using the above-mentioned Argo data in the Mediterranean sub-basins:

• number of observations, mean and standard deviation of potential temperature (θ) and salinity (S) near 0, 600 and 2000 m;

 \bullet number of observations, mean and standard deviation of θ and S near depth of salinity maximum;

• depth of salinity maximum.

The mean S at the depth of salinity maximum is displayed versus time in Figure 1.

Fig. 1. Monthly mean of S at the salinity maximum in the Mediterranean subbasins between December 2000 and June 2009.

Decorrelation scales of temperature and salinity

The time-lagged auto-correlations of θ and S at selected depths were calculated to estimate the decorrelation scales following the floats. For each float, a linear trend was removed from the data time series before computing the auto-correlation, in order to have a realistic measure of the data decorrelation. The auto-correlations of θ (Figure 2) and S are computed, by using a time step of 5 days. The Lagrangian integral time scale is computed by integrating to the first zero crossing of the auto-correlation function.

Fig. 2. Auto-correlation of temperature at 600 m versus time lag and integral time scale (vertical bar) for all the floats in the Mediterranean (trend is removed from the time series before computing the correlation).

Conclusions

Using the Argo data in the Mediterranean between December 2000 and June 2009, we have shown that:

• the Levantine sub-basin is in general the most populated with data spanning continuously between June 2001 and June 2009;

• the potential temperature exhibits a seasonal cycle near the surface in all the sub-basins, as well as the salinity in the Cretan and Levantine sub-basins;

• the characteristics of the temporal evolution of potential temperature and salinity at 600 and 2000 m show that the sub-basins can be mainly grouped in western and eastern sub-basins;

• trends are evident in the time series of monthly averaged temperature and salinity for some sub-basins, but their interpretation should be very cautious due to the non-uniform sampling of the floats, both in space and time;

• at 600 m the correlation coefficient for the potential temperature decreases to 0.84 after 5 days, and to 0.75 after 10 days. The zero-crossing occurs after about 140 days, whereas the Lagrangian integral time scale is about 60 days.

EXTREME CONDITIONS IN THE STRAIT OF ISTANBUL (BOSPHORUS)

E. Okus ¹, H. Altiok ^{1*}, A. A. Yilmaz ², S. Ovez ³, S. Tas ¹, N. Kiratli ¹, A. Yuksek ¹, N. Yilmaz ¹, A. E. Muftuoglu ¹ and H. I. Sur ¹

Abstract

The extreme conditions in the Strait of Istanbul are investigated based on observation of the chemical and bacteriological parameters together with hydrographic and current measurements. The upper and lower layer blockages occurred in 2003 at the strait which has a maximal exchange flow system. The distributions of the fecal coliform, nutrients, total suspended solids and dissolved oxygen along the strait during the blocking events indicate the behavior of the materials and its transportation in the strait. *Keywords: Bosphorus, Nutrients, Bacteria, Hydrography*

The Strait of Istanbul (Bosphorus) is a narrow, long and shallow channel which connects the Marmara Sea and the Black Sea. It has a two-layer exchange flow system. The upper layer with ~18 psu flows from the Black Sea and the lower layer with ~38 psu flows from the Sea of Marmara [1, 2]. The average volume fluxes of the layers (600 km³year⁻¹ in the upper layer, 300 km³/year⁻¹ in the lower layer) were calculated in terms of the salt and water budget of the Turkish Sea Straits [1, 3]. However, instant measurements of the volume fluxes change in a wide range since atmospheric conditions determine the flow exchange [4]. Blocking of the upper or lower layer are the extreme conditions in the strait. In this study both types of extreme conditions in the strait are presented. The two layer exchange flow in the Strait of Istanbul plays an important role on the environmental problem in the region. The discharge of waste water from the city of Istanbul has been eliminated by taking advantage of the strait flow structure. The volume fluxes and transport of materials between the Black Sea and the Sea of Marmara and renewal time of water and material in these seas mainly depend on exchange characteristics in the strait. Reliable estimates of these exchanges can be made only from data collected systematically and in a long term period including extreme conditions in the region.

The CTD (conductivity temperature depth) and ADCP (acoustic doppler current profiler) data were collected in the Strait of Istanbul in February and October 2003 by R/V ARAR of the Istanbul University, Institute of Marine Science and Management (IMSM-IU) The seawater samples were pretreated with persulphate digestion and analyzed by autoanalyser for total nitrogen (TN) and total phosphorus (TP) [5]. Among the bacteriological indicators of pollution, fecal coliform (FC) was studied by membrane filtration technique [6].

The lower layer blockage occurred in February 2003 when the strong northerly winds blew during several days (Figure 1). In the northern exit of the strait temperature and salinity were almost constant in the water column and its current directed to the south. The dissolved oxygen (DO) and total suspended solid (TSS) values were also homogenous throughout the surface to the bottom. Although the total nitrogen, total phosphorus and FC generally increased with depth till bottom due to the continuous deep discharge flow at the Strait of Istanbul [7], the vertical profile of the nutrients and FC were homogenous through the water column and bottom values were close to surface values during the lower current blockage. In the southern exit of the strait, the lower layer detected several meters in the bottom. Therefore, the deep discharge was blocked at the southern exit of the strait and could not reach to the northern exit during the lower layer blockage.

The upper layer blockage occurred in October 2003 when the strong southerly winds were dominant (Figure 1). Although salinity profiles at both exit of the strait indicated two-layer structure the current directions of the water column were the same in these two layers. Moreover the interface between the two layers was very thick and it was located upper depth along the strait. The bottom values of DO, TSS, TN, TP and fecal coliform were higher than the normal conditions and the beginning of the increase was above the halocline, primarily controlled by the velocity of the current flow during the upper layer blockage.

The blocking of the current flow is an extreme condition for the strait hydrography. The lower layer blockage is critical since the deep discharges given to the lower layer current flow are also blocked and the discharge diffuses to a larger zone in the water column, which might also affect the surface water quality. However, these extreme conditions instantly develop during strong meteorological events such as persistent northern winds encompassing rather small period of the whole year.

Fig. 1. Lower and upper layers blockage

EFFECTS OF THE ASSIMILATION OF SEA LEVEL ANOMALY IN THE SICILY CHANNEL REGIONAL MODEL

Antonio Olita¹*, Roberto Sorgente¹, Leopoldo Fazioli¹ and Alberto Ribotti¹

¹ CNR-IAMC U.O.S. di Oristano, Loc. Sa Mardini Torregrande(OR), Italy - a.olita@iamc.cnr.it

Abstract

Analyses assimilating remotely sensed sea level anomaly observations have been performed in the Sicily Channel for 2008 using a 3D eddy-resolving regional model. The output fields have been compared with those of a free run covering the same period. As expected the assimilation has a substantial effect on the spatial features produced. The root-mean-square difference map puts in evidence the areas where assimilation has larger influence.

Keywords: Circulation, Models, Sea Level

Preface

Operational oceanography systems encompass three main components: systematical observational data, numerical models, and robust data assimilation modules. The Sicily Channel Regional Model (SCRM), a nested eddy-resolving 3D model based on Princeton Ocean Model and developed during the Mediterranean Forecasting System projects, is the core of the system. Seasonal variability [1], inter-annual variability [2], and forecasting skills [3] have been verified in recent studies by means of the synergistic use of SCRM fields and observations. In order to provide the best estimate of the sea true state, the assimilation of along track sea level anomalies (SLA) has been implemented in the system. Two experiments, A1 (analysis) and A2 (free run), respectively with and without the assimilation of SLA, have been conducted simulating the year 2008.

Model setup

SCRM is driven at the surface by momentum, heat and water fluxes computed through the 6-hourly atmospheric fields (mean sea level pressure, air temperature at 2m, wind speed and direction at 10 m and cloud cover) by using the well known bulk formulae [4]. At the open boundaries, SCRM is nested with the coarse model MFS1671 [5] through an off-line one way nesting technique of the analyses daily mean fields of temperature, salinity and total velocity. The data assimilation software used is based on a 3D Variational scheme (OceanVAR) [6]. Vertical background error covariance is represented through Empirical Orthogonal Functions (EOFs), computed from the model outputs of a previous long-term simulation. Only the most significant EOFs are used. Horizontal covariance is modeled as a Gaussian function. The state vector contains all the state model variables (temperature, salinity, free surface elevation, velocity components), so the corrections are performed on all these variables. The 3D-VAR scheme finds its solution minimizing a cost function. The assimilated data is the Along Track Sea Level Anomaly (SLA) from Jason-1 satellite.

Fig. 1. Free surface elevation RMSD between experiments A1 and A2

Results

The Root Mean Square Difference (RMSD) time series of the free surface elevation shows the evolution of the SLA assimilation effects in time. A two months initial divergence of the two solutions is evident, during which the RMSD progressively increases. After this initial period the surface elevation RMSD ranges between 0.6 and 1 cm. Differences between the two experiments A1 and A2 are better evident by considering the variability of the

spatial features produced. An useful way to locate the areas where the assimilation has a larger impact is representing the RMSD map of the surface elevation (Fig.2). Largest values of RMSD (2.5 cm) are found in the area off the Lybian coast, in the Ionian Sea and between Sardinia and Corsica.

Fig. 2. RMSE map of the free surface elevation between experiments A1 and A2. Tracks of the assimilated SLA observations are also shown.

Final Remarks

Remotely sensed observations of sea-level anomaly have been assimilated into the SCRM by using a 3D Variational scheme. The system has been applied in a numerical experiment to examine the effects of the assimilation scheme. Changes observed in the surface elevation fields have a patchy distribution, which in first instance was found correlated to the presence/number of assimilated observations. The effects of such changes on surface circulation should be deeply investigated.

INVERTED BAROMETER OVERSHOOT AND GREAT ADRIATIC SURGE OF 21 JUNE 1978

Mirko Orlic^{1*}, Danijel Belusic¹, Ivica Janekovic² and Miroslava Pasaric¹

¹ University of Zagreb, Faculty of Science, Andrija Mohorovicic Geophysical Institute, Zagreb, Croatia - orlic@olimp.irb.hr ² Rudjer Boskovic Institute, Center for Marine and Environmental Research, Zagreb, Croatia

Abstract

On the morning of 21 June 1978 exceptional sea-level oscillations, having a trough-to-crest height of 6 m and a period of 10-20 min, occurred in Vela Luka Bay. Slightly less pronounced variability was observed elsewhere along the east Adriatic coast and, with some delay, along the west coast. In this presentation one of the hypotheses put forward to interpret the event, the one relating it to a mesoscale air-pressure disturbance, is supported by results of the analysis of all the available data and of the runs performed with the state-of-the-art meteorological and oceanographic models.

Keywords: Adriatic Sea, Air-Sea Interactions, Coastal Models, Sea Level

On the morning of 21 June 1978 a tsunami-like event occurred in the Adriatic Sea. With the trough-to-crest height reaching 6 m in Vela Luka Bay on the Island of Korcula and exceeding 1 m in a number of places along both the east and west coasts of the Middle and South Adriatic, this was the most pronounced such event observed in the Adriatic in the 20th century. There were no casualties in Vela Luka, but the town was so heavily damaged that the state of emergency had to be proclaimed. The event was extensively commented in contemporary newspapers, along with the fact that it did not correspond with an equally dramatic process in either the atmosphere above the Adriatic at the time, but although some of them did record intensified high-frequency variability, none was exposed to one of the sea-level maxima.

In the years following the event four different hypotheses on the generating mechanism have been proposed, with two of them finding the cause at the sea bottom and two in the atmosphere. The four hypotheses shared a common weakness: explanations of the relationship between the cause (earthquakerelated bottom movement, landslide, cvclone, or atmospheric gravity wave) and the consequence (surge) were not supported by a proper modeling. In this presentation one of the hypotheses, the one relating it to a mesoscale airpressure disturbance [1], is reconsidered by using all the available data as well as the state-of-the-art meteorological and oceanographic models. Careful analysis of the sea-level observations and measurements reveals that the sealevel heights at the east Adriatic coast were much larger than at the west coast and that the west coast oscillations mostly lagged behind the east coast variability [2]. A fresh look at the air-pressure data confirms the previous finding according to which a mesoscale atmospheric disturbance propagated at about 22 m/s in a northeastward direction above the area affected by surging, and also enables various timing errors in barograph records to be taken into account. Additionally, an analysis of a simultaneous wind record reveals that the disturbance lasted about 10 min.

The meteorological model employed (WRF-ARW) proves unable to reproduce the mesoscale disturbance coinciding with the surge, but shows that the background atmospheric conditions were favorable for the development of such disturbances. The oceanographic model ADCIRC-2DDI, forced by the air-pressure disturbance characterized by a 3 mbar increase, the shape of a boxcar function, and the other parameters as stated above, successfully reproduces sea-level variability in Vela Luka Bay reaching a few meters and thus surpassing the inverted barometer response by two orders of magnitude.

The enhancement appears to result from a four-phase process: (1) the airpressure disturbance travels from the west Adriatic coast to the mouth of Vela Luka Bay and generates a pronounced wave packet in the sea due to the speed of the forcing disturbance being close to the speed of shallow-water waves, (2) leading waves in the packet enter the bay and are amplified due to the funnelshaped form of the basin, (3) the waves are reflected at the bay head, and (4) the waves return to the bay mouth, are partially reflected there, and are constructively superimposed on the waves entering the bay from the open sea. The model also suggests that elsewhere in the Adriatic the conditions were not so close to the resonant ones as in Vela Luka Bay and that the scattering due to variable bathymetry and reflection from the east Adriatic coast resulted in waves that returned towards the west coast and generated considerable sea-level activity there. Comparison of the empirical sea levels with the modeled values carried out for the whole area strongly supports the rather weak mesoscale atmospheric disturbance as an adequate forcing agent.

The present interpretation of the Vela Luka surge of 1978 invokes only the

ray theory and therefore departs somewhat from the interpretation of other similar Adriatic events, e.g. those observed in Stari Grad and Mali Ston Bays in 2003 [3] and on the Island of Ist in 2007 [4], that was based on the ray theory in the open sea combined with the mode theory in the coastal basins.

A MOORED PROFILER FOR OCEANOGRAPHIC RESEARCH AND ENVIRONMENTAL MONITORING

Alexander G. Ostrovskii¹ and Andrey G. Zatsepin¹*

¹ P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Nakhimovsky Pr. 36, Moscow 117997, Russia -

Abstract

This presentation concerns the research and development of the ocean moored profiler Aqualog. This technique allows a user to obtain regular time series of oceanographic data at fixed geographical location by using conventional oceanographic probes, which are transported by a special carrier that moves vertically between surface and bottom of the sea. *Keywords: Monitoring, Currents, Deep Waters*

A moored profiler is a useful tool for multidisciplinary investigations such as water exchange and deep current structure. In the framework of conducting oceanographic research the profiler is a useful tool for field investigations of the variability of both biotic and abiotic parameters of the sea environment from a few hours to a few months. The estimation of the short-period variability and its impact on the generation of mixing is possible on the basis of regular probing during a sufficiently long time. To assess the dynamics of barotropic and baroclinic waves, eddies and wave-eddy structures and their role in the water transfer and exchange, it is necessary to observe the spatial peculiarities of hydrophysical parameters. This makes it necessary to conduct simultaneous probing by a set of profilers in a number of sea locations. Finally, a topical task is revealing climate signals in multi-year series of oceanographic data at fixed locations in sea basins. To achieve these objectives it is important to get regular and homogeneous ensembles of the observational data.

A new moored profiler named Aqualog was designed in P.P. Shirshov Institute of Oceanology in 2005-2009 (Fig. 1). It was tested at field trials in the Black Sea and the Caspian Sea. The profiler is built to carry a load of modern oceanographic instruments. It moves down and up along the mooring line as a sea 'lift' carrying various instruments including FSI Excell 2" Micro CTD probe, Nortek Aquadopp current meter, and AANDERAA Oxygen Optode 4330F. The payload of this sea elevator may also comprise other environmental probes e.g., fluorimeter and turbidimeter. The profiler mooring line is made of stainless steel wire that allows a user to extend the maintenance period of the mooring system up to several months. The programmable hardware of the profiler allows to set up an automatic operation algorithm (variable movement speed, time and period of the profiling, etc.).

Fig. 1. The profiler in the Black Sea waters. The profiler is photographed from above under a movement limiter at a depth of approximately 7 m right before another downward/upward profiling cycle. The vertically stretched mooring line is passed through the drive-wheel on the profiler. In the upper right part of the profiler an acoustic Doppler current meter Nortek Aquadopp is shown.

So far the typical depth range of Aqualog's operation was 5–600 m. With a titanium instrument housing the maximum operation depth reaches out to 3000 m. Vertical speed can be set up within 0.05 and 0.3 m/s. The payload is up to 4 instruments; 1 slot is available for mounting an optional ocean probe. Weight in the air is 62 kg without the sensors or up to 75 kg with the sensors. Start and stop is by magnetic switch or as preprogrammed. There is a light indication of the system status. The total profiling distance is about 800 km in still waters for the profiler with lithium battery pack. The Aqualog has an energy resource sufficient for profiling the water column in the programming regime for up to several months.

The custom measurement instruments are high-precision, stable and fastresponse. When the carrier is moving with the speed of 0.1 m/s the vertical profiles are measured with a vertical resolution of 0.05 m for pressure, conductivity and temperature (FSI Exell 2" Micro CTD), 0.6 m for the current speed (Nortek Aquadopp) and 0.8 m for the dissolved oxygen (AANDERAA Oxygen Optode 4330F).

The Aqualog was successfully tested during expeditions into the Black and Caspian Seas in 2005-2009. By using the Aqualog new data was obtained about inertial oscillations, mesoscale variability, and vertical exchange in the coastal waters. Over the north-eastern Black Sea shelf, the depth of the seasonal thermocline, the vertical gradient of density driven by temperature distribution and the current velocity gradient in the thermocline as well as the vertical exchange coefficient, all are substantially modulated by inertial oscillations and mesoscale vortices. Moored autonomous profiling stations located at a fixed geographical point represent the most preferable technical means for regional marine environmental monitoring. A moored profiler station inhibits a smaller risk of loss and facilitates technical services including power batteries and maintenance of the sensors.

OPERATIONAL FORECASTING FOR THE NORTHERN LEVANTINE, BLACK SEA AND THE TURKISH STRAITS SYSTEM: PROBLEMS AND PROSPECTS

Emin Özsoy¹*, Adil Sözer¹, Hazem Nagy¹ and Murat Gündüz¹

¹ Institute of Marine Sciences, Middle East Technical University, Mersin, Turkey - ozsoy@ims.metu.edu.tr

Abstract

Operational coastal ocean forecasts are developed for the seas encircling the Anatolian peninsula (Turkey) includig the northern Levantine Sea, Black Sea and the Turkish Straits System (TSS). An observing system of real-time coastal measurements has also been developed. Operational coupled ecosystem models are also aimed, with encouraging first results. The observational system consists of coastal sea-level and meteorological stations and an ADCP system in the Bosphorus Strait. The problems and prospects of forecasting and experiences to date are described.

Keywords: Straits And Channels, Black Sea

Coastal ocean forecasts for the northern Levantine Sea have been developed, and have been operational since 2005, driven by high resolution atmospheric forcing and nested in the MFS (Mediterranean Forecasting System) regional forecast models [1]. The model has a horizontal resolution of 1.35 km and 28 vertical sigma levels. Recently the forecast modelling has been updated to include the effects of major rivers in the Cilician basin of the northeastern Levantine, supplying the main fresh water inputs to the region, contributing significantly more than the present discharge of the Nile river into the Levantine Sea. Mersin Bay and Iskenderun Gulf, connected through a wide shelf region in the northeastern corner of the Levantine Sea alone receive most of the fresh water, therefore making it a region of freshwater influence (ROFI). On the other hand, the westerly flowing Asia Minor current is an often unstable jet that meanders and sheds eddies in the northern Levantine, and especially in the Cilician Basin, connected to the shelf that receives large amounts of fresh water, which are then dispersed by the eddies and meanders. Satellite data display the influence region of the dispersion pattern. A deep current, underlying the Asia Minor current, is generated along the steep shelf region to the west as the flow over the sill between the Cypriot and Turkish coasts induces an overflow that yeers to the north, steered by the slope topography. Levantine Intermediate Water formation, also observed in continuing experimental programs, has been captured in the forecasts in several early spring cases. Convective mixing in the shallow shelf area of the Mersin Bay and Iskenderun Gulf preceeds the leakage of this water first to the west and later to greater depths. The construction of an operational coupled ecosystem model has been tested with promising first results, but presently remains somewhat prohibitive in terms of computer runtime requirements.

Fig. 1. Forecast sea surface temperature and currents at 90 hrs after 1st of January 2010, northern Levantine sea.

Operational forecasts have been developed for the entire Black Sea, using high resolution surface atmospheric fluxes of mass, momentum and heat, as well as the monthly fresh water fluxes of the major Black Sea rivers that dominate the behaviour of the system. Annual mean fluxes are specified at the Bosphorus with time relaxation. The model has a horizontal resolution of 2.5 km and 30 vertical sigma levels. The main double-gyre circulation of the Black Sea, the 'im-current' structure, and major semi-permanent features such as the 'Sevastopol eddy' are well represented. The spreading of fresh water from the large rivers of the northwest shelf, primarily affects the shelf region, but also spreads to other parts of the Black Sea with the rim current.

Fig. 2. Black Sea operational forecast for 1 December 2009.

The implementation of an operational model for the Turkish Straits is a formidable task, because of the major problems of multi-scale coupling between different elements of the system and with the adjacent basins. The approach for a first level of understanding has been based on decoupling and studying separate parts, which individually have sufficient complexity. Despite the prohibitive requirements for resolution and physical processes representation, a reasonably resolving model of the Turkish Straits System is also attempted, and has so far yielded promising results.

A coastal observation network consisting of sea-level and surface meteorology sensors at 14 stations along the coasts and an ADCP profiling station in the Bosphorus has been set up to collect real-time data [2]. The system has been operational for about 2 years, and is aimed to complement the forecasting systems.

³ Institut Francais de Recherche pour l'Exploitation de la Mer, BP 70, 29480 Plouzane, France

Abstract

In the framework of the protection and management of coastal waters in the Mediterranean Sea, the city of Marseille (south of France) has been chosen to study the fate of chemical contaminant inputs and its impact over the adjacent marine ecosystems. A numerical tool is developped, based on the coupling of a hydrodynamical model, a sediment model, a biological model and a model of chemical contamination. The present work deals with the validation of the hydrodynamics' compartment by comparisons with observations, which constitutes a prerequisite for the future operational system. *Keywords: Coastal Models, Circulation, Coastal Processes, Gulf Of Lions*

The geomorphology and density of contaminant-generating industries of the city of Marseille is highly representative of large modern mediterranean cities. Marseille was thus chosen as a laboratory area for the development of a numerical tool dedicated to the assessment of the chemical contaminant raw inputs (from city to sea) and exports (from midsea to open sea) from the city. This tool is developed based on the coupling of a hydrodynamical model, a sediment model, a biological model and a model of chemical contamination. The present work deals with the validation of the hydrodynamics' compartment, based on the comparison with data issued from observational networks and campaigns at sea for the years 2007 and 2008.

The high resolution 3D coastal ocean model MARS3D (for 3D hydrodynamic Model for Applications at Regional Scale) has been applied to forecast the oceanic circulation off Marseille from the Rhone river to the Cap Sicié (south of France). For the RHOMA configuration (Fig 1), realistic numerical simulations were performed for the years 2007 and 2008, with forcing by the Rhone river, meteorological fields and by the surrounding general circulation known to be strongly constrained by the Northern Current.

A lot of observations providing the stratification and currents off Marseille were acquired from in situ oceanographic networks and from vessel cruises during the last decade. In order to validate the nested forecasting system, quantitative comparisons between observations and model results were performed. Statistics over long time series of temperature at three moorings (SOMLIT and MEDCHANGE stations) were computed to show the model skills in capturing the monthly to seasonal variability of the thermal structure. This comparison also shows that the model reproduces well the observed features associated with the shelf processes.

In particular, the wind strongly constrains the shelf circulation off Marseille [1] and the model reproduces the cooling of the sea surface waters due to upwelling caused by a wind blowing parallel to the coast when the ocean is stratified (in summer and fall).

During the strong Rhone river discharge of June 2008, we reproduced an intrusion of the Rhone river diluted (low salinity) waters observed into the southern bay of Marseille for several days under westerlies and south-easterlies at the Frioul island station.

In addition to those forcings, the general circulation is also of great influence. Intrusions of the northern current off Cassis from the south of the domain are observed and reproduced by the model in winter, due to the penetration of meanders over the narrow eastern part of the shelf [2].

This study received support from the IFREMER METROC project sustained by the Marseille water agency, the GIRAC project and the PNEC-EC2CO MASSILIA project.

The authors gratefully acknowledge J. Garrabou and the Medchange program as well as JG Harmelin and the 'Parc-Marin de la cote bleue' for communication of the MEDCHANGE T time series. We are grateful to the staff of the SOMLIT (Service d'Observation en Milieu Littoral) national network for littoral observations of the INSU (Institut National des Sciences de l'Univers) for providing the data from the SOMLIT-Frioul Marseille station.

DEEP CANYON AND SLOPE SUSPENDED SEDIMENT TRANSPORT IN THE WESTERN GULF OF LIONS

DURING THE 2006 INTENSE CASCADING PERIOD A. Palanques ¹*, P. Puig ¹, X. Durrieu de Madron ², A. Sanchez-vidal ³, A. Calafat ³, C. Pascual ³, S. Heussner ² and M. Canals ³ ¹Institut de Ciencies del Mar (CSIS),08003 Barcelona, Spain - albertp@icm.csic.es

Abstract

The network of mooring lines deployed between 300 m and 1900 m depth along Lacaze-Duthiers and Cap de Creus canyons and the southern open slope allowed to study the water and sediment transport in the Western Gulf of Lions during the 2006 intense cascading period. The dense water and sediment transport reached down to 1900 m depth and was both through submarine canyons and along the southern open slope towards the Catalan Margin. Sediment transported by cascading came either from the shelf or from resuspension of sediments previously deposited at mid-canyon depths. Open-sea convection processes combined with deep cascading pulses also generated sediment transport at deeper slope regions.

Keywords: Continental Margin, Particle Flux, Sediment Transport, Gulf Of Lions, Deep Sea Processes

Dense shelf water cascading in the north-western Mediterranean has been identified as a major transport mechanism able to generate high sediment fluxes in submarine canyons [1, 2, 3] and in the basin during the coldest years [4]. It is known that dense shelf water flows can transport shelf particles and erode and reshape the seafloor, increasing suspended and bed load sediment transport as they progress across the outer shelf and upper continental slope. However, observations of the spreading of dense shelf water cascading across the entire continental slope are scarce and its effects on sediment transport towards the continental rise and basin are largely unknown.

The north-western Mediterranean is a region of dense water formation due to the effect of strong and persistent northern winds (Mistral and Tramontana). The formation occurs on the shallow inner shelf of the Gulf of Lions and at open-sea, preferably in the area known as MEDOC site. Over the continental shelf, the intense wind-induced evaporation and cooling produce cold dense water that eventually overflows the shelf and cascades down the slope, especially though the westernmost submarine canvons. The process occurring in the basin is characterized by open sea vertical convection, and mixing of surface water with warmer but saltier Levantine Intermediate Water [5].

Recent studies have demonstrated that most of the off-shelf suspended sediment transport in the Gulf of Lions occurs in its westernmost sector, preferentially through the Cap de Creus submarine canyon. Based on this previous knowledge, a focussed monitoring strategy was designed within the HERMES project, to better constrain the contemporary sediment transport processes in this region. A network of mooring lines equipped with current meters and turbidity sensors at 5 m above bottom were deployed between 300 m and 1900 m depth along the axes of the two Lacaze-Duthiers and Cap de Creus neighbor canyons, as well as across the southern open slope from October 2005 to October 2006 (Fig. 1).

Fig. 1. Bathymetric map of the study area showing the location of the moored instruments. CCC: Cap de Creus Canyon. LDC: Lacaze-Duthiers Canyon.

Recorded data indicate that dense shelf water cascading was the main shelf-toslope sediment transport process in the area, acting from January to April-May 2006. The dense water and sediment transport was not only through submarine canyons, but also along the southern open slope. The most important suspended sediment transport event was due to the intense cascading pulse occurring in January 2006, which produced a strong sediment flux increase along the Cap de Creus Canyon down to 1900 m depth and also along the open slope at 1000 m depth. A significant sediment flux increase also occurred in March-April 2006 due to another intense cascading pulse. In this transport event, suspended sediment concentration only increased at 1000 m depth in the Cap de Creus Canyon and on the open slope, but not at the canyon head, suggesting a redistribution of sediments previously deposited at mid-canyon depths. Deeper than 1000 m, net fluxes show that most of the suspended sediment left the canyon and flowed along the southern open slope towards the Catalan margin, whereas a small part flowed downcanyon and was exported basinward through the canyon mouth. Additionally, the increase of the deep-sea near-bottom currents induced by open-sea convection processes, combined with the arrival of deep cascading pulses, also generated moderate but continuous suspended sediment transport at deeper slope regions.

Abstract

We present a merged technique for producing monthly mean air-sea heat fluxes values in the Aegean Sea from bulk formulae. The input variables are mainly drawn from the POSEIDON buoy network of the Hellenic Centre for Marine Research (HCMR). Time series derived from five buoys encompassing a period from January 2000 to December 2008 are used together with satellite data and coastal meteorological observations to estimate heat fluxes over the marine boundary layer. The estimated monthly mean values are further compared with widely used global gridded datasets. Keywords: Air-Sea Interactions, Heat Budget, Aegean Sea

Air-sea heat fluxes are crucial for understanding the role of the oceanic environment in the climatic processes as a main driver of the global atmospheric and oceanic circulations. But they are not readily quantified and their basic input variables mostly come from the International Comprehensive Ocean-Atmosphere Data Set (ICOADS, Voluntary Observing Ship program) since the buoy measurements are scarce and the satellites are still unable to provide accurately all the necessary variables [1, 2]. HCMR's Poseidon network consists of oceanographic buoys that monitor meteorological, sea state, upper ocean physical and biochemical data in a 3-hour time intervals [3]. The network is operational since late 1999 and provides four key variables needed for estimating the aforementioned heat fluxes. These are atmospheric pressure, air temperature, sea surface temperature and wind speed. Seasonal maintenance and sensors calibration ensures the network reliability. Cloud fraction is estimated based on 3-h observations provided by a number of coastal stations of Hellenic National Meteorological Service (Fig.1). Simultaneous cloudiness observations from 2-3 nearby stations are spatially interpolated to produce a composite cloud fraction at each buoy location.

Fig. 1. Buoy sites and the 9 meteo stations over the Aegean Sea.

Additionally, the specific humidity is estimated from the SSM/I brightness temperatures (F13, F14 and F15 platforms; [4]). Over the study area an average of 5-6 overpasses were available on a daily basis (while F14 was operational). In order to achieve more representative values, the satellite brightness temperatures from all the daily swaths are selected within a radius of 0.5° from the buoy site and are interpolated in time to be fitted in the 3-h interval dataset. The incoming solar shortwave radiation Qs is calculated from the Reed bulk formula using the List formula for clear sky irradiance as more appropriate for the Mediterranean Sea conditions. A correction to the clear sky insolation due to the aerosol attenuation is applied according to Tragou and Lascaratos [5]. The net longwave radiation Qb is computed using the most

suitable for the Mediterranean, Bignami formula. For the turbulent components, latent heat Qe and sensible heat Qh, the state-of-the-art COARE v3.0 algorithm is used [8]. As a general rule, monthly mean values are estimated when less than 10% data are missing. The final products are further statistically compared against the following heat flux datasets: a) the National Oceanography Centre of Southampton air-sea interaction gridded dataset [1]; b) the OAFlux project dataset of WHOI [6]; and c) the HIPOCAS Mediterranean Sea high-resolution atmospheric dataset [7]. Due to large gaps in our dataset a statistical comparison over a whole year is not possible, therefore only concurrent measurements are involved. Table 1 illustrates results from the preceded statistical comparisons. The period of comparison is referred to 2000-2006 for NOC dataset, 2000-2007 for OAFlux and 2000-2001 for HIPOCAS. According to the main statistical features the most suitable gridded product is appeared to be the OAFlux dataset for all the components except the net longwave radiation for which the HIPOCAS dataset seems to fit better. The relatively large biases of NOC dataset are apparently attributed to the different bulk formulae for the clear sky insolation and for the net longwave radiation. Qb from OAFlux dataset exhibits no correlation not only with the in situ data but also compared against the other two gridded products.

Tab. 1. Main statistics of the comparisons with the gridded datasets. N is the number of compared values.

RECORD-BREAKING SEA LEVELS IN THE NORTHERN ADRIATIC ON 1 DECEMBER 2008

M. Pasaric ¹*, S. Cupic ², N. Domijan ², N. Leder ² and M. Orlic ¹

¹ Hydrographic Institute of the Republic of Croatia, Split, Croatia

² Andrija Mohorovicic Geophysical Institute, Faculty of Science, University of Zagreb, Zagreb, Croatia - mpasaric@irb.hr

Abstract

Exceptionally strong storm surge that occurred on 1 December 2008, when record-breaking sea level was recorded in the Northern Adriatic, is analysed using sea-level data from tide gauges along the eastern Adriatic coast. The event was a result of fine tuning between the storm surge brought about by a series of synoptic atmospheric disturbances, the tide and the preexisting Adriatic basin-wide seiche, all superimposed on a significant sea level rise due to the low-frequency atmospheric disturbance related to planetary waves, whereupon the local seiche activity additionally increased the sea level. *Keywords: Adriatic Sea, Sea Level*

Fig. 1. The episode of exceptionally high sea level recorded at Bakar: (a) original airpressure time series and the data low-pass filtered at 10 days; (b) the recorded time series of 1-minute sea-level data and the tidal prediction; (c) the sea level upon removal of the tidal signal; (d) the sea-level time series, low-pass filtered at 10 days and the storm-surge activity related to synoptic atmospheric disturbances; (e) sea level, band pass filtered around 22 hours, which corresponds to the principal mode of the Adriatic basin-wide seiche and high-pass filtered (at 1 hour) time series representing the local seiche activity.

During late autumn and winter the coastal area of the Northern Adriatic is occasionally exposed to extremely high sea level (*acqua alta*), which floods the towns and brings great damage to urban infrastructure. Venice is most vulnerable to this phenomenon, but other towns in the region are sometimes also severely affected. One exceptional occurrence took place on 1 December 2008. On this occasion not only the Northern Adriatic coast was flooded, but the sea level rose high above its usual values along the greater part of the Dalmatian coast north of Split. The towns of Trogir, Šibenik, Zadar, Rijeka and many other were flooded while in some harbors ships were damaged. At Bakar the sea level reached 121 cm which is absolutely the highest value recorded at the longest operating Croatian tide gauge in use since 1929, with a 10-year break around Second World War. Exceptionally high sea level was also registered on the Italian coast of the Adriatic.

In Venice the sea level reached 156 cm [1], which is the fourth highest value since 1923.

The event was well documented by tide gauges of the Croatian network of permanent stations. The network was modernized in 2003 with digital instruments and GSM modems for the data transmission, thus providing real-time data and enabling the prompt and detailed analysis of the event. The peak event occurred at Bakar at 08:15 CET, with sea level reaching 121 cm; at Rovinj the highest instantaneous sea level (95 cm) was recorded at 11:36 CET, at Zadar the maximum (83 cm) occurred at 08:39 CET, at Split it was 71 cm at 07:02, while at Dubrovnik sea level maximum was considerably lower (50 cm). The beginning of the episode can be tracked two weeks before - a large-scale air-pressure disturbance, related to passage of planetary atmospheric waves, caused sea level to slowly rise (Figure 1) thus securing preconditions for the occurrence of extreme sea levels [2]. This intensified in the next days when a series of weather fronts passed over the Adriatic, each time triggering off the Adriatic seiche. Three days prior to the peak event a very strong sirocco started to blow, piling up water in the shallow Northern Adriatic. On the morning of 1 December 2008 yet another front passed over the Adriatic - the air pressure at Bakar reached its minimum value at 07:30 CET, just shortly before the tide reached its daily maximum and the preexisting Adriatic seiche was heading towards its maximum. Hence, when the tide reached its maximum at 08:15 CET sea level at Bakar went up to its highest level since the start of the uninterrupted measurements in 1949 and also likely since the start of the tide gauge 79 years ago. This record-breaking level was a result of fine tuning between the storm surge (~40 cm) brought about by a series of synoptic atmospheric disturbances, the tide (23 cm) and the preexisting Adriatic basin-wide seiche (13 cm), all superimposed on a 33 cm sea level rise due to low-frequency atmospheric disturbance related to planetary waves, whereupon the local seiche activity within the Bakar Bay contributed with additional 10 cm.

Abstract

We study the surface circulation of the Eastern Mediterranean basin over 2005-2007 by comparing drifter trajectories, models and altimetry. Using pseudo-Eulerian statistics, we investigate a way to validate the model or altimetry circulation schemes with drifter data measurements.

Keywords: Eastern Mediterranean, Circulation, Models

The surface circulation in the eastern Mediterranean Sea is investigated by means of surface tracked drifters, numerical models and altimetry data for the period spanning from November 2005 to October 2007.

Within the framework of the EGYPT/EGITTO program, a total of 97 drifters drogued at 15-m nominal depth were released between September 2005 and March 2007 in the Sicily Channel and the Ionian basin [1]. All drifters were tracked with the Argos Data Location and Collection System (CLS), Drifter positions have accuracy better than 1000m. After editing, the drifter position time series were linearly interpolated every 2 hours using the kriging technique, and were then low-pass filtered and subsampled every 6 hours. The velocities were computed by finite-centered differences [2]. It is important to note that, despite the hundredth of drifters and the 18 months duration, the resulting mean pattern remains highly constrained by the spatio-temporal distribution of the drifters, up to rendering artifacts due to mesoscale eddies [1].

The numerical simulations were carried out using the Mediterranean model MED16 [3, 4] and the extracted Mediterranean domain from the operational PSY2v2 forecasting system [5], regional configurations of the primitive-equation model Ocean Parallel [6]. The horizontal resolution of both models is 1/16°(5-7km) and there are 43 vertical levels. The models were forced by daily air-sea flux and wind fields from the analyses of the European Centre of Medium-range Weather Forecast (ECMWF).

The altimetric data available for this study from CLS are the geostrophic velocities deduced from Sea Level Anomaly maps. Data are interpolated over a regular 1/8°x1/8° grid, every 7 days [7].

Both modeled and altimetric data are low-pass filtered and interpolated in space and time at the drifter positions following the method of [2]. On a grid with 0.25°x0.25° mesh, pseudo-Eulerian statistics are computed (mean current, variance ellipses, mean and eddy kinetic energies).

For example, mean flow and kinetic energy are shown for in situ observations and MED16 (Fig 1). On one hand, some of the main features of the mean flow agree, for both model and drifters : i) the main flow of Atlantic Waters (AW) bifurcates, upon exiting the Sicily Channel, into a northern branch and a southeastward one; ii) the southeastward branch reaches Libya West of 20°E and iii) from ~24°E , the eastward coastal current along Africa associated with mesoscale eddies in agreement with [8], continues northward along the Middle-East slope.

On the other hand, model and drifters mean kinetic energies mostly disagree in several areas. For example, offshore between 24°E-31°E, both mean flows show complex patterns, mostly opposite between 24 and 27°E, even displaying a partial eastward flow. This is related to a strong signature of mesoscale patterns (mostly eddies like Ierapetra or Lybian eddies at this place) in the in situ data. Actually, a good agreement between these datasets requires an exact spatio-temporal correlation between the positions of the observed and modelled eddies.

In a next step, using the whole spatio-temporal sampling of the models, we will check whether this scheme is still relevant for validating the models.

Abstract

Inertial and internal waves in the Central Ligurian Sea are investigated by using long time series of high frequency observations of both ADCP currents and temperature profiles in the upper thermocline. Horizontal variability is dominated by the inertial currents which have a kinetic energy comparable with that of the mean currents. Time frequency analysis evidences the presence of internal waves having periods in the sub-daily band, between 6 and 17 h (the local inertial period). During summer, these vertical oscillations may affect the temperature time series at a fix depth up to several degrees.

Keywords: Air-Sea Interactions, Currents, Ligurian Sea, Time Series, Temperature

Data and methods

In order to investigate the variability of the upper layer, a mooring equipped with an upward-looking ADCP (Acoustic Doppler Current Profiler) RD&I Sentinel 300 kHz and CTD sensors was deployed in the open Ligurian Sea (43° 47.77' N; 9°02.85 E) near the meteo-oceanographic buoy ODAS Italia1. The ADCP sampled the upper 50 m of water column from 13 September, 2003 to 25 May 2004 and from September 2004 to June 2006 thus providing a long-term time series of 3-D currents data. Meteorological parameters, in particular wind speed and direction and atmospheric pressure, were measured each hour from the buoy ODAS at 13.5 m above the sea surface until 11 March 2004. Sea temperature and conductivity at six different depths, between surface and 36 m, were also collected each hour from the buoy. Spectral analysis and the methodology proposed by Jacobs et al. [1] were used to evidence the time spectral characteristics of the observed oscillations.

Results

The upper layer currents variability in the investigated area is mainly due to the inertial currents. They occur very often, can persist several days and have a kinetic energy comparable with that of the mean currents. The more energetic ones are found at the end of the summer, when the thermocline is still well developed, while during winter their amplitude is reduced. Inertial oscillations are very common in the ocean. They can be locally generated at the sea surface by changes in wind stress or by the rapid transit of a low and can persist for several days. These oscillations propagate energy far from the area of generation as well as downward in the water column, generating higher-frequency internal waves through non linear interactions [2]. For their contribution to the mixing, they are of particular importance in regions such as the Ligurian Sea, since they compensate the lack of the tidal mixing. No clear relation between local wind stress and the onset of horizontal inertial currents was found in this analysis. The existence of mixed layer inertial currents unrelated to wind forcing is reported by different authors. Van Haren and Millot [3] found similar results in the Ligurian Sea and gave evidence to the important role of the thermal stratification of waters in the vertical propagation. The time series of the vertical currents clearly show the occurrence of intermittent burst of oscillations reaching the amplitude of few centimeters per second. The signal was present in the entire sampled water column, but the amplitude attenuated with increasing depth. The time-frequency analysis confirms that these oscillations develop both in summer and in winter, even the episodes last only a few days. Their frequency varies in the sub-daily band, spanning from few cycles per day to the local inertial frequency (local inertial period is 17.3 h). Differently from the horizontal inertial currents, the comparison with available local wind time series evidenced a nearly one-to-one correspondence between the wind stress relative maximum and the occurrence of vertical currents oscillations, identified by a maximum of daily standard deviation, but at a first analysis their amplitude doesn't seem relate to the intensity of wind stress. Bursts of oscillation in the sub-daily band are detected also in the temperature time series in the upper thermocline. During summer months, when the thermal stratification reaches its maximum, the temperature variation at 35 m due to the internal waves reached more than 4 °C.

Fig. 1. Time series of daily mean wind stress magnitude and vertical velocities standard deviation.

A LATENT-CLASS APPROACH TO MISSING VALUE IMPUTATION IN INCOMPLETE MULTIVARIATE WAVE METRIC DATASETS

Marco Picone ¹*, Francesco Lagona ¹, Gabriele Nardone ² and Mauro Bencivenga ² ¹ GRASPA and DIPES - University Roma Tre, Rome, Italy - marcopic83@libero.it

² ISPRA - Marine Service, Rome, Italy

Abstract

We propose a latent-class model where the joint distribution of linear and circular data is specified through a finite mixture of conditionally independent Gamma and von Mises distributions. Missing values are imputed by drawing multiple imputations from the predictive distribution of the missing values given the observed data, at the maximum likelihood estimates. The procedure is illustrated on an incomplete dataset that includes measurements of wind speed and direction and significant wave height and direction, taken by a buoy and two tide gauges of the Italian wave-metric network.

Keywords: Waves, Wind/Font, Sicilian Channel

Environmental multivariate data are disseminated by environmental protection agencies for a variety of purposes, including the estimation of statistical models that detect significant relationships between different environmental measurements. Incomplete datasets, where some of the measurements are missing, pose a serious obstacle in the fulfillment of these purposes. There is an extensive literature about the estimation of statistical models in the presence of missing values. However, these methods often require the expertise of a trained statistician, as they involve both computational and methodological issues that can be challenging, depending on the nature of the mechanism that generate the missing values and the complexity of the model that is exploited for analysis. To reduce the workload of the data analyst, incomplete data should be provided in a way that they can be analyzed by "standard" methods, i.e. methods that require the availability of complete data information. Environmental data could be completed by imputing missing values according to an imputation model. This approach is referred to as single imputation. It is however well known that if the data analyst uses complete-data methods for analyzing the completed dataset by treating imputed values as if they were real data, this generally leads to variance estimates that are too low, confidence intervals which are too narrow, and wrong tests (real significance level above nominal level).

Multiple imputation (MI [1]) has been suggested as a way of overcoming the variance estimation problem that arises under a single-imputation strategy. Under a MI protocol, the data-base constructor (or imputer) and the end user (or data analyst) are thought as distinct entities. The data-base constructor draws a number of imputed values from the predictive distribution of the missing values, given the observed data, computed on the basis of an imputation model. The resulting completed datasets are appended together to provide an augmented dataset to the data analyst, who can exploit standard methods to simultaneously examine these datasets and, appropriately pooling the results, use them to correct for the variability in the imputations, which differs from the variability in the observed data. Directions about the pooling procedure are provided by the imputer and involve simple calculations, which can be carried out by a data-analyst who is not necessarily a trained statistician. Under a MI strategy, imputation is typically carried out by estimating a parametric model from the complete cases and using the predictive distribution of the missing data given the observed data to draw a number of imputations for each missing value in the incomplete dataset. Under a frequentist approach, the imputation model is estimated by maximum likelihood and imputations are drawn from the conditional distribution of the missing values, given the observed data, evaluated at the maximum likelihood estimate of the parameters that have been obtained from the observed data.

Latent-class, mixture models have been proposed as flexible imputation models when incomplete datasets include categorical [2] or mixed categorical and continuos variables [3]. We extend this approach to the case of linear-circular variables, by specifying a multivariate mixture of Gamma and von Mises distributions. The model clusters incomplete data into homogenous groups and exploits this classification to complete records with missing values. Parameters of the mixture model are estimated by maximization of the likelihood from the observed data, by a suitable E-M algorithm that allows for missing values. Imputations are then drawn from the multivariate conditional distribution of the missing values given the observed data, evaluated at the maximum likelihood estimate. We evaluate the performance of this imputation method by means of predictive intervals and nonparametric cross-validation.

Results of the MI procedure are illustrated on an incomplete dataset that includes hourly measurements of wave height and direction, taken in the period 10/13-11/11/2003 by the buoy of Mazzara del Vallo located at about 10 Km from the southern coast of Sicily. The dataset also includes eight-hours moving averages of wind speed and direction, taken from the two nearest tidal stations, respectively located at Porto Empedocle (Sicilian coast, about 100 Km from the buoy) and at Lampedusa Island (about 250 Km from the buoy).

FROM OCEAN MESOSCALE MODELLING TO OPERATIONAL OCEANOGRAPHY: A TRIBUTE TO A.R. ROBINSON

Nadia Pinardi 1*

¹ CIRSA, University of Bologna, Bologna, Italy - n.pinardi@sincem.unibo.it

Abstract

A.R. Robinson was the pioneer of ocean mesoscale modelling and data assimilation. His extraordinary knowledge about ocean mesoscale processes, advanced technologies for monitoring and numerical modelling made it possible for operational oceanography to emerge as a new science in support of the sustainable development of all marine activities. *Keywords: Circulation Models, Mesoscale Phenomena, Eastern Mediterranean*

A.R. Robinson (1932-2009) was the founder of ocean forecasting, starting from mesoscale modelling up to the development of the general methods for ocean forecasting. He defined the three methodological phases for forecasting mesoscale eddies in the ocean and carried out the experiments at sea and with numerical models to demonstrate the effectiveness of the methodology [1].

Starting with the MODE and POLYMODE experiments in the 70's, he showed that the ocean was dominated by mesoscale eddies 4-5 times the Rossby deformation radius and that the energy and vorticity processes of this flow field are characterised by frontal dynamics and baroclinic instabilities [2]. In 1983 he designed and carried out the first 'Real Time Forecasting Experiment' in the California Current [3]. In the figure the principle of ocean forecasting is summarized: collect synoptic data and produce an initial condition as accurate as possible to control the error growth by intense nonlinearities in the ocean [4].

Fig. 1. The essential components of the first real time forecasting experiment carried out by Robinson and collaborators in the California current in 1983 [3, 4]. The top of the picture shows the sampling pattern in a 150 x 150 kmsq region which was repeated three times giving rise to data that allowed to calculate the geostrophic streamfunction shown in the panel below. The direction of currents is shown by red arrows overlaid on the pictures.

Robinson devised the in situ data collection sampling methods and the modelling tools at the same time, capable to forecast nonlinear ocean mesoscale eddies up to few weeks in the future. His contribution to ocean forecasting was even more important for the seminal work carried out at the beginning of the eighties in understading and demonstrating the usage of Geosat altimeter data for ocean forecast initialization, a crucial step for operational oceanography [5].

At the same time he was thinking to demonstrate that forecasting was possible in the Gulf Stream area, a region extremely non-linear and ageostrophic so that, if forecast would be successful, it would demonstrate that ocean forecasting is possible everywhere in the world ocean. Again he invented a method to overcome the scarcity of data in this region: the feature model initializion method that combines the oceanographic knowledge of the processes and structures of the region with observations that are gappy and unfrequent. The first successful forecast of Gulf Stream evolution and ring detachment was then carried out in 1984 [6].

Meantime all these developments were undergoing in the Atlantic and Pacific ocean he turned his attention to the Mediterranean Sea, preparing the ground for the modern and scientifically based evidence of the large scale general circulation of the Eastern Mediterranean Sea. He was the father of the 'Physical Oceanography of the Eastern Mediterranean-POEM' program that lasted ten years and collected the first intercalibrated basin scale data sets at 0.5 degree resolution for the entire eastern basin. His description of the general flow field of the Eastern Mediterranean is a benchmark of our understanding of the Mediterranean Sea circulation. It shows new structures and phenomena, the sub-basin scale gyres instabilities, new eddy-gyres structures never revealed before, recurrent eddies phenomena not yet fully understood. His work pointed out the intense eddy dynamics of the South-Eastern Levantine area [7], the presence of anticyclonic gyres that merge and enlarge, depicting the intense quasigeostrophic turbulent cascade processes of this area [8]. After this phase, as part of a general methodology for starting ocean forecasting activities in the world ocean, he dedicated a major effort to implement ocean forecasting in the Sicily Strait and Ionian Sea, describing the dynamics of these areas at unprecedented resolution and demonstrating the quality of forecasting [9] .

Abstract

The surface circulation of the Eastern Mediterranean (EM) is studied using drifter data between 1990 and 2009, with particular attention to the Sicily Channel, and the Ionian and Levantine Seas. The drifter trajectories and the pseudo-Eulerian statistics computed from them (maps of mean circulation and eddy variability) reveal strong quasi-permanent surface currents over the continental slopes and in several anticyclonic gyres. Seasonal and interannual variability of the surface currents is mostly evident in the Sicily Channel and Ionian Sea.

Keywords: Circulation, Eastern Mediterranean

Surface drifters of various designs have been operated in the EM since 1990 as part of operational (military) and research programs to monitor the surface currents and the sea surface temperature. The most common drifter designs are the SVP and the CODE systems for which the water following characteristics are good and quantified [1]. All drifters were located by, and transmitted data to, the satellite Argos system. Recent models were also fitted with GPS receivers to increase the position accuracy and sampling frequency. The drifter data were processed and arranged in web-based databases under the MedSVP program. In particular, the data used in this work were interpolated (kriging) and low-pass filtered to exclude tidal and inertial motions. They were provided by a total of 487 drifters spanning the period January 1990 to November 2009 and amounting to a total of about 91 drifteryears. The drifter data (Figure 1) show the Atlantic Water (AW) entering in the Sicily Channel in two preferential paths, one close to the Tunisian coast (the Atlantic Tunisian Current), the other one located in the central and northern portion of the region, corresponding to the Atlantic Ionian Stream (AIS) [2, 3]. The surface currents are notably influenced by the wind forcing, with enhanced AW flow into the EM during NW Mistral winds prevailing in winter. This seasonality mainly driven by the winds is also evident in the southwestern Ionian [3]. In the northern Ionian, the drifters indicate both seasonal and interannual variabitlities with (1) a mean anticyclonic circulation dominating prior to mid-1997 and extending the AIS towards the NE [4]; (2) a general cyclonic circulation between mid-1997 and 1999, with the southern limb of the cyclone advecting AW towards the E in the central Ionian, and (3) alternating anticyclonic (cyclonic) circulation patterns in summer (winter) in 2006-2007 [3].

Fig. 1. Composite diagram of all the low-pass filtered drifter trajectories in the EM (excluding the Adriatic and Aegean Seas) between January 1990 and November 2009.

East of 20°E, the eastward motion of AW takes places in the Libyo-Egyptian Current (LEC) on the African continental slope and in the form of numerous anticyclonic eddies created by the instability of the LEC (Libyo-Egyptian Eddies, LEEs [3]), by the wind curl (Ierapetra and Pelops Eddies) and by topography. The northern limbs of some of these eddies in the open sea correspond to the Mid Mediterranean Jet put forward by the Physical Oceanography of the Eastern Mediterranean (POEM) project [5]. In the eastern Levantine Sea, the Lagrangian data reveals a strong coastal/slope northward current off the Middle East coast [3] along with several eddies presumably created by the instability of the coastal current. In particular, recent measurements in 2009 has confirmed the complexity of the surface circulation in this region and the persistence of strong eddies between Cyprus and Israel. In the northern Levantine, including the Cilician sub-basin, the drifter data are too scarce to deduct robust and significative results on the surface circulation. Pseudo-Eulerian statistics [2, 3] confirm the above results and provide a more quantitative description of the EM surface currents in terms of mean flow (Figure 2), eddy, seasonal and wind-induced variabilities. Kinetic energy levels of the mean (MKE) and fluctuating (EKE) components of velocity are high in the major currents and eddies mentioned above, and in general the EKE tend to exceed the MKE, indicating the predominance of the fluctuations with respect to the mean.

Fig. 2. Mean surface circulation of the EM based on the drifter data shown in Figure 1 averaged in bins of $0.25^{\circ} \times 0.25^{\circ}$.

Abstract

The analysis of a compilation of deep CTD cast conducted in the western Mediterranean from 1998 to 2009 have documented the role that dense shelf water cascading off the Gulf of Lions plays in transporting suspended particulate matter from the coastal regions down to the basin. Deep CTD casts revealed that after the 1999 and 2005-2006 major cascading events the Western Mediterranean Deep Water was characterized by the presence of a thick bottom nepheloid layer that scaled in thickness with a thermo-haline anomaly generated by the mixture of dense waters formed by deep convection at open sea and by cascading off the Gulf of Lions shelf. The aim of this contribution is to characterize the observed bottom nepheloid layers and determine their spreading and residence time in the western Mediterranean basin.

Keywords: Western Mediterranean, Hydrography, Sediment Transport, Gulf Of Lions

Suspended particulate matter in the oceans plays a key role as extractors from, transporters through and sources to the water column of many major and minor elements, being responsible for maintaining most oceanic chemical concentration gradients [1, 2]. Particles are introduced into the ocean by biological production, rivers, glaciers, wind and bottom sediments resuspension. Biological, chemical and gravitational influences then act to remove particles from the water column. These removal processes, however, occur on much shorter time scales than the formation, movement or mixing of oceanic water masses. Particles, therefore, do not act as pure conservative tracers of water masses. However, their presence and concentration can indicate the location and intensity of oceanographic processes, particularly those involving the resuspension of sediments in deepsea environments due to strong bottom currents, and be used as a tracer of water motions [3, 4].

The northwestern Mediterranean is one of the regions of the world where massive open sea dense water formation occurs because of cooling and evaporation of surface waters during winter-time [5]. Concurrent with this oceanographic process, coastal surface waters over the wide shelf of the Gulf of Lions also become denser than the underlying waters and cascade downslope, usually through submarine canyons, until reaching their equilibrium depth [6].

Dense shelf water cascading (DSWC) can last for several weeks and the associated strong currents can induce erosion and resuspension of surface sediments in the outer shelf/upper slope [7, 8] and, therefore, generate bottom nepheloid layers (i.e. layers of water that contains significant amounts of suspended sediment). Such layers can be detached at intermediate levels when the density of the mixture of water and particles reach their neutral buoyancy depth. In very dry, windy and cold winters, such as in 1999, 2005 and 2006, DSWC off the Gulf of Lions was exceptionally intense and reached depths >2000 m, evolving into a thick bottom nepheloid layer that spread along the lower continental slope and across the basin (Fig. 1).

The observed bottom nepheloid layers scaled in thickness with the thermohaline anomaly generated by the mixture of DSWC and dense waters formed by deep convection at open sea, the later only bringing "blue water" free of particles to the basin, being up to 650 and 1450 m thick after the1999 and 2005-2006 events, respectively. Concentrations within the bottom nepheloid layer in the central part of the basin were usually around 0.3 mg/l (i.e. 0.1 mg/l above background levels), reaching higher concentrations close to the continental rise, with near-bottom peaks up to 2 mg/l. These bottom nepheloid layers could be observed to progress from the Gulf of Lions and Catalan margin towards the central part of the northwestern Mediterranean basin, reaching south of the Balearic Islands and west of Sardinia after the 1999 event, and covering the entire basin after the 2005 and 2006 events. Thickness and concentration of the bottom nepheloid layer diminished with distance away from their source and also with time. The turbidity signal could be barely distinguished one year after the 1999 event, but the one generated after the 2005-2006 events can be still clearly detected, confirming that fine particles in dilute nepheloid layers can have residence times of several years [3].

Fig. 1. Vertical profiles of suspended sediment concentration (SSC) and $\sigma\theta$ from a hydrographical transect conducted across the Barcelona continental margin, from 300 down to 1700 m depth on 24 March 2005. The inset map shows the detailed location of the CTD casts.

ESONET-EMSO DEEP SEAS OBSERVATORIES IN EUROPE: TOWARDS A COMMON INFRASTRUCTURE

Ingrid Puillat ¹* and Roland Person ¹

¹ IFREMER BREST, Département Géosciences Marines, 29280, Plouzané, France - ingrid.puillat@ifremer.fr

Abstract

ESONET is a Network of Excellence launched in March 2007 for 4 years (2007-2011) and coordinated by IFREMER. It involves 14 European countries, more than 50 institutions and SMEs, about 300 scientists, engineers and technicians. The network prepares the technical specifications to implement a permanent observatory infrastructure in the deep ocean around Europe with the ability to monitor a large range of physical, chemical and biological parameters. Amongst eleven key areas around Europe, four of them, located in the Mediterranean zone will be presented. An overview of the possible infrastructure at European scale will be presented. The conclusions will explain how this European observatory initiative is well integrated in a world wide "Deep sea observatory wave". *Keywords: Open Sea, Sampling Methods*

European Seas Observatory NETwork (ESONET, http://www.esonetemso.org) is a Network of Excellence (NoE) launched in March 2007 for 4 years (2007-2011) and coordinated by IFREMER (France). ESONET involves 14 European countries, more than 50 institutions and SMEs, about 300 scientists, engineers and technicians. Its budget is around 70 M€ as total cost, with a EU grant of 7 M€

The ESONET network prepares the technical specification to implement a permanent observatory infrastructure in the deep ocean around Europe with the ability to monitor a large range of physical, chemical and biological parameters and to constitute a part of the marine branch of the global monitoring system of the Earth. The ESONET observatories will provide information on global change, warnings of natural hazards and a basis for sustainable management of the European Seas. The NoE unifies the communities and prepares the technical specifications of the seafloor and water column infrastructure that will be implemented by the European infrastructure project EMSO (coordinated by INGV). The NoE manages some common activities programs of members organisations and the main part of the work is driven in the framework of observatories Demonstration missions. Amongst networked tasks the most important ones are:

- the establishment and the recognition of involved international groups per site to prepare the implementation of Regional Legal Entities on the nodes of the infrastructure (EMSO PP project),

- to update the scientific objectives relevant to deep sea observatories at the top research level ([1]),

- the preparation of standardisation issues: sensor interface, sensor registry, data management for instance ([2]).

- to build a general business plan to be updated according each ESONET node and to prepare the implementation strategy,

- education, outreach and communication, for users, scientists, stakeholders, students, customers.

Eleven key areas around Europe have been identified as specific targets selected for relevant science programmes of potential hazards, geo hot spots, ecosystem processes, and oceanography: Arctic ocean, Norwegian margin, Nordic Sea, Porcupine Seabight and Abyssal Plain, MOMAR zone (Azores), Gulf of Cadiz, Ligurian Sea, East Sicily, Hellenic node, Black Sea, Marmara Sea (figure 1). The five former sites will be presented: scientific issues, infrastructure and their possible future as deep sea observatory. The Ligurian site has already been described in a previous article ([3]) and some updates will be given. As it is partly linked with the Antares neutrinos telescope and the KM3net project the link with the Hellenic node will be explained. The Black Sea activity in ESONET is still seldom. The East Sicily node is managed partly in the framework of an ESONET demonstration mission named LIDO (http://www.esonet-noe.org/main_activities/demonstration_missions). LIDO raised from a need to understand more about the role of sound production and reception in the behaviour, physiology, and ecology of marine organisms. Anthropogenic sound, including sound necessary to study the marine environment, can interfere with the natural use of sound by marine organisms. The Marmara zone is one place where great ESONET activity takes place, in the framework of an other Demonstration Mission, named MARMARA –DM. focused on Seismic science. A specific attention will be paid on this 2 Mediterranean Demonstration missions and on testing operations to be deployed on cabled sites.

Fig. 1. Eleven ESONET nodes plus one testing site (Kosterfjiord)

Launched the 1st march 2007, great progress has been driven regarding all this issues on the ESONET sites. Here will be presented an overview of the progress made on Mediterranean sites and of the possible infrastructure at European scale. The conclusions will explain how this European observatory initiative is well integrated in a world wide "Deep sea observatory wave".

MODELING CARBON CYCLING AND SEQUESTRATION IN THE ADRIATIC SEA

Stefano Querin¹*, Gianpiero Cossarini¹, Cosimo Solidoro¹ and Alessandro Crise¹

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS - Sgonico/Zgonik (TS) - Italy - squerin@ogs.trieste.it

Abstract

Biological and continental shelf pump play a major role in carbon cycling and sequestration in the intermediate and deep layers of the sea. A state of the art numerical model of the Adriatic Sea general circulation is coupled with a biogeochemical model to study and quantify these processes. Two scenarios are examined in detail: winter 2006/2007 and winter 2007/2008. In the former, mild weather conditions did not trigger any relevant dense water flux, which, instead, has been measured for the 2007/2008 case study. The results of the simulations show different biogeochemical properties and different air/sea CO₂ exchange rates, both in good agreement with experimental observations.

Keywords: Adriatic Sea, Carbon, Models

Marine systems play a crucial role in the global carbon budget, in particular, the oceans are thought to absorb about 40% of the antropogenic CO_2 [1]. The biological pump and the continental shelf pump are two among the mechanisms that foster the transport of carbon in the intermediate and deep layers of the sea (Fig. 1). The components of these processes are:

- primary production (PP) which uses the carbon (DIC) taken up through air/sea exchanges;

- sinking of organic material (POC);

- vertical transport of dissolved organic (DOC) and inorganic (DIC) carbon through downward fluxes associated with dense water formation.

Fig. 1. Simplified scheme of the biological and continental shelp pump

The Adriatic Sea is considered to be a key area for the sequestration of atmospheric carbon in the interior of the Mediterranean Sea. This study presents the results obtained by running a numerical model of the Adriatic Sea for the period november 2006 - august 2008. The simulations, set up in the framework of the VECTOR project, aim at understanding the dynamics and fluxes of the biogeochemical properties of the basin, paying particular attention to the formation and transport of dense water masses (~7°C, 38 psu, 1030 kg/m³), which originate in the Northern Adriatic Sea in winter and spread southward along the basin. Model features can also help in investigating the seasonal variability of the mesoscale structures and the effect of air-sea interactions on the general circulation.

The simulations are carried out customizing the MITgcm, a three-dimensional, finite volume, non-hydrostatic, general circulation model [2]. The physical model is coupled with a medium complexity biogeochemical model specifically developed for the Adriatic Sea [3] and a model which solves the carbonate chemistry system [4]. The computational domain spans north of the Otranto strait (from latitude 40.3° N to 45.9° N), with a horizontal resolution of $1/32^{\circ}$ (~ 3.4×2.4 km) and 51 unequally spaced levels. Initial and open boundary conditions are obtained from the $1/16^{\circ}$ operational model of the Mediterranean Sea run by INGV. The main rivers flow rates are derived from in situ measurements (when available) or yearly averages and are modeled in such a way as to consider both the thermohaline and momentum contribution. Surface atmospheric forcing is interpolated from high resolution atmospheric models (ETA006 and ALADIN).

The physical model reproduces the mesoscale seasonal variability correlated with the thermohaline properties of the water column. Short term (few days) response to the major atmospheric forcings (Bora and Scirocco wind) also show a good agreement with experimental observations. The biogeochemical model simulates carbon and phosphorus cycles paying particular attention to production, sinking and recycling processes.

The integrated model has been tuned to reproduce several experimental observations related to different environmental conditions. In particular, two scenarios are examined in detail: winter 2006/2007 and winter 2007/2008. In the former, mild weather conditions did not trigger any relevant dense water flux, which, instead, has been measured for the 2007/2008 case study. For both scenarios, the carbon budgets are estimated in three relevant sub-basins, vertically organized as follows:

- northern continental shelf;

- central pits (subdivided into 2 sub-layers);

- southern pit (subdivided into 3 sub-layers).

The results of the simulations show different biogeochemical properties and dynamics for each of the six boxes, and different air/sea CO_2 exchange rates, both in good agreement with experimental observations.

A FORCED OCEAN-ATMOSPHERE MODEL TO PERFORM LONG-TERM HYDRODYNAMIC RESPONSE INDUCED BY ATMOSPHERIC FORCING WITHIN THE STRAIT OF GIBRALTAR.

Emma Reyes ¹*, Miguel Bruno ¹ and Alfredo Izquierdo ¹

¹ University of Cadiz, Applied Physics Department, 11510, Puerto Real, Spain - emma.reyes@uca.es

Abstract

This study investigates the response of the Atlantic inflow induced by atmospheric forcing in the Strait of Gibraltar during intense and persistent easterly wind episode. The hydrodynamic response is successfully simulated using a high-resolution oceanic numerical model forced by an atmospheric mesoscale model. Numerical simulations show the raising of the Atlantic-Mediterranean interface along the Morocco's northern coast indicating the development of upwelling in this area while the interface sinks down near the downweling region in the south Atlantic coast of Spain. The joint action of the high atmospheric pressure over the Mediterranean and the easterly wind drastically reduce the Atlantic inflow.

Keywords: Strait Of Gibraltar, Upwelling, Air-Sea Interactions, Atmospheric Input, Currents

Circulation in the Strait of Gibraltar consists of several concurring processes. One of these processes is the direct action of the winds along the Strait. Dominant easterly/westerly winds appear to originate upwelling/downwelling phenomena, which subsequently will modify the circulation patterns and the interface depth [1, 2 and 3]. It is known that under intense easterly winds upwelling events occur along the Morocco's northern coast while the downwelling is developed in the south Atlantic coast of Spain. Analysis of one month numerical simulations between September and October 2008, coincident with the GIBRALTAR-08 oceanographic survey period, were performed with a two-dimensional, non-linear, two-layer, free-surface, boundary-fitted coordinate, hydrostatic ocean model UCA2.5D [4] at grid resolutions down to 1 km, forced with the Fifth-Generation NCAR / Penn State NonhvdrostaticMesoscale Meteorological Model MM5 [5] fields. The atmospheric model domain has been implemented for the Gibraltar Strait, covering the Western Alboran Sea and small part of the Gulf of Cadiz, while the curvilinear ocean model grid is limited to the Strait of Gibraltar and embedded in the larger atmospheric model domain (see Figure 1 for details).

Simulations have been performed with three different forcing cases to determine the response of the circulation patterns and the interface depth to the atmospheric pressure and wind forcing separately. The first simulation was performed by forcing the ocean model only with surface wind, the second simulation included also atmospheric pressure forcing and the third one has been obtained being forced by atmospheric pressure and surface winds. For the validation process, the different outputs of the model have been compared with a set of *in situ* meteorological and oceanographic data collected during GIBRALTAR-08 survey, which took place in the Strait of Gibraltar onboard the R/V Sarmiento de Gamboa conducted during fall season in 2008. Nevertheless, considering the joint effect of the high atmospheric pressure in the western Mediterranean basin, significant reductions in the Atlantic flow could therefore reverse at the same time that the Atlantic-Mediterranean interface raise, taking place the development of upwelling in the Morocco's northern coast. The numerical solutions closely match the experimental results discussed in [6].

Model simulations show that the effect of the easterly wind by itself is to decrease the intensity of the Atlantic inflow and the interface depth.

DENSE SHELF WATER CASCADES IN THE PALAMÓS CANYON. COMPARISON WITH THE CAP DE CREUS CANYON

Marta Ribó¹*, Pere Puig¹, Albert Palanques¹ and Claudio Lo Iacono² ¹ Institut de Ciències del Mar, CSIC, Barcelona, Spain - mribo@icm.csic.es ² Unitat de Tecnología Marina, CSIC, Barcelona, Spain

Abstract

The Palamós and the Cap de Creus submarine canyon heads were instrumented during two consecutive winters to study their respective role in the dynamics of the sediment transport on the northwestern Mediterranean Sea. Several events of dense shelf-water cascading (DSWC) were identified and compared among them. Sediment transport during DSWC at the Palamós canyon is significant during eastern and also northern storm events, but not related with river floods. However, the magnitude of transport events in the Palamós Canyon is one order of magnitude lower than in the Cap de Creus Canyon. *Keywords: Sediment Transport, Continental Margin, Western Mediterranean*

Submarine canyons incised in continental margins are meant to be preferential pathways for the exchange of water and particles between the coastal area and the open sea. Hydrodynamics and sediment transport processes in submarine canyons depend upon several forcing conditions in the region such as general circulation, bottom morphology and atmospheric regime [1, 2]. The off-shelf sediment transport through submarine canyons, due to storms and river floods, can be significant and recently dense shelf-water cascading (DSWC) has been identified as an important transport mechanism able to generate high sediment fluxes in submarine canyons [3]. DSWC can transport large amounts of water and sediment, reshape submarine canyon floors and rapidly affect the deep-sea environment [4]. DSWC is seasonal, resulting from the formation of dense water by cooling and/or evaporation over the shelf, and occurs on both high- and lowlatitude continental margins. The aim of this study is to determine the presence of DSWC events at the Palamós canyon head during winter conditions, and to compare these events with the contemporary ones recorded in Cap de Creus canvon head.

The Cap de Creus Canyon, located at the northwestern Mediterranean Sea belongs to a complex network of submarine canyons cutting the Gulf of Lions continental margin. The Palamós canyon is located 20 km southward from the Cap de Creus canyon. The head of both submarine canyons reaches the continental shelf-edge by the 90 m depth contour, and the canyon rims are about 2 - 3 km away from the coastline (Figure 1). At the southern end of the Gulf of Lions, storm-induced downwelling can be combined with DSWC and enhance sediment transport through submarine canyons during winter-time [3]. The Cap de Creus submarine canyon has been intensively studied during the past years as it acts a major transport conduit during DSWC events. On the contrary, little information exists about the sediment transport processes operating within the Palamós submarine canyon [5].

Observational work during this study consisted of a series of field measurements carried out with two instrumented moorings during winters 2006-07 and 2007-08 deployed at the heads of the Palamós and Cap de Creus submarine canyons around 300m depth (Fig. 1). These moorings were equipped with a current meter with temperature, conductivity, pressure and turbidity sensors, placed at 5 m above the seafloor. Multibeam bathymetry from both canyon heads was also acquired and used to determine the canyon axis morphology, which was considered to compute down-canyon fluxes. Forcing conditions were obtained from oceanographic buoys and gaps in the wave height and peak period time series were filled with models outputs. Daily river discharges from nearby rivers were also analyzed.

Sediment transport events during winter 2006-2007 and winter 2007-2008 were quite similar. Down-canyon current velocities >60cm/s were detected in the Cap de Creus Canyon, and >40cm/s in the Palamós submarine canyon. Increases in current speed were associated with subtle drops in temperature (~1 °C) related to DSWC, and peaks of suspended sediment concentrations (SSC) of ~160 mg l⁻¹ in the Cap de Creus Canyon, and ~6 mg l⁻¹ in the Palamós canyon head. Two eastern storm events that generated temperature and current fluctuations were registered between 16th and 19th of February 2007 and between the 2nd and 5th of January 2008. These storm events enhanced DSWC events at both submarine canyons. A northern storm event on the 6th of March 2008 also occurred, but only generated DSWC at the Palamós, and not at the Cap de Creus Canyon.

During the study period there was no relation between sediment transport events and nearby river discharges. The amount of sediment transported during the DSWC events is one order of magnitude greater at the Cap de Creus canyon than at the Palamós Canyon. This corroborates the idea that most of the offshelf sediment transport in the northwestern Mediterranean during DSWC events occur at the southwestern end of the Gulf of Lions, through the Cap de Creus Canyon [3, 4].

LAGRANGIAN AND EULERIAN OBSERVATIONS OF THE SURFACE CIRCULATION IN THE TYRRHENIAN SEA

Abstract

In this paper the Tyrrhenian Sea surface circulation is investigated by means of lagragian and altimeter data. Respect to the traditional cyclonic circulation, the analysis reveals a significant and unexpected complexity. The circulation is modulated by a series of mesoscale/sub-basin structures, of both transient and semi-permanent nature. The pseudo-Eulerian statistics computed with the two datasets evidenced the representativeness of a joint analysis of altimeter and drifter data Keywords: Circulation, Remote Sensing

Introduction

This paper focuses on the study of the Tyrrhenian Sea, a sub-basin of the western Mediterranean whose surface and near surface dynamics are still relatively poorly known [1, 2], in particular as to its southern region. A set of 53 surface drifters deployed in the Tyrrhenian Sea between December 2001 and February 2004 was analyzed. Simultaneous satellite remotely-sensed altimeter, covering the period 2001-2004, was associated to this dataset in order to supplement the drifter data with continuously and uniformly sampled observations, and to characterize the seasonal and the higher frequency variability of the surface circulation. The investigation was based on trajectory analysis and on the computation of the pseudo- Eulerian statistics using the same binning and space-time averaging for drifter and altimeter data.

Results and discussion

The analysis reveals a new more complex circulation pattern respect that drawn in literature [3, 4]. In fact the cyclonic circulation is modulated by a series of mesoscale/sub-basin structures, of both transient and semi-permanent nature. These structures are particularly important in the southern region of the basin where they overcome by far the mean flow pictures. The North Tyrrhenian Cyclone (NTC) and the North Tyrrhenian Anticyclone (NTA) are the main structures in the northern region of the Tyrrhenian Sea. In the southwestern side of the basin a double core cyclonic gyre is present that captures the major portion of the AW entering in the basin. New structures of the circulation are picked out in the southern region of the Tyrrhenian Sea as the South Tyrrhenian Anticyclone (STA), between 12-13 E and 39-40 N, an anticyclonic circulation near the northern coast of Sicily, and finally a gyre having a cyclonic rotation offshore the Calabrian coasts.

The study of altimeter data has highlighted a certain degree of seasonal variability in the circulation pattern. The circulation structures present in the western side of the basin are stronger in summer than in winter, contrarily the circulation features in the south eastern region are more important in winter than in summer.

The pseudo-Eulerian statistic computed with drifter and altimeter measurements has highlighted the sampling and dynamical differences between this two dataset. The value of MKE is greater for the altimeter data than for drifters, on the contrary the EKE energy levels computed from the altimeter are lower than those obtained from drifters. To ascertain the consistency between the Lagrangian measurements and the altimeter dataset, and to evaluate if the observed differences can be related to different sampling capability or dynamical processes, the pseudo-Eulerian statistics derived from the drifters have been spatially smoothed and the altimeter data have been resampled along drifter trajectories. Altimeter data sampled over drifter trajectories and the spatially smoothed pseudo-Eulerian statistics derived from drifter have quite similar values of MKE levels of energy, but the variance ellipses and the EKE levels are very different, in fact the levels of energy computed from altimeter measurements are always smaller than those from drifters.

Therefore, it is possible to conclude that the standard interpolated products of altimeter data lose a considerable part of the signal, even if they ensure a wider and more regular sampling than drifters.

ON THE FUTURE OF THE EASTERN MEDITERRANEAN TRANSIENT

Wolfgang Roether 1*

¹ Univ. Bremen, Bremen, Germany - wroether@physik.uni-bremen.de

Abstract

The evolution of the Eastern Mediterranean Transient (EMT) to date has been documented in some detail. Presently, the deep waters are still in a transient state, with salinity distinctly enhanced relative to the classical situation. It is argued that, because of this, of long time scales of deep-water recirculation, and of expected climatic changes, transient conditions in the deep waters will prevail for a long time, with even an uncertain outcome. This contrasts strongly with the quasi-equilibrium situation that prevailed during the pre-EMT era.

Keywords: Eastern Mediterranean, Global Change

While our 1987 Meteor observations confirmed the classical view how the thermohaline system of the Eastern Mediterranean operated [1], the 1995 cruise (both cruises under the POEM umbrella) revealed the entirely disturbed situation [2] now known as the EMT. Dominant EMT features were a T-S inversion in the deep waters and a highly increased salinity over much of the water column, most strongly so below the inversion. A rather steady but far more moderate salinity increase was found also prior to the EMT (Fig. 1). However, T and S were always found to decrease with depth without any positive evidence of an inversion. The evolution after 1995 was further monitored by Meteor cruises in 1999 and 2001. The hydrographic observations (by OGS) together with our own tracer data and much information from other work revealed many remarkable features. One was the Aegean dense-water outflow in 1993 averaging as high as 3 10⁶ m³/s (3 Sv), related to isopycnals being raised by several hundred meters. The density of the Aegean-derived deep waters (referenced to an appropriate isobar) was hardly different from that of the classical Adriatic outflow [3]. Presently the deep waters are still far from an equilibrium state, and how the Eastern Mediterranean's thermohaline circulation will be organized in the long run is an open question.

Fig. 1. Eastern Mediterranean salinities below 2000 m depth, 1910 - 2001 (courtesy B. Klein). Much of the scatter in the early data is measurement noise. The straight line is a linear fit to the pre-EMT data since 1948.

In this context, I address a potential paradigm change: During the period from the first observations (1910) up to the 1980s a quasi-equilibrium prevailed, proving to be basically stable against whatever disturbances occurred. The Adriatic acted as the principal deep-water source while the Aegean added to its preconditioning [3]. The deep waters generated formed one coherent cell of lateral spreading and upwelling. This structure was completely disturbed by the EMT (since about 1990), with the Aegean dwarfing the Adriatic as the deep-water source. It appears that the EMT was a unique event, brought about by accidental coincidence of a number of factors. After 1995, decreasing density restricted the Aegean outflow waters to middepths, which eventually enabled the Aegean to precondition the Adriatic again. However, a further ingredient is inclusion of upwelling deep waters. As its salinities distinctly exceed the pre-EMT values, the inclusion tends to raise salinity and density of deep waters newly formed. Considering that deep-water that preserved the formed.

such changes will modify the depths to which such waters penetrate and also their circulation pathways. The salinity increase has been highest in the Levantine deep waters, so that the effect will be strongest in the Aegean, which might help inducing another Aegean event. Reaching the Adriatic implies a delay on the order of 100 years [4], which, together with varying pathways and assisted by the moderate deep-water volume relative to those of the ocean at large, might induce oscillation. On such time scale, further salinity enhancement will arise from the expected regional decrease in precipitation [5]. I conclude that the deep waters will continue to be transient for a long time, and that even the outcome cannot be predicted with certainty.

Acknowledgements: It was Allan Robinson who, admirably, developed, together with Paola Malanotte-Rizzoli, the international cooperation that enabled the POEM effort, which made my Meteor work possible. Allan attended the Meteor cruises of 1987 and 1995. The OGS observations were directed by B. B. Manca, and in 1987, by the late A. Michelato. I am deeply indebted to all my coworkers in Bremen and at sea and to the EU and national funding agencies for support.

IN SITU DETECTION OF TSUNAMI AND OTHER SEA LEVEL RELATED HAZARDS - FROM A CONCEPTUAL APPROACH TO IMPLEMENTATION AT MEDGLOSS STATIONS

Sergiu Dov Rosen¹* and Sagi Raz²

¹ Israel Oceanographic & Limnological Research and MedGLOSS Focal Center, Haifa, 31080, Israel - rosen@ocean.org.il ² Raz - Handasa Bio-medical engineering

Abstract

This paper presents first author's concepts for fast in situ detection of sea level induced hazards (tsunami, seiche, extreme sea levels, storm surge, extreme sea states, meteo tsunamis) and their implementation at sea level stations of MedGLOSS network. This is accomplished via real time low latency multi sensors (atmospheric pressure, wind, sea level) data gathering and by the processing and analysis of the data, using a specially developed software package. The basic idea is based on gathering the sensors data for a number of overlapping and time sliding windows of varying length and frequency and by analyses of cross correlations, trends, spectral and cross spectral data analyses.

Keywords: Sea Level, Tides, Time Series, Sampling Methods, Instruments And Techniques

Introduction

The importance of rapid detection and alert of tsunamis for providing early warning against such events has reached full recognition already at the first meeting of the Intergovernmental Coordination Group for the Tsunami Early Warning and Mitigation System in the North Eastern Atlantic, the Mediterranean and Connected Seas (ICG/NEAMTWS), because of the relatively small size of the Mediterranean Sea and the implicit short warning times for sites on its coasts. Along with the adopted decision for setting up a multi parameters and multi hazard early warning system, detection of these hazards using sea level monitoring sensors implicates continuous low latency monitoring of the sea level surface elevation at selected sites. While typical tsunami waves have wave periods from above 5 minutes to about 60 minutes (at least in the Mediterranean), there are additional infragravity waves in this wave period range of other origins which may superpose or be miss-identified as tsunami waves. Such infragravity waves can be due to bounded wave groups, as well as free waves such as edge waves, atmospheric pressure fluctuations (meteo-tsunamis), wind gusts, etc. Within the list of other hazards induced by sea level rise we may list flooding and/or coastal erosion due to storm surges via wind induced set-up (usually associated also with barometric lows), due to storm waves induced large superelevation within the surf zone (growing towards a maximum at the waterline) and extreme spring tides. Hazards due to sea level lowering, inducing coastal erosion and removal of various types of debris from the land and foreshore are due to tsunamis, while wind induced set-down or barometric highs may lead to navigation problems. It is thus obvious that the monitoring of sea surface fluctuations for the detection of tsunami waves must be capable to monitor at the same time other types of sea level fluctuations due to non-tsunamigenic origin and for this reason a low latency monitoring rate of the sea level is compulsory.

Paper contents

The paper will discuss the following aspects:

a. Monitoring and proper identification methods of the type of sea level hazard as a function of the location of the monitoring station (deep water, transient depth, surf zone, inside a harbour).

b. Present approach used for detection of tsunami waves in deep water for early warning.

c. The conceptual approach used for detection of tsunami waves in deep water as well as near the shore, separately for each type of location.

d. The sensors complementary to tide gauges, sampling rates and methods of data processing for rapid identification of sea level hazards.

e. Conceptual approach used for rapid detection of the hazards, including multi size and overlapping sliding data windows and the short term trend analyses, identification of the infragravity waves due to bounded long waves via Smoothed Instantaneous Wave Energy History (SIWEH) analyses (Funke and Mansard, 1979), run length (Battjes and Van Vledder, 1984), temporal and spatial group steepness via Hilbert transform (Haller and Dalrymple, 1995), etc.

f. The approach chosen for the development of the special software package for rapid detection of sea level related hazards using the low latency data from submerged Paroscientific pressure sensor, Aanderaa wind station and Setra barometer with which are equipped some of the real time MedGLOSS sea level stations selected for participation in the preliminary NEAMTWS tsunami detection pilot network.

To enable the above concepts, first the MedGLOSS RT MONITOR software real time clock data gathering, analysis and real time

data transmission was developed by the second author based on the specifications of the first author, and implemented at a number of MedGLOSS stations using the National Instruments LabView software development package and cRIO-9072 CompactRIO Controller and Chassis Integrated System with WINDOWS XP PRO operating system.

Based on the low latency data gathered by the RT MONITOR software, a sequence of windows of the data, covering overlapping and the sliding time windows from 17 minutes to 1/2 day are used to for fast determination via trend analyses, spectral and cross spectral analyses, correlation and other statistical data analyses methods as indicated above, based on the observed data, when such event is encountered and the sources leading to the fast sea level changes (tsunami, infragravity waves, seiche, storm surge, etc.). Finally, in the case that such an event would be detected, a near real time warning communication via Internet will be generated.

WINTERTIME CROSS SHELF CIRCULATION AND SHELF/SLOPE INTERACTION OFF THE CENTRAL ISRAELI COST

Zvi Rosentraub ¹*, Ayal Anis ² and Ron Goldman ¹

¹ Israel Oceanographic & Limnological Res., POB 8030, Haifa, 31080 Israel. - zviros@ocean.org.il

² Depts. of Marine Sciences and Oceanography, Texas A&M university, Galveston, TX 77551,USA

Abstract

Results are presented from two field experiments, conducted during winters 2007/8 and 2008/9, and modeling work focusing on winter cross shelf and slope transport processes off the central Israeli coast. Our study shows that this transport is, apparently, driven by both downwelling circulation off the Israeli coast and by the strong impact of the flow of the adjacent deep sea upon the flow over the upper slope and over the narrow Israeli shelf due to the presence of an along-slope jet, open sea meanders, and eddies. *Keywords: Continental Shelf, Levantine Basin, Circulation*

Results from two field experiments, conducted during winters 2007/8 and 2008/9, and modeling work focusing on winter cross shelf and slope transport processes will be presented. Our study shows that this transport is apparently driven by both downwelling circulation off the Israeli coast and by interaction between the flow over the narrow Israeli shelf and that of the deep sea. In comparison to studies of upwelling systems, downwelling driven circulation has been relatively little explored in the world ocean. Moreover, while modeling studies and a limited number of field experiments suggest that flow dynamics in the deep sea have a strong impact on the cross shelf/slope transport in the region, this has been only slightly explored [1, 2].

Field measurements included extensive hydrographic surveys using vesselmounted and a vessel- towed ADCPs (acoustic Doppler current profilers) and CTD (conductivity, temperature, depth) casts off the central Israeli coast (depths from 10 to 800 m), long-term time-series measurements of watercurrents and thermal structure in the water column from bottom mounted ADCP sites over the shelf (water depths of 25, 60, and 130m) and Aaanderaa RCM7 current meters moored at a site on the upper slope (300 m depth). Several thermistors were attached to the mooring line of the upper and shelf break sites. These measurements were complemented by forecasts and simulations using the Princeton Ocean Model (POM) with grid resolution of 1.25, nested within the eastern (ALERMO) and the general (OGCM) Mediterranean Sea models. This study is part of an ongoing US-Israel Binational Science Foundation funded project, which also includes microstructure and turbulent profile measurements aimed at combining the meso-scale and micro-scale transport and mixing processes.

The ADCP surveys revealed the temporal and high spatial variability of the currents on the shelf and slope region with length scales of O(10-20 km), accompanied by cross shelf transport due to the presence of eddies and onshelf intrusions of deep sea meanders up to the inner shelf. They also confirm the occasional existence of an along-slope northward baroclinic current jet during the winter season and provide important information about its structure. The surveys, with the help of the modeling simulations, show the along-slope jet to be part of the cyclonic jet following the eastern rim of the Levantine Basin during and following the southeastern winter storms or as a local intrusion of a deep sea current.

Measured velocities of the jet were relatively high with speeds as high as 1m/s and the jet was found to interact with the upper slope to produce strong northward currents close to the seabed. Data from the current meter sites showed that the downwelling flow over the shelf and at the shelf edge was mostly confined to the bottom boundary layer (BBL). This is believed to be due to the presence of seaward Ekman veering of the velocity within the BBL (vertical extent of 20-30 m) occurring during winter storms and during the relaxation period after the storms. The seaward flow at the BBL over the shelf break was found to be higher during the presence of an along-slope jet due to the stornger velocities over the seabed.

A persistent characteristic of the currents over the shelf break was the increase of current velocity with depth, resulting in a local maximum with speeds as high as 1 m/s at the top of the BBL. This local maximum is consistent with the existence of significant horizontal density gradients observed over the shelf break during the two winter experiments These density gradients were accompanied by a deep density front on the upper slope during the presence of the along-slope jet. Towards the end of the winter season the frontal jet weakened and the water column at the 300 m site became mixed, allowing for the strong upper layer currents to reach the bottom. Although the presence of

both the along-slope jet and the downwelling circulation were well simulated by the numerical model, the strength of the jet was underestimated and the model failed to reproduce the observed increase of the current speed with depth over the shelf break.

Fig. 1. Current vectors at -14 m from ADCP transects: 25 Feb 2009. Also shown are the positions of the CTD stations during the cruise (circles) and fixed current mooring stations during 17 Dec 08- 31 Mar 2009 (X).

INVESTIGATING CHANGES IN THE ATLANTIC WATERS CHARACTERISTICS ALONG THE EGYPTIAN MEDITERRANEAN COAST

M. A. Said ¹*, M. A. Gerges ¹, I. A. Maiyza ¹, M. A. Hussain ¹ and A. A. Radwan ¹

¹ National Institute of Oceanography and Fisheries (NIOF), Alexandria, Egypt - mamsaid2@hotmail.com

Abstract

The paper investigates the changes in characteristics of the Atlantic Waters (AW) as they move eastwards along the Egyptian coast in the South-eastern Mediterranean. The study analyzed a long series of temperature, salinity and σ_t data, collected by several expeditions that were carried out by research vessels of different nationalities, including Egypt, during the period 1959-2008, averaged for the winter and summer seasons. The paper also examined the long-term (50 years) changes that occurred in the characteristics of the water masses off the Egyptian coast as a result of damming the Nile River in 1965 and the subsequent cessation of its discharge into the Mediterranean.

Keywords: Eastern Mediterranean, Temperature, Salinity, Time Series

The long-term (1912-1971) time series of data on the Nile River discharge into the Mediterranean before and after the construction of Aswan High Dam in 1964 showed that the average yearly discharge before damming was of the order of 62 km^3 . The summer of 1964 witnessed the last normal Nile flood, which was exceptionally high and reached 63.73 km^3 . From 1966 to 2007, the Nile discharge remarkably decreased to a yearly average of 3.92 km^3 . Moreover, the annual cycle of the discharge has also changed from July or August to the winter months of December, January and February. Such a change in both the total amount and pattern of fresh water discharge to the Mediterranean would certainly affect the physical, chemical as well as the biological conditions of the southeastern part of the Mediterranean Sea.

In winter, the surface water temperature varied between 16.6 and 18.5°C, with slightly colder or warmer spots. The surface salinity changes between 38.60 and 39.30, with a general trend of increasing eastwards. The most prominent feature of the salinity distribution at the surface is the presence of a nucleus of salinity > 39.00 that lies between longitudes 27-29°E. This nucleus is characterized by low temperature (16.6°C) and high density 28.7st. The above feature coincides with the location of the well-recognized gyre known as Mersa Matruh gyre. In summer, the surface water temperature varied between 22 and 28°C. The area of slightly cold water is the area of the Mersa Matruh gyre. In order to study the vertical space variability of the hydrographic parameters, the average winter and summer values of each of the water temperature, salinity and density st were presented on a vertical section taken parallel to the Egyptian Coast along latitude 32°30'N and between 25°30' and 34°E longitudes.

Only one surface water mass could be observed during winter in the upper 200 m layer. This surface water mass is characterized by temperature values ranging from 15° to17°C, salinity maximum in the range of 38.90 - >39.10 and corresponding density values of 28.5-28.9 st. Three water masses could be observed in the upper 250 m layer in summer, as follows: The surface water mass, occupying the upper layer from 30 to 50 m depth, with temperature values of 22° to 28°C and salinity 38.8 to 39.20. The subsurface water mass with temperature values of 16° to 22°C and minimum salinity (<38.60-38.80). This water mass is of Atlantic origin, characterized by oxygen maximum of values >5.2 ml/l, and occupies the 50-150 m layer. Below this layer, the Levantine intermediate water mass (LIW) of temperature <16°C and maximum of salinity (38.90-39.10) is clearly identified. These water masses were previously observed and discussed in detail by Said et al. [1]. Temperature and salinity anomalies indicated increasing trends for both temperature and salinity that reached 0.62°C/dec and 0.067/dec, respectively for the Mediterranean surface waters, and 0.56°C/dec for temperature and 0.035/dec for salinity for the Atlantic water (Fig.1).

Millot [2], using an autonomous CTD set at 80 m depth on the Moroccan shelf to monitor the inflowing AW during the period 2003-2007, found that the AW has encountered considerable salinification at the rate of about 0.05/yr, i.e. ~0.2 in the 4-year period of observation. The obtained results confirm that the increase of temperature and salinity of AW with time are attributed to both anthropogenic modifications, especially the Nile damming, and the local climatic changes, which need further investigation.

Fig. 1. Time series from 1958 to 2008 of (a) temperature and (b) salinity for the Atlantic waters $% \left({{{\bf{n}}_{\rm{B}}} \right)$

CLIMATE CHANGE AND MARITIME INDUSTRY

Fani Sakellariadou 1*

¹ Dept of Maritime Studies, University of Piraeus, Piraeus, Greece - fsakelar@unipi.gr

Abstract

Climate change is regarded as one of the major environmental and socioeconomic issues that Earth has to face. Maritime industry contributes significantly to the global greenhouse effect as shipping emissions are increased significantly with time. Efforts have to focus on green shipping initiatives under an international and holistic approach. *Keywords: Atmospheric Input, Global Change, Pollution, Temperature*

Nowadays, climate change represents one of the greatest environmental and socioeconomic threats of Earth. It is the product of natural processes, responsible for long-term climate fluctuations, and anthropogenic activities, that over the past several decades had a rapid increase in global average temperatures. Human influences are related mainly to ozone layer depletion and greenhouse effect reinforcement. There is a general tendency for a global agreement to control climate change, reduce further human impact and find all possible ways to achieve a reasonable adaptation to the current change.

Maritime industry has various environmental effects associated with the life cycle of the ships, the construction and use of ports and the carried goods. It affects the environmental quality of air, water and land. The most important pollutants are carbon dioxide, nitrogen oxides [1], sulphur dioxide, heavy metals, petroleum hydrocarbons, antifouling agents, particulates, invasive species from ballast water discharges, various scrapping materials including hazards. They are discharged from maritime traffic (cargo spills, oily bilge discharges, ballast water, antifouling paints and sewage), port activities (sewage, cooling waters, spills), solid waste (dumping), port construction and maintenance dredging, shipyards and repairing zone. Often, they lead to eutrophication, acidification and biodiversity loss. World maritime community focuses attention on the importance of shipping safety, maritime security and environmental health. Maritime industry has an effect to climate change mainly due to the greenhouse gases emitted. Although pollutant emissions from land based sources are gradually decreased, those from shipping are increased. In the coming future the situation will be worse, if no action will be taken, as transport at sea is increasing by an annual 5% on average. Last forty years, the world merchant fleet has grown by 70% while the transport has almost tripled [2, 3]. Respective problems are more severe in coastal areas and especially ports. Dirty smoke pouring out from ships funnels has a major impact on the air quality of coastal cities. Oxides emitted to the air are responsible for the acid rain that affects seawater pH in the semi-closed water basin of a port. The same does not apply to the open sea.

Considering the Mediterranean basin, the situation asks for an effective action to be taken, as the sea is a major oil transportation route. It is estimated that each year, up to one million tons of crude oil from accidental spills, illegal bunkering and tank cleaning practices, as well as inadequate harbour facilities are discharged into the sea. The effects of the respective pollution are very severe, as the Mediterranean, besides its rather small extent equal to the one per cent of the world's marine areas it is regarded as the biotope of up to six per cent of the total marine species, including some of the most endangered ones.

However, it has to be mentioned that shipping is basically an environmentally sound means of transport, able to carry large quantities of goods with a relatively low energy demand. Emissions of air pollutants from ships can be eliminated by applying engine technology innovations, using after treatment techniques, burning better quality fuel. Both, the adoption of air pollution prevention regulations and the application of economic tools will be very useful. The general concept of the environmental status stabilization and the further environmental quality improvement should also incorporate the general public awareness of the issue. Current research focuses on green shipping that considers limitation of ecosystem impacts from shipping activities, less fossil fuel dependence, promotion of renewable technologies and limitation of safety hazards. The matter asks desperately for an international as well as holistic approach.

Maritime industry, due to its international character, needs a global agreement to control its negative effects to the environmental quality. Such attempts have been made in the Marine Environment Protection Committee of the International Maritime Organization of United Nations. In addition, The European Union has also studied the various implications derived from an EU co-ordinated action aiming to the reduction of air pollutants emitted from ships.

Marginal external costs of air pollution from shipping can be estimated using the impact pathway approach that traces emissions through dispersion and environmental chemistry, exposure of sensitive receptors, impacts and economic valuation using the willingness to pay approach. These estimates could be very helpful especially as the contribution of shipping emissions to trans-boundary air pollution impacts is increasingly recognized.

WINTER 2009. A NEW STEP IN THE WESTERN MEDITERRANEAN TRANSITION

J. Salat ¹*, M. Emelianov ¹, P. Puig ¹, J. Font ¹ and J. L. Fuda ² ¹ Institut de Ciències del Mar (CSIC), Barcelona, Spain - salat@icm.csic.es ² Centre d'Océanologie de Marseille (COM), Marseille, France

Abstract

The signal of Deep Water Formation (DWF) activity in winter 2009 has been tracked through the HydroChanges (HC) time series, particularly in the classical MEDOC point (HCM: 42° N, 5° E) and on the Catalan continental rise (HCC: $41^{\circ}28^{\circ}$ N, $3^{\circ}40.4^{\circ}$ E), and from CTD data obtained during three cruises during 2009. The results pointed out to an absence of cascading and a new step towards a salinisation of the WMDW newly formed by open sea convection in the western side of NW Mediterranean. The updated data reveal that older WMDW, slightly colder and less saline, has been displaced towards the SE. The salinity of the newly formed WMDW after winter 2009 was ~ 0.005 higher than the previous one, with a potential density increase of 0.002-0.004 kg/m³. *Keywords: Deep Waters, Water Convection, Western Mediterranean*

Introduction

A new structure of the WMDW since 2005 forming a 'hook' in the θ S diagram has been extensively described in recent papers and summarized in the CIESM Monograph 38 [1], being one of the major effects of what has been termed as Western Mediterranean Transition (WMT). The structure of the WMDW shows three water types: a θ S minimum below the LIW, corresponding to the WDMW before 2005, followed by a relative maximum of θ S and a new relative minimum of θ S at the bottom. This three points, or water types forming the 'hook' structure will be named respectively as 'O', 'N' and 'C' as in [2]. This presentation is devoted to the characteristics and distribution of the WMDW newly formed in winter 2009. To avoid confusions, the whole structure of the WMDW present before the 2009 modification will be indicated as PDW, and the contribution of this year as NDW.

Data available and results

After two relatively mild winters of 2007 and 2008 with almost no activity of DWF, HCM series from 2200 m depth, displayed an abrupt shift of S (+0.010) and θ (+0.040°C) between 13 and 15 February 2009 [3]. While θ slowly recovered the previous values, the S shift lasted at least until the end of May, when the mooring was recovered. Data from the HCC site, at 1850 m depth, showed similar shifts 5-6 days later (Fig.1). As in HCM, θ progressively recovered the old values and S was slightly reduced during the next months, but when the mooring was recovered in September, a difference of (+0.006) still persisted. Therefore, the potential density of the deepest layer suffered an increase between 0.002 and 0.004 kg/m³ in 2009. Unfortunately no CTD probe was available during the recovery operation to examine the hydrographic structure above the mooring site.

Fig. 1. θ S diagram of the HCC series

In both HCM and HCC moorings near bottom currents and turbidity were also recorded. At the HCC site, the current was steadily slow (<10 cm/s towards the south) until 19 February. Then it became unstable with some fluctuations that

lasted one week. After this instability episode the current shifted towards the SE during two weeks. After 7 March, currents recovered the southwards direction but with much stronger velocities (>30 cm/s) up to 12 March when slowed to <10 cm/s again. Suspended sediments were low except during the acceleration period (8-12 March), being consistent with a signal of local sediment resuspension.

Data from CTD casts in the NW Mediterranean after this DWF period were obtained in the framework of the FAMOSO Project in March (8-23), May (1-13) and September (14-20) 2009. Although sampling in those cruises was not dedicated to study the spreading of the newly formed WMDW (NDW), data obtained can be suitable for this purpose as there were several deep casts between HCM and HCC sites. The first CTD casts in March showed almost homogeneous waters from 0 to 2400 m in front of the Catalan coast (41°30'N, 3°30'E) with θ and S corresponding to the NDW values observed in the HC series. This NDW was present in several stations not only in March but also in May and still in September, at least in the NW sector. The thickness of the layer occupied by the NDW was higher (>300 m) in the stations located near the continental slope, becoming thiner towards the east and south. Accordingly, the whole PDW structure was displaced upwards and southeastwards.

Discussion

February 2009 has been much colder and windy than the two precedent years in the western side of the Gulf of Lions and along the Catalan coast. Northerlies were very frequent and some of them were very strong (e.g. the storm of 4-7 March with sustained winds of 40 m/s). Under such atmospheric forcings a response similar to that in winter 2005 could be expected, with strong convection and deep cascading. However, there is no evidence of this latter phenomenon in 2009, probably due to the water properties over the shelf at the beginning of the stormy period. While autumn 2004 and winter 2005 were very dry, autumn 2008 end winter 2009 were wet. Therefore salinity over the shelf had to be much lower than in 2005 thus preventing an excessive increase of the density. However, in open sea, the convection could be as active as it was in 2005 involving again important amounts of LIW over a large area, including zones near the continental slope where WIW formation typically takes place. For instance, the short time interval between the shift in HCM and HCC (less than one week for a distance of >120 km), or the structure found in the first CTD casts of the FAMOSO cruise in March, reveal a probable local origin of the perturbation. From now, the NDW reaching the bottom layer should mix with the C water type of PDW near the bottom contributing to a new increase of salinity in the bottom layer and pushing upwards, one step more, the O water type (from before the start of the WMT in 2005). As these O waters are located just below the LIW, a further decrease of the salinity of the intermediate waters reaching the western slopes can be expected in the following years, as it has been observed in the MOW at Gibraltar after the WMT.

EAST MEDITERRANEAN TRANSIENT AND DENSE WATER DYNAMICS IN THE AEGEAN SEA

Ettore Salusti ^{1*}, Volfango Rupolo ² and Salvatore Marullo ² ¹ Istituto Nazionale Fisica Nucleare, Roma, Italy - ettore.salusti@roma1.infn.it ² ENEA - CR Casaccia, Roma, Italy

Abstract

The relation between East Mediterranean Transient (EMT) and deep water formation in the Aegean Sea is studied using the last two decades of infrared satellite data, available hydrological data and a theoretical model based on the dynamics of density currents crossing and outflowing from a strait. The results of this analysis were then interpreted in the light of the simulations produced by a numerical model for the last 40 years. *Keywords: Deep Waters, Aegean Sea*

Dense water formation processes play a fundamental role on the thermodynamics of the Mediterranean Sea. Such processes in the Aegean Sea are known from a very long time. Lacombe et al. [1] stated how the North Aegean very dense waters are probably renewed by the dense waters formed in wintertime in the gulf of Saros. Miller [2] reported deep temperatures from 10.0 to 14.5 °C which, together with the high salinity, made this sea particularly interesting on thermodynamic grounds. El-Gindy and El-Din [3] estimated that about 50% of the dense waters in the Cretan Sea were originated in the Mount Athos region. Recently such processes received a remarkable attention as main sources of the Eastern Mediterranean Transient. During the CIESM Workshop on Dynamics of Mediterranean deep waters (Malta, 27 - 30 May 2009, published as CIESM Monograph 38), among other fundamental points attention was focused on the origin of this EMT. Some further analyses were therefore suggested as a detailed investigation about the dense water formation regions as the Cretan Sea, the Turkish shelf (Limnos Plateau) or the Northern Aegean (Samothraki Plateau). We therefore analyzed historical satellite images (year 1985-2009) of the whole Mediterranean Sea comparing sea surface temperature anomalies of the Adriatic Sea with the corresponding ones observed in the Aegean Sea. SST maps where kindly provided by the GOS laboratory of ISAC/CNR in Rome (http://gos.ifa.rm.cnr.it).

Then we used the available hydrologic data of the Aegean Sea to validate the results of such satellite comparison . We so obtain a yearly estimate of the dense water production of these two very thermodynamic seas, to check the original estimate of El-Gindy and El-Din [3]. One has to remark a fundamental difference between the Adriatic (with a rather simple and flat morphology) and the very complex Aegean sea bottom. There are some depressions, as the North Sporades Basin (~ 1500 m maximum depth), the Mount Athos Trough (~ 1000m maximum depth) and the Trough between Samothraki and Limnos (~ 1600 m maximum depth) in its northern part only, that can play the role of dense water reservoirs. These estimates are compared with results of recent numeric experiments [4] that interestingly evidence the role of the northern Aegean shelf dense waters on the basin thermodynamics and the importance of the Eastern Mediterranean Transient. Comparing numerical and satellite data we focus our attention on the possibility that similar but less intense outflows from the Aegean could have happened previously in the past. We finally study the effect of a novel version of the classical Bernoulli suction that takes into account entrainment and bottom friction [5] to emphasize outflow from a marine strait, as Antikithira, Kithira and Kassos [6].

A NEW BUOY FOR MEASUREMENT AND REAL TIME TRANSMISSION OF SURFACE SALINITY

J. Salvador¹, P. Fernández¹, A. Julià¹, J. Font¹* and J. Pelegrí¹ ¹ Institut de Ciencies del Mar (CSIS),08003 Barcelona, Spain - jfont@icm.csic.es

Abstract

A surface buoy has been designed to measure temperature and salinity with high accuracy and transmit the data by satellite for a long period of time in studies of mesoscale or long scale oceanography. Prototypes have been built and tested in two different versions: to collect data close to the surface or at a depth of 100-150 m depending on the objectives of the experiment. These buoys are mainly used for Lagrangian measurements after being released from a vessel, although long duration tests have also been made with moored units mainly in the NW Mediterranean.

Keywords: Salinity, Temperature, Instruments And Techniques

Measuring oceanographic variables, mainly temperature and salinity, from drifting buoys is an important component in many process studies or long duration ocean circulation observations. Nowadays several kinds of buoys are manufactured to operate as surface drifters or profiling floats. But in both cases no commercial versions exist that provide sufficiently reliable salinity data close to the surface, since the occurrence of biofouling (in surface buoys) or the risk of surface particles being ingested into the measuring circuit (in profiling floats) can easily degrade the accuracy of recorded data.

The Institut de Ciències del Mar (CSIC, Barcelona), as contribution to two different research projects (MIDAS, Microwave measurements and algorithms development for the SMOS mission, and CANOA, Upwelling current in NW Africa), has developed and further tested a platform to record oceanographic parameters and transmit them in real time. The main characteristic of the platform is its modularity and versatility.

The support structure is a 380 mm diameter buoy formed by two semispheres injected in propylene charged with glass fibre. The two halves are fixed through 24 points and an o-ring gasket to ensure water-proof sealing. Two eight-pin communication connectors can be adapted to each semisphere. The overall structure has been tested for pressure and confirmed a good behaviour up to 7000 hectopascals. To adapt the temperature-salinity (T, S) measurements probe an inox structure was added to the buoy with four union points and a support for the instrument (Fig. 1).

Fig. 1. Moored version of the buoy with the inox structure to attach the SBE37SI probe $% \left[{{\rm{T}}_{\rm{T}}} \right]$

This buoy has been used both in Lagrangian studies, transmitting data while drifting, and in Eulerian studies, moored in a fixed point. The Lagrangian version uses the same mechanical configuration than the SVP (Surface Velocity Program) drifter [1] adopted as standard by the World Ocean Circulation Experiment, it was deployed in the second cruise of the CANOA project in November 2008. Several configuratios were tested and one of them succeeded to record a surface (T, S) time series for over a year, this buoy still drifting and transmitting (T, S) data in early 2010. For Eulerian measurements one buoy was moored during 2007 and 2008 in the Medes islands, a small coastal archipelago in the NW Mediterranean, with very good results in terms of batteries duration and sensors stability. At present two units are moored in Las Cruces, Chile (September 2008, LINCG-Global project) and one in Colima, Pacific coast of Mexico (May 2009, EMPAM project).

Fig. 2. Preliminary prototype of the drifting buoy with an additional flotation in the line that connects to the standard cyclindrical drogue

The control electronics is formed by a Microchip 16F876A microcontroller that manages the data acquisition, implements a compression algorithm and sends the information to a SEIMAC X-CAT transmitter. The platform can adapt transmitters for the Orbcomm and GlobalStar systems, plus Argos that is the one now implemented. The system incorporates supercapacitors to use low cost batteries and to avoid sudden power decreases due to high energy consumption in short times (1 A during transmission).

The units built until now use a SeaBird microcat CTD probe, model SBE37SI. This instrument has a temperature drift of 0.0002°C/month and a conductivity drift of 0.0003 S/m/month. The designed buoy can use any other sensor able to send data through a serial port, and can be also adapted to record analogic information.

This technological development has been mainly funded by the Spanish National R+D Plan through projects CANOA (CTM2005-00444/MAR) and MIDAS-4 (ESP2005-06823-C05). J. Salvador and P. Fernández acknowledge the support of the technicians formation program of the Spanish Ministry of Education and Science / Ministry of Science and Innovation.

Abstract

Increases in sea surface temperatures (SSTs) have been recorded to occur globally, with the Mediterranean SSTs rising about twice as much as those of the global oceans. Here we analyse and compare satellite remote sensing SST data with in-situ data for the period 1996-2009 in the Levantine Basin. Further, temperature and salinity profiles from oceanographic cruises in this region were extracted from various databases, in order to study the interannual variability at the surface layer (0-10m). We show that the Levantine Basin has undergone SST as well as sea surface salinity (SSS) increases, during the last 14 years, occurring at both interannual and seasonal time scales. The driving mechanisms of these changes need to be investigated, as they may be driven by changes in latent heat losses and by the variability in regional wind speeds.

Keywords: Surface Waters, Temperature, Salinity, Remote Sensing, Levantine Basin

Preface

The reality of global warming since the industrial era is manifested in part by changes in global surface temperatures. Past studies have documented global SST increases between 0.3°C and 1.0°C over the last millennium [1], with the most rapid warming occurring over the past 30-40 years [2, 3]. Regional SST increases have also been reported in the Mediterranean for each of its two basins [4, 5]. Overall, SSTs across the Mediterranean as a whole have been rising about twice as much as those of the global oceans [6].

Results and Discussion

Analyses of annual mean SST data indicate that over the last 14 years (1996-2009) a general warming has occurred over the Levantine Basin, and occurred at an average rate of approximately 0.05°C per year. This increase in average SSTs is also seen in the seasonal averages, especially during the summer. Spatial variability in the decadal warming is depicted in the SST anomalies, with positive anomalies dominating most of the Levantine during the later part of the 14-year time period. An area southeastern of Cyprus is seen during some years to be warming up much more strongly than the rest of the Levantine Basin. This area corresponds with the Cyprus warm core eddy [7]. Empirical Orthogonal Function (EOF) analysis was performed on the seasonal SST data to examine their spatial and temporal patterns of variability, as well as on the annual data. The spatial eigenfunctions of mode 1 show that the seasonal and annual SSTs across the entire Levantine share high positive eigenfunctions and thus varied in a spatially coherent manner over time. Therefore, the SST variability is characterized by a broad, basin-wide warming (mode 1). The seasonal principal component (PC) of the same mode (PC1). which depicts the time variation of the first mode, varied over the years supporting the fact that the Levantine is experiencing a strong seasonal cycle. The PC1 of the annual data supports the fact that higher than average SSTs were observed across the Levantine during the later part of the 14-year time period. An asymmetry in the N-to-S direction is depicted in the spatial eigenfunctions of mode 2. Areas in the northern Levantine are out of phase from areas in the southern parts of the basin, creating a dipole pattern of heating and cooling at interannual and interseasonal time scales. Analysis of the in-situ SST and SSS data does not reveal any time-scale patterns. However, the pattern of in-situ SST variability is shared by the patterns of SSS. Further, satellite SST data are strongly correlated with the in-situ SST data. The driving mechanisms of these changes need to be investigated, as they may be driven by changes in annual latent heat losses and by the variability in regional wind speeds. Finally, it will be valuable to investigate future trends in SSTs to determine whether the observed patterns of SSTs represent a continued pattern of persistent warming or a new direction for an everchanging Levantine Basin.

SUBINERTIAL VARIABILITY OF THE EXCHANGED FLOWS AT THE WESTERN EXIT OF THE STRAIT OF GIBRALTAR

A. Sanchez-Roman¹, J. Garcia-Lafuente¹, F. Criado-Aldeanueva¹, J. Delgado¹, J. M. Vargas¹, J. Soto-Navarro¹, J. C. Sanchez-Garrido¹, C. Naranjo^{1*} and C. Calero¹

Abstract

Four year-long time series of Acoustic Doppler Current Profiler (ADCP) observations at a single station in Espartel sill have been analysed in order to investigate the subinertial flows through the Strait of Gibraltar. Estimated net flow at the western exit of the Strait has been compared with atmospheric pressure over the north eastern Atlantic (parameterised by the NAO index) and sea level pressure and wind-stress in the western Mediterranean. The main driving force is the atmospheric pressure over the Mediterranean Sea, although wind stress in the Atlantic side of the Strait may contribute appreciably to subinertial net flow. *Keywords: Atmospheric Input, Western Mediterranean, Water Transport, Strait Of Gibraltar*

The western Mediterranean Sea is dynamically connected to the Atlantic Ocean through the Strait of Gibraltar. The excess of evaporation (E) over precipitation (P) and river runoff (R), together with the conservation of mass and salt in the Mediterranean basin drive the two-layer baroclinic exchange in the Strait. This exchange has been traditionally described as an inverse estuarine circulation [1] with an upper flow Q_1 of about 1 Sv (1 Sv = 10^6 m^3 s⁻¹) of fresh (S_A \approx 36.2) and warm Atlantic Water spreading into the Mediterranean basin, and a lower flow Q_2 of relatively cold and salty (S_M \approx 38.4) Mediterranean Water. A long term barotropic flow $Q_0 = Q_1 - Q_2$ of the order of 0.05 Sv is necessary to balance the water deficit (E-P-R) of the Mediterranean Sea. The exchange is not steady but highly variable. According to the timescale of the process under study this variability has been traditionally classified into tidal, subinertial and long-term (seasonal and interannual). Subinertial flows, with periods from a few days to a few weeks or months, are mainly driven by meteorological forcing [2, 3] and are related to atmospheric pressure fluctuations over the western Mediterranean [4]. These flows are mainly barotropic (depth independent) although a baroclinic contribution can be identified due to the effects of local winds over the Strait.

In this work, ADCP velocity records collected over Espartel Sill (ES) are used to investigate the subinertial fluctuations of the exchanged flows at the western exit of the Strait of Gibraltar. Data from ES are the most recent recorded in the Strait. This station was placed at 35° 51.70'N, 5° 58.60'W in September 2004 and it is still acquiring information so five year-long time series are now available, this making the analysis of the flow seasonality a feasible task. A four year-long subset (from September 2004 until January 2009) has been used in this work. The ES station is part of the Spanishfunded INGRES project. The two-layer character of the exchange requires an interface definition to compute the transports. The easier and more obvious definition (after removing tidal fluctuations, which distort the two-layer exchange during part of the tidal cycle) is the surface of zero along strait velocity that separates water flowing into the Mediterranean and water flowing out. Subinertial velocities only reverse in very exceptional situations of extreme meteorological forcing. On the other hand, seasonal and interannual variability are always too weak to reverse flows. Therefore, the surface of null along-strait velocity is appropriate to carry out an analysis of the two-way exchange at subinertial frequencies [3]. ADCP data from ES were used to compute the Mediterranean outflow (more details in [5]) whereas the net flow (and hence the Atlantic inflow) were estimated from a mass-balance over the Mediterranean. Finally, atmospheric pressure and wind stress observations collected both in the Alboran Sea and the Strait of Gibraltar have been used together with the NAO index in order to analyse the response of the exchanged flows to the meteorological forcing and its seasonality.

The net flow has a mean value of 0.04 Sv at it presents a seasonal signal of around 0.04 Sv amplitude with maximum in September and minimum in March, similar than that obtained by [3] in the eastern Strait. The time-averaged Mediterranean outflow is -0.77 Sv with a maximum (absolute) value in April and minimum in November [5] (seasonal signal of 0.025 Sv amplitude). The Atlantic inflow was eventually estimated from both transports. It presents a mean value of 0.81 Sv with seasonality quite similar to that of the net flow. Meteorologically induced net flow fluctuations are chiefly driven by atmospheric pressure changes over the Mediterranean sea showing a negative correlation that turns positive for the Mediterranean outflow due to the baroclinic response of the exchanged flows. Wind stress must be also taken into account since it may appreciably contribute to subinertial net flow.

Abstract

The SESAME-IT4 cruise covered a large area of the Western Mediterranean Sea characterized by strong gradients. On the basis of satellite images and physico-chemical properties different regions were individuated. These regions showed also different biological populations. These data underline that DOC plays an important role in carbon fluxes in the Mediterranean Sea. *Keywords: Carbon, Organic Matter, Western Mediterranean, Surface Waters, Nutrients*

The Western Mediterranean Sea is an area characterized by the strongest gradient observed in the whole basin. The analysis of the ten years climatological map of chlorophyll a shows that SESAME-IT4 survey covered regions characterized by very low Chl a concentrations exhibiting a sub-tropical regime (no bloom), as well as areas with maximum Chl-a concentrations (the Gulf of Lions), where intense blooms are observed [1]. The cruise was carried out in March-April 2008, which is the period characterized by the maximum biomass accumulation. Main goal of the survey was to get information on the functioning of different trophic systems in terms of biomass, nutrients, carbon accumulation and/or carbon export. Satellite images confirmed what we expected from the literature (high gradients and strong biomass accumulation). In particular the occurrence of strong variability and intense mesoscale activity was observed as well as an extended bloom in the northern part (> 40°N) of the study area. Another feature that emerged from satellite images is the occurrence of an anticyclonic eddy in the central part of the study area (S-IT4-008). In situ data evidenced that in the northern stations (>40 $^{\circ}N)$ water column was well mixed and the chimney of winter convection was still visible; in contrast in the southern stations, stratification was more pronounced. The evaluation of the residual nutrients confirmed that the bloom in the Gulf of Lions was still in progress.

Fig. 1. Phytoplankton abundance and composition at the surface (5 m), superimposed to the map of sampling stations. The black diamonds indicate all the sampling stations (CTD, DOC, O₂, Nutrients), the black squares indicate the stations where biological parameters (phytoplankton, mesozooplankton, bacterial, abundance and composition) were also measured.

Phytoplankton abundance and composition showed that small flagellates dominated everywhere and that the composition was different between the northern and the southern stations with a higher percentage of diatoms (small non-colonial species) in S-IT4-0015 and S-IT4-017 (Fig. 1). In the microplankton fraction (cells> 20 μ m) collected by net samples, Silicoflagellates dominated at S-IT4-017 and S-IT04-015, where the highest abundance of nanoplankton was also observed (Fig. 1). Mesozooplankton communities were numerically dominated by copepods in the whole area, but at S-IT4-015 salps also occurred with high abundance. These pelagic tunicates play an important role in C export, due to their high reproduction rates, efficient feeding on particles in a wide size-range, and production of large and fast sinking fecal pellets. The northern stations were also characterized by the highest bacterial abundance (14.1x 10^5 cells mL^-1) about twice that found below 41 °N.

Tab. 1. Integrated average in the layer 0-100 m for PO_4 , NO_3+NO_2 , POC and DOC. The ratio C.N and C:P were calculated by using the integrated average.

	PO ₄	NO ₃ +NO ₂	POC	POM	POM	DOC	DOM C:N	DOM
Station	Μц	Μц	Μц	C:N	C:P	μМ		C:P
S-IT4-008	0.01	0.17	3.804	7	182	72	13	529
S-IT4-013	0.15	3.61	2.971	8	209	54	375	70
S-IT4-015	0.10	3.61	5.430	7	142	53	12	296
S-IT4-017	0.10	3.70	4.634	6	106	55	(306

Despite the marked difference in biomass, POC fluxes were 70 mg C m⁻² d⁻¹ in S-IT4-017 and 38 mg C m⁻² d⁻¹ in S-IT4-008. A large gradient was observed in DOC, with a minimum (49 mM) in areas with a well mixed water column, a maximum (72 μM) at S-IT4-008 and values of 53-55 μM at the other stations (Tab. 1). As it is very probable that DOC production was very high in the northern stations, the low values observed there can be explained to some extent by the mixing and by very fast consumption due to the production of labile material and/or to a high efficiency of microbial loop. One interesting feature is that the C:P ratio in both POM and DOM was clearly affected by the trophic regime: low C:P ratios were found where PO₄ was available, suggesting the occurrence of POM and DOM rich in P and hence a less extent of P recycle; in contrast, in conditions of P limitation (S-IT08), most of the P available in the POM and DOM was efficiently used, resulting in higher C:P ratio (Tab. 1). The S-IT4-08, shows a peculiar behavior: here the nutricline was located at 150 m and the highest DOC concentrations were found (72 µM). TS properties evidence the presence of a different water mass, likely isolated by surrounding waters by the anticyclonic circulation. The low nutrients concentrations, the low biomass, the high C:P ratios in both POM and DOM and the high DOC concentration, all indicate an advanced stage of seasonal cycle. The accumulated DOC plays an important role in carbon fluxes because it can be transported below the mixed layer when the thermocline breaks. A rough estimate of the relevance of such transfer suggests that, in the Mediterranean Sea, the role of DOC in C export is comparable to that of POC.

Abstract

HYDROCHANGES is an international program supported by CIESM (www.ciesm.org/marine/programs/hydrochanges.htm) initiated in 2002, to monitor the long-term variability of hydrographic properties of Mediterranean water masses – a priority in the context of global warming. We present an overview of the most recent observations and attempt to link the different time series. *Keywords: Hydrology, Time Series, Monitoring*

HYDROCHANGES (HC) is a network of continuous, long-term measurements of temperature (θ) and salinity (S) in the Mediterranean. The HC monitoring strategy is based on *permanency*, to address the long-term variability, *key sites* to address specific processes, *simplicity of logistics* with a local management and short shiptime requirement for maintenance, and *simple instrumentation* (short moorings generally a few meters above the seafloor, supporting self-contained quality CTDs). Moorings are located in key places (Fig. 1) to track the signals indicative of specific processes driving the Mediterranean functioning, especially in straits and channels and in regions where dense water formation (DWF) occurs, either open-sea convection or shelf cascading. Data sets (Fig. 2) have been already widely exploited, also linking them with repeated CTD sections [1, 2, 3, 4, 5, 6].

There are some evidences of interannual θ (and S) increases (e.g., Fig. 2a, 2c and 2g), but the HC time series are too short vet to address issues on long-term variability. Nevertheless, they have demonstrated their relevance to accurately detect effects of DWF processes. This is particularly evident in the NW basin, showing the succession of offshore convection and shelf cascading in early 2005 and 2006 (Fig. 2). The mooring time series in the lower Catalan continental slope (Fig. 2g) recorded with unprecedented details the succession of episodes contributing to DWF in 2005: the arrival of open-sea convection water (positive jumps of θ and S in late January), the shelf cascading water (drop in θ and S in early March), and a warmer and saltier situation after April. Such a succession of events was recorded in 2006 too, while in early 2009 only signals pertaining to a less intense open-sea convection were recorded. The mooring at 42°N-5°E (Fig. 2f) also shows DWF in 2009, one week earlier, with an abrupt positive jump in θ and S in late February. The parallel marked increases of θ and S in the Sardinian Channel (SC) since summer 2005 (Fig. 2c) are likely to contain the remote signal of what happened in the northern part of the basin, with the new deep water slowly passing through the channel to reach the Tyrrhenian.

The various time series at Gibraltar (Fig. 2h) provide an insight in the interannual and seasonal variability of the outflow [3, 5] and inflow [4]. The latter has to be considered for DWF issues, as [4] reported a huge S increase (0.05/year) in the inflow between 2003 and 2007. In the outflow, the significant θ drop in March 2005 and 2006 might be directly related to a possible rapidly propagating barotropic response of DWF [6]. The monitoring of the Sicily Strait (SS) and the Corsica Channel (CC) is a fundamental task for the quantification of the highly variable heat and salt import from the Eastern Mediterranean, through the Tyrrhenian Sea, towards the western DWF sites (Fig.2b and 2d).

To improve HC we must add moorings in other key regions which are not currently monitored and add supplementary sensors to the CTDs (pressure systematically, oxygen and turbidity recommended). The complementary use of moored CTD vertical profilers would be a great asset, especially in the DWF areas. It requires also the dissemination of common practices (sampling frequency, processing, calibration frequency, archiving) and the set-up of a HC database and meta-database. The common access to all time-series would support efforts for linking the signals observed in both basins and at their connecting points, in order to get the comprehensive picture of the functioning of the Mediterranean. While it is likely to remain a long-lasting challenge, the precise monitoring of the θ and S is already providing reference data.

A "NATURAL" TRACER RELEASE EVENT IN THE WESTERN MEDITERRANEAN SEA

K. Schroeder ^{1*}, H. L. Bryden ², G. P. Gasparini ¹, M. Borghini ¹ and A. Ribotti ³ ¹ CNR-Istituto di Scienze Marine, section of La Spezia, Italy - katrin.schroeder@sp.ismar.cnr.it ² National Oceanography Centre, Southampton, UK ³ CNR-Istituto per l'Ambiente Marino Costiero, section of Oristano, Italy

Abstract

Oceanography is mainly an observational science where direct controlled experiments are hardly feasible. In the past some tracer release experiments have been carried out, that allowed to keep track of water parcels using stable compounds, in a classical lagrangian approach. Recently, intense deep water formation events in the western Mediterranean have produced high volumes of a new deep water, significantly warmer, saltier and denser than previously. These peculiar characteristics are mixing very slowly with the surrounding water and are still detectable in the whole basin. Thus, there has been a natural tracer release event where the tracer is temperature, or salinity, and for the first time we can track the evolution of the new deep water with standard CTD profiles, along its route from its formation region toward Gibraltar.

Keywords: Deep Waters, Western Mediterranean, Circulation

Since 2005 the deep waters of the western Mediterranean Sea (WMED) have experienced significant physical changes, which are likely to be caused partially by the Eastern Mediterranean Transient (EMT). This connection between the two basins, where one anomaly induced the other one decade later, may be a considered as a Mediterranean Sea Transient, MST [1].

The major change involved a change in the deep stratification, with an abrupt increase of temperature, salinity and density in the deep layers of the whole western basin [2]. The sharp signature (Fig. 1) provides for the first time the possibility to unequivocally identify the deep water formed during one specific winter throughout the basin, using only CTD data.

Repeat stations measured from 2005 to 2009 in wide regions of the WMED give the chronology of the new deep water spreading from its formation region towards Gibraltar and towards the Tyrrhenian Sea. Each year, the signature became evident in wider and wider regions, allowing a time-scale estimate of the spreading, which could only have been possible otherwise with a designed tracer release experiment. This time, the tracers are the sharp temperature, salinity and density increases in the bottom layer (Fig. 1).

Fig. 1. Temporal evolution of the "tracer" signature (here density) south of the Balearic Islands.

For more than 25 years the scientific community is aware of the fact that the Mediterranean outflow is composed either by Levantine Intermediate Water (LIW), originating in the Eastern Mediterranean Sea (EMED), and by Western Mediterranean Deep Water (WMDW), which is aspired through the Strait of Gibraltar by Bernoulli suction [3, 4]. The direct outflow of the deep waters may affect the abyssal circulation of the Mediterranean Sea as well as the circulation of the adjacent ocean. In 2005 the new WMDW was found in a wide areas of the WMED, along its spreading pathway, even in the northern part of the Algerian subbasin and in stations near the entrance of the Alboran subbasin. In 2006 the new WMDW was present in almost the entire WMED, excluding the Tyrrhenian and the western Alboran subbasins. More recent data, collected in 2008, clearly show that the only subbasin that has not yet been reached by the new WMDW is the Tyrrhenian Sea. In 2008 the new deep water signature was found at the entrance of the shallower Alboran Sea (Fig. 2a), where its interface with the overlying water was at 950 m depth. Here the unequivocal identification of the winter-04/05 formed deep water near Gibraltar was possible thanks to the particular shape in the TS diagram. Therefore, its detection at about 100-150 km from the Strait of Gibraltar, allows an estimate of the

temporal scales of its spreading: a deep water mass formed in February-March 2005 in the NW-MED has almost reached Gibraltar in 33 months. The fraction of new WMDW still seems to be very low and no signature could be found at stations west of Gibraltar. Nevertheless, the route of the WMDW hypothesized by [3] is confirmed. Indeed also the anomalous WMDW is flowing westward along the Moroccan continental slope, which is an indication of the anticyclonic Alboran gyre extending throughout the water column.

Most recent data (Nov. 2009) seem to detect an increase presence of the "tracer" along the axis of the canyon in the Sardinia Channel, on the way to the Tyrrhenian Sea (Fig. 2b). Fig. 2c evidences that the new WMDW has just got over the sill (1930 m) dividing the Algerian basin from the Tyrrhenian Sea.

Fig. 2. CTD stations in (a) 2008 in the Alboran Sea and (b) 2009 in the Sardinian Channel, evidencing the spreading of the new WMDW (black squares = presence of new WMDW, empty squares = absence). (c) Zoom of the sill region in the Sardinian Channel (the bathymetric grey scale is for (a) and (b) only).

VARIATIONS IN THE SEA SURFACE TEMPERATURE OF THE BLACK SEA DURING THE 20TH CENTURY

Georgy Shapiro¹*, Dmitry Aleynik² and Laurence Mee² ¹ University of Plymouth, Plymouth, UK - gshapiro@plymouth.ac.uk ² Scottish Association for Marine Science, Oban, UK

Abstract

There is growing understanding that recent deterioration of the Black Sea ecosystem was partly due to changes in the marine physical environment. This study focuses on sea surface temperature variability over the 20th century. Results show that the deep Black Sea was cooling during the first three quarters of the century and was warming in the last 15-20 years; on aggregate there was a cooling trend. The Western shelf was more volatile and did not exhibit a statistically significant trend. The cooling of the deep Black Sea is at variance with the general trend in the North Atlantic and may be related to the decrease of westerly winds over the Black Sea, and a greater influence of the Siberian anticyclone. The timing of the changeover from cooling to warming coincides with the regime shift in the Black Sea ecosystem.

Keywords: Black Sea, Continental Margin, Deep Sea Basins, Temperature

Fig. 1. The CUMSUM charts for aggregated temperature anomalies on the western shelf (a) and deep sea (b), and the CUMSUM charts for air temperature anomalies at coastal stations Odessa (c) and Yalta (d).

Introduction

Europe's four regional seas (the Baltic, Black, Mediterranean and North Sea) have all suffered major ecological change in the past three decades. The causes of degradation of the Black Sea ecosystem have been frequently cited as eutrophication due to increased fluvial nutrient load as a result of the Green Revolution [1] and the arrival of invasive species [2]. However, there is an increasing appreciation that current climate change can trigger a major response in the structure and function of marine ecosystems on a decadal timescales [3, 4, 5]. The warming of the World Ocean over recent decades has been firmly established [6]. In the Black Sea, studies of long term changes of the physical properties are sparse.

Data and methods

The source of data for this study was obtained from a number of reputable sources including the World Ocean Database 2001, the Romanian Marine Research Institute, the Goddard Institute for Space Studies and some others. In contrast to previous Black Sea studies, the monthly temperature anomalies rather than the absolute values are used as indicators of temporal changes in Sea Surface Temperature. The benefit of using anomalies is that unlike the absolute temperatures, the SST anomalies are highly correlated at stations separated as far as 1200 km [7]; this fact allows aggregating observational data over large areas of the Black Sea.

Results and Analysis

The SST and air temperature trends over the 20th century were estimated with both parametric and non-parametric statistical methods by calculating coefficients of linear regression, as well as Pearson, Spearman and Kendall-tau correlations. All four statistical methods clearly show that there was a definite cooling trend in the deep Black Sea over the 20th century at negative rate of (- 0.86 ± 0.3) °C per 100 years. On the western shelf there is no statistically significant trend. The linear trend in the air temperature in the central Black Sea represented by the data set from Yalta weather station is negative showing a modest cooling at (-0.3 \pm 0.1) °C per 100 years. In contrast to this, air temperature in the western Black Sea measured at Odessa weather station shows a positive trend at (0.3 ± 0.2) °C per 100 years. A further analysis using a CUSUM method has been carried out on an interannual and decadal scale showing a number of regime shifts in the deep Black Sea in years 1927, 1966, 1968, 1986 and 1997. On the western shelf, the regime shifts and the most significant cooling periods of the SST are associated with the most severe winters observed in 1947, 1954, 1985 and 1987. Unusual temperature trends in the Black Sea could be attributed to the variations in the overlying weather pattern, however the link is non-linear.

A relatively small (R=0.65) correlation coefficient between variations in air and sea temperatures exemplifies a non-linear response of the sea to changing weather conditions. The analysis of CUSUM charts suggests that it is the shifts in the established weather regimes on a decadal scale rather than interannual variations of meteorological forcing which lead to changes between warming and cooling phases of SST evolution, particularly in the shelf regions. The shelf and the deep sea response show different patterns of their responses to the weather conditions, which results in de-coupling of the SST variations of on the western shelves and the deep sea.

LONG TERM VARIABILITY OF THE PHYSICAL PARAMETERS IN THE BENTHIC BOUNDARY LAYER OVER THE BLACK SEA SHELF

Georgy Shapiro ¹*, Friedemann Wobus ¹, Dmitry Aleynik ² and Claire louise Griffiths ¹ ¹ University of Plymouth, Plymouth, UK - gshapiro@plymouth.ac.uk

² Scottish Association for Marine Science, Oban, UK

Abstract

The purpose of this study is to identify long-term changes of hydrological parameters in the benthic boundary layer (BBL) on the Western Black Sea shelf. This is done to provide underpinning information for the study of carbon cycle. Interannual variability and smooth changes in the parameters of the benthic boundary layer which are thought to be related to variation in rates carbon sequestration are assessed.

Keywords: Anoxia, Black Sea, Continental Shelf, Temperature

Introduction The chemical structure of the Black Sea waters is largely determined by the location and the strength of the pycnocline. The oxycline and the chemocline occur at the same depth intervals as the halocline, because of similarity in the mechanisms of vertical exchanges [1]. As the data for Dissolved Organic Carbon (DOC) on the shelf is sparse we test a hypothesis that a similar statement is valid for DOC, so that much abundant data on physical parameters can be used as proxy. We use the near-bottom temperature as indicators for physical conditions in the benthic boundary layer on the shelf. The physical reason for this is that interannual variations in the near-bottom temperature are directly related with the volume of cold waters [2] which are formed on the shelf and then exported into the deep sea. Despite early claims on possible shoaling of the anoxic interface, the vertical position and structure of the chemocline appear reasonably stable within the last few decades [3]. However, seasonal and interannual temperature and salinity variations do exist in the upper layer that are subsequently evidenced in the bottom boundary layer on the Western shelf due to winter convection.

Data and Methods

The majority of the available data suitable for the study of the BBL was taken on the extensive North West shelf, which is the focus of the present report. In this study we identified climatically averaged parameters on a dense horizontal grid of 0.25° as well as monthly anomalies (deviations from the climatology) using over 17,000 stations. Water masses and the chemicals contained therein, which are located in the BBL on the shelf below the upper pycnocline are unlikely to surface due to vertical mixing process. The upper level of the bottom boundary layer was determined by the deepest level to which vertical mixing due to waves and wind can reach if the energy for mixing is limited by a certain threshold, which for this study was taken 10kJ/m². We consider here the energy required to completely mix a water column as the difference between the potential energy of the stratified water column and the completely mixed water column. The constant density of the mixed water column can be derived from the original density profile using the principle of the conservation of mass, such that both potential energies can be expressed as a function of the measured density stratification.

Fig. 1. Climate: shelf areas (≤ 200 m) covered by waters denser than the mixing depth (W_{mix} = 2,500/5,000/10,000 J m⁻²)

Results and analysis

Comparison of the available vertical profiles of nutrients, DOC and water density has shown that strong density stratification is linked to stratification in nutrients and DOC so that variation in physical parameters can be used as proxies for their biochemical counterparts. The layer below the upper pycnocline forms a 'communication channel' for nutrients and carbon to be removed from the shelf ecosystem. During the winter-early spring month the water masses contained within the 'communication channel' could come into contact with the oxygenated surface waters via isopycnal movement. However, during the summer-autumn month (May to November) these water masses are completely isolated from the surface. The areas on the shelf (depth <200m) which are occupied by the 'locked' BBL waters vary during the year as well as average temperature of these waters. For this study we are using temperature anomalies rather than absolute values to avoid statistical bias when aggregating the data over large geographical areas, such as western Black Sea shelf. The anomalies were calculated for a density range that was fixed for each summer month (May-November) using sigma-theta = 14.2 as a fixed upper limit and a lower limit was the shelf edge (i.e. 200m isobath).

The analysis allowed us to answer the following questions: (i) What are the areas of the Western BS shelf where the near-bottom waters can not be mixed vertically ('locked out water masses')? How these areas change from month to month ? What is the interannual variation of temperature in the locked waters? The intra-annual variability of the 'locked out' areas occupied by bottom waters and the inter-annual variation of the area –aggregated temperature anomaly are shown in Figs 1.and 2.

Fig. 2. Temperature anomalies aggregated over the shelf volume of 'locked' waters (as defined by $\sigma_{\theta}{=}14.2$) and averaged over summer months (May-November) shown as function of time + 5yr running mean. Error bars = 1 standard deviation.

SEA SURFACE TEMPERATURE AND CHLOROPHYLL NON-SEASONAL VARIABILITY IN THE AEGEAN SEA BY MEANS OF EOF ANALYSIS OF SATELLITE DATA

N. Skliris¹*, A. Mantziafou¹, S. Sofianos¹, A. Gkanasos¹ and A. Lascaratos¹

¹ University of Athens, Ocean Physics and Modelling Group, Bld. Phys-V, Athens 15784, Greece - nskliris@oc.phys.uoa.gr

Abstract

Empirical Orthogonal Function (EOF) analysis is applied to 8-day composite AVHRR-derived Sea Surface Temperature (SST) and SeaWiFS-derived surface chlorophyll (Chl) data (1998-2005) to study the variability of the two parameters in the Aegean Sea from sub-seasonal to interannual time-scales. Results indicate low SST non-seasonal variability, which is controlled by synoptic weather variations and anomalies in the north-south wind-stress component. On the other hand, variations in the Dardanelles chlorophyll inflow and in the riverine nutrient inputs regulate the large intra-annual and interannual variability of Chl. *Keywords: Aegean Sea, Temperature, Chlorophyll-a, Dardanelles*

Introduction

The Aegean Sea displays prominent hydrodynamic features involving all time/space scales such as strong baroclinic and topography-induced currents, upwelling regions and frontal zones with important implications on the dynamics of plankton ecosystems. Although the region is often considered to be an oligotrophic environment large gradients of primary productivity have been observed and the highly productive areas are mainly located in the northern basin [1]. In the present study eight years of satellite-measured SST and Chl are analysed in order to capture the dominant space/time features of the Aegean Sea surface variability.

Method

Daily global SeaWiFS ocean colour data (1998-2005) with 1/12° spatial resolution available from the Distributed Active Archive Center at the NASA Goddard Space Flight Center are used. In order to convert ocean colour to chlorophyll-a concentration, all the available SeaWiFS data of the raw measured wavelength bands are re-processed with the MedOC4 bio-optical algorithm, built specifically for the Mediterranean Sea [2]. The construction of SST maps is based on a re-analysis of AVHRR Oceans Pathfinder SST timeseries of the Mediterranean Sea at a 1/16° resolution-grid [3]. EOF analysis (i.e. based on the Singular Value Decomposition method) is applied to the 8-day anomaly time series of the two datasets (i.e. the total harmonic seasonal cycle is removed from the original time series) to study the non-seasonal (intra-annual and interannual) variability of the two parameters.

Fig. 1. EOF decomposition of the SST anomaly dataset. Spatial amplitudes (left panels) and temporal modes (right panels). The variance explained by each EOF mode is also depicted. The 22-point (176-day) running mean (dark lines) suppresses signals with timescales less than a year and represents interannual variability.

Results and discussion

Data analysis shows that non-seasonal signals account for the largest part of the Chl total variance (~70%), whereas SST variability is overwhelmed by the

seasonal cycle (~98%). EOF results for the SST anomalies (Fig. 1) indicate that non-seasonal variability is induced by synoptic atmospheric weather variations (1st EOF) and anomalies in the north-south wind-stress component mainly occurring during the summer upwelling regime (2nd EOF and 3rd EOF).

EOF analysis of Chl anomalies (Fig. 2) shows large intra-annual variability and clear interannual signals, associated with much larger production during the bloom periods of specific years (i.e. in 1999 and 2004). Results indicate that Chl non-seasonal variability is mainly controlled by variations in the Dardanelles chlorophyll outflow (1st EOF and 3rd EOF), in the position of the hydrological front and the Samothraki anticyclone (2nd EOF), and in the riverine nutrient inputs within the North Aegean Sea. EOF and correlational analysis of the anomaly time-series demonstrate that non-seasonal variations of the two parameters are much less linked than in the global ocean, implying that mixing and upwelling processes play a minor role in controlling surface chlorophyll variability in the Aegean Sea.

Fig. 2. Same as Fig.1 but for the Chl anomaly dataset.

REAL TIME REGIONAL FORECASTING SYSTEM INTO THE SICILY CHANNEL

Roberto Sorgente^{1*}, Antonio Olita¹, Leopoldo Fazioli¹ and Alberto Ribotti¹

¹ CNR-IAMC U.O.S. di Oristano, Loc. Sa Mardini, Torregrande (OR), Italy - roberto.sorgente@cnr.it

Abstract

Real time short-term forecasts of the circulation in the Sicily Channel are operationally produced and their accuracy against satellite sea surface temperature fields is evaluated from August 20th to October 20th 2009 on a daily basis. This analysis allowed us to assess the skill of the present ocean forecasting system.

Keywords: Models, Circulation, Straits And Channels, Sicilian Channel

The Forecasting System

The Sicilian Channel Regional Model Forecasting System (SCRMFS) is based on a nested eddy resolving numerical model implemented in the Sicily Channel area. It is driven at the surface by the hourly forcing from the Limited Area Model ETA/SKIRON atmospheric forecast fields with a horizontal resolution of 10 km [1]. The atmospheric forcing parameters include: mean sea level pressure, air temperature at 2 m, wind speed and direction at 10 m, convective and accumulated precipitation and cloud cover. The net short-wave radiation flux and the downward long-wave radiation flux at the sea surface are provided directly by the weather prediction model at 1-hour interval, while latent and sensible heat fluxes are given by the bulk aerodynamic formulae. Surface momentum fluxes are calculated using the computed drag coefficient of Hellerman and Rosenstein [2]. At the open boundaries, the SCRMFS is nested with the coarse model MFS1671 [3] through an off-line one way nesting technique of the forecasted daily mean fields of temperature, salinity and total velocity. This method was found to be computationally efficient and sufficiently robust to transmit information across the lateral boundaries without excessive distortion [4]. The SCRMFS is initialized daily in slave mode, then through the downscaling and optimization of coarse resolution forecast fields (temperature, salinity and current velocity) using the Variational Initialization method, named VIFOP [5]. It allows to reduce the high frequency oscillations during the initial conditions (spin-up time) [6]. SCRMFS produces daily 5-day forecast, in slave mode, providing detailed information on the mesoscale and sub-mesoscale components that cannot be resolved by the coarse resolution model. The performance of SCRMFS depends on the accuracy of the hourly surface wind stress and heat fluxes provided by SKIRON, but in a slave mode forecast the quality of the initial conditions derived from the downscaling of the first forecasted day of the coarse resolution model is even more critical.

The validation

The dataset used for the online validation is the daily NRT Optimally Interpolated Sea Surface Temperature (OISST), obtained from the AVHRR (Advanced Very High Resolution Radiometer) night-time data acquired and processed at ISAC-GOS of CNR. The level of agreement between the forecast and the truth (assumed to be given by the satellite observation) is computed using basic statistics, such as the correspondence between the mean forecast and mean observation (BIAS), the root mean square error (RMSE), the standard deviation (σ) and the Sea Surface Temperature Skill Score (SSTSS).

Results

The daily averaged scores have been computed for each forecast cycle over the period 20 August – 20 October 2009, in agreement with the largest horizontal temperature gradients due to the warm waters over shelf areas and the well-known upwelling along the south of Sicily, induced by the Atlantic Ionian Stream and its summer features. Between the fifth and last forecast cycle (Fig.1, top), the RMSE estimates a range approximately from 0.9°C to 0.6°C, while the standard deviation presents higher values. Then the SSTSS increases from 0°C to 0.4°C (Fig. 1, bottom). This means that the last forecast cycle (24 hours before) is about 40% better than the fifth (120 hours before). The averaged biases for the five cycles range from 0.16°C of the first cycle to -0.05°C of the fifth, with a clear negative trend. So the model is on average warmer the first 3 and colder the last 2 forecast days than the observations

Conclusions

The performance of SCRMFS against satellite SST has been evaluated by means of standard statistics. Notwithstanding the use of only satellite observations for a short period in time, this preliminary assessment of the forecasting system shows a reasonable performance in comparison to other forecast numerical models available from the bibliography [7] which, in slave mode, are greatly dependent on the accuracy of the coarse resolution model furnishing the initial conditions.

Fig. 1. Top: Standard deviation (dashed line) of the model SST field and RMSE (continuous line) between model and satellite SST, averaged for each forecast cycle; Bottom: Skill Score averaged for each forecast cycle.

ESTIMATION OF THE ATLANTIC INFLOW THROUGH THE STRAIT OF GIBRALTAR FROM CLIMATOLOGICAL AND IN SITU ADCP DATA

J. Soto-Navarro^{1*}, F. Criado-Aldeanueva¹, J. García-Lafuente¹, A. Sánchez-Román¹ and C. Naranjo-Rosa¹ ¹ Physical Oceanography Group, University of Málaga, Málaga, Spain - javiersoto@uma.es

Abstract

A combined reanalysis, satellite and experimental dataset has been used to calculate a four-year time series of the Atlantic inflow through the Strait of Gibraltar. An indirect estimation of the net flow through the strait from the hydrological cycle has been combined with direct Mediterranean outflow measurements, collected in the Espartel sill (western Strait of Gibraltar), resulting a mean inflow of 0.814 Sv with a seasonal cycle of 0.026 Sv amplitude peaking in September. Two possible forcing mechanisms are suggested for this cycle: a main barotropic one, related to the ocean-atmosphere water deficit and a secondary baroclinic one related to the hydrological conditions in the strait.

Keywords: Strait Of Gibraltar, Water Transport, Air-Sea Interactions, Hydrology, Sea Level

The importance of the exchange through the Strait of Gibraltar for the Mediterranean termohaline circulation and hence for the entire Mediterranean climate is well known. Several works have studied this exchange, most of them focusing on the evaluation of the net flow and the Mediterranean outflow, but only a few of them describe the Atlantic inflow. The latter are based on experimental measurements of about two-year long time series [1, 2, 3]. In this work we make an indirect estimation, climatologically and experimentally based, of a four-year long time series.

$$\frac{dM}{dt} = S\frac{d\xi_M}{dt} = P - E + R + B + G$$

Eq.1 describes the mass budget in the Mediterranean Sea that is used to calculate the net flow, where the left-hand side, dM/dt , is the mass time-variation, S the Mediterranean surface and ξ_M the mass-induced sea level anomaly. The righthand side terms are the different contributions to the budget: precipitation, P, evaporation, E, river discharge, R, the exchange with the Black Sea through the Turkish Straits, B, and the net flow through the Strait of Gibraltar, G. NCEP monthly mean data has been used to evaluate evaporation and precipitation. The mass contribution to the sea level anomaly has been calculated subtracting from AVISO total level the steric contribution computed from the water column salinity and temperature data of the ECCO model dataset. Data of river discharge and exchange with the Black Sea have been obtained from the works of [4] and [5] respectively. Once estimated the net flow, direct ADCP measurements of the outflow collected in the Espartel sill (western Strait of Gibraltar) have been used to calculate the inflow. A mean value of 0.814 Sv, with a seasonal cycle of 0.026 Sv amplitude peaking in September, has been obtained, in good agreement with the previous works [1, 2, 3].

Fig. 1. Inflow (Q_1) , outflow (Q_2) and net flow (Q_0) through the Strait of Gibraltar anomalies. The anomalies has been represented for a better visualization of the importance of the seasonality of each component, Q_0 and Q_2 , to the inflow calculation.

Two possible forcing mechanisms have been considered to explain the seasonal cycle of the Atlantic inflow. The first and main one of barotropic nature, related to the ocean-atmosphere water deficit, strongly dependent of E-P, whose seasonal cycle also peaks in September. The second one has baroclinic nature and is related to the hydraulics conditions in the strait, which implies that both

the inflow and outflow velocity depends on the square root of their density difference [6]. This means that an increase (decrease) in the outflow (inflow) density produces an increase in both velocities and vice versa. Thus, during summer, when sea surface temperature reaches its maximum, the surface layer density decreases due to the associated volume increase. This feature is also reflected in the maximum of the steric sea level in September [7] and produce an increase in the inflow velocity that contributes to the September peak.

Abstract

During KM3NeT project, an intense observational activity was conducted in the Ionian Sea, mainly south-east of Capo Passero (Sicily) and off the south-western tip of Peloponissos (Greece). The several oceanographic cruises performed from 2006 to 2009 permitted to describe the current status of the deep layer, together with its recent evolution. While newly formed Adriatic dense water is the principal abyssal signature in the western Ionian, the Cretan water vein fills all the deep layer in the eastern Ionian. These observations confirm that the deep Ionian Sea is undergoing significant changes, especially after the Adriatic Sea has became an active source of dense water again.

Keywords: Deep Waters, Circulation, Ionian Sea

The Ionian Sea collects the dense waters formed in the Eastern Mediterranean in its abyssal plain. The Adriatic Sea was the main source of these waters up to the end of the 80's. After that date, an important climatic variation occurred (the Eastern Mediterranean Transient) which had an impact on the whole Eastern Mediterranean, and a new source started up in the Aegean Sea. The Aegean water was warmer, saltier and denser than the one formed previously in the Adriatic Sea, so it filled the deepest layers of the Ionian [1]. Around 1995 the Aegean source dropped and the Adriatic became an active source again, producing new water whose temperature and salinity were warmer and saltier when compared to the past [2, 3]. The several oceanographic cruises performed in the Ionian Sea from 2006 to 2009 permitted to follow the recent evolution in the abyssal hydrography, and provided some insight into their variability.

Fig. 1. Vertical section of potential temperature (°C), salinity, density (σ 2 units), dissolved oxygen content (µmol/l) in July 2007 between 1500 m depth and the bottom.

In July 2007, a hydrographic section covered the central Ionian basin from Sicily to Greece almost synoptically (Fig. 1), giving a nearly complete zonal view of the abyssal layer. The physical-chemical properties from 1800 m to the bottom show distinct water masses, with significant differences both in temperature and salinity. A clear gradient can be observed in correspondence to the meridional ridge which separates the central and the eastern deeps. On the western side, below 2000 m, a marked stratification is found with warmer and saltier water superimposed on a fresher and colder layer. Both the layers extend their influence upto the central abyssal plain. The two water types are probably of Adriatic origin, but the higher oxygen content close to the bottom suggests that the most recent Adriatic water is warmer and saltier than before. On the eastern side, higher salt content and higher temperature evidence the presence of Cretan

water in the deep column, mainly concentrated between 2000 and 3000 m of depth.

A comparison between observations off Sicily from different periods evidenced a certain water mass variability: an almost homogeneous stratification below 2500 m is sometimes replaced by a situation characterized by the presence of several water masses, identified by closed structures. Current measurements, acquired from May 2007 to May 2009 at 3000 m of depth near the Maltese shelf break and about 20 miles eastward, evidence the prevalence of a southward flow at the first site and a north-westward one at the second, while the oscillations of the two currents are inversely correlated. This suggests a circulation frequently organized along a cyclonic pattern, as indicated by the closed structures observed from the hydrography. More energetic currents are found close to the shelf break, and a pronounced variability is observed at both the sites, on the seasonal and the interannual time scales.

These results depict a variable cyclonic abyssal circulation that is more energetic when compared to previous measurements collected in the same area. The increased activity has probable links with the new Adriatic dense water flowing into the region.

Abstract

Winter geostrophic circulation patterns in 2000 and 2001 in the northern Adriatic, as a result of bottom density distribution, were different. Formed earlier in autumn under different atmospheric forcing, they remained stable even in conditions of above average surface heat losses. This suggests that forecast of the northern Adriatic geostrophic circulation patterns is attainable several months in advance.

Keywords: Adriatic Sea, Circulation

Introduction

The northern Adriatic is influenced by the Po River, one of the largest in the Mediterranean basin. In winters termed as type A, bottom density is higher in the eastern than in western part of the northern Adriatic, while for winters of type B the situation is opposite (1). The Po River waters more likely spread across the northern Adriatic in winters of the type A (in preparation). As a consequence, large phytoplankton production in the entire northern Adriatic is expected to occur in A winter types, whereas dense water formation characterizes the B ones. In this work winter oceanographic conditions of type A and type B, for 2001 and 2000 respectively, were analyzed.

Data and methods

Data collected during six large oceanographic cruises at three transects (45 stations; Fig. 1) in the northern Adriatic were used to plot distributions of temperature, salinity, density and geostrophic currents relative to 30 dbar surface (Oct 1999, Jan 2000, Feb 2000, Oct 2000, Dec 2000, and Feb 2001). Daily values of meteorological data and surface fluxes in the region, as well as the Po River flows were also analyzed for the periods Oct 1999 - Feb 2000 and Oct 2000 - Feb 2001.

Fig. 1. Map of the northern Adriatic with position of stations

Results

Winter geostrophic circulation patterns in both 2000 and 2001 remained stable between the two subsequent cruises (Jan and Feb 2000; Dec 2000 and Feb 2001). In the winter of 2000 there was a cyclonic gyre off the Po River delta while in the winter of 2001 in the same area an anticyclonic gyre was present (Fig. 2). The differences in circulation patterns were due to differences in bottom density distribution (Fig. 2). Monthly values of northern Adriatic surface heat losses for both Jan 2000 and 2001 were above their long-term means (not shown). Bottom density fields were already formed in late autumn, starting from October (not shown). The autumn of 1999 was characterized by many bora episodes and very large surface heat losses while in 2000 by strong sirocco events and moderate surface heat fluxes.

Fig. 2. Distribution of bottom density and of surface geostrophic currents relative to the 30 dbar surface in February 2000 (a and b) and February 2001 (c and d). A and C represent anticyclonic and cyclonic sense of rotation, respectively

Conclusion

The results strongly support the hypothesis that autumn conditions determine the next winter geostrophic circulation patterns, allowing us to forecast the northern Adriatic winter hydrographic conditions.

Abstract

The EGYPT (Eddies and GYres Paths Tracking) - EGITTO program data sets provide an unprecedented insight into the Eastern Basin surface circulation. They confirmed the Atlantic Water (AW) path be an anticlockwise circuit along the basin slopes, and its frequent offshore dispatching related to the paddle-wheel effect of the mesoscale eddies generated by the southern part of the circuit, the Libyo-Egyptian Current. However, in opposition with earlier observations, several eddies have been tracked drifting westward for several months, up to one year. The study of the circulation in the Eastern Basin remains a challenge yet. Keywords: Eastern Mediterranean, Circulation

Our knowledge and understanding of the circulation in the Eastern basin have yet to be improved. The EGYPT/EGITTO program (2005-2007) was a main effort to acquire in situ observations in the Eastern Basin, with a focus on its southern part that has been little sampled up to now. Platforms included a 1year 7-mooring array, a network of 125 CTD casts, ~ 200 XBTs, ~100 surface drifters, ~15 Argo profilers, and the continuous coverage with thermal satellite images to allow for targeted sampling [1]. In the south the circulation of the Atlantic Water (AW) has been clearly shown anticlockwise and alongslope [2, 3], in agreement with numerical simulations [4]. However the corresponding distribution of the lower salinities most often appear complex, that is highly variable in space and time. Indeed the Libyo-Egyptian Current (LEC) is unstable, and generates mesoscale (anticyclonic) Libyo-Egyptian Eddies (LEEs) [5]. The numerous interactions between the LEC and one or more LEEs induce a paddle-wheel effect, that dispatch AW first offshore and then around the LEEs [6]. That was shown during the EGYPT-1 campaign: on the CTD transect from the Libyan shelf to the Greek slope (figure 1), the minimum of salinity was found on the northern edge of the eddy LE. Another LEE, downstream LE and south of the wind-induced Ierapetra eddy (I-2005, figure 1), also concurred to dispatch AW on the eastern edge of I-2005 (see the corresponding drifters trajectories on fig.5k of [3]). The figure 2 illustrates this paddle-wheel effect: AW is indeed transported offshore eastward, but on the successive edges of LEEs: there is no such permanent path as the so-called "Mid-Mediterranean Jet" (MMJ). Now, because LEEs can remain motionless, drift, and/or interact with neighbouring ones for several months, they have a significant weight in statistics that can lead to artefacts. This is the case for instance of the Lagrangian statistics on the drifters trajectories, of which the mean displays a strong jet offshore Libya. When this evokes a MMJ, it is actually the northern edge of a LEE [7].

Fig. 1. Sampling during the EGYPT-EGITTO program, with the main eddies indicated for Spring 2006.

These LEEs, and Ierapetra as well, can actually perturb the circulation down to the bottom (~3000m), as shown by the deeper currentmeters [8]. Now, contrary to the general eastward drift observed during 4 years on the period 1996-2000 (over 1000 IR images analysed [9]), in 2006 3 LEEs drifted westward alongslope for months, one for more than 1 year [8]. One hypothesis put forward is the abrupt change of the steepness of the slope [10]. But such a change occurs only for in eddy (LEE1) off Libya at 24°E. Additional analyses are thus required. The study of the Eastern Basin circulation might be more difficult than that of the Western Basin: while the weight of the mesoscale dynamics and the variability it induces imply to

acquire additional such high resolution synoptic surveys, rising problems to gain authorizations for sampling are most likely to keep their number low. The Eastern Basin is likely to remain a challenge for some time.

Fig. 2. Trajectory of a surface drifter from February to May 2006.

INTERMEDIATE AND DEEP CIRCULATIONS IN THE EASTERN BASIN OF THE MEDITERRANEAN: FOCUS ON ITS CENTRAL PART FROM THE EGYPT OBSERVATIONS (2005-2007)

Isabelle Taupier-Letage ¹* and Claude Millot ¹

¹ CNRS/Université de la Méditerranée/COM, Toulon, France - Isabelle.Taupier.Letage@ifremer.fr

Abstract

The Eddies and GYres Paths Tracking (EGYPT, 2005-2007) program was an unprecedented effort to acquire observations in the Eastern Basin, both in situ and remotely sensed. The intermediate and deep circulations between Crete, Libya and Egypt are studied here using mainly the time series of a one-year array of 7 moorings equipped with 30 currentmeters and 10 hydrological probes, and the dense network of 125 CTD casts (10-20km-spaced) realised during the EGYPT-1 campaign (April 2006). *Keywords: Circulation, Eastern Mediterranean, Mesoscale Phenomena*

The similarity of the surface circulation patterns between the Western and Eastern Basins prompted original ideas [1]: following our previous work in the Algerian subbasin, in order to improve our knowledge and understanding of the circulation in the Eastern Basin, we conducted the program EGYPT, with the major aim to monitor the path of the Atlantic Water (AW) -with a focus on the Libyo-Egyptian Current (LEC)-, and the Mediterranean Waters (MWs) [2, 3, 4]. We collected current time series with a network of 7 moorings, ~70km spaced, equipped with 5 to 6 currentmeters and hydrological probes from surface (~60m) to the bottom. We initially planned to deploy the moorings off Egypt, since there is no shelf and we could have easily sampled most of the AW flow when alongslope, but we were finally not allowed to do so. The moorings had to be moved off Libya, with two main drawbacks: they were further offshore due to the shelf (over which the AW flows for a great part), and the bathymetry is complex. And finally the upper part of 4 out of 7 moorings went adrift after fish bites, which prompted their anticipated recovery after one year (April 2006 - March 2007), instead of the planned 2year duration. But the dense CTD network of 125 casts (one out of two down to the bottom) realized during the EGYPT-1 cruise (April 2006) allowed a dense sampling (10-20 km spaced) at subbasin-scale, including the southern shelf and south of Crete. The other observations acquired, among which satellite thermal images, drifters and ARGO profilers, have been listed in [5].

Fig. 1. The passage of a LEE (from east to west) over the mooring 3 during summer 2006, showing the associated anticyclonic currents down to the bottom. a) SST image from mid-August 2006 showing the LEE and Ierapetra (I), EGYPT moorings network (triangles), b-e) records at mooring 3 of current in b) surface, c) intermediate (scale +/- 0.5m/s) and d) bottom layer (scale +/- 0.25m/s), and of e) potential temperature in the bottom layer (scale 13.5-13.7° C).

As expected [2], between Libya, Egypt and Crete the intermediate and deep MWs circulate anticlockwise and alongslope, when not disturbed by mesoscale eddies generated by either the LEC (the Libyo-Egyptian Eddies: LEEs) or the wind (as Ierapetra). We specify the main pathways of the MWs known to form in the Adriatic, the Aegean and the Levantine subbasins, and evidence unreported intermediate water from the Adriatic. As expected from our understanding of the Western Basin functioning, waters at depths 500-1500m are relatively old, so that they are more homogeneous and their circulation is generally weaker than below. At depth (> 3000m), the circulation is markedly influenced by the complex bathymetry, as well as

possibly by eddies such as Ierapetra and LEEs, which we show can extend that deep (figure 1). The deeper currents display a high variability in both direction and velocity, with peaks up to 40cm/s a few metres above the bottom. The deepest T and S display variations over ranges of 0.05° C and 0.01, up to ~0.10°C and 0.02 during few-day episodes (figure 1e). Such a high variability is obviously due to the heterogeneity of the deep waters formed far to the north. It is thus clear that deep waters encounter little mixing while spreading and circulating from their formation areas.

A consequence is that the climatological data bases, necessarily based on (historical) sparse data in both time and space, are to be used with extreme caution when it comes to deducing water pathways (cf the LIW path problem when applying unattended statistics on Algerian subbasin data sets [6]), or any climatological signal [7]. In this context, the EGYPT data set can be regarded as a snapshot of reference for 2006-2007. Correlatively, given the natural variability of AW [8] or MWs [9] in the whole Mediterranean Sea, all riparian countries should foster the regular monitoring at basin scale, using not only moorings and thermosalinometers on merchant lines (e.g.Hydrochanges and Transmed CIESM programs, resp.), but also yearly CTD cross-basin transects, an effort sustained for few years now by Italian colleagues in the Western Basin [10].

CURRENT OBSERVATIONS IN THE BOSPHORUS STRAIT DURING EPOS

W. Teague ¹*, E. Jarosz ¹, J. Book ¹, S. Besiktepe ², M. Hulbert ¹ and A. Quaid ¹ ¹ Naval Research Laboratory, Stennis Space Center, MS, USA - teague@nrlssc.navy.mil ² NATO Undersea Research Centre, La Spezia, Italy

Abstract

Pairs of acoustic Doppler current profilers (ADCPs) were deployed at each end of the Bosphorus and Dardanelles Straits as part of the United States Naval Research Laboratory's Exchange Processes in Ocean Straits (EPOS) project. All 8 current moorings were deployed in September 2008 and remained in place for about half a year in the Bosphorus and for one year in the Dardanelles. This is the first time that comprehensive current measurements coincident to both straits over seasonal time scales have been made. An overview of the current structure and variability is given here for the Bosphorus Strait to provide insight into the complexity of the TSS dynamics.

Keywords: Bosphorus, Currents

The Turkish Straits System (TSS; Figure 1) consists of the Bosphorus Strait, Sea of Marmara, and Dardanelles Strait and is the only connection between the Black and Mediterranean Seas [1]. The main objective of EPOS is to understand the synoptic variability of the exchange flows in the TSS by study of the currents, temperature, salinity, and microstructure. In close collaboration with the Turkish Navy Office of Navigation, Hydrography and Oceanography and the NATO Undersea Research Center (NURC), the R/V Alliance was used for the mooring work and data collection. The ADCPs were housed in trawlresistant moorings referred to as Barnys (Figure 2). The nearly full watercolumn current profiles are used to describe the vertical current structure and the seasonal variability of the two-layer current system in the straits, with focus here on the Bosphorus Strait.

Considerable differences in average flows, current variability, and layer thicknesses were found. Layer interfaces ranged from about 15 to 40 m depth in the Bosphorus Strait while integral time scales for the along strait current components were 6-9 days and maximum observed currents were 231 cm/s. While largest current speeds were observed in the upper layer at the southern end of the Bosphorus, largest speeds were observed in the lower layer at the northern end of the strait. Greatest range in velocity was at the southern end where the currents ranged from -231 to +115 cm/s. Depth dependent processes dominated and were relatively strong in the Bosphorus. Dynamical processes were very different between the ends of the strait. Numerous current reversals were found in the top layer and interestingly can be predicted from the integrated wind stress. We expect that results from this experiment will enhance our understanding of the dynamics in the TSS and will lead to additional field and modeling efforts.

Fig. 1. Turkish Straits System (TSS)

Fig. 2. Shown here is a view of a Barny platform on the sea floor. The ADCP is contained in the Barny and is located at the top. An outer ring of reinforced cement provides impact resistance and ballast. The overall smooth profile minimizes the risk of being fouled by fishing gear and makes the Barny highly resistant to trawling. The entire mooring is recovered at the end of the deployment via acoustic release of a pop-up float that carries a recovery line and the ADCP to the surface.

TIME-SERIES ANALYSES OF ATMOSPHERIC AND MARINE OBSERVATIONS ALONG THE TURKISH COAST

Ersin Tutsak ¹*, Emin Özsoy ¹ and Y. sinan Husrevoglu ¹

¹ Institute of Marine Sciences, METU, Erdemli, Turkey - ersin@ims.metu.edu.tr

Abstract

Time series and spectral analyses are applied to surface atmospheric (wind velocity, air temperature, barometric pressure, relative humidity) and sea level data obtained from monitoring stations along the Turkish coast. Analyses of time series longer than a year identify main time scales of transport and motion while establishing seasonal characteristics, i.e. distinguishing, for instance, between winter storms and summer sea-breeze system. Marine flow data acquired by acoustic doppler current profilers (ADCP) are also analyzed to better understand the response of the dynamics along the Turkish coast to short-term climatic variability. Cumulative results obtained from these analyses determine temporal and spatial scales of coastal atmospheric and marine fluxes of momentum, heat and buoyancy as affected by the regional climate system. *Keywords: Time Series, Sea Level, Air-Sea Interactions*

Introduction and Methods

The total of 12 atmospheric and marine coastal monitoring stations along the Turkish coast of the Mediterranean, Aegean, Marmara and Black Seas and the Bosphorus and Dardanelles Straits (Figure 1) traverse approx. 2500 km of coastline with a maximum separation of approx. 800 km. The stations were installed within the framework of the Turkish Meteorology and Oceanography Excellence Network pilot project coordinated by the Institute of Marine Sciences, Middle East Technical University. These automatic data acquisition systems collect surface atmospheric data (air pressure, wind, air temperature, and relative humidity) in addition to sea-level measurements acquired by electronic tide gauges.

The main objective for establishing this coastal monitoring network is to obtain long-term time series of surface atmosphere and ocean data in an attempt to understand and quantify regional climatic variability in the Turkish coastal system as well as the effects of such variability on the Mediterranean-Black Sea coupling through the Turkish Straits System (TSS). The TSS is sensitive to climatic changes and potentially causes such changes in the adjacent basins [1]. The sea level difference over the Bosphorus plays an important role for the overall flow. Sea level is highly variable through the Turkish strait system and is influenced by the Black Sea and the Mediterranean oscillations, but is not affected by the tidal oscillations [2]. Over the Black Sea strong winds can control the water flow of the Bosphorus strait, thus the mean sea level of the Black sea at intra-seasonal frequencies. The Mediterranean water flow into the Black sea can be blocked as the northerly winds blow. Also, sufficiently intense southerlies may cause to cease the upper layer flow from Black Sea [3].

Based on measurements, taken during longer than a year, time series and spectral (auto-, cross-, and rotary spectra) analyses are performed to exhibit the measurements in both time and frequency domains, which enable to detect temporal and spatial scales of phenomena, oscillations and correlations of the observations in distinct areas.

Fig. 1. Coastal observation stations along the Turkish coasts

Results

Spectral analyses of the sea level indicate basin oscillations of several days to weeks in addition to diurnal and semi-diurnal oscillations in sea level forced by the winds, barometric pressure differences and storm surges. Frequently, a sea level difference of about 40 cm is observed between the Black and Marmara Seas, which vanishes during some blockage events of the Bosphorus upper layer.

Abstract

The biogeochemical cycles of the major elements and the associated structure of the planktonic functional groups are investigated in the northwest Mediterranean Sea in relation with the seasonal and interannual variability of the hydrodynamic/atmospheric forcing. *Keywords: Western Mediterranean, Models*

A 3D physical-biogeochemical coupled model has been implemented to represent cycles of biogenic elements (carbon, nitrogen, phosphorus and silica) and pelagic plankton groups in the NW Mediterranean Sea.

The hydrodynamic mesoscale SYMPHONIE model [1] has been used forced by high resolution atmospheric fluxes. The biogeochemical model is defined by three size groups of phytoplankton and of zooplankton, hetrotrophic bacteria, two size classes of particulate organic matter, dissolved organic matter and four inorganic nutrients. The representation of the phytoplankton processes is derived from the model ECO3M [2] that has been increased in complexity in the present work. The heterotroph model is an adapted version of the stoichiometric model developed by [3] and applied at the study area by [4].

Fig. 1. Interannual variation of the simulated (A) maximum mixed layer depth (m) and (B) mean primary production (gC $m^{-2} d^{-1}$) over the north-western Mediterranean sea for the 2004-2008 period.

The calibration and validation of the coupled model were performed through comparisons with complementary observations: data at the DYFAMED deep station in the Ligurian Sea, data of SOMLIT coastal stations and satellite images. The model results reasonably reproduce the recorded spatial and temporal variations.

Then the model was used to estimate a budget of the biogenic elements in the area over the period 2004-2008 characterized by a varying intensity of the major physical (deep convection, shelf dense water cascading, general circulation)

(Figure 1A) and biogeochemical processes (Figure 1B).

FOOTPRINTS OF MESOSCALE EDDY PASSAGES IN THE OTRANTO STRAIT (ADRIATIC SEA)

Laura Ursella¹, Vedrana Kovacevic¹, Miroslav Gacic^{1*} and Isaac Mancero-Mosquera¹

¹ OGS-Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Trieste, Italy - mgacic@ogs.trieste.it

Abstract

Mesoscale eddies play an important role in transferring particles, nutrients and other passive material vertically or horizontally. Their typical dimensions are of the order of several internal radii of deformation. In the Adriatic Sea the baroclinic radius of deformation is of the order of 5 km. Here, the footprints of mesoscale eddies propagating through the Strait of Otranto are shown, and their formation mechanism and area are hypothesized.

Keywords: Adriatic Sea, Mesoscale Phenomena, Currents

Introduction

On average, an inflow takes place along the eastern coast of the Strait of Otranto (70 km wide and about 800 m deep channel connecting the Adriatic and Ionian - Fig.1), while the outflowing current occupies its western portion. Besides, an outflow of the Adriatic Dense Water (AdDW) occurs as a density-driven current in the bottom layer pressed against the continental margin of the western coast [1]. Previous observational studies in the Strait of Otranto [2] presented evidences on the unstable flow in the shear zone between the northward and southward currents and explained them in terms of the near-inertial waves and counterclockwise mesoscale eddies, appearing as a 10-day variability in the current record.

Fig. 1. Study area with the position of moorings and principal axes of subinertial current oscillations. Upper insert: Adriatic Sea with the study area denoted by the rectangle. Lower insert: the schematic of the vertical section with the three ADCP moorings positioned within the AdDW outflow (denoted by dashed line).

Data and Methods

Currentmeter data obtained from three moorings with bottom-mounted upwardlooking Acoustic Doppler Current Profilers (ADCPs), that were maintained from September 1997 until June 1999 and from November 2006 until April 2007 at a transect in the core of the outflowing Adriatic Dense Water, are analyzed. Data were quality controlled and the missing data for periods less than 6 hours were linearly interpolated. Harmonic analysis was performed in order to de-tide the time series and, finally, a low-pass filter (33-hour cut-off period) was applied to remove inertial oscillations, thus obtaining sub-inertial non-tidal flow.

Results

The principal axis analysis of the sub-inertial flow shows that currents, especially those close to continental margins, are strongly polarized along isobaths (Fig.1). Low-pass records at all three moorings reveal energetic events of vertically uniform current vector rotation at about a weekly time-scale (Fig.2). Rotary spectra reveal their clockwise (counter-clockwise) sense of rotation at station V3 (V4), while wavelet analysis shows their timing. The two moorings close to the center of the strait show coherent current vector rotation suggesting a southwestward propagation of mesoscale eddies trapped by the bottom topography. Eddy dimensions are estimated to be between 20 and 30 km while the propagation speed is about 7 cm/sec. Eddy passage leaves a strong signal in the turbidity time-series as well, probably due to sediment resuspension by strong currents and their advection through a canyon. We hypothesize that the eddies' generation is based on the conservation of the potential vorticity for the water column passing over the sill about 100 km located upstream of the section, as suggested by [3] for the Denmark Strait. The stretching of the intermediate water layer induces cyclonic vorticity and the formation of eddies that propagate southwestward following isobaths.

Fig. 2. Stick diagram of one cell per mooring for the period 16 November -31December 2006: V2 nominal cell depth 545 m (grey line), V3 nominal cell depth 720 m (black thick line) and V4 nominal cell depth 898 m (black thin line). The mean over the indicated period was removed from each time-series.

Abstract

Data bases such as MEDATLAS [1] have proved to be an extremely valuable tool for assessing long term changes. Nevertheless, recent works have shown that the irregular time and spatial distribution of data can decrease the robustness of the analyses [2, 3]. Monitoring programs with systematic samplings are required in order improve the estimations of long term changes, but this arises the question of whether or not data from new monitoring programs and "old" data bases can be merged in order to construct long time series. In this work we check the homogeneity of time series constructed from MEDATLAS data base and the monitoring program RADMED in the Spanish Mediterranean. Time series extending from 1900 to 2008 show the warming and salting of the Western Mediterranean (WMED).

Keywords: Western Mediterranean, Monitoring, Time Series, Temperature, Salinity

The Spanish Mediterranean was divided in four different areas (squares in fig. 1) and all the temperature and salinity profiles from 1900 to 2000 in MEDATLAS data base were compiled. Because of biases recently reported in batithermographs [4], only bottle and CTD data were used. Time series within each square were vertically interpolated at 23 pressure levels from 0 to 2500 dbar. These series were merged with averaged profiles obtained from oceanographic stations from RADMED (IEO) and l'Estartit oceanographic station (ICM/CSIC) within the corresponding square. In this way we construct temperature and salinity time series extending from 1900 to 2008.

Fig. 1. Squares where MEDATLAS data were compiled and RADMED stations (dots). The triangle is l'Estartit oceanographic station.

First the homogeneity and normality of time series was checked by means of Alexanderson homogeneity tests and Kolmogorov-Smirnov tests. Both temperature and salinity time series were accepted as homogeneous after the corresponding tests. The length of these time series has shown that the WMED has increased its temperature at the three layers considered, that is, upper (0-200m), intermediate (200-600m) and deep (600m-bottom). The heat absorbed by the water column is equivalent to a heat gain of 0.23 Wm⁻². The salinity of the intermediate and deep layer also increased in a statistically significant way (fig. 2). These series show a strong decadal variability that makes it difficult to distinguish between those changes that are operating continuously in time, very likely as a result of climate change, and those that are the result of the inner variability of the climate system. The inclusion of data from the early twentieth

century allow us to estimate long term changes, although decadal variability can not be resolved in this part of the time series. Our results highlight the nonlinear character of the temperature and salinity time series and linear trends can only be considered as mean increments for the whole period of time. Furthermore, the homogeneity of the time series obtained and the continuity of the ongoing monitoring programs provides a tool for studying the effects of climate change in the Mediterranean. A correlation analysis with time series of heat absorbed by the upper 700m in the North Atlantic evidence that the WMED and the present time series can be considered as a proxy for larger scale climate change studies.

Fig. 2. Left column are mean temperatures for the upper, intermediate and deep layers averaged for the four areas selected. Right column is the same for salinity.

TYRRHENIAN SEA CIRCULATION IN SPRING 2004: OBSERVATION AND MODEL RESULTS

A. Vetrano^{1*}, E. Napolitano², R. Iacono², K. Schroeder¹ and G. Gasparini¹ ¹ CNR - Istituto di Scienze Marine, La Spezia, Italy - anna.vetrano@sp.ismar.cnr.it ² ENEA CR-Casaccia, Roma, Italy

Abstract

Hydrological and current measurements collected in the Tyrrhenian Sea during May-June 2004 are analyzed with an inverse boxmodel (IBM) to establish the mean spring circulation patterns of the basin. These patterns are compared with those provided by a high resolution, primitive equation model (POM) implemented over the area to simulate the mean basin circulation during the survey. The good agreement between the two circulation fields represents a solid evidence for the reliability of the estimated dynamical structures. Moreover, the POM reveals the short spatial variability of the basin not always resolved by IBM because of the low spatial resolution of the in-situ measurements. The comparative study indicates the Tyrrhenian basin as a highly dynamically active region of the Mediterranean Sea, characterized by a rich mesoscale dynamics. Keywords: Circulation, Tyrrhenian Se, Mesoscale Phenomena, Models

The Tyrrhenian Sea (TS) is a deep basin of the Mediterranean Sea characterised by a complex bottom bathymetry: A narrow continental shelf, a large shelf slope and a deep central part with a large number of isolated volcanic seamounts. Up to the 90s, TS was considered the most isolated basin of the Western Mediterranean Sea, characterized by a wind-driven circulation. Recent findings suggest that TS is a key region for the water masses exchanges between the eastern and the western Mediterranean Sea, playing an important role as a reservoir of heat and salt for the Mediterranean basin [1, 2]. A detailed description of the circulation at the level of the main water masses is still lacking.

This work is aimed at achieving a novel picture of the typical TS spring circulation patterns, based on observations collected during two recent dedicated oceanographic cruises conducted between May and June 2004 (Fig. 1). The hydrographic dataset, integrated with long-term current measurements (at the Sicily strait and the Corsica channel), has been used to estimate the absolute geostrophic flow with a linear Inverse Box Model (IBM). The IBM method [3] provides a correction to the relative geostrophic velocity field, assuming conservation of water properties inside boxes, which are closed volumes of water bounded by the geographical margins (coastline and bottom) and by the hydrographic transects. Two isopycnal surfaces (28.9 kg/m3 and 29.1 kg/m3) are chosen as boundaries between layers, corresponding to the resident water masses: Atlantic Water (AW), Levantine Intermediate Water (LIW) and Tyrrhenian Deep Water (TDW).

The IBM assessment of the circulation has been compared with the simulated circulation from a high resolution numerical model (the Princeton Ocean Model, POM), forced with ECMWF wind stress fields averaged over the cruise period. Initial and boundary conditions are obtained by interpolating on the POM grid the temperature, salinity, velocity and surface elevation fields produced by the Mediterranean Forecasting System (MFS). Both the initial and the boundary data are averaged over the cruise period. The model is forced at the open boundaries by net mean barotropic transports simulated by MFS.

Fig. 1. Comparison between IBM (a) and POM (b) current fields at 75 m, representative for AW circulation.

Fig. 1a shows the IBM estimated geostrophic velocities (small arrows perpendicular to hydrological transects) at 75 m of depth, superimposed to the dynamic heights distribution (dotted curves) at the same depth, referenced to the surface. From both fields, a sketch of the main AW patterns (continuous curves) has been drawn and compared with a similar sketch resulting from the horizontal velocity field of the POM simulation (Fig. lb). The ten dynamical structures distributed all over the basin in both IBM and POM fields are numbered likewise, tolerating small differences in position and shape. The largest structure is the Bonifacio gyre 9, which is a permanent cyclonic circulation due to the year-round westerly jet of wind blowing through the Bonifacio strait. This gyre displays remarkably close features in the two estimates. Moving south, good agreement is found for the anticyclone 3, just above the Sicily tip, and for the cyclonic circulation 4, more to the east. The eddy 8 is well developed in POM as a wide current meander. Most of these structures are coherent with the corresponding intermediate and deep circulation patterns (not shown), indicating a strong barotropic component of the flow. For the sake of completeness, horizontal surface and intermediate mass fluxes for the main streams and gyres are shown in Fig. 2.

Fig. 2. IBM horizontal mass transports (Sv) through transects for AW (a) and LIW (b).

Concluding, the results indicate the presence of a rich mesoscale dynamics, until now poorly resolved, likely to be strongly influenced by the interaction of the surface forcing with the complex bathymetry of the basin. Moreover, the good agreement between the geostrophic reconstruction of the IBM and the velocity patterns of the POM indicates that the main deduced circulation patterns are representative of a typical TS spring condition.

Abstract

A novel approach in detecting and determining water mass changes is documented in the paper, based on a Self-Organising Maps (SOM) method. We used the method to extract and classify long-term variability (1957-2009) of temperature, salinity, dissolved oxygen and nutrients at a single station in the deep South Adriatic Pit. The extracted vertical profile patterns and their variability are associated with the known Adriatic water masses. We also tested the capacity of the method to recognize the masses by changing the dimensions of SOM nodes and by varying the number of input parameters.

Keywords: Adriatic Sea, Deep Waters, Time Series

Adriatic water masses are known to play an important role in ventilation of deep layers of the Eastern Mediterranean, and the South Adriatic Pit (SAP) is recognized as a place where most of the deep waters are formed [1] inside of a cyclonic gyre. The formation can be enhanced or modified by other masses [2]: (i) very cold North Adriatic Dense Water, which is turbulently sinking along the western SAP perimeter, and filling the deepest layers of the pit, and (ii) saline Levantine Intermediate Water (LIW) which is coming into the Adriatic through the Otranto Strait and preconditioning the generation of the Adriatic water masses. There are several studies describing a long-term variability and interplay between the Adriatic water masses [2, 3]. This paper will document the use of a state-of-the-art method for extraction of patterns from time series, the Self-Organising Maps (SOM) method, and its application to the long-term series of thermohaline and chemical parameters in the South Adriatic. We analysed the series of temperature (T), salinity (S), dissolved oxygen (DO), ortophosphate (HPO₄²⁻) and total inorganic nitrogen (TIN) concentrations measured at the D1200 station (42°13'N, 17°42'E) located in the nortern SAP in the 1957-2009 period. These series have been quality checked for bad values, offsets and spikes, normalized by standard deviation and mean value of each parameter, and introduced to SOM.

SOM is an artificial neural network based on unsupervised learning [4]. It consists of a nonlinear cluster analysis mapping of high-dimensional input data onto a two-dimensional output space. The gaps in the input data are treated by the method, allowing SOM to effectively extract patterns from large data sets. Thus, the SOM method has been widely used in various fields of studies ranging from economics to sciences, including oceanography [5]. In this analysis we used 2x3 SOM arrays, which allows for the detailed extraction of the characteristic water profiles, but we also tested the sensitivity of the method by applying 2x2 and 3x3 SOM arrays to the data. Sensitivity to the input variables has been tested as well, by introducing different groups of parameters to SOM (all, without TIN, without HPO₄²⁻, without DO, without nutrients, only T and S) and assessing the variations of characteristic patterns and Best Matching Unit (BMU) evolution in time. BMU is the number of the SOM solution that can be identified according to the minimum Euclidian distance between certain input data field and all SOM solutions.

Figure 1 plots the profiles of 2x3 SOM BMUs for all parameters. The profiles adequately resemble the Adriatic water masses. The resemblance is the most obvious for the salinity BMU profiles. For example, BMU1 can be associated to a strong LIW inflow to the Adriatic, as it is characterised by very high salinity, low DO and high nutrients in the intermediate layer. The generation of the Adriatic Deep Water (ADW) may be seen in BMU2 and BMU4, as these patterns are characterised by vertical homogeneity between 200 and 600 m. Temporal evolution of the BMU in time (not shown) depicts the variations of water masses in the area. For example, BMU1 is appearing around 1970, 1980, late 1980s and mid 2000s, when LIW intrusions have been detected [2]. However, some additional changes in BMU patterns and their temporal evolution are obtained when restricting the input variables to T, S and DO, and especially when using only T and S in the analyses.

The results highlight the advantageousness of the SOM for water mass assessment, as objective classification may be made for an area. Therefore, the method may be used for objective classification of the overall Adriatic masses, and may introduce new insights in our knowledge of existing water mass definitions, especially when including chemical parameters in such an analysis.

Fig. 1. Characteristic profiles (BMU1 to BMU6) of termohaline and chemical parameters as extracted by the 2x3 SOM from the data collected at D1200 station between 1957 and 2009.

STRONG FORTNIGHTLY OSCILLATIONS OBSERVED IN THE ADRIATIC SEA

Abstract

This paper documents the occurrence of strong fortnightly oscillations in the Adriatic Sea, frequently observed in the current measurements. For that purpose we analyzed half-decadal sea level series and long-term currents collected within different parts and layers of the Adriatic Sea. The fact that strong 10-20 day currents are occasionally in-phase with the Mf sea level tide gives a hint on a possible mechanism responsible for the generation of these oscillations. Additionally, these currents are usually strongly amplified during a weakly stratified season, indicating a baroclinic mechanism responsible for the multiplication of the fortnightly currents. *Keywords: Adriatic Sea, Tides, Currents*

There are a number of studies that document the 10-20 day oscillations in current fields, which are frequently observed in the Adriatic and Mediterranean Seas [1-4]. Although the atmospheric forces have been suggested as the generator of these oscillations, such a hypothesis is still not proved and no significant interconnection with the strongest currents has been found. Therefore, we attempted to connect the observations with another force not considered in any of the documented literature, and that includes the propagation of the fortnightly wave [5, 6] coming from the Atlantic Ocean through the Strait of Gibraltar, being modulated and amplified by the topography, stratification and atmospheric processes.

We focus our study in the Adriatic Sea, as continuous multi-decadal hourly sea level series are available there, together with several long-term (about a year) current measurements. We have used the data collected at the Rovinj (RO) and Split (SP) tide gauges from 1957 to 2005, and the ADCP deployed off Dubrovnik between 27 November 2007 and 23 January 2009 at the depth of 84 m. For the assessment of the atmospheric influence we used available hourly air pressure data from Bari (BA) and Trieste (TR) meteorological stations during the same interval, analyzing their difference (gradient) that generates the winds along the Adriatic.

First we performed classical spectral analysis and found that a significant sea level energy peak between diurnal and semi-annual periods is occurring only at 13.66 days, equalling the Mf tide period. By applying harmonic analysis we estimated a Mf amplitude of 0.89±0.42 cm at Split and of 0.97±0.44 cm at Rovinj, with no changes in phase between them, indicating that the barotropic Mf tidal wave is much larger than the Adriatic. Then we extracted 10-20 day currents from the ADCP station by applying a band-pass Butterworth digital filter. It may be seen that both the barotropic Mf currents and sea levels are often in-phase (Fig. 1), indicating a progressive nature of these oscillations. The predominantly barotropic currents are changing into baroclinic ones in early April, when stratification is beginning to develop in mid latitudes. The first oscillatory event, occurring in April, is in-phase with the air pressure gradient oscillations over the Adriatic, which is following the documented speculations on atmospheric origin of the generating force of 10-20 day oscillations. However, the second and the strongest 14-day oscillatory currents event in 2008 may be observed from mid May to early July, when the atmospheric pressure gradient at these periods was quite low. The oscillatory currents with maximum velocity amplitude of 15 cm/s were in-phase with the Mf tide for more then 4 cycles. The in-phase character between the current oscillations and the force, which may be observed through the water column, also indicates that the Mf tide could be the generating force.

Two other documented studies are favouring the Mf tide to be a generator of such oscillations. Martin et al. [4] tried to reproduce the fortnightly oscillations observed at Palagruža Sill by state-of-the-art ocean numerical model, which includes all of the atmospheric forcing but not fortnightly tides at the open boundary. They did not reproduce the oscillations, yielding us to the conclusion that the force is outside of the model like fortnightly tides. Other study, given by Kovacevic et al. [3], documents the 10-20 day variability in deep Otranto Strait currents. We found both observations to be in-phase with the Mf sea level tide in the Adriatic.

Fig. 1. The top panel shows band-pass filtered along-Adriatic air pressure differences as computed from Bari and Trieste measurements. The middle panel displays the Mf sea level tide. The bottom panel contains band-pass filtered alongshore currents measured off Dubrovnik in 2008 (the most top and most bottom current series are at 6 and 70 m, filled in by the equidistant 4-m layers).

We believe that similar fortnightly oscillations may be found in other parts of the Mediterranean Sea, still unexplained as nobody considered the Mf tidal wave as a possible generator. In addition, the significance and strength of the Mf tide over the open Mediterranean waters should be mapped through the process-oriented numerical studies, which will prove the capacity of the Atlantic Mf tide to propagate within the Mediterranean and to amplify at topographical barriers and during stratified conditions.

Abstract

The relation between physical and biological processes affecting the Mediterranean Sea surface layer was investigated by means of different Empirical Orthogonal Function (EOF) decompositions over remotely sensed chlorophyll-a (CHL), sea surface temperature (SST) and Mediterranean Absolute Dynamic Topography (MADT) weekly time series (1998-2006). From the climatological point of view, there is an inverse relationship between CHL and SST, which is explained in terms of enhanced/reduced nutrient inputs to the surface layer as a result of the reduced/enhanced water column stratification. The correlation analysis over EOF results identified physical-biological interactions at both short and long term time scales, and from local to basin scales. *Keywords: Phytoplankton, Temperature, Sea Level*

The relation between physical and biological processes affecting the Mediterranean Sea surface layer was investigated by means of different Empirical Orthogonal Function (EOF) decompositions over remotely sensed chlorophyll-a (CHL), sea surface temperature (SST) and Mediterranean Absolute Dynamic Topography (MADT) weekly time series (1998-2006). The EOF analysis generally requires complete time series of input maps, with no data voids. While respective data providers interpolated SST and MADT time series, CHL maps present several data voids due to the presence of persistent cloud cover. In this context, in order to fill in missing data, the Data INterpolating Empirical Orthogonal Functions (DINEOF) technique was applied to CHL images. A validation exercise, comparing 1304 *in situ* observations with space-time co-located satellite data, showed that, at weekly time scales, the DINEOF procedure improves data quality by filtering out the noise.

Fig. 1. Field climatologies (1998-2006) for CHL (a), SST (b) and MADT (c). Zero level contour line is superimposed onto the MADT map.

From the climatological point of view, a tight correlation exists between CHL and both SST and MADT (Fig.1). The basin and sub-basin scales inverse relationship between CHL and SST (r=0.64) is explained in terms of Behrenfeld hypothesis [1]: i.e., surface heating enhances water column stratification, which in turn prevents nutrient entrainment into the euphotic mixed layer, and vice versa. At more local scale, highly productive open-ocean areas are found to correspond with well-known and defined dynamical structures (as highlighted by the MADT field): in the WMED, these areas are represented by the cyclonic gyre in the Gulf of Lion, and all along the Algerian Current from the western Alboran Gyre down to the border between Libya and Tunisia across the southern sector of the Sicily Channel. In the EMED, this coupling appears in relation to the Ierapetra Gyre, though less clearly.

This analysis, on a side, provides enlightening insights on the physicalbiological coupling, but on the other it is unable to investigate such a coupling on other than climatological time scales. The correlation analysis applied to EOF results, by exploring all time scales, helps giving deeper comprehension about these relationships. Results from the single EOFs, along with a crosscorrelation analysis, identified physical-biological interactions at both short and long term temporal scales, and from local to basin spatial scales. In particular, the high correlation (r=0.9) between CHL and SST first modes describes the immediate response of phytoplankton concentration to the annual cycle of the water column stratification, at both basin and sub-basin scales. A completely different mechanism links the MED open ocean spring bloom to the DWF processes, in the north western MED. This is described by the 5.5 months phytoplankton delayed response to local surface cooling (as described by CHL and SST second modes). In fact, on one hand, the total amount of nutrients available in the offshore surface waters depends on the deep convection events occurring in late winter [2]. On the other hand, the DWF phenomena are characterized by a fundamental pre-conditioning phase, during which the surface stratification is significantly reduced.

Despite the good correlation between phytoplankton biomass variability and the temperature field at seasonal time scale, this analysis was unable to identify the co-variability between the two parameters at interannual timescale. We interpret this as due to the strong annual component, which definitely dominates the overall signal within both the first two EOF modes. In order to highlight then the presence of longer time scale signals and to investigate the covariance between the phytoplankton biomass and surface conditions at interannual timescales, the annual cycle and higher frequency signals have been removed from EOF data input. This data manipulation consisted in removing the weekly climatology from each weekly field of the time series, and then of applying a low-pass filter (one year moving average). This data filtering showed the link between phytoplankton biomass variability and two distinct interannual signals: a) the modified surface circulation pattern consisting in a northward shift of the Algerian current, along with its intensity increase, and the reduced cyclonic circulation in the whole eastern basin; b) to the surface heat content anomalies during 1998/1999 (particular cold winter) and 2003 (summer heat wave). This data filtering enabled to investigate the processes that influence the phytoplankton space and time distribution over longer time scales. In particular, the phytoplankton biomass variability was linked to two distinct interannual signals. The first is the modified surface circulation pattern consisting in a northward shift of the Algerian current, along with its intensity increase, and the reduced cyclonic circulation in the whole eastern basin (r=-0.87). One possible explanation is that the reduced advection of the relatively richer waters of Atlantic origin (in terms of nutrients and biomass) in the Tyrrhenian and Ionian Seas and its increased dispersal into the western WMED result in a progressive decrease of F-LCHL concentration in the central MED, creating the positive patch in the western WMED. The second is the surface heat content anomalies in 1998/1999 (particular cold winter) and 2003 (summer heat wave) (r=0.52), driving the phytoplankton dynamics in the central WMED, with few months delay. The observed impact of the water column stratification dynamics onto the phytoplankton biomass variability recalls the described simple model [3].

DIRECT ESTIMATE OF WATER, HEAT AND SALT TRANSPORT THROUGH THE STRAIT OF OTRANTO

Sadegh Yari¹*, Miroslav Gacic¹, Vedrana Kovacevic¹ and Vanessa Cardin¹

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, 34010, Trieste, Italy - syari@ogs.trieste.it

Abstract

Water, heat and salt transport across the Strait of Otranto are estimated. Historical data sets (from December 94 through November 95) are used in this study [1, 2]. A new methodology (Variational Inverse Method [3]) is used to reconstruct the current, temperature and salinity fields over a regular grid, from the sparse measurements across Strait of Otranto. The direct method [4], which is simply spatial integration of production of current, potential temperature, specific heat capacity and water density over the transect area, is applied to gridded data to calculate the transport rates. The air-sea heat fluxes are calculated for the period of study to compare with heat advection through the Strait. The fresh water budget is estimated as well. *Keywords: Adriatic Sea, Strait Of Otranto, Water Transport, Heat Budget*

The water, heat and salt transports through the Strait of Otranto are estimated applying direct method to historical current and hydrographical data (from December 94 through November 95). A variational inverse method based on a variational principle and a finite element solver is used to reconstruct the current, temperature and salinity fields across the Strait section from sparse measurements. Characteristics of the current field obtained by this new application are comparable to the historical studies [2]. The main features, such as the existence of the horizontal anticlockwise shear in the strait with inflow (northward currents) on the east and outflow (southward currents) on the west, and a two-layer system in the central deep portion (with inflow in the surface and outflow in the bottom layer) are reproduced. The mean annual inflow and outflow water transport rates are estimated as 0.901±0.039 Sv and -0.939 \pm 0.315 Sv, respectively, and the net transport is equal to -0.032 \pm 0.208 Sv. Thus, on a yearly time interval, the inflow and the outflow are practically compensated. The seasonal variation of water transport across the Strait of Otranto shows that the maximum exchanges take place during winter and spring, while the minimum exchanges are in summer. The errors of the inflow transport rates are almost always less than 10%, while the errors of outflow transport rates have large values 30%-50%. This is due to low spatial resolution of the current measurements in the lower layer of the central part of the cross section, which is located mostly in the outflow region. Consequently, the higher error on outflow influences the net transport rates and finally these estimations are associated with larger errors.

The heat and salt transports due to advection process are calculated for the first time. These estimations are carried out for five monthly periods, namely December 1994, February, May, August and November 1995. Considering these five periods representative of the seasonal cycle during the year (Autumn 1994 and four seasons of 1995), their average values show that there is a net heat advection into the Adriatic Sea on a yearly basis. The estimated value of advected heat and the corresponding error are 2.408±0.490 TW, which is equivalent to a heat gain of 17.37±3.53 W m⁻² for the whole basin. The heat exchange through the air-sea interface is estimated by applying the bulk formulas to the meteorological data, namely the ERA-40 reanalysis data set extracted from European Centre for Medium-Range Weather Forecasts (ECMWF). The average surface heat flux for the study period is estimated as a heat loss of -36±152 (std) W m⁻² through the air-sea interface over the Adriatic Sea. The final estimates of the advected heat through the Strait of Otranto are compared and discussed with the relationship to air-sea heat exchange over the Adriatic Sea. The two values are expected to balance each other in order to close the heat budget of the basin. The possible reasons for a difference to occur are discussed. On an annual time scale the advected heat should be compensated with the air-sea heat loss. However, on a seasonal time scale a significant disagreement might be expected. This is due to seasonal variation of the heat content of the Adriatic Sea, seasonal cooling or warming. Moreover, it can be related to the fact that the heat advection and surface heat exchange are basically two different mechanisms in time and space. Therefore, the spatial and temporal scales of these processes are different. Consequently, they can not balance each other on a short time scale as monthly or even a seasonal one. The potential temperature distribution indicates that the upper layer (first 200 m from the surface, including thermocline layer) is associated with higher temperature and elevated variability, while the lower layers are associated with lower temperature and smaller variability. This fact may set up the different role that each of the two layers plays in transporting heat. To examine this, the heat transport rates are then calculated for the two layers separately: the upper layer from sea surface down to 200 m depth and the lower layer from 200 m depth to bottom. The results show that the upper layer has larger contribution to the heat transport into the Adriatic Sea (heat

gain), and as the net heat transport, the inflow of heat prevails in this layer. The lower layer contributes significantly to the heat transport away from the Adriatic Sea (heat loss). In fact, the net heat transport rates are negative, which means that the outflow of heat dominates in this layer.

The effect of temporal variation of the temperature field, which remains unsolved by using hydrographic surveys, is examined by simultaneous time series of current and temperature measurements. The contribution of eddy heat fluxes to total heat advection is estimated. The contribution is less than 6% [5]. Therefore, by calculating the heat transport from averaged current and temperature distributions, we asses the major part of the total heat transport, and consider it as representative of the total heat due to advection. The direct estimation of heat transport can be used as a constraint for validating the airsea heat fluxes [6]. Therefore, by considering the advected heat as a reference, one can tune the bulk formulas to modify the estimation for the air-sea heat fluxes.

On a yearly basis, the salt transport is estimated as an input of salt equal to 0.05×10^6 Kg s⁻¹. The average annual fresh water budget is estimated as -0.002 Sv, equivalent to 0.45 m yr⁻¹ for the entire Adriatic Sea. The import of salt that is less than the gain of fresh water is in agreement with the fact that the Adriatic Sea is a dilution basin. The brief results of water, heat, salt and freshwater transports are presented in Table 1 [5].

Table 1. Water, heat, salt and freshwater transports across the Strait of Otranto [5]. Units are in Sv ($10^6 \text{ m}^3 \text{ s}^{-1}$), TW (10^{12} Watts) and MKg/s (10^6 Kgs^{-1}).

Period	Water (Sv)	Heat (TW)	Salt (MKg/s)	Freshwater (Sv)
Dec. 94	0.045 ± 0.182	2.068 ± 0.148	0.007 ± 0.086	-0.001
Feb. 95	0.163 ± 0.206	2.633 ± 0.259	0.033 ± 0.091	-0.001

DARDANOS: A WERA SYSTEM FOR MONITORING THE DARDANELLES OUTFLOW IN THE AEGEAN

V. Zervakis ¹*, G. Korres ², Z. Kokkini ¹, E. Tragou ¹ and T. Karambas ¹

¹ Department of Marine Sciences, University of the Aegean, Mytilene, Greece - zervakis@marine.aegean.gr ² Institute of Oceanography, Hellenic Centre for Marine Research, Anavissos, Greece

Abstract

The University of the Aegean and the Hellenic Centre for Marine Research have jointly installed a WERA HF radar system at the eastern coast of the island of Lemnos, Greece, in an effort to continuously monitor the surface Dardanelles current, a permanent feature carrying Black Sea Waters into the North Aegean Sea. Through this effort, the two Greek institutions aim ato estimating the volume flux of Black Sea Waters into the Aegean, as well as fluxes of biochemical properties responsible for the meridional oligotrophy gradient in this Mediterranean basin.

Keywords: Aegean Sea, Coastal Systems, Dardanelles, Black Sea

The Mediterranean and Black Seas are two neighboring seas of highly contrasting thermohaline and biochemical character, connected through the Turkish Straits System (TSS, i.e. the Dardanelles Strait, the Marmara Sea and the Bosphorus Strait). The water exchange through the Straits plays a critical role in the thermohaline and biogeochemical functioning of both seas. The deep layer of the Black Sea is continuously fed by Mediterranean waters through the subsurface Bosphorus current, maintaining the high salinity stratification of the basin [1] and thus, their permanently anoxic conditions [2]. The Black Sea waters (BSW) entering the Mediterranean as the surface Dardanelles current, form a light brackish layer over the North Aegean, playing a crucial role in controlling deep water formation processes in the region [3], and maintaining a meridional gradient in the oligotrophy of the Aegean Sea [4]. It is still unclear from climatic predictions whether the freshwater deficit of the Mediterranean, or the warming of the sea will prevail, thus contributing to lower or higher stratification of the sea. Thus, the insulating role of the BSW surface layer of the North Aegean may become even more crucial in controlling the thermohaline functioning of the basin. As the freshwater budget over the large Black Sea catchment area largely determines the characteristics of the exchange, the latter may become a significant climatic index for the region. For the above reasons, the University of the Aegean and the Hellenic Centre for Marine Research have recently installed a WERA High Frequency system for monitoring surface currents on the east coast of Lemnos island. The HF system, named "Dardanos", is able to monitor surface currents at semi-hourly intervals and 1.5 km resolution as far as the Dardanelles exit thus providing a formidable tool for high-frequency monitoring of the surface circulation of the region (figure 1).

Fig. 1. Surface current map from October 25th, 2009. The darker shades at the northern part of the domain (corresponding to higher velocities) define the extent of the Dardanelles current

Our initial planning required that the system's range extends to the mouth of the Strait, in order to be able to separate the Dardanelles Current from a very energetic anticyclone that often contributes to the current through the Lemnos - Imvros channel. The HF system has been in operation since October 2009, and preliminary analysis of the data reveals that the system fulfills the above requirement about 30% of the time. Furthermore, the range of the system appears to vary depending on weather conditions. We examine the potential bias such behaviour could pose on the estimated Dardanelles volume fluxes.

A possible challenge is the estimation and removal of Stokes drift from the observed currents in order to assess the Dardanelles outflow. It should be noted that a linear antenna array (beam forming method) would permit a direct measurement of the wave field, however such a methodology was not applicable in this case due to topographic restrictions. Preliminary analysis has also revealed the sporadic presence of areas of erratic measurements, possibly due to electromagnetic noise in the region. Such errors should be readily removed through statistical methods.

While HF radars are being used worldwide mainly for operational purposes and for process studies (especially for coastal dynamics studies), it is -to our knowledge- the first time that such a system will be exploited in climatological monitoring of basin exchange and thermohaline functioning. The Department of Marine Sciences of the University of the Aegean aims at exploring different methodologies of estimating mixed-layer-depth and assume slab-layer behaviour in an effort to estimate the volume flux of Black Sea Waters into the Mediterranean. This time series will be compared with estimates from previous studies. The Hellenic Centre for Marine Research plans to exploit the information in improving its circulation predictions for their operational oceanography project and other climatological applications. The produced information will also be available for studies of the ecological functioning of the North Aegean, of pollutant dispersion (taking the Dardanelles exit as a potential point source of pollution in case of a marine accident), and in any related operational oceanography applications.

The installation of the HF system in Lemnos was supported by the project "Prevention and management of sea-originated risks to the Coastal Zone (CORI), funded by INTERREG-IIIB Archimed. Testing and quality control was supported by the MarinERA MedEX project.

THE CYPRUS WARM EDDY AND THE ATLANTIC WATER DURING THE CYBO CRUISES (1995-2009)

George Zodiatis ^{1*}, Dan Hayes ¹, Isaac Gertman ² and Yianna Samuel-rhoads ¹ ¹ Oceanography Centre, University of Cyprus, Nicosia, Cyprus - gzodiac@ucy.ac.cy ² Israel Oceanographic and Limnological Research, Haifa, Israel

Abstract

In '80s, during the few seasonal POEM (Physical Oceanography of the Eastern Mediterranean) cruises in the SE Levantine Basin was first depicted a multi-pole gyre, the Shikmona, formed by three eddies with the Cyprus one being most pronounced and an offshore cross basin current, the Mid Mediterranean Jet. A considerable much larger amount of seasonal in-situ data were collected from various observing platforms in the SE Levantine Basin from 1995-2009, mostly in the framework of the CYBO cruises and secondary by some other collaborative cruises and projects. These new in-situ data sets show a strong spatial and temporal variability of the Cyprus warm core eddy, of the Atlantic Water and of the associated MMJ displacement in the area. *Keywords: Levantine Basin, Circulation Models, Cyprus Arc, Currents*

Preface

The general circulation in the Eastern Mediterranean as inferred from several cruises in 1960s and 70s [1], shows an anticlockwise flow with sub-basin features in the Levantine Basin, with the Rhodos gyre being the most well pronounced. In '80s, during the POEM international field experiments [2,3], a more detailed structure of the mesoscale circulation was defined to consist of several alternative cyclonic and anticyclonic gyres and eddies. Further, it was first shown that as a result of the interaction between these cyclonic (Rhodos) and anticyclonic (Mersa Matruh and Shikmona) gyres, an offshore cross basin jet is generated, named the Mid Mediterranean Jet (MMJ). In the SE Levantine the POEM group defined the Shikmona gyre as a multi-pole gyre, consisting of 3 eddies, of which the Cyprus one is the most well pronounced. Despite the fact that the Levantine Basin is characterised with the highest salinity at the surface and intermediate layers of the Mediterranean, less saline waters of Atlantic origin spread at the sub-surface layers, almost throughout the basin, as a results of the water volume compensation for the high rates of the sea water evaporation in the Levantine and of the outflow of the intermediate water into the North Atlantic [1].

Discussion and Results

The analysis of new in-situ datasets gathered in the SE Levantine during the period 1995-2009 from CYBO and CYCLOPS cruises, HaiSec cruises, NRT data of the CYCOFOS observing system, as well as extended use of satellite remote sensing data collected during the same periods, helped define in details not only the daily and seasonal, but also the inter-annual variability of the dominated mesoscale flow features and of the water masses displacement in the region.

These long term seasonally collected in-situ datasets reveal that the dominant and permanent flow feature in the SE Levantine is the Cyprus warm core eddy, that undergoes significant seasonal and inter-annual fluctuations in terms of its shape, size, intensity and location. Moreover, the establishment of a secondary warm eddy in the SE part of the study area was found during periods when the Cyprus eddy became weaker, as was shifted westward for about 80 nm away from Eratosthenes SM. Also during the long term CYBO campaigns it was found the re-establishment of the non permanent Shikmona gyre, when the coexistence of 2-3 warm eddies was observed. Particularly, during certain short periods related to the generation and destruction mechanism of the warm core eddies circulated within the Shikmona gyre, when it is present. The latter is recently evident from drifters trajectories, gathered by the NEMED project, which show that the instability of the strong northward current flowing along the Israel-Lebanese coast generated an anticyclonic eddy. The latter, detached away from this northward current towards the area of the secondary eddy, as observed by CYBO cruises.

These new data confirm the previous works [2, 3] that the MMJ enters the study area from the southwest, after crossing offshore the basin from the southwest. Furthermore during the CYBO cruises it was found that this jet meanders between Cyprus and the northern periphery of the Cyprus warm core eddy [4, 5]. The Cyprus warm core eddy, the Shikmona gyre (when appears), the smaller-scale non permanent cyclonic and anticyclonic eddies in the region, increase the complexity of the MMJ flow path and thereby of the AW transport in the SE Levantine.

The AW in the SE Levantine is very well pronounced during summer periods, mostly at the sub-surface depths, below the thermocline (~40 m) and down to the depth of ~80m, with salinity as low as 38.65-38.9. Periodically the AW

was also defined at the surface, in the western part of the SE Levantine. During winter mixing processes the AW mostly is absent from the region, however, in winter periods with mild weather conditions all over the Mediterranean, the AW can be traced in the study area at the surface too. Throughout the study period the AW is well pronounced south and southwest of Cyprus. The MMJ is documented to transfer the AW eastward within the Levantine Basin. It was found that the MMJ transfers the AW along the periphery of the Cyprus warm core eddy, at the subsurface layers. AW has also been observed close to the Egyptian coast, as a result of a westward re-circulation, either of the MMJ or of a current flowing eastward along and closer to the Egyptian coast. During most of the examined periods the MMJ was found to be a main flow pathway for transferring the AW within the SE Levantine Basin.

Fig. 1. Schematic of the general circulation in the SE Levantine showing the Cyprus eddy, the secondary eddy and the MMJ, as depicted from the CYBO cruises, 1995-2009.

Abstract

In the deep layers of the Western Mediterranean, an almost constant trend towards higher temperature and salinity has been observed since the 50's, with an acceleration on these trends in the 90's decade, as a result of the propagation of the EMT signature, from east to west. Indeed, an exceptional deep water formation event has been documented in winter 2004/2005 in this basin. After this intense event, the large volume of new deep water formed has caused an uplifting of the old deep water, replenishing the deep basin with the new warmer and saltier water. In order to detect the effects of water mass changes and vertical displacement, we investigated the variability of seawater properties on isopycnal and isobaric surfaces from 1995 to 2008, with special attention to the last years, when the WMT have been happening.

Keywords: Western Mediterranean, Deep Waters, Density

The recent acceleration of deep temperature and salinity changes in the Western Mediterranean (WMED) [1] has been followed by a major change in the basin after 2005 deep water formation processes. These events have produced the basin-wide spreading of a deep thermohaline anomaly, which is called Western Mediterranean Transition (WMT, [2]). Temperature and salinity changes on isobaric surfaces have two effects added: changes along isopycnal surfaces (related to water mass changes) and those induced by the vertical displacement of isopycnals (related to wind stress curl and formation rate of deep water) [3]. These authors proposed the following equation to evaluate how the two effects lead to changes on each pressure level:

 $\left. \frac{d\theta}{dt} \right|_p = \left. \frac{d\theta}{dt} \right|_\sigma - \left. \frac{dp}{dt} \right|_\sigma \frac{\partial\theta}{\partial p} \right|$

This methodology has recently been applied for the first time in the WMED [4]. The aim of the present work is to indentify how intense deep water events could move upward old deep water and what would be the effect of the vertical displacement of isopycnals (referred to as heaving [3]) when temperature and salinity changes are studied on isobaric surfaces. We focus on the WMT because of the larger volume of deep water formed than previous years. Therefore, the heaving should have an important effect on temperature and salinity changes estimated on isobaric surfaces.

We have analyzed temperature and salinity data from the DYFAMED station from 1995 to 2008, as well as data from different surveys carried out from 2004 to 2008 on board of the R/V Urania, owned by CNR-ISMAR.

Fig. 1. A) Potential temperature, b) salinity and c) pressure evolution along some selected density surfaces from 1995 to 2008. Data from the DYFAMED station.

Preliminary results show salinity and temperature increases along both isopycnals and isobaric surfaces since 1995 up to 2004 in the intermediate and deep layers (fig 1 a and b show temperature and salinity evolution along isopycnal surfaces). But, after the WMT event, temperature and salinity increase in the bottom layers while they decrease in the intermediate layer. Concerning the WMT, the volume of deep water generated during this event is larger than in previous years [5], causing the upward displacement of old deep water (Figure 1c shows the shallowest levels achieved by all the represented

isopcynals in 2006). The effect of this upward movement was a cooling and freshening on isobaric surfaces (dashed black line in fig 2 A and B). In this case isopycnal and heaving contribution have the same sign, adding both effects, resulting in a cooling and freshening effect on isobaric surfaces which are larger than those that really affected the water masses by themselves.

Fig. 2. A) T and B) S anomalies on isobaric surfaces (black line), and their both contributions: isopycnal (grey line) and heaving (dashed black line). These anomalies correspond to 2006 (after the WMT) with the 2004 (before the WMT) profile as reference.

The authors acknowledge the Observatoire de Villefranche sur Mer Service d'Observation for providing the DYFAMED monthly CTD time series (http://www.obs-vlfr.fr/sodyf/home.htm).

WHAT DOES INDUCE TEMPERATURE AND SALINITY CHANGES IN THE WMED ALONG THE SECOND HALF OF THE 20TH CENTURY?

Patricia Zunino¹*, Manuel Vargas-Yañez¹, M. Carmen García-Martinez¹ and Francina Moya¹ ¹ Instituto Español de Oceanografía. Centro Oceanográfico de Málaga, Fuengirola, Spain - pzunino@ma.ieo.es

Abstract

Temperature and salinity evolution in the Western Mediterranean have always been studied on isobaric surfaces. But TS changes on pressure levels can be affected by changes on isopycnal surfaces and due to the vertical displacement of isopycnals (referred to as heaving). Temperature changes induce salinity changes and vice versa. The main objective of this work is to quantify which process dominates TS changes along the second half of the 20th century. *Keywords: Western Mediterranean, Global Change, Time Series*

In most of the works carried out in the Western Mediterranean (WMED), temperature and salinity trends have been estimated on isobaric surfaces. It is well known that Western Mediterranean Deep Water has warmed and increased its salinity during the second half of the 20th century [1]. Concerning temperature trend in the intermediate layer, different figures have been provided by different authors, lots of them statistically non significant, even some of them are contradictories [1]. A possible explanation to the previous is that changes on isobaric surfaces have two effect added: changes on material surfaces (related to water mass changes) and those caused by the vertical displacement of isopycnals (related to wind stress curl and formation rate of deep water) [2]. These authors proposed the methodology to evaluate how former effects affect to changes on each pressure level. This methodology has recently been applied for the first time in the WMED [3]. Usually, temperature changes in water mass induce salinity changes and vice versa. Depending whether temperature or salinity induces the change, two different processes have been defined: purewarming or pure-freshening [2]. Besides, when temperature or salinity changes on pressure levels are produced by the vertical displacement of isopycnals, the process is named pure-heaving [2].

The objective of the present work is to indentify what process dominates different sub periods along the 20^{th} century as an extension of the previous work [3].

Fig. 1. Map for the Western Mediterranean. Rectangles identify the areas for which MEDAR Group's [2002] data have been obtained. The final data set is made of averages for the whole WMED. These averages are weighted by the box areas

Salinity and temperature data were extracted from MEDAR database, from 1943 to 2000, and from different selected regions of the WMED (squares in fig. 1). The final data set was made of averages for the whole WMED. Temperature, salinity and density reference profiles were obtained averaging data from 1960 to 1990. We have estimated TS changes on isobaric surfaces and its two different contributions, isopycnal changes and heaving, following the methodology explained in [3]. And finally, the relative strength of each process (pure-warming, pure-freshening and pure-heaving), in terms of percentage variance explained can be estimated solving equations (17) proposed in [2].

Preliminary results show that more than one process coincide explaining the same percentage of variance in a same pressure level and sub period (fig. 2). This is because the equation system has been solved considering that only a single process induces the property change. But, matching processes at each pressure level are not always the same, and this is related to the temperature and salinity vertical gradients and to the magnitude of the TS changes in the different layers of the water column. Indeed, the dominating process in each sub period is related to abrupt temperature and/or salinity changes documented in previous works as well as to intense events of deep water formation.

Fig. 2. Percentage variance explained by pure warming (dashed black line), pure freshening (black line) and pure heaving (grey line) for four different pressure levels (300, 500, 700 and 1000 dbar).

DISTRIBUTION DU APCO2 ET DES FLUX AIR-MER DE CO2 DANS LE GOLFE DU LION (MEDITERRANEE OCCIDENTALE)

Nadira Ait-Ameur 1* and Goyet Catherine 2

¹ Ecole Nationale Supérieure des Sciences de la Mer et de l'Aménagement du Littoral, 16000, Alger, Algérie - Nameur@Gmail.Com ² Université de Perpignan via Domitia - Laboratoire IMAGES, 66860, Perpignan, France

Abstract

Ce travail constitue la première description de la distribution du ΔpCO_2 (pCO₂eau-pCO₂air) et des flux air-mer dans les eaux de surface du golfe du Lion au cours des mois de février, mai, juin et septembre 2001. Le rôle de cette zone côtière comme source ou puits de CO₂ pour l'atmosphère est influencé par les apports du Rhône. Le golfe du Lion est en moyenne, sur l'ensemble des campagnes, une faible source de CO₂ pour l'atmosphère (+17,7 mmol/m²/jour) mais se comporte comme un puits de CO₂ en mai (-3,3 mmol/m²/jour) et juin (-10,8 mmol/m²/jour) suite à une forte production primaire conséquente à un enrichissement des eaux de surface en sels nutritifs par les apports du Rhône.

Keywords: Air-Sea Interactions, Carbon, Gulf Of Lions

Introduction

En Méditerranée nord occidentale, généralement considérée comme oligotrophe, les apports fluviaux du Rhône influencent la productivité du golfe du Lion. Le golfe du Lion est caractérisé par un fonctionnement hydrodynamique complexe qui a des répercussions significatives sur le système biogéochimique de la région et sur le cycle du carbone. Les zones côtières et les plateaux continentaux représentent 7% de l'océan global. Étant le lieu de transition entre l'environnement terrestre et océanique, ces zones jouent un rôle tampon recevant directement les perturbations anthropiques. En Méditerranée, les travaux concernant les échanges air-mer de CO2 sont peu nombreux : le bassin liguro provençal [1], [2], le détroit de Gibraltar [3], et la Mer Egée [4]. Nous proposons donc de présenter dans ce travail une première climatologie de la distribution du ΔpCO_2 et des flux air-mer de CO₂ dans le golfe du Lion et d'évaluer le rôle de cette zone côtière, influencée par les apports anthropiques, comme source ou puits de CO2 pour l'atmosphère au cours des quatre périodes : février, mai, juin et septembre 2001. Cette étude a été réalisée dans le cadre du programme SARHYGOL (Suivi Automatique Régulier de l'Hydrologie dans le GOlfe du Lion).

Méthodologie

La pression partielle de CO₂ (pCO₂) a été calculée à partir des mesures d'alcalinité totale (AT) et du carbone inorganique dissous (TCO₂) en utilisant les constantes d'équilibre de Goyet et Poisson [6]. Les mesures d'alcalinité (AT) et de TCO₂ ont été réalisées par la méthode de potentiométrie avec une incertitude de +/- 4 µmol/kg. Les flux air-mer de CO₂ (FCO₂, mmol/m /jour) ont été calculés en utilisant les vitesses moyennes journalière de vents enregistrées à bord au cours de la période d'échantillonnage. Le coefficient d'échange a été calculé selon Wanninkhof [7].

Résultats et discussion

La distribution du ΔpCO_2 (pCO₂eau – pCO₂air), dans la zone d'étude, sur l'ensemble des campagnes, montre une grande variabilité spatiale et temporelle (figure 1). Elle varie de -232 μ atm à +91 μ atm.

Fig. 1. Distribution du ΔpCO (µatm) des eaux de surface du golfe du Lion en fonction de la longitude pour les mois de février, mai, juin et septembre 2001.

En février, la campagne ne couvre que la partie ouest du golfe du Lion. Pour cette période le ΔpCO_2 varie de -19 à +17 µatm avec une moyenne de 6,8 ± 9 µatm. En février cette partie est principalement en équilibre avec l'atmosphère et se comporte comme une faible source de CO_2 pour l'atmosphère avec un flux moyen net de 0,7 mmol/m²/jour. En mai, la campagne couvre l'ensemble du golfe du Lion. Pour cette période, le ΔpCO_2 varie de -232 à +52 µatm avec une moyenne de -14 ± 34 µatm. C'est dans la zone côtière située à 4,75°E et 5,13°E de longitude que les plus grands écarts en pCO₂ entre l'eau et l'atmosphère sont observés (respectivement -140µatm et -232 µatm). A cette période les eaux de surface sont un puits de CO₂ pour l'atmosphère (-3,3 mmol/m²/jour). En juin, le

bassin présente aussi une grande variabilité du ΔpCO2 (-95 à +91 µatm) avec une moyenne de 41 ± 45 µatm et un flux moyen net entrant de -10,8 mmol/m²/jour. En septembre, la distribution du ΔpCO_2 varie de +25,7 à +84 µatm avec une moyenne de 50±13 µatm. A cette période le golfe du Lion est une source de CO_2 pour l'atmosphère avec un flux net de +54,7 mmol/m²/jour. L'utilisation de l'équation empirique de Takahashi et al. [5] a permis de montrer que pour les campagnes de septembre et février c'est le paramètre « température » et le mélange vertical qui semble contrôler la distribution de la pCO2 dans les eaux de surface. En revanche il apparaît que pour les périodes de mai et juin c'est le paramètre « Biologie, Production primaire » qui contrôle sa distribution dans la zone côtière. Les fortes sous saturations en CO2 des eaux de surfaces observées en mai et juin dans la partie est du golfe du Lion sont associées à de très fortes concentrations en chlorophylle « a » qui excèdent les 4 µg/l avec des pics pouvant atteindre 7 µg/l en juin dans la zone côtière. Les apports importants en sels nutritifs par le Rhône enrichissent les eaux de surface (eutrophisation) et favorisent la production primaire qui joue un rôle important dans l'absorption du CO2 atmosphérique.

Au vu de ces résultats, il apparaît que, dans le golfe du Lion (zone de transition entre le milieu côtier et le milieu océanique), la distribution du ΔpCO_2 est contrôlée par de nombreux processus. Bien qu'il se comporte, sur l'ensemble des périodes étudiées, comme une source de CO₂ pour l'atmosphère avec un flux moyen net de +17,7 mmol/m²/jour, il reste néanmoins un puits non négligeable pour les mois de mai et juin pour lesquels la distribution du ΔpCO_2 est contrôlée par le phytoplancton dont la productivité (nous supposons) est accrue par les apports du Rhône en sels nutritifs. Un échantillonnage saisonnier plus exhaustif nous permettrait de connaître plus précisément le rôle puits ou source de CO₂ du golfe du Lion à l'échelle annuelle.

BIOACCUMULATION OF HEAVY METALS BY THE BROWN ALGA CYSTOSEIRA SP. ALONG THE TURKISH COAST OF THE AEGEAN SEA

Idil Akcali¹ and Filiz Kucuksezgin¹*

¹ Dokuz Eylul University Institute of Marine Sciences & Technology - filiz.ksezgin@deu.edu.tr

Abstract

Brown algae *Cystoseira* sp. and to gain additional information on the environmental conditions of the area seawater samples were collected from six sampling stations along the Turkish coast of the Aegean Sea. Concentrations of Cd, Pb, Cu, Zn, Mn and Fe were measured for both algae and seawater samples. The heavy metal concentrations detected in algae showed significant differences among all stations. The data obtained from this study were also compared with those obtained from previous studies. Metal concentrations recorded at the stations may be used for background levels for interspecific comparison within the Aegean area. *Keywords: Bio-Accumulation, Metals, Aegean Sea*

Introduction

Heavy metals, reaching the marine environment directly or indirectly, are dangerous pollutants which can effect human health. Determination of metal concentration in an area is important to provide information about the levels of metal contamination and environmental quality. On that basis macroalgae have been used as biomonitors of heavy metal pollution in marine environment because they have high accumulation capacity, bind only free metal ions, represent the metal concentration of their locality quite well and they are widely distributed [1,2]. Brown algae have high metal accumulation capacity from surrounding water and they are good indicators of their environment because they are physiologically unable to regulate the uptake of trace elements [3,4]. *Cystoseira* species were used in this study because of these characteristics of the phylum and because they widespread along the coast of the Aegean Sea.

Materials and Methods

The *Cystoseira* sp. and water samples were collected in six stations in April, 2006 from the Northern (Çanakkale), Middle (Izmir) and the Southern (Marmaris – Mugla) parts of the Aegean coast. Three subsamples of each macroalgae sample (approximately 1 g dry weight) were digested in microwave digestion system with acid mixture solution. The water samples were collected in preconditioned polyethylene bottles. Ion exchange technique, using Chelex-100 resin was applied for heavy metals in water samples [5]. All the analyses were performed by Varian atomic absorption spectrophotometer [6].

Results and Discussion

Metal concentrations in *Cystoseira* decreased in the order Pb<Cd<Cu<Zn<Mn<Fe; in seawater the sequence was Pb<Cd<Cu<Mn<Zn<Fe. The highest levels for all metals in *Cystoseira* were measured in Marmaris region except Cd and Pb. There were positive correlations in *Cystoseira* sp. between Cd-Zn, Cd-Fe, Cu-Zn, Cu-Mn, Cu-Fe, Zn-Mn, Zn-Fe and Mn-Fe (Spearman correlation coefficient, p<0.05). Pb and Cu concentrations in the alga were positively correlated with the respective concentrations in the seawater. Cd, Pb, Cu, Zn and Mn concentrations in *Cystoseira* sp. were lower than those from other areas [7,8,9].

²¹⁰PO, ²¹⁰PB, ¹³⁷CS AND HEAVY METAL CONCENTRATIONS IN MUSSELS, FISH SPECIES, SEDIMENTS AND SEA WATER IN DIDIM, TURKISH COAST OF AEGEAN SEA

S. Aközcan¹, A. Ugur¹, G. Yener¹, B. Özden¹*, E. Aslan¹ and I. Filizok¹ ¹ Ege University, Institute of Nuclear Sciences - banu.ozden@ege.edu.tr

Abstract

Intense agricultural activities with dense use of fertilizers and Menderes river and streams carrying industrial and agricultural residues into the sea cause additional pollution in Didim region. In this study, concentrations of ²¹⁰Po, ²¹⁰Pb, ¹³⁷Cs and heavy metals (Zn, Cu, Fe, Cd, Mn, Ni, Pb, Cr) have been measured in mussels (*Mytilus galloprovincialis*), sediments, fish species and sea water collected from Didim (Aegean Sea) monthly.

Keywords: Aegean Sea, Bio-Indicators, Pollution, Radionuclides, Metals

 ^{210}Pb (t_{1/2} = 22 years) and ^{210}Po (t_{1/2} = 138 days) are decay products of $^{238}\text{U},$ and their main source in the environment is atmospheric radon. Both radioisotopes have a strong affinity for particles, but have different binding mechanisms. ²¹⁰Pb adsorbs on particle surfaces whereas ²¹⁰Po is considered as an important source of the natural radiation received internally by marine The main source of ¹³⁷Cs in marine environment can be organisms [1,2]. attributed to worldwide fallout deposition from atmospheric nuclear weapons testing (1941-1981) [3]. In the literature, there is no data for ¹³⁷Cs for Didim coastal area. Most of the particle-reactive radionuclides released into the aqueous phase eventually reach the sediments. The accumulation, retention and transport of particle reactive radionuclides is strongly associated with sediment and sedimenting particles [4]. Marine organisms are commonly used as environmental matrices in chemical and radioactive monitoring programmes because they accumulate persistent pollutants at concentrations orders of magnitude above those in the water [5]. In our project supported by IAEA, there were significant differences in 210 Po and 210 Pb concentrations in mussel samples due to the stations. Therefore, this research has been emphasized on Didim station which is located on the western coast of Turkey and indicated in Figure 1. ²¹⁰Po, ²¹⁰Pb, ¹³⁷Cs and heavy metals (Zn, Cu, Fe, Cd, Mn, Ni, Pb, Cr) concentrations of marine samples are measured monthly to determine the sources of marine pollution in this area. For mussel (Mytilus galloprovincialis) samples and fish species, in order to minimize the effect that size (age) exerts on the radionuclide concentrations: specimens of standard size in groups were selected. Sediment samples were taken by bottom-grap. Each sample is ovendried to constant weight and was sieved before analysis. After applying chemical procedure with some acids, polonium was spontaneously plated onto a copper discs. Measurements of ²¹⁰Po were realized through its 5.30 MeV alpha particle emission, using ²⁰⁹Po (4.88 MeV alpha emission, $t_{1/2} = 109$ a) as the internal tracer [6,7]. ²¹⁰Po was measured by alpha spectrometry using a Passivated Implanted Planar Silicon detector (Ortec Octete Plus PIPS detector). The samples were then stored at least 6 months to allow decay of ²¹⁰Pb and subsequent radioactive growth of ²¹⁰Po. The ²¹⁰Pb activity was calculated from the ingrowth of ²¹⁰Po, assuming zero initial ²¹⁰Po activity. ¹³⁷Cs concentrations were measured by HPGe dedector (model of Tennelec, 184 cm³ p-type coaxial). Heavy metal concentrations (Zn, Cu, Fe, Cd, Mn, Ni, Pb, Cr) were measured by ICP-OES (Perkin-Elmer 2000 DV). Concentrations of ²¹⁰Po and ^{210}Pb in mussels were in the range of 34 ± 9 and 2303 ± 383 Bq kg⁻¹ (dry weight); non-dedectable and 64±6 Bq kg⁻¹ (dry weight), respectively. Among the fishes, small pelagic plantkton feeding fish like sardine (Sardine pilchardus) ²¹⁰Po and ²¹⁰Pb concentrations in the tend to accumulate more ²¹⁰Po. sediment samples varied between 24±5 and 126±6 Bq kg⁻¹; 18±3 and 59±4 Bq kg-1. The values of Cd, Cr, Cu, Fe, Mn, Ni, Pb and Zn in mussel, sediment and fish (except Cd in fish) samples found lower than the acceptable limits. The levels of ¹³⁷Cs concentrations in mussels, sediment , fish species and sea water samples were found relatively low.

DETERMINATION OF HEAVY METALS IN FISH SAMPLES FROM TRABZON COAST OF THE EASTERN BLACK SEA

Nigar Alkan^{1*}, Ali Alkan² and Muammer Aktas² ¹ Central Fisheries Research Institute Trabzon / Turkey Technical University Faculty of Marine Sci. Comburgut Trabzon Turkey

² Karadeniz Technical University, Faculty of Marine Sci, Çamburnu, Trabzon-Turkey - anigar@gmail.com

Abstract

In the present study, concentration of heavy metals (Cu, Cd, Fe, Mn, Pb, Zn) were determined in the two different demersal (benthic) fish species of red mullet (*Mullus barbatus ponticus*) and whiting (*Merlangius merlangus euxinus*). Samples were collected from the two stations in the Black Sea. One of the stations is Sürmene Bay and the other is Yomra Bay in Trabzon-Türkiye. The concentrations of metals (Cu, Cd and Pb) were determined by using GFAAS, Zn, Fe, and Mn by using FAAS. *Keywords: Black Sea, Demersal, Bio-Accumulation*

Introduction

The pollution of the aquatic environment with heavy metals has become a worldwide problem during recent years, because they are indestructible and most of them have toxic effects on organisms [1]. The eastern Turkish Black Sea coast is not an industrialized area, and the agricultural activities are greater in the eastern region than along the western Black Sea coast. Such activities involve, the application of pesticides and artificial fertilizers in widely diversified habitat, including agricultural croplands, and hazelnut and tea plantations [2]. Different aquatic organisms often respond to external contamination in different ways, where the quantity and form of the element in water, sediment, or food will determine the degree of accumulation. Contaminants in the sediment are taken up by benthic organisms in a process called bioaccumulation. When larger animals feed on these contaminated organisms, the toxins are taken into their bodies, moving up the food chain in increasing concentrations in a process known as biomagnifications. As a result, fish and shellfish, waterfowl, and freshwater and marine mammals may accumulate hazardous concentrations of toxic chemicals [3].

Material and Method

The size of the fish collected varied in November 2009, depending on the species, between 11 cm and 22 cm, and their age was from 4 to 1.5 cm years. The separated fish were put in petri dishes to dry at $105 \, {}^{0}\text{C}$ until reaching a constant weight. Dried fish were placed into digestion flasks and ultra pure concentration HNO₃ and H₂O₂ (7:1 v/v) was added. The digestion flaks were heated to 200 ${}^{0}\text{C}$ until dissolution. The temperature control microwave heating device was used for digestion of the dried fish meat for determination the metals with spectroscopic methods. After dissolution diluted with water and analyzed for heavy metal concentration using atomic absorption spectrometer [4].

Results and Discussion

Heavy metal concentrations determined in the fish samples same length groups from the two different regions. Cu, Cd, Fe, Mn, Pb, Zn analyses results are given in Table 1. Region differences are observed Fe and Mn in the first group whiting and Zn in the third group whiting. Cd concentrations are differences all off group whitings and Pb concentration in the first and second group whitings are considered significant. Except Pb, all metal concentrations in the red mullet samples from Sürmene and Yomra Bay are not determined differences(p>0.05).

COMPOSITION, SPATIAL VARIABILITY AND SOURCES OF SEDIMENT PAHS IN TWO NEIGHBORING AQUATIC ENVIRONMENTS

Bedri Alpar¹* and Selma Ünlü¹

¹ Istanbul University, Institute of Marine Sciences and Management - bedrialpar@gmail.com

Abstract

The distribution, composition and sources of PAH mixtures in the sediments of the Gulf of Gemlik, sea of Marmara, and in a freshwater lake at its eastern extension, indicate characteristic spatial variability depending on various anthropogenic inputs. While atmospheric inputs are similar for both cases, other contributions are related to the spatial characteristics of riverine and terrestrial inputs and other activities such as shipping, fishing and agriculture. On the basis of several diagnostic criteria and principal component analysis -multiple regression models used to assess the type of process through which PAHs were generated, pyrogenic origin is dominant, even petrogenic PAHs also occur in combination with pyrogenic PAHs. *Keywords: Pah, Sediments, Pollution, Marmara Sea*

Introduction:

Polycyclic aromatic hydrocarbons (PAHs), a group of particle-reactive hydrophobic organic chemicals, are deposited in aquatic sediments from a variety of sources. Their importance as an environmental hazard derives from their potential carcinogenic and mutagenic properties. Lower-molecular-weight PAHs, which may be acutely toxic, are less strongly adsorbed compared with the heavier species. PAHs migrate towards bottom sediments due to their extremely low solubility in water, so that sediments are the best media in evaluation of PAH impacts to aquatic environments.

Although it is not routinely applicable, PAH ratios, molecular indices and principal component analysis (PCA)-multiple regression models can be used in delineating the origin of sediment PAHs; natural or anthropogenic. Worldwide data may be helpful in understanding of their source apportionment. In the present study, evaluation of the sediment PAHs in the Gulf of Gemlik, SE part of the Sea of Marmara, and in Lake Iznik, a freshwater lake at its eastern extension, provides baseline information for hydrocarbon origin in the sediments of these two different aquatic environments.

Experimental details:

Before extraction, the surface samples (upper 5 cm) from the Gulf of Gemlik [1] and Lake Iznik [2] were thawed and homogenized until textural and color homogeneity was achieved. The concentrated extract was analyzed by gas chromatography/mass spectrometry (GC/MS), which is enable the identification of organic compounds presented at very low concentrations and in complex mixtures. The system was calibrated for the 12 priority pollutant PAHs using the internal standard calibration procedure described in US EPA method 8000. The method detection limits for Phe, Ant, Flu, Py, B[a]A, Ch were at the order of 1.0 ng/g dry sediment, while they were around 0.1 ng/g for other PAH compounds.

Results:

The sediment PAHs in both of the aquatic environments are closely related to the spatial variability of riverine and terrestrial inputs and other activities such as shipping, fishing and agriculture. Atmospheric inputs contributed for both cases, due to heating with coal, petroleum coke particles and biomass burning from various sources. The majority of sedimentary PAHs indicate pyrogenic origin, even though petrogenic PAHs do also occur in combination with pyrogenic PAHs. Eastern and southern shores of the Gulf of Gemlik were contaminated with higher-molecular-weight PAHs. The diagnostic ratios of Ph/Ant, B[a]P/(B[a]P+B[e]P) and IP/(IP+B[ghi]P) were found relatively more useful in source identification for the study areas. BaA/228 provides a useful tool for distinguishing pyrolytic PAHs, which are generated by incomplete combustion of petroleum, coal, and biomass as in the cases of industrial usage and household heating and cooking. The ratios of Phe/Ant, Ch/B[a]A, Ant/178 and IP/(IP+B[ghi]P) represent decisive differences between two basins while no diagnostic ratios are sensitive sufficiently to the sediment type, possibly due to rapid anthropogenic contamination.

Regarding the diagnostic power of PAH ratios and PCA-multiple regression models, three PAH origins were described; a) severe anthropogenic inputs with pyrolitic and petrogenic mixed pattern, b) pyrolytic and slightly petrogenic inputs, c) pyrolytic atmospheric inputs. The first factor is responsible for 52.5% of the total variance and attributed to composite sources of unburned petroleum and coal combustion. It is in agreement with the elevated-PAH concentrations mainly occurred due to sea port activities and river transportation. The second factor is responsible for 15.8% of the total variance and attributed to the inputs due to burned petroleum and liquid fossil fuel oil combustion (e.g. vehicular engine emission, gasoline and diesel). It is dominated along the southern half of the gulf where marine transportation is heavy. The last factor, weighted in B[a]P, B[ghi]P and IP, is responsible for 10.3% of the total variance. It can be considered as indicator for strongly pyrolytic and atmospheric inputs of petroleum combustion (heating with coal, petroleum coke particles) and biomass burning from various sources (wood, soot, grass and dried dung). It is dominant throughout the Lake Iznik as well as along the northern coastal water of the Gunlik.

CHEMICAL CONTAMINATION OF WESTERN COASTAL MEDITERRANEAN WATERS: THE MYTILOS PROJECT

Bruno Andral ¹*, François Galgani ¹ and Corinne Tomasino ¹ ¹ IFREMER - bruno.andral@ifremer.fr

Abstract

The MYTILOS project aimed to draw up a preliminary report on coastal chemical contamination on a Western Mediterranean scale (continental coasts, Balearic Islands, Sicily, Sardinia, Corsica and Maghreb), on the basis of transplanted mussel methodology. MYTILOS project allowed to identify background levels between the differents sub-basin and contaminated sectors. The most highly-impacted zones were mainly situated adjacent to urban and industrial centers and the outlets of major rivers. On a global scale we can observe that the levels in the Mediterranean Sea are in the same range than other area worldwide. Main differencies are concerning the maximum values that are related to local high contamination. *Keywords: Monitoring, Bio-Accumulation, Chemical Analysis*

Most monitoring programmes now include the use of biological indicators (1). This is based on the assumption that levels of trace contaminants accumulated in biological tissues represent the time and space integrated value of these contaminants in the surrounding waters. In the Mediterranean Sea, the specie Mytilus galloprovincialis is widespread, but in some locations natural populations are rare or absent. The transplantation method compensated this scarcity and allows controlling the source, age, and stage of sexual maturity of the samples (2). MYTILOS project has backed by the INTERREG III B / MEDOC programme, steered by Ifremer and backed by Toulon Var Technologies, in cooperation with the ICRAM, IEO, PSTS, IMEDEA, CSIC, Catalan water agency, INSTM, ISMAL, INRH and University of Agadir, MYTILOS has also backed by the PNUE/PAM - MEDPOL. Tree cruises (2004, 2005, 2006) deployed 149 stations during 3 month, between march and july along Western Mediterranean shores. A total of 124 stations were retrieved (82.5 %). All the results are expressed by mg or µg/kg dry weight of flesh. The distribution of lead was relatively homogenous, with a median value of 1.17mg/kg. However, two sites were pinpointed as being particularly impacted by lead: the Portoscuso industrial site in Sardinia , with a maximum of 8.25 mg/kg and the zone spanning Portman to El Portus in spain from 5.3 to 6.25 mg/kg which was home to a thriving mining industry during the period of 1960-1990. Levels of cadmium were globally homogenous throughout stations, with a median of 1.28 mg /kg. A few stations showed relative peaks of around 2 mg/kg: Filicudi and Ustica stations in Sicily, Aguilas and Adra in Spain. Several sites impacted by mercury were recorded: first and foremost the Portoscuso site, with a maximum level of 0.31 mg/kg, witnessing significant contamination generated by a large industrial complex. Concentrations of nickel were around 1.1 mg / kg. Extreme values were found in some sampling sites in Sud West sub basin especially in Tunisia (Tabarka [3.18 mg/kg]) and, Algeria (Oued Zhor [2.89 mg/ kg]). The median value of the sum of DDTs compounds was 3 µg/kg.Significant peaks were recorded in the North West and Tyrrhenian sub-basin specially in front of Marseille (15.47 µg/ kg), Barcelone (15.17 g/ kg) and Napoli (15.34µg/ kg). Algiers also showed a high level (10.23µg/ kg) equivalent to the overall levels recorded at stations in front of the following rivers: Ebre, Rhône and Tevere. Regarding the sum of the 10 congeners of PCBs, the distribution show a similar profile. The median value of the sum of PCBs compounds was 8,98µg/kg.

Fig. 1. PCB in mussels (\sum PCBi ng.g⁻¹ dry weight)

The results show the presence of sites impacted by PCBs, in Barcelona (63.87 μ g / kg), Marseille (103.52 μ g / kg), Napoli (91.48 μ g / kg) and Algiers (51.13 μ g / kg). This characteristic presence off the coast of major urban centres is further confirmed by values obtained in Sardinia at La Madalena (58.49 μ g / kg), situated adjacent to a major naval base.

Results relating to the sum of the 16 dosed molecules for PAH showed a median value of 44.4µg/kg. Two peaks have been identified at Marseille (105.5µg/kg) and Piombino in Italy (80.8µg/kg), adjacent to a large industrial complex. On the campaign scale, all measured contaminants showed equivalent levels to those recorded by the RINBIO network (2). This similarity related to both highest levels and background noise recorded at the 124 study stations. This method is also valuable in that it makes it possible to confront the data to that available on Mytilus galloprovincialis and Mytilus edulis while respecting equivalent biometric criteria. Comparison of these findings with data from the National Observation Network of the water quality on French coasts. Comparison of data among differents studies , however, are generally complicated by subtancials changes that have been made in the analytical methods, saisonnality of sampling, number of congener for the organic compound and must be exercised with caution. On a global scale we can observe that the levels in the mediterranean sea are in the same range than other area worldwide.

Abstract

Nuclear receptors (NRs) form a superfamily of ligand-dependent transcription factors in metazoans, where they regulate many biological functions (e.g. reproduction, development and homeostasis). NRs can be modified by anthropogenic contaminants, which can cause cancer and endocrine disruption in humans and wildlife. Marine organisms disturbed by endocrine disrupting chemicals, can have reduced testicular development and fertility, masculinization of female specimens (imposex), etc. In this context, we evaluated the genetic characterization of the retinoid X receptor (RXR) in varied metazoan species (from invertebrates to vertebrates), and we modulated RXR 3D structures to predict the binding affinity of environmental pollutants, obtaining insight into the resilience of RXRs in marine organisms to the effects of endocrine disrupters.

Keywords: Genetics, Biodiversity, Pollution

The study of biological systems in atomic detail is a multidisciplinary field combining knowledge from sciences such as Mathematics, Physics, Chemistry, Biochemistry, Biology and Informatics. It as been previously used with great success to understand enzymatic mechanisms, to predict the binding free energy of two molecules, and in the design of new drugs based on structural information. Although this approach may have the availability to predict if a pollutant may activate a hormone receptors or interfere with the enzymatic activities of an organisms, it has not been a common approach in risk assessment studies of aquatic contaminants, despite it potential great utility in Ecotoxicology. Moreover, integrative efforts using state-of-the-art methodologies at the gene-level (comparative genomics) and protein-level (comparative proteomics) may be the ultimate bridge between structural biology and molecular evolution [1]. The evolutionary study of the RXR protein across a wide range of metazoans (from invertebrates to vertebrates) is important to reveal how mutations have accumulated in this functional constrained protein over millions of years of evolution. The understanding of such genetic basis can provide fundamental biological insight about protein evolution and ecological fitness [2, 3].

In this study, we have retrieved RXR sequences from 57 metazoan organisms (invertebrates and vertebrates) and we have performed a detailed search for selection signatures. First, we have used single-site analyses for detecting selection at the gene level [1].

However, these analyses may be biased against even moderately conservative proteins because the primary criterion involves a comparison of nonsynonymous and synonymous substitution rates, not allowing for the possibility that adaptation may come in the form of very few amino acid changes [1].

Second, we have additionally used powerful statistical methods at the proteinlevel considering the nature of the amino acid change ("conservative" or "radical" depending on the magnitude of the physicochemical difference between amino-acids, and the physical location of amino-acid sites in the three-dimensional (3D) protein structure [1].

Finally, third, we have determined the 3D structure of several RXRs, using homology-modeling [4], a reliable technique to computationally infer an unknown protein 3D-structure (>50% amino-acid identity) based on the experimentally determined 3D-structure of a related protein [e.g. Human and Biomphalaria (mollusc) RXR crystal structures].

We identified several aminoacids that seem to be essential to RXR activation by organotins and methoprene acid, and therefore, will allow the future identification of potential environmental pollutants RXR agonists based on their conformational characteristics. Typically, RXR ligands contain a carboxylate group, which is important in their ability to be buried stably in the predominantly hydrophobic pocket. This functional group is involved in an ionic interaction with the strictly conserved basic residue of R316 of helix H5 and forms a hydrogen bond with the backbone carbonyl amide group of the β turn residue A327. Although tributyltin (TBT), a widespread marine contaminant, bind RXR with high specificity and induce RXR activation (similarly to the natural ligand 9-cis retinoic acid), it lacks a carboxylate group. Hence, the protein-ligand interaction of TBT is very different from those seen with other known RXR agonists. In order to further demonstrate the utility of bioinformatics in foreseeing the capability of environmental pollutants to bind hormone receptors and enzymes, the RXR of a Cnidarian (Actinia equina, the most common species of sea anemone along coastal areas in Europe and the Mediterranean) have been partially cloned (based on degenerate primers, PCR on cDNA, cloning with pGemTeasy system from Promega, and sequencing), and the 3 D structure of Actinia equina was developed based on homology modelling with the Human and Biomphalaria (mollusc) RXR crystal structure, which will be of great utility to subsequently evaluate the capability of TBT, triphenyltin (TPT), methoprene acid, and 9-cis retinoic acid to activate the cnidarian RXR.

CONCENTRATIONS OF ²¹⁰PO AND ²¹⁰PB IN PLANKTON FROM DIFFERENT ZONES OF AEGEAN SEA

Fatih Dursun Arslan¹, Aysun Ugur¹ and Banu Özden¹*

¹ Ege University, Institute of Nuclear Sciences - banu.ozden@ege.edu.tr

Abstract

Aquatic organisms are capable of concentrating toxic elements within their tissues. In the study, plankton samples have been evaluated for their bioavailability as biomonitors of ²¹⁰Po and ²¹⁰Pb in Aegean Sea. The concentrations of ²¹⁰Po and ²¹⁰Pb in plankton samples collected in the period of 2004-2005 have been presented. The samples were collected from four distinct regions (Aliaga, Nemrut, Foça and Izmir Bay). The concentrations of ²¹⁰Po and ²¹⁰Pb in plankton samples were determined using alpha spectrometry.

Keywords: Plankton, Aegean Sea, Monitoring

 $^{210}\mathrm{Po}$ and $^{210}\mathrm{Pb}$ are naturally occurring radionuclides within the $^{238}\mathrm{U}$ decay chain, with half-lives of 138.38 days and 22.3 years, respectively. These radionuclides areconsidered as an important source of internal radiation dose to marine organisms [1]. Planktons can accumulate radionuclides very rapidly and retain them for a long time [2]. ²¹⁰Po level increases with additional material derived from coastal erosion, particulate matter flux from atmosphere and biogenic activity within the aquatic environment. The main source of ²¹⁰Po in these study regions is the river run-off (Bakirçay and Gediz) from the catchment areas. Wastes which arise from petrochemical and fertilizer industries at Aliaga region effect the contamination in the regions. In our project supported by IAEA, ²¹⁰Po concentrations in fish species fed with planktons were determined much higher than the average values [3]. Significant amounts of ²¹⁰Po may be transferred to humans via diet. For these reasons, there is a need for investigation of the accumulation of ²¹⁰Po and ²¹⁰Pb by planktonic organisms. All the sampling stations (Aliaga, Nemrut, Foça and Izmir Bay) are located on the western coast of Turkey and indicated in Figure 1.

Fig. 1. The map of sampling location

Plankton species were present in a very wide size range. The cut off sizes used for sample collection in this work (45 µm and 120 µm) were selected to characterize two size classes. Then the samples were weighed and dried in the oven. After standard addition ofpolonium tracer, each sample was completely dissolved with HNO₃, H₂O₂ and HCl. Polonium was spontaneously plated onto a copper disc in 0.5 M HCl in the presence of ascorbic acid to reduce of Fe⁺³ to Fe⁺² [4,5]. Measurements of ²¹⁰Po were realized through its 5.30 MeV alpha particle emission, using ²⁰⁸Po (95±1.311 mBq g⁻¹) as the internal tracer. After the first deposition of ²¹⁰Pb, the residual 0.5 M HCl was kept to allow the samples. The sample was re-plated and the ²¹⁰Po activity was determined. ²¹⁰Pb (precursor of ²¹⁰Po) concentrations were determined from ²¹⁰Po activities measured after attaining the radioactive equilibrium. The range of ²¹⁰Po concentrations in plankton samples were observed between 10±2 -

 207 ± 23 Bq kg⁻¹(dw). According to obtained results, the concentrations of 210 Po in industrial regions are higher than other regions. Petrochemical industry on the coast of Aliaga is an agent for high level of natural radionuclide in the region. The relationship between 210 Po concentrations and biomass of plankton was found nonlinear.

Abstract

Oil pollution of the Eastern Mediterranean Sea was investigated at 5 stations from Syria in 2007 and 23 stations from Mediterranean Sea in August 2008. The oil level was determinated using references Iraq crude oil and chrysene. The highest oil pollution in East Mediterranean Sea at Turkish Part, Syrian Part (2007), Lebanon Part, South of Cyprus for crude oil was found as 98,87µg/L, 69,24 µg/L, 20,29 µg/L, 90,96 µg/L, respectively. A comparison of the present results Turkish coast part are more polluted than the examined area. *Keywords:Oil pollution, surface water, Mediterranean Sea*.

Keywords: Eastern Mediterranean, Pah, Surface Waters

Oil pollution in East Mediterranean Sea were investigated earlier [1-7]. Oil pollution level was investigated in Mersin- Iskenderun area, Eastern Part of Mediterranean Sea was examined before and after Iraq petroleum pump [6]. The reference oil used in these studies was crude oil [1,6,7] and chrysene [2-5]. In this study the samples were collected by R/V YUNUS-S during the August in 2008 (Figure 1). The seawater sample was taken in 2,8 L amber glass bottles containing 15 ml dichlormethane (DCM) for preservation. The samples were extracted with DCM and distilled. The residue was dissolved in hexane and analyzed by UVF (Shimadzu RF 5301) at 310/ 360 nm (ex/em). In this study we used references as Iraq crude oil and chrysene (Aldrich). Sampling stations are shown in Fig 1.

Fig. 1. Sampling stations in Mediterranean Sea

The equation of calibration curve for Iraq crude oil: y=427,50xC+2,38 r²= 0,99, for chrysene: y=2134,05*C-3,55 r²= 0,99.

The oil pollution level examined in sea water are shown in Figure 2. The oil pollution level in Eastern part of Mediterranean were found as $0.4 \ \mu g/L$ (crude oil references) [1], $488,28 \ \mu g/L$ in 1996, $204,6 \ \mu g/L$ in 1997 [6], $2596 \ \mu g/L$ in 1999 for Iraq crude oil equivalent and $455,42 \ \mu g/L$ for chrysene equivalent [7], $25,2 \ \mu g/L$ in 1982 (chrysene equivalent) [2], $1,25 \ \mu g/L$ in 1998 [5]. We found the highest oil pollution level in East Mediterranean Sea as Turkish Part $98,87 \ \mu g/L$ for crude oil and $20,05 \ \mu g/L$ for chrysene at station 21, at Syrian part $69,24 \ \mu g/L$ for crude oil, $4,04 \ \mu g/L$ for chrysene at station 14 and at south of Cyprus part $90,96 \ \mu g/L$ for crude oil, $18,39 \ \mu g/L$ for chrysene at station 5.

When compared the results of Turkish coast part of East Mediterranean Sea the pollution level increased during the years. This paper presents the first oil level determination in area of East Mediterranean countries included Turkish, Syrian, Lebanon and Cyprus (two parts- North and South).

OIL POLLUTION IN THE SURFACE WATER OF THE AEGEAN SEA IN 2007 AND 2008

Esra Billur Balcioglu ¹*, Pelin Saliha Ciftci ¹ and Mine Cardak ¹

¹ Istanbul University Fisheries Faculty Ordu cad. No 200 Laleli/Istanbul, Turkey - ebillur@istanbul.edu.tr

Abstract

Oil pollution of the Aegean Sea was investigated at 13 stations in August 2007 and 11 stations in August 2008. The oil level was calculated using references as Iraq crude oil and chrysene. The highest oil pollution was found as $63,09 \mu g/L$ at Station 13 in 2007 and $93,58 \mu g/L$ at station 2 in 2008. A comparison of the present results with data obtained earlier in the same region the oil pollution level increased during the years.

Keywords: Aegean Sea, Surface Waters, Pah

Oil pollution is a major problem of sea water. In this study oil pollution was determined in the surface water of the Aegean Sea at 13 stations in 2007 and 11 stations in 2008. The samples were collected by R/V YUNUS-S during the August in 2007 and August in 2008. Sampling stations are shown in Fig.1. The seawater was taken in 2,8 L amber glass bottles and 15 ml dichlormethane (DCM) was immediately added for preservation. The seawater samples were extracted with DCM. The extract was distilled and the residue was taken with hexane and analyzed by spectrofluorophotometer (Shimadzu RF 5301) at 310/360 nm (ex/em). References used are Iraq crude oil was used as reference according to suggestion [1] and chrysene (Aldrich) [2].

Fig. 1. Sampling station in Aegean Sea

The equation of calibration curve for Iraq crude oil: $y=427,50xC + 2,38 = r^2 = 0,99$ for chrysene: $y=2134,05*C - 3,55 = r^2 = 0,99$. The oil pollution amount in sea water samples are shown in Fig. 2. Oil pollution of the Cretan Sea, Southern Aegean Sea was found at the range of 0.092- 0.317 µg/L [3] in the region of Northern Aegean Sea (Thermaikos Gulf), Greece. Total PAH concentration was ranged from 9,7 to 36,2 ng/L [4]. In Turkish part of Aegean Sea, the oil concentrations were found in coastal and open sea area 0.09- 25.5 µg/L [5], 0.10-2 µg/L and Aliaga and Izmir Bay 10-25 µg/L [6], in Northern Aegean Sea [8]. As can be seen in Fig.2 the highest oil pollution level was found highest at station 13 as 63,09 µg/L in 2007 and station 2 as 93,58µg/L in 2008. Limit value of oil in sea water is reported as 2.5 µg/L by WHO. According to our findings the pollution level of examined area are higher than limit value given by WHO. When compared all results with earlier findings, the oil pollution level was found are higher than previous studies.

Fig. 2. The oil concentrations found in the samples $(\mu g/L)$

DNASE ACTIVITY AS A NEW BIOMARKER FOR MARINE ENVIRONMENTAL CONTAMINATION: FIELD STUDY

Iris Batel¹*, Maja Fafandel¹, Lorena Peric¹ and Ines Kovacic¹

¹ Center for Marine Research, Ruder Boškovic institute - bihari@cim.irb.hr

Abstract

In mussels *Mytilus galloprovincialis* collected at different sampling sites and in those injected with organic seawater extracts the DNase activity in the hepatopancreas was higher than in mussels from a maricultured area or control mussels respectively. The enzyme activity in hemocytes decrease, increase or remain constant depending on the specific contamination of the sampling site. The DNase activity, as a novel biomarker, can be useful for the monitoring of marine environmental contamination. *Keywords: Pollution, Adriatic Sea, Bivalves, Enzymes*

Introduction

The wide range of mollusks response to pollutants provides grounds for the development of various methods for water toxicity evaluation and development of new biomarkers. The activity of lytic enzymes, such as acid DNase, can provide a new promising model for such studies. The response of acid DNase activity to toxic industrial pollutants in the freshwater snail [1] and in mussels from contaminated areas [2] or in mussels exposed to marine pollutants [3] was recently reported. The aim of this study was to validate the acid DNase activity as a new biomarker for environmental contamination in mussels collected at sampling sites with different pollution histories and in mussels injected with organic extracts of different seawater samples.

Materials and methods

Mussels *Mytilus galloprovincialis* were collected at 6 different locations: shipyard (S2, S6), harbor (S3), river mouth (S4) and urban/industrial waste area (S7). Mussels from a maricultured area served as a reference sample. Another group of mussels was injected with organic extracts of seawater samples collected from different locations along the Croatian Adriatic Coast. The water samples have been collected in a protected area (S1), shipyard (S5), harbor (S9) and urban/industrial waste areas (S7, S8). Mussels injected with DMSO were used as experimental control. After 1h the acid DNase activity was measured in hemocytes and hepatopancreas according to Fafandel et al. [3].

Results and discussion

The specific DNase activity in hemocytes and hepatopancreas of native and injected mussels is presented in Table 1. In mussels collected at sampling sites S2, S3, S4, S6 and S7 the DNase activity in the hepatopancreas was significantly higher than in mussels from a maricultured area. The enzyme activity in hemocytes was significantly higher only at sampling sites S3, S4 and S7. The highest DNase activity in both tissues has been detected in mussels collected at sampling site S7, an area under high influence of urban/industrial wastes. In mussels injected with organic extracts of seawater from various sampling sites (S1, S5, S7 and S9), the DNase activity in the hepatopancreas significantly increased, when compared to the control. The highest enzyme activities (cca. twice as higher as in the control) have been detected in mussels injected with organic extracts of seawater collected in a shipyard ad harbor. The enzyme activity in hemocytes significantly increased only in those mussels injected with organic extracts from the sampling site S9 (harbor) and significantly decreased for those injected with extract from the sampling site S8 (urban/industrial waste area). The suppression of enzyme activity as a specific response of hemocyte acid DNase to organic extract S8 (urban/industrial waste area) could be consistent with its effect on cells of the bivalve immune system [4], including fluctuations in hemocyte numbers [5]. The DNase activity in the hepatopancreas of both native and injected mussels revealed sampling site S7 as the polluted one.

Conclusion

The potential use of the acid DNase response in hepatopancreas and hemocytes of mussels *Mytilus galloprovincialis* for the determination of mixed marine environmental contamination is confirmed. The DNase activity as a biomarker could be applied for both native and injected mussels. The latter might be used when the native ones are not available. At the same time, the DNase activity could be included during the determination of various enzymes activities in protein microarrays in the monitoring of integrative biological effects of contaminants.

Abstract

This work contributed to the study of accumulation of eight metals such as Cu, Cd, Cr, Ni, Mn, Al, Fe and Pb in the Gastropod *Patella caerulea* collected at three stations along the Tunisian North coasts. Result showed that the mean values of the heavy metals in soft tissues were relatively higher at CB station, considered as the worst affected region among the studied areas. The order of metal accumulation in the animal was: Fe >> Al >> Mn - Cu > Ni – Pb > Cr > Cd, where, Mn, Cu, Ni and Pb were changeable in their order at different stations.

Keywords: Gastropods, Metals

P. caerulea is selected as a cosmopolite bioindicator for the biomonitoring of metal traces in Mediterranean. Between 30 and 40 specimens were handpicked in the tidal zone from three sites (Bizerta Channel, La Goulette and Sidi Rais). Organisms were depurate and soft tissue was dried, Pulverized and mineralized. Heavy metals analyses were performed in the limpet samples according to the method described by AOAC (2000) [1]. Comparison between stations for the concentration for all metals revealed that The highest mean values of the heavy metals in soft tissues of *Patella caerulea* were found: at CB station, for Cd (1.50) μ g g⁻¹, Cr (2.78) μ g g⁻¹ and Fe (2.59) mg g⁻¹. We also notice at the same station relatively high mean values for Ni, Al and Pb (3.43, 402.16 and 3.51 μ g g⁻¹), respectively (Table 1).

Tab. 1. Mean concentrations of metals in soft tissue of *P. caerulea* collected from the North coasts of Tunisia since summer 2006 until the spring 2007^{a} mg.g⁻¹

	-

This contamination could be attributed to wastes discharged from Bizerta city and the ships awaiting transit through Bizerta Channel. This zone also receives waste effluents from different industrial unities. Mean iron concentration was much greater than that of the other metals in each station. Similar results reported that Iron is the predominant metal in marine molluscs from the Mediterranean Sea ([2], [3], [4]). Cd concentrations were minimal. The levels found in this work are lower than those registered in limpets from some other parts of the Mediterranean coasts ([5], [6]). Lead levels in P. caerulea were in the same order of magnitude in 3 stations. In this present study, Lead concentrations in limpets were higher than those mentioned by [7] in Gulf of Suez and ([5], [8], [6]) in Italy. However, toxic metal concentrations (Cd, Pb) remain lower than the thresholds recommended by the World Health Organisation (WHO). We notice that the order of metal accumulation in the animal at different stations was: Fe >> Al >> Mn - Cu > Ni - Pb > Cr > Cd. where, Mn, Cu, Ni and Pb were changeable in their order at different stations. The observed variation in metal levels in P. caerulea at different stations may be related to the environmental conditions of the area and to the physiological conditions of the animal regarding the metal.

Abstract

Mercury concentrations were determined in tissues and organs of two cetacean species (Stenella coreuleoalba and Tursiops truncatus) stranded along the Italian coasts between 2000 and 2009. According to previous authors, mercury accumulates preferentially in liver and shows a positive correlation with length in both analysed species. Mercury concentrations found in this study are generally higher than those found by previous authors in tissues of dolphins from Atlantic areas. Significant differences were also found for Hg contents in different marine areas within the Mediterranean basin suggesting the existence of different and separated populations of S. coreuleoalba and T. truncatus.

Keywords: Cetacea, Mercury

Large amounts of organic and inorganic chemicals enter estuarine and coastal marine environments from natural and anthropogenic sources. Several metals, such as mercury, are considered highly toxic [1], and, at least in dolphins, are accumulated throughout the entire life of an individual. The main aims of this research is at attempting to: (1) verify, on the basis of a new and larger dataset, previously reported mercury distribution patterns in cetaceans; (2) verify differences on mercury concentrations between sampling areas within the Mediterranean basin to assess the importance of cetacean as indicator of marine pollution. Samples of muscle, liver, lung, kidney and heart were collected from specimens of S. coeruleoalba (n=12) and T. truncatus (n=12) that were foundstranded along Italian coasts during the period 2000-2009. Metal concentrations were measured by ICP-AES Varian Vista MPX. Liver shows the highest concentrations of Hg in all analysed species. Positive correlations emerges between Hg concentrations and length in all analysed tissues indicating that bioaccumulation occurred over time. Mercury concentrations found in this study seem to be higher than those found by previous authors in tissues of dolphins from Atlantic areas. Higher Hg concentrations were found in liver of specimens from the French coast [2] and Adriatic sea [3]. Dolphins seem to exhibit lower Hg concentrations in Ligurian sea [4] and Sicily channel (this study). These differences may reflect the existence of different and separated populations of S.coreuleoalba and T. truncatus in Mediterranean basin with different feeding habitats exposed to different anthropogenic activities.

Abstract

The geochemical characterization of organic matter (OM) within phosphatic pellets (100-500 μ m) and their surrounding matrices (<50 μ m), collected from ypresian phosphorites (Ras-Draâ mine, Tunisia) indicates that : (1) Total Organic Carbon (TOC) content is more important in matrices than in pellets from the same layer; (2) A Marine planktonic origin of OM (Type II domain) contained in both fractions; (3) A diagenetic evolution of OM up to, and not beyond, the stage of humic compounds in both fractions; and (4) A higher abundance of extractable humic compounds in pellets (~70% TOC) and a lower extraction yield in matrices (~18% TOC). Such differences in geochemical properties between pellets and matrices are indicators of an allochtonous origin (fecal origin) of these grains within their embedded sediments.

Keywords: Organic Matter, Fecal Pellets, Geochemistry

Introduction

Several investigations of Tunisian phosphatic deposits have already showed that phosphatic components are essentially concentrated in phosphatic grains, called "pellets", varied in size (mainly 100 to 500 μ m). These grains are surrounded by a sedimentary matrix, also named exogangue. The origin of phosphatic pellets has long been an intriguing problem, especially with regard to the source of the accumulated phosphorus. Two convergent hypothesis for the origin of pellets were proposed: either pellets were diagenetic, authigenic, bodies formed within and from the matrix and still containing chemical elements inherited from the matrix, or the pellets were allochtonous bodies (for example faecal pellets), formed outside the matrix. The present work aimed to carry compared studies of their geochemical properties and to draw some relevant conclusions on the genesis of the Ras-Draâ ore pellets.

Material and methods

The studied samples were collected from the Ras-Draâ deposit (southern Tunisia), witch is a natural continuity of the great Gafsa-Metlaoui phosphatic basin (Fig. 1). The phosphatic grains ("pellets", 100 to 500 μm in mean diameter) were separated from their surrounding sediments ("matrix", $<50 \,\mu m$) by granulometric fractionation under water. The comparative study of both fractions was performed by: global chemical analyses (CNS elemental analysis), Rock-Eval (RE) pyrolysis and humic substances (HS) extraction and fractionation according to the IHSS (International Humic Substances Society) procedure.

Results and discussion

Elemental analysis: The Total Carbon (C_T) content in the phosphatic pellets is ~ 2.31% compared to ~ 3.52 % in the matrices. Total Nitrogen and Sulphur contents (N_T and S_T) are also significant and fairly homogeneous in the two respective fractions (N_T pellets ~ 0.03 %, N_T matrices ~ 0.07 %, S_T pellets ~ 0.11 %, S_T matrices ~ 0.16 %).

Rock-Eval pyrolysis: The TOC content, given by the RE pyrolysis, varies between 0.30 % and 1.62 % in phosphatic pellets and between 1.22 % and 4.05 % in their adjacent matrices. The geochemical characterization of OM contained in the two fractions by RE pyrolysis concludes, on one hand, to the planktonic origin of the OM (Type II domain), in both fractions, and, on the other hand, to a low degree of maturity of the pelletal and matricial OM (RE Tmax < 430 °C). **Humic substances extraction**: The HS yields from the pelletal and matricial OM shows a high content of humic compounds isolated from pellets (humic carbon up to 75% of TOC) and a lower one in adjacent sediments (humic carbon less than 21% of TOC), along with the higher content of HU (low mature kerogen) in surrounding sediments and the lowest in the pellets. Such high amounts of humic compounds are similar to those isolated from Gafsa-Métlaoui phosphorites (Belayouni and Trichet 1983).

Fig. 1. Location map of the Ras-Draâ phosphate ore deposit in the Gafsa-Métlaoui basin, Tunisia (source: www.earth.google. fr)

Conclusion

Several organic geochemical data from the phosphatic grains and their surrounding matrix reveal great differences between the both fractions. Such differences excludes that the pellets formed authigenetically within and from their embedded sediments. The reasons of these different properties must been sought in the origin and the diagenetic history of the grains and of the matrix. Instead, as recently hypothetized (Ben Hassen 2007), these phosphatic pellets must have an allochtonous source, namely a biological origin since they are, very certainly, fish feces.

Abstract

The accumulation of tributyltin (TBT), dibutyltin (DBT) and monobutyltin (MBT) in the North-western Adriatic Sea food web was investigated by evaluating contamination and stable isotopes ratios (13C/12C; 15N/14N) in biota and sediments. Results showed higher contamination in estuarine areas as well as their accumulation with increasing trophic levels. *Keywords: Food Webs, Adriatic Sea, Pollution, Bio-Accumulation*

TBT has been directly introduced in the marine environment due to its extensive use as biocide in antifouling paints [1]. Several studies reported various toxic effects and a widespread bioaccumulation of butyltins (BTs) in different species of marine and coastal ecosystems [2]. Accumulation of tributyl and triphenyltin compounds in marine food webs of coastal waters was reported, however it is still unclear whether biomagnification through food-webs occurs [3]. Recent studies have rapidly advanced the understanding of biomagnification profiles of environmental pollutants using 13C/12C and 15N/14N but their application to BTs is still limited [4]. Sediments and biota samples (zooplankton, bivalves, crustaceans, cephalopods, bony fish; total number of samples = 41) were collected in autumn 2008 in an estuarineriverine and a coastal-marine area of the North-western Adriatic Sea. Analyses were performed in bivalves on whole soft tissues while in crustaceans. cephalopods and bony fish on muscle pooled from several individuals. Stable isotopes (13C/12C; 15N/14N) were analysed by a CHN analyzer coupled with Isotope Ratio Mass Spectrometer. BTs were analysed on freeze-dried samples by high resolution gaschromatography coupled with ion trap mass spectrometer (HRGC-MS²) after ultrasonic solvent extraction, Grignard methylation and clean-up. values ranged between -28.22 ‰ and -16.56 ‰ with lower values in biota and sediments from the riverine-estuarine area compared to the coastal-marine ones. 15N/14N ranged from 4.74 ‰ to 13.88 ‰, with higher ratios recorded for bony fishes (both in the riverine-estuarine and coastal-marine area) compared to cephalopods, crustaceans, bivalvia and zooplankton. SBT (TBT+DBT+MBT) ranges in sediments and in biota were <10 - 83 and <10 - 114 ng Sn g⁻¹ dw (dry weight), respectively. TBT generally accounted for the major fraction (average ~40%) of ΣBT. Higher levels of contamination were observed in the riverine-estuarine samples. The significant negative correlation found between TBT, DBT, ΣBT and 13C/12C (Spearman rank correlation; R ranged between -0.38 and -0.46 p<0.05) in the higher taxonomic groups (crustaceans, cephalopods and bony fish) could reflect higher BTs contamination in the riverine-estuarine area. Bioaccumulation of BTs increased with the trophic levels as highlighted by the significant positive correlation between TBT, DBT, **DBT**, **DBT**, and 15N/14N (Spearman rank correlation; R ranged between 0.40 and 0.43; p<0.05). Further work is in progress in order to confirm the biomagnification hypothesis with a greater number of samples and taxa allowing a comparison with the few studies based on a similar approach [4], [5].

Abstract

Decision N. 2455/2001/EC sets out the first list of 33 substances or groups of substances that have been prioritised for action at European Community level. Nonyl- and octylphenols are included in this list of priority and hazardous substances due to the risk to, or via, the aquatic environment, in accordance with the Article 16 of European Water Framewok Directive 2000/60/EC (WFD) [1]. A method for the selective determination of 4-tert-octylphenol, 4-nonylphenol and 4-n-nonylphenol in surface water samples was developed and validated, based on solvent extraction and HRGC-ITMS (high resolution gaschromatography coupled with ion-trap mass spectrometry). Assessment of method performance gave good results in terms of accuracy, precision, selectivity and sensitivity. *Keywords: Chemical Analysis, Pollution, Monitoring*

Introduction

The European Union (EU) Water Framework Directive 2000/60/EC (WFD) [1] sets up environmental objectives to achieve "good chemical status" for all European water bodies by 2015. "Nonylphenols" and "octylphenols" are listed as priority hazardous substances in Decision n. 2455/2001/CE [2]. The Directive 2008/105/EC [3] lays down environmental quality standards (EQS) for priority substances and certain other pollutants amending the WFD. EU Member States need to develop and to implement a quality-assurance/quality control (QA/QC) system to ensure that all monitoring results meet the levels of accuracy fixed by Directive 2009/90/EC of 31.07.2009. Nonylphenols and octylphenols are two groups of substances with general formulas HO-C₆H₄- C_9H_{19} and $HO-C_6H_4-C_8H_{17}$, respectively. Alkylphenolic compounds in the aquatic environment originate primarily from the degradation of the industrially produced mixtures of alkylphenol polyethoxylates, resulting in complex mixtures of branched isomers which differs on the basis of branching and position of the alkyl chain with respect to the phenolic hydroxyl group [4]. The denomination of alkylphenols used in legislation, as well as in scientific literature, has proved sometimes ambiguous for identifying mixtures and single isomers. In this work a method was devised for analysing 4-tertoctylphenol (4-t-OP; 1,1,3,3,-tetramethyl-4-buthylphenol, single compound, CAS# 140-66-9), 4-n-nonylphenol (4-n-NP; linear-chain isomer, single compound, CAS# 104-40-5) and 4-nonylphenol (4-NP; mixture of parasubstituted isomers, CAS# 84852-15-3 and CAS# 25154-52-3) in surface water samples. 4-NP is usually quantified in environmental samples by using technical mixtures of isomers, which can be resolved by HRGC-LRMS only at a group level [4,5].

Materials and methods

The method is based on extraction with toluene followed by clean-up on a silica-gel column. Qualitative and quantitative determination was carried out by means of HRGC-ITMS. ¹³C labelled 4-n-NP was used as internal standard and added to the sample before extraction. In order to determine precision and accuracy, the performance of the method was assessed by the analysis of spiked water samples, as no certified reference materials were available.

Results and discussion

The identification of analytes was performed on the basis of chromatographic retention time and by comparing Full Scan mass spectra of the analyte in the sample and in the calibration standards, after calculation of area ratios of characteristic ions as confirmation. 4-NP mixture eluted as a group of partially resolved peaks (5 to 11 depending on the selected ion) leading to distinctive chromatographic patterns. The quantitative determination was performed by means of the internal standard method. Calibration curves were calculated from the ratios of chromatographic areas of the analyte and the internal standard as a function of concentrations. 4-NP were quantified by the sum of areas of the identified peaks. Average recoveries of the analytes in spiked samples ranged between 89 % and 108 %. Good sensitivity was achieved. Limits of quantification were respectively 10 ng L⁻¹ for 4-n-NP and 100 ng L⁻¹ for 4-NP. The developed method has provided reliable analytical performance coupled with a relatively simple sample treatment.

Abstract

Part of the pollutant load generated by the Venice urban system can be transferred to the sediment of the shallow water areas surrounding the city. These areas were studied in order to assess metals level and distribution in the sediment, and to highlight possible contributions due to the city. A moderate pollution was found in the surface sediments (0-30 cm), with concentration of the main contaminants ranging between 6% (Cd) and 29% (Hg) of the mean value measured in the canal network. The comparison of metal concentrations with SQGs revealed a low ecotoxicological risk for the surveyed areas, excepting for Hg, which values exceed the ERM guideline (0,71 mg/kg d.w.) in 75% of samples. Concentration trends along the vertical profile pointed out a diminution of both metal contamination and the finer particle content with time. *Keywords: Sediments, Metals*

The City of Venice, located in the middle of the lagoon, has a population of about 60000 inhabitants and an average additional daily presence of about 75000 units (tourists and commuters). Its 40 km long canal network receives inputs of particulate matter and pollutants from the urban sewage system and point and non-point sources, such as atmospheric deposition and urban runoff, building erosion and corrosion of metal structures, boat traffic [1]. Even though the canal network has a high capability in retaining particles and associated contaminants, a fraction of the total load is transferred to the lagoon [2] by tidal currents. The export is enhanced by particle resuspension due to the boat traffic. Contaminants can therefore accumulate in the sediment of the shallow water areas surrounding the city, which are characterized by a low hydrodynamics. Aim of this study was the assessment of the pollution level in the sediment of these areas, also to evidence possible contributions due to the city. Thirty centimetres-long cores where collected in 2003 and 2004 from 69 sampling sites; cores were sliced into 10 cm layers and analyzed for grainsize distribution and metals (As, Cd, Cr, Cu, Hg, Ni, Pb, Zn) concentration. A further sediment characterization survey was made in 2008, collecting 26 new cores. Surface sediment samples are mainly constituted of silt (mean content = 55.1 %, $\sigma = 14.7$ %), but display a high variability in grain-size characteristics. A positive gradient of the mud (d<63 mm) content is observed towards the West. Table 1 shows metal mean concentration in each analysed sediment layer; for comparison, mean values determined in the whole canal network are reported [1]. The table also shows the percentage distribution of concentration data with respect to the three concentration ranges which are discriminated by the NOAA Sediment Quality Guidelines (SQGs): effect range-low (ERL) and effect range-median (ERM). Concerning the spatial distribution, Cd (0,1-6,9 mg/kg d.w.), Cu (5-144), Pb (4-126), and Zn (27-327) show the greater variability among the shallow water areas. On the average, these metals have a concentration of about 10% with respect to values measured in the canal network. Arsenic, Cr, and Ni concentrations are relatively low in the investigated areas, as well as in the canal system. An effective fingerprint due to the city is observed for Hg (Figure 1). Its concentration is always higher than the ERL value (0,15 mg/kg d.w.), and higher than the ERM value (0,71 mg/kg d.w.) in 75 % of samples. As the other metal concentrations never exceed the ERM, the ecotoxicological risk of the sediment is enhanced by mercury. Concerning the surface layer (0-10 cm), a comparison between data from sediments collected in 2003-04 and in 2008 was made. Lower values characterize almost all samples analysed in 2008, pointing out a diminution of concentrations with time. This is accompanied by a greater presence of finer particles with depth, as resulting by the examination of grain-size along the vertical profile.

Tab. 1. Metal mean concentrations (mg/kg, dry weight) in the investigated areas and in the Venice canal network. In the last three rows, the percentage distribution of concentration data with respect to the NOAA SQGs is reported.

Abstract

Source-specific lipid biomarkers have been investigated in settling particles recovered from a 1-year sediment trap experiment in the SW Black Sea in 2007-2008. Biomarker amounts and fluxes unravel major marine organic carbon sources. Their temporal patterns mainly reflect primary production variability both quantitative and qualitative (phytoplankton species succession). Comparisons with bulk parameters allow characterising the settling material and assessing the main processes controlling carbon export. *Keywords: Time Series, Particle Flux, Carbon, Black Sea*

Gaining insights on carbon cycling and on carbon export is one of the tasks of the European project SESAME. To this purpose, three mooring lines were deployed for 1 year in the Western and Eastern Mediterranean and in the Black sea, each equipped with two sediment traps set at mid- and deep waters. Besides bulk parameters (mass flux, organic carbon, carbonates, opal) we have conducted a study on molecular lipid biomarkers in settling particles aimed at assessing the sources of the organic carbon and at providing clues on major processes that control carbon export/cycling. Here we present data from the Black Sea deployment ($43^{\circ}01N-29^{\circ}28E$, 2000m water depth) spanning the period from October 07 to December 08, with a 15-days resolution. The investigated source-specific biomarkers are *n*-alkanes, highly branched isoprenoids (HBI), sterols, alkenones and diols. They have been analysed by gas chromatography and gas chromatography-mass spectrometry following published procedures [1].

Long chain *n*-alkanes tracing terrestrial sources generally show medium-range concentrations typifying a system that does not receive major terrestrial inputs. Nevertheless, their temporal variations reveal an elevated contribution of terrestrial organic carbon in April-May 08, a period of enhanced discharges of the Danube River. Yet, marine organic sources, deriving from primary production, are predominant in the study area. Specific sterols (brassicasterol, 24-methylene-cholesterol) and HBI trace diatom inputs and show extremely high concentrations and fluxes, typical of highly productive marine settings. Diatoms appear to be major sources of the exported organic carbon in late fall 08, where HBI suggest the presence of *Rhizosolenia* diatoms. Secondary maxima are observed in late spring 08, and fall 08 (Figure 1).

Fig. 1. Fluxes of brassicasterol and 24-methylene-cholesterol tracing diatom inputs in settling particles in mid-waters (full circles) and deep waters (open circles)

The concentrations and fluxes of diatom-biomarkers clearly depict the temporal patterns of downward organic carbon fluxes, suggesting that diatom production exert a main control on carbon export. Besides, diatom biomarkers also portray the temporal variability of opal fluxes. Very high amounts and fluxes of alkenones are observed, consistent with the important coccolithophorid production (mainly *Emiliania huxleyi*) in the Black Sea. The temporal patterns delineate a major coccolithophorid bloom in spring 08 that contributes to the organic carbon fluxes and clearly controls the carbonate flux variability. In addition, dinosterol and diols trace inputs from dinoflagellates and nannoplankton species that show important temporal variation. Biomarkers derived mainly from zooplankton (e.g. cholesterol) show elevated

concentrations and fluxes in time intervals characterised by very abundant phytoplakton-biomarkers. Thus, the downward transfer of marine organic carbon appears to be linked to significant zooplankton grazing. Comparisons between the mid-depth and deep traps show that the transfer is rapid and that carbon recycling is not very important, leading to enhanced carbon sequestration in this marine site. Overall, the biomarker data-set sheds light on the origin of organic carbon in settling particles in the SW Black Sea and enables determining its major marine sources linked to the primary production. Biomarker temporal variability allows explaining the patterns of the export organic carbon (but also carbonate and opal) and assessing primary controls on downward fluxes.

Abstract

Une étude saisonnière des teneurs en zinc (Zn), cuivre (Cu), plomb (Pb) et cadmium (Cd) a été effectuée chez le mollusque bivalve Donax trunculus récolté dans les côtes sableuses de trois stations du Golfe de Tunis : Kalâat El Andalous (KA), Radès (R) et Borj Cedria (BC). Les résultats ont montré que les concentrations en métaux analysés diminuent dans l'ordre suivant : Zn > Cu > Pb > Cd, dans les trois stations. La bioaccumulation en Zn, Pb et Cd est pratiquement la même chez les individus des trois sites. À l'exception du Pb, nous avons enregistré une variation saisonnière des teneurs en métaux analysés dans les trois stations. *Keywords: Bivalves, Pollution, Trace Elements*

Introduction

Au cours de ces dernières décennies, l'activité anthropique (industrielle, économique) a entraîné une augmentation continue des concentrations des éléments métalliques dans l'environnement marin. En effet, les stations étudiées localisées au niveau du Golfe de Tunis ont été sélectionnées dans le but d'évaluer l'impact des rejets d'oueds (Medjerda, Méliane et Soltane qui débouchent respectivement dans la plaine de [KA], [R] et [BC]) sur les organismes aquatiques qui vivent dans ces sites. Dans ce travail, une attention particulière est portée sur le suivi de l'évolution de la teneur en Cd, Pb, Zn et Cu au niveau de la chair du mollusque bivalve *Donax trunculus*.

Matériel et méthodes

Les échantillons ont été prélevés dans les stations d'étude durant la période allant de juillet 2004 à mai 2005. Le dosage des métaux a été effectué par un spectrophotomètre d'absorption atomique avec flamme (Air acétylène). L'indice de pollution métallique (MPI) a été utilisé [1] pour déterminer le degré de pollution de chaque station. Il est obtenu par l'équation : MPI= $(CF_1xCF_2x....CF_n)^{1/n}$, où CF_n est la concentration du métal (n) dans l'échantillon. Les concentrations en métaux analysés sont exprimées en mg/Kg du poids sec. La significativité des différences entre les moyennes a été analysée par ANOVA.

Résultats et discussion

Les résultats de cette étude (tableau 1) ont montré que les Donax de chaque station accumulent différentes quantités de métaux dans leurs tissus et que le Zn et le Cu sont les métaux les plus abondants. Dans un ordre de significativité (p≤0,05), le Zn et le Cu sont suivis par le Pb. Les concentrations de ces métaux sont similaires à celles obtenues chez d'autres bivalves [1]. L'élément qui présente les concentrations les plus faibles dans les deux populations de Donax est le Cd. Pour le Zn, le Pb et le Cd, aucune différence significative (p <0,05) n'a été signalée entre les Donax des trois stations. Quant au Cu, les concentrations enregistrées dans la station de KA sont significativement plus élevées que celles enregistrées dans R (p≤0,001) et BC (p≤0,01). La variation saisonnière de la teneur en Pb est peu importante. Cependant, les concentrations printanières en Zn et Cu des Donax de KA diffèrent significativement (p≤0,05) des concentrations enregistrées durant les autres saisons. Quand au Cd les teneurs signalées sont souvent faibles ou non détectables hormis le pic printanier chez les Donax de R $(0,66\pm0,01)$ et le pic automnal des Donax de BC $(0,64\pm0,18)$ qui sont les plus montré que le MPI des Donax de BC est supérieur à celui de R et KA. Ces ions métalliques accumulés au niveau de la chair de Donax proviennent, probablement des eaux usées non traitées, industrielles et urbaines qui amènent des quantités considérables de métaux et ce par le biais des oueds Medjerda, Méliane et Soltane qui débouchent au niveau des endroits très proches de nos stations.

Selon les normes européennes [2] qui ont été fixées pour autoriser la consommation de ces organismes (Pb: 1.5 mg/kg, le Cd: 1 mg/kg et le Zn: 100 mg/kg de poids frais), nous pouvons dire que les Donax de cette étude ont des teneurs en Pb, Cd et Zn inférieures à la limite des teneurs tolérées pour la consommation humaine.

Abstract

The Moroccan north-western coasts receive continually high inputs of organic matter mostly anthropogenic, from ship and boat traffic discharges and untreated sewage and waste water discharges. So, it was urgent to assess the degree of contamination by hydrocarbons in the zone from Fnideq to Kaâ Asrass, using biota samples (cockles). In this investigation, the study of hydrocarbons is based on the analysis of chemical indicators (n-alkanes hydrocarbons, isoprenoids, hopanes, LAB) to characterize the contamination's sources (biogenic and petrogenic).

Keywords: Bivalves, Chemical Analysis

Material and methods

Sampling On spring 2003, samples of *Acanthocardia tuberculata* commonly known as cockles, were collected from 7 sites at the western moroccan mediterranean sea.

The bivalves have been immediately shelled, crushed and freeze-dried. *Hydrocarbon analysis* Entire organisms tissues were crushed, freeze-dried and soxhlet extracted (5g) with methanol for 10h. Perdeuterated internal standard (n-C24D50) was added before the extraction. The saponification of the lipid extract was performed with KOH/distilled water (0.7N, 2:3) for 2h. Afterwards liquid/liquid extraction was made with n-hexane 3 times. The lipid extract was concentrated and separated by column chromatography on neutral alumina/silica (v: v) (5% deactivated) and eluted, with 20ml n-hexane. The F1 fraction corresponding to aliphatic hydrocarbons was concentrated under vacuum evaporation to dryness and then re-dissolved in 50 μ l prior to the analysis by gas chromatography GC/FID and GC/MS.

Preliminary Results

The distribution of n-alkane in all samples shows a trace of terrestrial biogenic inputs, (important peak n-C27 and n-C29) [1]. n-C17 was detected in some samples, it indicate a phytoplanctonic origin [2]. It also shows an important presence of n-C18 and n-C20 related to bacterial origin [3]. UCM was present in the lower molecular weight range, linked to bacterial degradation of natural organic inputs [4]. Moreover, the CPI close to unity suggests an oil contamination [5]. Prystane was absent in most samples except for the O2 site. Inversely to Phytan, it was absent only in O8 site. The Ratios C17/Pr and C18/Py > 1 indicate a petrogenic contribution which is also confirmed by Pr/Py<1. On the other hand, hopanes series were determined in the GC/MS by monitoring m/z 191 in some samples collected from the study area. The identified component had the thermodynamically stable $17\alpha(H)$, $21\beta(H)$ configuration which is indicative of pollution from fossil fuel products [6]. A series of peaks were identified as being the linear alkylbenzene (LAB). They are used as raw material for synthesizing linear alkylbenzene sulfonates (LAS), which are the anionic surfactants commonly used in synthetic detergents [5]. The concentration of total LAB is summered in the Table. such levels were reported by [6, 7, 5].

CHARACTERISTICS OF STABLE ISOTOPE EMPIRICAL DISTRIBUTIONS IN PRECIPITATION AT CENTRAL EUROPEAN GNIP STATION - LJUBLJANA, SLOVENIA

Mihael Brencic ¹* and Polona Vreca²

¹ Department of Geology, University of Ljubljana - mihael.brencic@ntf.uni-lj.si

² Department of Environmental Sciences, Jožef Stefan Institute, Jamova cesta 39, SI-1000, Ljubljana

Abstract

Empirical distributions of hydrogen and oxygen stable isotope time series at Ljubljana – Slovenia GNIP precipitation station has been explored. Results show bimodal empirical distribution of hydrogen and oxygen stable isotope data. Bimodal distribution was described as representation of the two populations modelled by two component mixture of Gaussian distributions. The mixture of two populations was described as discrete event by seasonality dependent bimodal distribution. *Keywords: Time Series, Geochemistry, Geochemical Cycles*

Keywords. Time Series, Geochemistry, Geochemical C

Introduction

Discussion

Precipitation can be described as stochastic process that varies temporarily and spatially; it can be expected that their chemical and isotopic characteristics can be described in the similar way. Literature abounds on stochastic modelling of precipitation amount and intensity time series; however stochastic models dealing with chemical characteristics of precipitation are few and stochastic modelling of isotopic time series is even more in the background. The intention of the paper is therefore to explore stochastic characteristics of hydrogen and oxygen stable isotope time series.

Methods

Stochastic characteristics are represented on the hydrogen and oxygen stable isotope time series of Ljubljana precipitation. Ljubljana is a GNIP-network precipitation station where composite monthly precipitations samples are collected. Operation of the Ljubljana station started on May 1981 and proceeds until today. It is central European station where influences of the precipitation originating from Atlantic and Mediterranean air masses are present. Average LMWL is close to GMWL. [1], [2] On the monthly data values exploratory analyses was performed and kernel densities were calculated.

Results

Results show that empirical distribution of both data series is bimodal. Bimodality of empirical distribution p(x) was model as two component mixture of Gaussian distributions $f(x|\mu_1,\sigma_1)$ and $f(x|\mu_2,\sigma_2)$ with parameters μ_i,σ_i . The model can be described as $p(x)=af(x|\mu_1,\sigma_1)+(1-a)f(x|\mu_2,\sigma_2)$ where the appearance of particular component was modelled as discrete event by seasonality dependent bimodal distribution.

Fig. 1. Kernel densities of oxygen and hydrogene stable isotope composition at GNIP Ljubljana station

The model is interpreted as mixing of the Atlantic and Mediterranean are masses in the approximate share of 3:1.

Abstract

Mussel biodeposits accumulation and oxidation were studied by means of 3 different numerical models: an early diagenetic model, a population dynamic model and a deposition model. Models were applied at a long-line farm located in the Northern Adriatic Sea by using a dedicated set of field data. Both field data and model results showed that biogeochemical alterations induced by the mussel farm are markedly lower compared to the extent of the impacts commonly reported for fish cages. Nevertheless, a model sensitivity test indicate that organic matter flux, sediment geochemistry and nutrient recycling can vary remarkably as a function of the stock of the mussels and the environmental forcings scenario considered.

Keywords: Aquaculture, Models, Organic Matter, Bivalves, Adriatic Sea

Introduction During the last two decades, shellfish production raised questions concerning the environmental impact and sustainability of shellfish farms, at both local and regional scales [1]. Numerical models have proven to be useful science-based tools for site-selection and ecological carrying capacity assessment [2]. Models capable to represent the interactions of mussel biodeposition with sedimentary redox processes are currently lacking in the field of aquaculture, although monitoring techniques based on biogeochemical measures were found to be more cost-efficient than the ones based on macrofaunal community structure [3]. The main objective of this work was to study the applicability of a novel approach to model the interaction between mussel farm biodeposition, sediment geochemistry and nutrient recycling.

Methods Vertical profiles of sediment porosity, and concentrations of organic carbon, NH4⁺, NO3²⁻, SO4²⁻, dissolved inorganic P, Mn²⁺ and Fe²⁺ were collected at a mussel farm located off-shore Chioggia (approximately 20m depth). Two field campaigns were carried out at two stations located underneath the farm, in February and July 2007. Radiometric dating analysis was carried out on cores collected underneath the lines in order to assess the sedimentation rate. N:C and P:C elemental ratios were determined on the faeces produced from a set of individuals (180) collected from a marked rope along 8 field campaigns (July 2006 - May 2007). A current-meter was deployed from July to September 2006 and from April to May 2007. Mussel density and husbandry practices were estimated on the basis of regular interviews with the farmers [4]. The standing-stock of the mussels and the production of biodeposits were simulated through a population dynamic model (PDM) of M. galloprovincialis [5]. The OM rain underneath the mussel farm was estimated by means of 3D particle tracking models [6]. Aerobic and anaerobic pathways of organic matter (OM) oxidation were modelled by means of a 1D reaction-transport early diagenetic model [7]. The diffusive fluxes of dissolved constituents at the sediment-water interface were calculated on the basis gradients of their concentrations. Model application was carried out in three steps: 1)the flux of OM from the farm was estimated through an inverse use of the early diagenetic model: this was calibrated by minimising the distance between predicted profiles and field data, under a set of constraints; 2)the OM flux from the farm was independently estimated by coupling the population dynamic and particle-tracking models; 3)different sensitivity tests were carried out, in order to study the potential impact of the mussel farm, associated with the different scenarios of mussel standing-stock, bathymetry and hydrodynamic regimes.

Results and discussion The flux of OM originated by the farm, estimated by calibrating, Fig. 1, the early-diagenesis model was of approximately 15 g C m⁻² y⁻¹, lower but comparable with the fluxes estimated by coupling the population dynamic and particle-tracking models (Fig. 1). These fluxes are lower than the range measured by [8] underneath a mussel farm located in a Canadian lagoon, 20-150 g C m⁻² y⁻¹. Results from the particle tracking model indicate that ~ 95% of OC deposited within 500m from the farm boundaries, on a total surface of 6.5 km⁻². As regards oxygen penetration depth, TS concentrations and dissolved nutrients profiles, results indicate that the impact of a mussel farm per unit area is markedly lower than the one induced by finfish cage farming. However, the overall impact of OM oxidation on the N and P cycles can be regarded as significant, given the extension of the licensed areas. Results from the sensitivity tests, indicate that the entity of the impact can vary dramatically in response to the scenario considered,

suggesting the potential use of this type of models as decision support tools for site-selection and farm dimensioning.

Abstract

Until the early 1970's the Turkish Straits System was one of the richest and most productive marine environments in the world [1]. Due to pollution stemming mainly from land-based pollution and maritime traffic, this sensitive ecosystem is now facing the threat of degradation.

Keywords: Marmara Sea, Bosphorus, Pollution

Introduction

It has been estimated that on a global scale, up to 70% of pollution in the seas originate from land-based sources [2]. The marine environment of the Marmara Sea has become increasingly vulnerable; whose oceanographic features do not help much its self-purification capacity. This inland sea is a semi-enclosed water body of 11111 km² with an average depth of 260m connecting the Mediterranean and the Black Sea via the Canakkale (Dardanelles) and Istanbul Straits. Domestic pollution load is generated mainly by the Istanbul Metropolis and its surroundings where 1/5 of Turkey's population live [3]. Furthermore large industrial facilities amounting to 60 % of the total, located on the bays and coastal areas constitute the most significant portion of local land-based input into the Marmara Sea is confronted with severe environmental degradation due to ship-originated pollution generated mainly by the bilge/ballast waters of tankers and cargo vessels.

Material and Method

The study was carried out in the Istanbul Strait and Marmara Sea (Figure 1). The water quality monitoring sampling frequency of the Istanbul Strait was designed to monitor the sea water quality on a monthly basis at the monitoring stations, whereas the Marmara Sea stations were followed on seasonal basis for a comprehensive set of parameters enabling the identification of the physical, chemical, biological state of the marine environment for all the stations.

Fig. 1. Study area

Results

The land-based pollution load for the Marmara Sea generated by major hotspots was calculated during the compilation of the Istanbul Master Plan study. DHI found out that the major hot-spots is Istanbul (contributing with almost 65% of the total land-based pollution to the Marmara Sea) [4]. The Marmara region is the most developed in terms of industrialization, with a wide variety of industries concentrated in the Gulf of Izmit, Gemlik and around Istanbul. The build-up effect of pollution has started to spread over the continental shelf, giving rise to a widespread deterioration of the natural balance in the marine ecosystem. Difficult natural conditions such as the intricate geometry of the Istanbul Strait, sharp turns on the navigation route, harsh meteorological conditions and transient changes in the flow regime coupled with increasingly dense maritime traffic create a serious risk of accident. Significant amounts of crude oil spill have been the major cause of ecological damage experienced so far as a consequence of maritime accidents. The ecological hazard generated by oil spill has resulted in the decrease and/or extinction of surface and subsurface fish species and crustaceans.

Discussion

The experimental results of a ten-year monitoring, study from the year 1996 to the year 2005, indicates an improvement with regard to nutrient load in the surface waters of the Marmara Sea after the commissioning of the deep-sea outfalls. But there is still incremental and point source pollution in the Marmara Sea with high phytoplanktonic activity. Therefore, pollution is still a concern for the receiving waters of Istanbul and in the Marmara Sea basin in general despite large investment expenditures allocated to Istanbul [5,6]. The accidents caused by tankers and cargo ships resulting in loss of human life, property and damage to the environment have been creating great public concern. Pollution derived from the maritime traffic in the Istanbul Strait and Marmara Sea is no exception. Besides sea accidents, illegal practices such as pumping of bilge and waste water, and unloading of dirty oil and garbage by transit vessels in particular, contribute to marine pollution, which also affects recreational beaches [7].

Abstract

We present first results of a study started in January 2008 and focused on the analysis of the variability of carbonate system in the Gulf of Trieste (N. Adriatic Sea). Total alkalinity, pH, and mayor physical and biogeochemical parameters were measured at PALOMA station (centre of the Gulf). We evidenced the role of direct inorganic carbon riverine inputs, sea water temperature and production / regeneration processes as mayor drivers of the observed carbonate system variability during the studied period. *Keywords: Adriatic Sea, Ph, Coastal Systems, Carbon*

Introduction

The Gulf of Trieste (Adriatic Sea) is the Northernmost area of the Mediterranean which, as other sub-tropical continental shelf areas, experiences a strong seasonal cycle. Here, the pronounced cooling of the coastal waters during winter (7-8°C) and the mixing due to Bora wind events increases the solubility of CO₂ in water, permitting its potential sequestration in the denser bottom waters by the mechanism of the physical carbon pump. In summer, the warming of surface waters (28°C) and the scarce circulation may invert the flux of CO₂ with the atmosphere, particularly during period of low primary production. Because of the low inertia of this shallow coastal ecosystem compared to the deep sea and of its pronounced seasonal cycle, the Gulf of Trieste is thought to be highly sensitive toward the climate changes and the global atmospheric CO₂ rising. For this reason, the increase of CO₂ dissolved in seawater and the consequent decrease of pH might lead in this area to earlier changes of the marine environment due to ocean acidification than elsewhere.

We present first results of a study started in January 2008 and focused on the analysis of the variability of carbonate system in the Gulf of Trieste with respect to riverine inputs, sea water temperature and production / regeneration processes.

Methods

Since January 2008, pH, Total Alkalinity (TA) and physical/chemical parameters were acquired on monthly basis, on the whole water column at the site PALOMA (centre of the Gulf, 25m depth, close to the dynamic pylon PALOMA – Advanced Oceanic Laboratory PlatforM for the Adriatic sea). pH have been measured by the spectrophotometric method [1,2] with a precision of \pm 0.001 and the results were expressed on "total scale" in µmolH⁺/Kg _{SW} at 25°C (pH_T@25°C). TA has been measured by potentiometric titration at 25° C (precision \pm 2 µmol/kg) and the results were controlled with sea water certified as reference material (supplied by dr. A.G. Dickson). The other parameters of the carbonate system (pCO₂, pCO₂@15C°, DIC, Revelle factor, "Omega"Ar, "Omega"Ca) were computed from pH, TA, salinity, temperature, SiO₂, PO₄ with the "CO2sys" program. To our knowledge this is the first time serie of this set of parameters collected in the N. Adriatic Sea.

Results and Discussion

From October to March, the water column was homogeneous and well ventilated. $pH_T@25^\circ C$ was generally low and constant (avg 7.920), because of the increased CO_2 solubility caused by the low water temperature (down to 8.0°C) and by the exceeding respiration compared to primary production. During the stratified period of both years (April – Sept.), the combined effect of high temperature and CO_2 assimilation in the upper waters determined the highest values of $pH_T@25^\circ C$ (Tab 1). In contrast, the remineralization processes in the bottom layer (Apranent Oxigen Utilization – AOU = 142 μM) prevailed on the effect due to the high water temperature (18.9°C) determining the lowest values of $pH_T@25^\circ C$ observed during the whole time series (Tab 1).

TA concentrations (Tab 1) were higher than in open Mediterranean sea (~ $2600 \ \mu mol/Kg$ [3]) due to the inflow of rivers with a carbonatic drainage basin. TA variability was mainly modulated by riverine inputs with variable TA concentrations and by the occurrence of strong remineralization processes in the bottom layer (Aug.- Nov. 2008, up to 2693 μ mol/kg) as shown by the relationship with AOU.

The seasonal evolution of in situ pCO_2 was deeply influenced by the variations of temperature. Despite the production processes in the upper water column, the effect of temperature increased pCO_2 at values higher than 400 µatm on the whole water column, from August to December 2008. In contrast, its values were always lower than 350 µatm from January to June 2009. If we assume an average value of 380 µatm for atmospheric CO_2

concentrations, the Gulf of Trieste was supersaturated from August to December 2008, acting as a potential source of CO_2 for the atmosphere; on the contrary surface waters were undersaturated from January to June 2009 acting as a potential CO_2 sink.

An exception to this trend was the high pCO_2 value (523 μ atm) observed in April 2009, in surface low salinity waters (S=27.6), which was ascribed to the ventilation of CO₂ from supersaturated riverine waters.

The superficial pCO₂@15C° values were compared with those reported from other European coastal zones [4]. From the relatively few data collected, pCO₂@15°C presented a clear seasonal cycle with lower values in summer (258 μ atm) and higher in winter (495 μ atm) wiht an amplitude of 236 μ atm. This cycle was more similar to what reported for the North Sea coastal zones than to the olygothrophic coastal site studied in the western Mediterranean.

Despite the high alkalinity, the pronounced variability of Revelle factor and of "Omega" Ca and Ar evidence the overall weak buffering capacity of carbonate system in the Gulf of Trieste.

HEAVY METALS DISTRIBUTION IN MARINE SEDIMENTS OF THE EAST ADRIATIC SEA

Ana Castelli ¹* and Zoran Kljajic ¹

¹ Institute of Marine Biology - ana.bulatovic@t-com.me

Abstract

Heavy metals (Cd, Pb, Cu, Zn and Ni) concentration and distribution were determined in marine sediments along the Montenegrin coast in the East Adriatic as there is luck of historical, continuous data about heavy metals pollution of this area. The distribution shows that metals concentration decrease in the sediment samples from SE to NW along the coast. The concentrations are generally not high, revealing that the investigated coastal area is not polluted.

Keywords: Adriatic Sea, Metals, Sediments

Introduction

Sediments are usually regarded as the ultimate sink for heavy metals discharged into the marine environment, thus determination of the distribution and concentrations of the heavy metals in sediments is of great importance in environmental pollution studies [1]. The study area is the Montenegrin coast which belongs to the Eastern South Adriatic. The Adriatic Sea is located in the central-north part of the Mediterranean Sea. It is relatively shallow sea especially subjected to pollution due to its semi-enclosed character [2]. Heavy metals in the surface sediments from Montenegrin coast may originate either from natural sources (weathering, pluvial and fluvial erosion), but also from anthropogenic sources (e.g. industrial and municipal effluents, port activities, traffic, rivers, atmospheric inputs). Surface sediment samples collected from the seven near-shore and off-shore stations along the Montenegrin coast were analyzed for Cd, Pb, Cu, Zn and Ni. In the investigated area seven stations (Figure 1) were selected from the entrance of the Boka Kotorska Bay to the mouth of the Bojana river in order to estimate level of concentrations and to present spatial distribution of chosen metals that are mostly associated with anthropogenic inputs [1].

Fig. 1. The investigated area with sediment sampling sites

Meterials and methods

Seven sediment samples (on location 2-1 was sand) were taken in November 2007 with italian research vessel "G. Dallaporta" by using box corer. Concentration of Cd, Pb, Cu, Zn, and Ni in surface sediment samples were determined by Energy Dispersive Polarised X-ray Fluorescence (EDPXRF).

Results and discussion

Metal concentrations in the sediment samples (dry weight) range from 10.64 to 24.35 mg/kg for Pb, from 0.0893 to 0.2713 mg/kg for Cd, from 61.43 to 109.40 mg/kg for Zn, from 20.46 to 44.30 mg/kg for Cu and from 172.69 to 325.70 mg/kg for Ni. Minimal concentration of investigated metals was registered in front of the entrance of the Boka Kotorska Bay on locations 1-1 (Cu, Zn, Ni) and 1-2 (Cd). The exception is Pb which minimal concentration on position 4-5 which is located 14.5 km from the mouth of the Bojana river. Comparing near and off-shore concentrations for Pb, Cd, Cu, Zn and Ni it can be noticed that all metals have shore side concentration less than metal concentrations distant from the coast. The obtained concentrations for Pb, Cd, Cu and Zn are comparable or less than those reported for sediments from

different parts of the Adriatic ([3], [4]). According to some sediment quality criteria ([5], [6]), low concentrations of the examined metals indicate that investigated sediment is not polluted. Exception is Ni which level is higher than in the surroundings.

Conclusion

The distribution shows decreasing concentration trend for all metals going in SE-NW direction along the coast and increasing concentration trend with the distance from the shore side. This can be explained with the influence of the Bojana river inside and outside of its estuary, as well as with general anticlockwise circulation of the Adriatic waters. Comparisons indicate that sediment of the examined area is not polluted.

Acknowledgement

Sediment samples were collected during oceanografic cruise within the joint Italian-Montengrin project ADRICOSM STAR, supported by Italian Ministry for the Environment, Land and Sea and Montenegrin Ministry for spatial planning and environment (2007-2010).

ESTIMATION OF THE GREEK COASTAL ZONE CONTAMINATION BY THE MEANS OF BIOINDICATORS

Vassiliki - Angelique Catsiki ¹*, Caterina Tsangaris ¹, Evangelia Strogyloudi ¹ and Francois Galgani ²

¹ HELLENIC CENTRE FOR MARINE RESEARCH - cats@ath.hcmr.gr

² IFREMER

Abstract

The contamination of the Greek coastal zone was investigated in the framework of the Programme MYTIMED (INTERREG IIIb - MEDOCC). Caged mussels were transplanted in 38 sites along the Greek coastline. Measured contaminant levels in caged mussels were similar to those from previous studies and achieved to differenciate contaminated and unpolluted areas. Mussels from Saronikos and other gulfs were the more contaminated, followed by Ionian sea, North. Central and Eastern Aegean areas had intermediate concentrations and South Aegean and Libyan areas had the lowest. Biomarker's and metal's statistical analysis showed similar results with small exceptions. However biomarker's and bioaccumulation's results are complementary and offer different information for the environmental status of a site.

Keywords: Bio-Accumulation, Metals, Bio-Indicators, Monitoring

Introduction

The contamination of the Greek coastal zone was investigated in the framework of the Programme MYTIMED (INTERREG IIIb - MEDOCC). The Programme aimed evaluating the chemical quality of Eastern Mediterranean exploiting the active biomonitoring qualities of mussels [1].

Materials and methods

Caged mussels originated from an aquaculture in Saronikos gulf, were transplanted in 38 sites along the Greek coastline in depths ranging from 20 to 30 m and occasionaly deeper for a period of 3 months. Metals (Cu, Ni, Mn, Zn and Fe) and biomarkers (Metallotheioneins, Acetylholynesterase, Catalase and Glutathione-S-Transferase) were determined in 4-5 pooled replicates from each station. The standardisation of metallic results was based on the condition index, while biomarker results were not standardised.

Results and discussion

The recovery of cages reached 92%: only 3 cages couldn't be collected. Mortality was less than 20% that is similar to previous studies [2]. Concentration of metals expressed in $\mu g/g$ dry weight ranged from 2.33 to 5,81 for Cu, 1.61 to 7,56 for Ni, 38 to 233 for Zn, 1,76 to 11,0 fro Mn and 38 to 182 for Fe. Metallothioneins ranged between 94 and 225 $\mu g/g$ tissue, Acetylholynesterase activities between 165 and 326 U/mg protein, Catalase activities between 0,7 and 3,59 U/mg protein and Glutathione-S-Transferase activities between 35.9 and 70.4 nmoles CDNB/mg protein.

Generally the measured contaminant levels in caged mussels were similar to those from previous studies in native populations [3], [4], [5] and achieved to describe differences between contaminated and unpolluted areas Fig 1.

Fig. 1. Average values of Cu and AChE in transplanted mussel samples along Greece

In order to simplify the data we grouped the sampling stations in 8 groups as follows: Ionian sea, North Aegean, Central Aegean, South Aegean, east Aegean, Liberian Sea, Saronikos gulf, and Gulfs (Korinthiakos, Thermaikos, Evoikos and others gulfs). Analysis of variance between the 8 metal datasets showed similar

results for all metals and revealed statistically significant differences among the 8 areas (P<0.05) Saronikos and the other gulfs being the more contaminated, followed by Ionian sea stations. North, Central and Eastern Aegean areas had intermediate concentrations while South Aegean and Libyan areas had the lowest. Biomarker's statistical analysis showed also similar results for all of them. Although the observed differences among the areas were not statistically significant, the obtained pattern was similar with that of metals, with the exception of Libyan stations witch showed stress. The above phenomenon could possibly be attributed to other kind of stress than contaminants, since the used species reached there its geographical limits.

Fig. 2. Cluster of mean values of measured parameters per main geographical Greek area

The clustering of data (Fig 2)-containing mean values of each parameter per geographic area was in accordance with ANOVA analysis foundlings. However we have to note that biomarker's and bioaccumulation's results are complementary and offer different information for the environmental status of a site.

Abstract

Organic matter sources in sediments from the north of Moknine hypersaline system were assessed using lipid biomarkers. Alkylbenzenes in the C18-C22 range, with an even carbon number predominance and a maximum at C19, occur in substantial abundance in most sediment samples. High molecular weight alkylbenzenes are only present in low concentration <1%. Total aromatic hydrocarbons are essentially composed of the isomers of C18, C19 and C20 alkylbenzenes. Cyclization and aromatization of linear alkanes was probably the pathway for the formation of most aromatic units upon organic matter diagenesis. *Keywords: Geochemistry, Bacteria, Coastal Systems, Evaporites, Organic Matter*

Introduction

Alkylbezens moleculars have been detected in particulars geologicals systems under sulphate reduction conditions [1]. These systems are characterized by evaporitic deposits (carbonates and salt). In the present work we report the result of the study of aromatic fractions in the recent sediments of the hypersaline Moknine system. We identified the origin of aromatic fraction composed by the alkylbenzenes and the dynamic system in the recent.

Geological setting

The Moknine sebkha is an evaporator system from eastern zone of Tunisia and it belongs to group of the Sebkha with lozenge morphology near the Mediterranean sea. Periphery deposit is composed by sand and silty-sand (SM9) and medium zone and central part are composed by clay deposits and covered by Halite.

Methods

Sediments samples were collected from 3 sites (site 9, 10 and 12) of Moknine sebkha using PVC tube (75 mm of diameter). Samples were extracted with chloroform in a soxhlet extractor for 12h. Total extracts were fractionated by column chromatography on silica gel with different solvent sequentially. Aromatic hydrocarbons were obtained by eluting with a mixture of hexane and chloroform (2V/1V) and analysed by gas chromatography/mass spectrometry (GCMS) on Agilent Technologie 6890N connected with Agilent 5973 Network mass spectrometer (operated at 70eV, cycle time 2.24s, and range m/z: 35-600). Ratios of various biomarkers were calculated using peak heights. Compound were quantified by integration of appropriate mass chromatograms of m/z 91 and 105 (alkylbenzene, phytanylbenzene).

Results

Mass chromatography of m/z 91 reveals the presence of homologous series of n-alkylbenzene ranging in most samples from C18 to C22 in different profiles from the north of the Moknine sebkha. Sometimes peaks on C23 to C31 are detected in sediment. This distribution can be explained by the low biological diversity in hypersaline environments [2]. Moknine sebkha, is restrict evaporator environment where only cyanobacteria and algae developed [3]. All samples are dominated by linear alkylbenzenes which thought to be formed by cyclization and aromatization of precursor possessing linear carbon skeletons. They are substituted at different positions (1, 3, 4, 5, 6 and 7) and originate or are diagenetically transformed lipids. Generally, it's accepted that fatty acids derived from biological organisms are likely precursors of alkylbenzene in sediment via well-known sedimentary dehydration and cyclization reactions [4].

Two compound are identified C19 : 1-methyl-4-dodecylbenzene and 1ethylundecylbezene or 3phenyltridecane and C20 : 1-methyl-4tridecylbenzene components, characterized by a base peak at 105 and 119 and corresponding molecular ions at m/z 260 and 274. The highest concentrations of isoprenoid benzenes occur in clay sediments of the centre which is associated with high concentration of halite. In this context halophilic archaebacteria have been suggested previously as a source for sedimentary phytanylbenzene [5]. In the Moknine sebkha these component derived from algae or cyanobacteria. In fact, the similar structure of the phytanyl benzenes and natural quinones when the isoprenyl group position is compared with the methyl groups in the aromatic ring [1]. The presence of phenylbenzene in the Moknine system could be related to highly reducing palaeoenvironments.

Conclusion

Organic matter constitutes a minor but important fraction of hypersaline Moknine system sediment. Sources of organic matter include primary production within the system; input of terrestrial material and products connected to microbial activity in water and sediment. The distributions of the alkylbenzene compared to the n-alkanes distribution show that the carbon number distributions of these alkylbenzene compounds resembled those of the n-alkanes found in the same sediment with the high odd carbon preference between nC17-nC31. This indicates that the alkylbenzene could have been formed by direct cyclization and aromatization, while the n-alkanes could have been formed by decarboxylation of the straight chain fatty acids.

EVALUATION DES TENEURS EN CADMIUM, PLOMB, MERCURE ET EN BENZO(A)PYRÈNE DANS LA CHAIR DE *RUDITAPES DECUSSATUS* DU LITTORAL TUNISIEN

L. Chouba ¹*, N. Mzoughi ¹, C. Tissaoui ¹, Z. Souli ¹ and R. M'rabet ¹

¹ INSTM, Port de Pêche 2060 La Goulette, Tunis – Tunisie - lassaad.chouba@instm.rnrt.tn

Abstract

La palourde reste l'espèce la plus estimée en Tunisie, elle est répartie le long du littoral tunisien avec une concentration plus importante au Nord et au Sud. L'étude de la composition en métaux traces et en benzo(a)pyrène (BaP) de cette espèce provenant des différentes régions de la Tunisie a été réalisée dans ce travail. Les résultats montrent que la palourde des zones Sud présente des concentrations plus importantes en Cd, en Pb et en BaP que les zones Nord. Pour le Hg, la teneur trouvée varie d'une zone à l'autre, le maximum est enregistré au niveau de Tunis.

Keywords: Metals, Bio-Accumulation, Bivalves

Matériel et Méthodes

Les échantillons *R. decussatus* prélevés sont mesurés et pesés. Ensuite, la totalité de la chair est récupérée, homogénéisée, lyophilisée, broyée et tamisée. La minéralisation est effectuée par micro-onde (Mellistone). Les dosages des métaux Cd et Pb sont réalisés par Spectrophotométrie d'Absorption Atomique (SAA type Varian 220Z) à four graphite, celui du Hg par la SAA en vapeur froide. L'assurance et le contrôle qualité sont assurés par l'utilisation de matériau de référence certifié (Nist 2976). Les analyses de benzo(a)pyrenne selon la méthode de l'UNEP [1]. Une analyse statistique moyennant les Analyses en Composantes Principales (ACP) [2] a été utilisée pour comparer les régions.

Résultats et Discussion

Les analyses ont été effectuées sur 4 lots de 25 spécimens provenant de cinq zones, Sfax (S), Gabès (G), Médenine (M), Bizerte (B) et Tunis (T) (Figure 1) durant les années 2007 et 2008. Les dosages des éléments chimiques ont été réalisés par SAA et par GC/FID.

Fig. 1. Zone des prélèvements des échantillons de la palourde (*R. decussatus*) le long des côtes tunisiennes (B:Bizerte,T: Tunis,S: Sfax, G:Gabes, M: Médenine)

Les moyennes et les écarts types des teneurs en métaux traces et en benzo(a) pyrène dans la masse molle de la palourde provenant des différentes zones sont résumés dans le tableau 1. Les résultats montrent une variation nette entre les sites étudiés, sauf pour le BaP qui est du même ordre de grandeur dans toutes les zones.

Les teneurs en métaux traces montrent que la palourde des zones Sud de la Tunisie S, G et M présente des concentrations plus importantes en cadmium que les zones Nord B et T. En effet, elles sont dues aux rejets anthropiques et industriels dans cette région [3]. Pour le Hg et le Pb, les doses trouvées varient d'une zone à l'autre. Le maximum est enregistré au niveau de la zone de Tunis (T), caractérisée par la présence de stations thermiques. Les concentrations en BaP considérées comme indicateur de pollution par les HAP [4] ne présentent pas une différence entre les zones. Cette étude montre que la bioaccumulation

des métaux traces dans la palourde varie en fonction des zones. Les faibles teneurs enregistrées dans certaines zones dénotent la faible contamination du milieu par les éléments en traces. En effet, les travaux d'Ennouri [5] et de Sfriso [6] montrent que la bioaccumulation dans les bivalves dépend de la disponibilité des métaux dans le milieu qui est lui-même tributaire des rejets anthropiques et industriels déversés. L'analyse statistique nous a permis d'identifier trois groupes, le premier constitué par Sfax et Médenine présentant la contamination la plus forte, le second formé par Tunis indiquant une contamination par le Pb et enfin le dernier groupe renfermant Bizerte où les éléments dosés sont faibles par rapport aux autres zones. Donc, la qualité de la palourde dépend étroitement de la zone où elle vit et par conséquent du type de nourriture et de l'état du milieu environnant. On peut conclure que ce travail nous permet d'avoir un aperçu de la qualité chimique de l'ensemble du milieu étudié. Toutefois, il faut noter que le degré de contamination par les micropolluants dosés dans la palourde tunisienne reste largement inférieur aux normes usuelles (Tableau 1).

MERCURY BIOACCUMULATION IN THE EUROPEAN HAKE (MERLUCCIUS MERLUCCIUS) FROM THE GULF OF LIONS AND THE BAY OF BISCAY

D. Cossa ^{1*}, M. Harmelin-Vivien ², C. Mellon-Duval ¹, V. Loizeau ¹ and S. Crochet ¹

¹ IFREMER - dcossa@ifremer.fr

² Université de la Méditerranée

Abstract

Total (HgT) and methylmercury (MeHg) concentrations were measured in the muscle tissues of European hakes (*Merluccius merluccius*) from the Gulf of Lions (Northwestern Mediterranean) and the Bay of Biscay (Northeastern Atlantic). Similar chemical measurements have been performed on plankton samples and fish preys sampled in the same areas. Relationships between HgT and MeHg concentrations and the size, sex, δ 15N (indicator of food web structure), growth rate and habitat of the fish were examined. Difference in growth rate between the two environments and change in feeding habits when the fish is entering adulhood seem to be the major factors governing the mercury bioaccumulation. *Keywords: Fishes, Mercury*

Introduction

Mercury biomagnification in aquatic food webs is well established (Luoma and Rainbow, 2008). This process results from high efficiency of uptake and slow excretion of methylmercury (MeHg) in biota. In this context, differences in the Hg bioaccumulation in the same fish species caught from different environments can be due to factors such as mercury bioavailability, fish growth rate and specific food web structure of the fish habitat. Here, we document the bioaccumulation of HgT and MeHg in the muscle of the hake (Merluccius merluccius) from the Gulf of Lions (NW Mediterranean) and the Bay of Biscay (NE Atlantic); the aim of this study was to improve our understanding of mercury bioaccumulation pathways in marine fish.

Studied sites

The samples were collected along the shelves and continental slopes of the Bay of Biscay (BB) and Gulf of Lions (GL) in 2002 and between 2004 and 2006 respectively.

Methylmercury in the water column

The vertical distributions of MeHg in the water column near the fish sampling stations exhibit similar patterns in the two studied areas: concentrations were low in the photic zone and they increased downward within the organic matter mineralization zone; this is consistent with recent observations made in the open waters of the Mediterranean Sea (Cossa et al., 2009). L

Fig. 1. Methylmercury *versus* delta 15N in the muscle of hakes and their preys from the Atlantic and Mediterranean

Effect of trophic position

The bioaccumulation and biomagnification of MeHg in the hake muscle, and in plankton, suprabenthos and other components of the food web are illustrated on figure 1 using $\delta 15N$ as a proxy of the trophic level. The increase of the MeHg concentration with the trophic level agrees with the current paradigms (Hoffman et al., 2003). However, we observed two special features: (i) a shift toward higher $\delta 15N$ for hakes from BB compared to similar size individuals from the GL, and (ii) higher MeHg concentrations in the muscle of the Mediterranean hake (GL), in spite of their lower $\delta 15N$. In fact, the shift for high $\delta 15N$ concerns not only the Atlantic hake but also its whole food web since similar $\delta 15N$ (4.1 %0) are found for plankton mixture from GL and phytoplankton from BB. It is also noteworthy that the slope of the relationship MeHg vs $\delta 15N$ is steepest for adult hake from GL. This last observation is

probably related to the changes in feeding habits when the fish is entering adulthood, i.e., 25 cm for GL hake and 40 cm for BB. These changes go with the differences in the growth rates of the hake between the two studied environments (Fig. 2).

Fig. 2. Total length versus age of hakes from the Atlantic and Mediterranean

Effect of fish growth rates

The higher growth rate of hakes from the Bay of Biscay relative to those of the Gulf of Lions (Mellon-Duval, in press) may produce a biological dilution of the MeHg mercury absorbed by the fish and accumulated in the muscle tissue. Individuals enter adulhood when they reach 2 years in both areas.

Abstract

Distribution of Cd, Pb, Cu, Zn and dissolved organic carbon (DOC) in water column of Bjejajka anchialine cave were studied seasonally (wet and dry periods). Metal amounts in water column were significantly higher compared to those found in seawater samples taken in near vicinity (100 m). Unusually elevated concentrations of cadmium (up to 300 ng L^{-1}) were found in water column of Bjejajka cave, which are two orders of magnitude higher than in nearby surface seawater (~ 7 ng L^{-1}). DOC amount in cave water column (up to 10.5 mg C L^{-1}) was enhanced comparing to open seawater (up to 3 mg C L^{-1}), and diminished below halocline. Elevated concentrations of trace metals and DOC in Bjejajka anchialine cave were of natural origin caused by biogeochemical processes. *Keywords: Metals, Organic Matter, Adriatic Sea*

Experimental

Bjejajka anchialine cave in the remote Mljet National Park is connected hydraulically with Adriatic seawater. Tide inside the cave follows outer surface seawater level, but replenishment of the water is restricted by the karst rock. The water in the cave has a long residence time compared to a fully-flushing cave. This anchialine environment reveals a number of characteristics, such as well-developed halocline and hypoxia. Water samples for Cu, Cd, Pb, Zn and DOC determination were collected during 2009 by speleo scuba-diver. Metal measurements were performed by differential pulse anodic stripping voltammetry (DPASV), while DOC was obtained by high temperature catalytic oxidation using a non-dispersive infrared detector. Trace metals concentrations are presented as dissolved and total fractions. Total metal concentrations were measured in acidified (pH < 2), unfiltered and UV irradiated samples, while dissolved metal and DOC concentrations were obtained from filtered (0.45 µm) samples. Additionally, temperature, salinity, pH and dissolved oxygen concentration were determined directly in water column of anchialine cave. Salinity increased with depth in the range from 3 ‰ at the surface to 38 ‰ in bottom water layer, showing water column stratification.

Results and discussion

Metals concentrations throughout entire water column of Bjejajka anchialine cave were significantly higher compared to metals amount found in seawater samples taken in near vicinity (about 100 m). Total metal concentrations in cave's water column were found as follows: Pb from 0.05 to $1.4 \,\mu g \, L^{-1}$, Cu from 0.73 to 4.82 μ g L¹ and Zn from 0.74 to 3.05 μ g L¹. Moreover, cadmium concentrations in water column of Bjejajka cave were greatly elevated compared to Cd amounts found in surface seawater. In January 2009, substantial concentrations of total Cd were found in bottom water layer (300 ng L⁻¹) and in surface layer 45 ng L⁻¹ in Bjejajka cave water column. However, in surface seawater samples collected in the vicinity of the Bjejajka cave, quite low total concentrations were measured, i.e. 7 ng L⁻¹ Cd, 30 ng L⁻¹ Pb, 200 ng L⁻¹ Cu and 200 ng L⁻¹ Zn. Bjejajka cave was developed in Mesozoic dolomites with limestone lenses. It has been demonstrated that dolomitic rocks can contain elevated concentrations of Zn, Pb, and Cd [1]. Mineral leaching of such lithologies is responsible for the increased Pb, Zn and particularly Cd amounts in waters of Mljet NP [2]. Cd concentrations in anchialine cave water column increase linearly with salinity (Fig. 1A). It implies mineral leaching of dolomitic rocks by seawater entering the cave, hence carrying Cd into the bottom layer of cave's water column. Also, cave's water receives considerable metal amounts by wet deposition and soil weathering. Hence, Cd, Pb and Zn contents have been enhanced in cave's upper water layers during and after rainy periods. Furthermore, a colony of bats inhabits Bjejajka cave. Cadmium concentration in guano of these flying mammals was found to be 1.8 mg kg⁻¹ wet weight. Since the Cd concentration in bat guano has not been reported so far, we compared it with amounts usually reported in Eastern Adriatic Sea coastal sediments that contain significantly lower Cd content (< 0.8 mg kg⁻¹ wet weight) [3]. Apparently, natural process of bat guano leaching also was the source of cadmium elevated concentrations in water column and sediment of Biejajka cave.

DOC content in cave's water column was enhanced (up to 10.5 mg C L⁻¹) compared to seawater (up to 3 mg C L⁻¹) and generally decreases with depth and linearly with increasing salinity (Fig. 1B). It suggests that terrestrial input by soil weathering and bat guano leaching would be the source of elevated

DOC concentrations.

In studied area, without considerable anthropogenic influence, natural processes of mineral leaching, soil weathering and input of terrestrial natural material were likely responsible for significantly elevated trace metals and DOC concentrations in water column of an anchialine cave.

Abstract

Preliminary study of bivalves' soft tissue exposure to trace metals (Cd, Pb, Cu and Zn) from water column in the Mljet NP, was done. Elevated trace metal concentrations in water column and bivalves were observed in semi-enclosed saline lakes. Determined concentrations were most likely from the natural source, taking into account hydrogeological characteristics of the investigated area. *Keywords: Adriatic Sea, Metals, Bivalves*

INTRODUCTION

Mljet NP is part of the Mljet island in Croatian Southern Adriatic with two connected saline lakes as its main water body (Fig. 1). Veliko Jezero (VJ) and Malo Jezero (MJ) lakes were developed in Mesozoic limestones and dolomites, which are semi-enclosed and connected to the open sea by narrow channel. It is very important to highlight that dolomitic rocks can contain elevated concentrations of Zn, Pb and especially Cd [1]. For metals determination composite soft tissue samples of nearly equal bivalves length were prepared, as accumulation of metals is connected with biotic and abiotic factors governed by their size and age [2]. Metals concentrations were measured by differential pulse anodic stripping voltammetry (DPASV).

Fig. 1. Mljet National Park map

RESULTS AND DISCUSSION

Bivalves' samples were taken from Malo jezero lake, Veliko jezero lake and open sea coastal area. Bivalves investigated were: Arca noae. Mytilus galloprovincialis, Modiolus barbatus and Ostrea edulis. There are major differences in the uptake rate of dissolved metals among different species of bivalves [3]. E.g. scallops and oysters have the highest uptake rate constants for different metals as result of their high pumping rates. Within Malo Jezero lake underwater karstic spring (freshwater efflux by dolomite rocks leaching and soil weathering, showed high metal concentrations) is located. Karstic spring input raised metal concentrations in waters of the National park water body [4]. Therefore, metal concentrations (Zn, Pb and especially Cd) in the water column and in bivalves, were over expected values. Most interesting were Cd concentrations in tissues of Modiolus barbatus and Ostrea edulis that were over 1 mg/kg wet weight in all investigated Mljet water bodies (MJ and VJ) (Table 1). Considering the National bylaw on toxins, metals, metaloids and other harmfull substances in food, maximum allowed values of Cd in the tissue of shellfish is 1 mg/kg, while in Ostrea edulis 1.68±0.09 mg/kg in MJ and 0.37±0.03 mg/kg in VJ, were found. In Mytilus gal. and Arca noae were below 1 mg/kg due to different metabolism of these bivalves [3]. Cd dissolved concentrations in the Mljet NP lakes were enhanced due to input of its considerable amounts through the karstic spring and dissolved cadmium concentrations in Mljet NP water body were: MJ (near karstic spring) 18.7 \pm 1.4 ng L⁻¹, in VJ 12.0 \pm 0.6 ng L⁻¹ and in the open Adriatic sea 6.4 \pm 0.9 ng L⁻¹. All metal concentrations in bivalves were given as mass in wet weight. Zn, Pb and Cu concentrations in composite bivalve soft tissue samples are shown in Table 1. As an example, metals concentrationsin Ostrea edulis were found to be: Zn 1322 \pm 39 mg/kg in MJ and 251.3 \pm 8.8 mg/kg in VJ; Cu 34 \pm 1.26 mg/kg in MJ and 26.41 \pm 3.01 mg/kg in VJ; Pb 0.22 \pm 0.04 mg/kg in MJ and 0.10 \pm 0.01 mg/kg in VJ (all mass concentrations are in wet weight). In the water column of all Mljet NP water bodies concentrations of these metals were enhanced, especially after heavy rainfalls. The lack of anthropogenic influence on the lakes metal concentrations, suggested natural sourcing of these elements into the lakes. It should be taken into account that Cd is present in the water column mostly in dissolved form, appropriate for accumulation in bivalves. Zinc and copper were partly adsorbed onto particles but still in significant amount as dissolved and available for accumulation by bivalves. Pb is adsorbed the most onto particles and its concentration in bivalves' soft tissue was lowest.

This study showed, unequivocally, the suitability of bivalves as metal biomonitors, as metal concentrations are not necessarily elevated due to anthropogenic activities. Unexpectedly high metal concentrations (cadmium the most) in the water column and bivalves originated from dolomite rocks and was brought to waters by leaching and soil weathering during rainfalls. Enhanced cadmium level in bivalves over allowed concentrations regulated by national bylaw on harmful substances in food, was determined to originate from natural source, dolomite rocks leaching, in the first place.

Abstract

A preliminary study of distribution of total trace metal concentrations (Cd, Pb, Cu and Zn) and physico-chemical parameters (water temperature, pH, dissolved oxygen (DO), dissolved organic carbon (DOC) redox and salinity) in water column of anchialine cave Orljak in the well stratified Krka River estuary (Croatia) has been performed. Metal amounts and physico-chemical parameters in cave water column were compared with related column in Krka River estuary. *Keywords: Estuaries, Metals, Adriatic Sea, Organic Matter*

Study area & methodology

Recently anchialine objects as a very unusual aquatic environments became target of interdisciplinary research [1,2]. The Orljak cave is unique anchialine cave at Eastern Adriatic coast because of its connection with brackish water. Anchialine cave Orljak is located in Cretaceous limestone with macro fossils 50 m from coast in lower part of the Krka River estuary. Cave is 23 m deep and 90 m long with two water bodies (2 and 7 m) probably well hydraulically connected with estuary water (tides are notable).

Fig. 1. Location of anchialine cave Orljak.

Physico-chemical parameters (water temperature, pH, dissolved oxygen, redox potential and salinity) were measured in situ by Hydrolab MiniSonde 4a equipped with the following sensor: pressure (depth), T, conductivity/salinity, pH (with Ag/AgCl/KCl sat as reference), Eh (Pt xire with the same ref as pH), O2 (by amperometric measurement). Samples for DOC and trace metal analyses (Cd, Pb, Cu and Zn) were taken by scuba divers, respecting a principle of a "clean sampling technique" in summer 2009. Concentrations of DOC were determined using a TOC-V analyser (Shimadzu), calibrated using sodium hydrogenophtalate standard solutions, with an accuracy of 0.8 μ MC. Total trace metal concentrations were measured in unfiltered, acidified (pH < 2) and UV irradiated water samples (24 h, 150W mercury lamp, Hanau, Germany). Determination of Cu, Cd, Pb and Zn concentration were performed by differential pulse anodic stripping voltammetry (DPASV) using static mercury electrode (663 VA STAND, Metrohm, Switzerland) connected to μ AUTOLAB potentiostat (EcoChemie, Utrecht, The Netherlands).

Results and discussion

Values of physico-chemical parameters (water temperature, pH, dissolved oxygen (DO), from anchialine cave Orljak and the Krka River estuary are graphically presented in Figure 1 A and Figure 2 B, respectively. Total metal concentrations and dissolved organic carbon (DOC) from cave and estuary are graphically presented in Figure 1 C and Figure 1 D, respectively. Quite low and constant DOC concentrations along the cave water column profile reflect

absence of autochthones DOC productivity by phytoplankton, as well as neglected anthropogenic influence (Fig. 2A). Total metal concentrations of zinc, cadmium and lead in anchialine cave's water were higher comparing to concentrations in estuary waters, while total copper concentrations were higher in estuary waters due intensive boat traffic [3].

Fig. 2. Vertical profiles of temperature, pH, salinity, redox, dissolved oxygen (DO), dissolved organic carbon (DOC) and total concentrations of Zn, Cd, Pb and Cu in Orljak Cave and Krka River estuary.

Abstract

Concentrations of Cd, Co, Cu, Fe, Ni, Pb and Zn were determined in marine algae. Certain macroalgae species were chosen among the green, brown and red algae species at Sinop stations in the Turkish coast of the Black Sea in 2009. The concentrations of the heavy metals Co, Cu and Zn in the present study are higher, but Fe, Ni and Pb are lower when compared with previous study in the same region.

Keywords: Algae, Black Sea, Metals

INTRODUCTION

Sinop is located at the outermost point on the Turkish coast line of the Black Sea. The fishing potential of this region is important for production of fish meal and oil from fresh anchovy fish. The Black Sea has been subject to very high levels of pollution due to industrial activity, municipal wastewaters, agricultural chemicals, oil pollution and airborne particles. The macroalgae species are usually used to indicate heavy metal levels in both estuarine and coastal waters throughout the world. In benthic food webs, macroalgae are key links and they act as time-integrators of pollutants [1]. Sinop is the main station where our investigation on the heavy metal pollution of marine algae have been carried out since 1986, because it is route on the anchovy fish migration [2]. Some papers have been published concerning heavy metal concentrations measured in macroalgae species collected from the Sinop region [3],[4],[5],[6].

MATERIALS AND METHODS

The aim of this study is: (1) to determine the concentration of Cd, Co, Cu, Fe, Ni, Pb and Zn in macroalgae samples collected from different stations of the Sinop region during 2009 and (2) to compare the present results with the similar studies have been carried out in the same region of the Black Sea. 6 sampling stations of macroalgae were establised in Sinop region (Akliman, Pazaryeri, Karakum, Ormankampi, Yaykil, Gerze). The marine algae species were Enteromorpha intestinalis, Enteromorpha linza, Ulva lactuca, Cladophora serices (green algae), Cystoseira barbata (brown algae) and Gelidium crinale, Ceramium rubrum, Corralina officinalis, Coralina ssp. (red algae). About 500 g of the fresh weight were harvested at low tide. The samples were rinsed to remove sand and epiphytal materials (1) in the sea water and (2) then with top water and (3) distilled water. They then were dried at 85 °C and homogenized. All procedure of the method was similar to that previously described [5]. The concentration of the heavy metals were determined by ICP-MS.

RESULTS

The heavy metal concentrations in marine algae are shown in Table 1. Errors will be calculated from counting statistics. The highest uptake in macroalgae species at the sampling sites were as follows: Cu and Ni in G. crinale, Fe and Pb in E. intestinalis, Zn in C. sericea and Co in U. lactuaca. The heavy metals accumulated in different algal taxa were: in green algae, Fe, Pb and Zn; in brown algae Co; in red algae Cu and Ni. The Cd concentrations in tested macro algae samples were found to be below the lower limit detection (<0.01). The highest amounts of heavy metals in macro algae samples were found as: Co and Pb in Akliman; Cu and Ni in Yaykil and Fe and Zn in Karakum.

CONCLUSION

In previous study, the heavy metal levels were investigated in C. barbata and E .linza collected from the Sinop during the period of 1998-2000 [6]. Our results showed that Co. Cu and Zn concentrations are higher, but Fe. Ni and Pb levels are lower than in the same macroalgae species collected from the Sinop in 2000. A comparison of the present results with data reported for similar macroalgae species from other Turkish marine environment, suggest that the heavy metal levels are not higher in the Sinop region than Bosphorus and Marmara Sea macroalgae.

EVALUATION DU TRANSFERT DU CADMIUM LE LONG DE LA CHAINE TROPHIQUE DANS LA REGION DE SKHIRA (GOLFE DE GABES)

Lamia Dammak¹, Asma Hamza¹, Abderrahmen Bouain² and Ines Hamdi²* ¹Institut National des Sciences et Technologie de la Mer, 3018, Sfax, Tunisie

² Faculté des Sciences de Sfax, 3018, Tunisie - ineshhamdi@yahoo.fr

Abstract

Cette étude porte sur le transfert du Cadmium dans la chaîne trophique, dans la région de Skhira. Il s'agit d'une zone qui est soumise essentiellement au rejet des eaux de refroidissement de la chaîne de traitement des phosphates et du terminal pétrolier Trapsa. Le suivi semestriel de ce métal dans différents organismes récoltés dans la zone a permis de mettre en évidence deux types de transfert : du sédiment vers les phanérogames et du sédiment vers la palourde. Le gradient automne - printemps a été défini. *Keywords: Cadmium, Posidonia, Gulf Of Gabes*

Introduction

Ce travail porte sur des chantillonnages semestriels dans la région de Skhira aux abords de l'usine de transformation des phosphates, le port de pêche de Zaboussa et le terminal pétrolier de TRAPSA. Nous avons essayé de déterminer l'accumulation du cadmium dans différents organismes récoltés dans la région afin d'évaluer le transfert le long de la chaîne trophique.

Matériel et Méthodes

La zone Skhira est située à la partie Sud-est de la région de Sfax, elle fait également partie du golfe de Gabès, Sud de la Tunisie. L'échantillonnage (automne et printemps) a ciblé le sédiment, des phanérogames, le bivalve *Ruditapes decussatus* et le sparaillon *Diplodus annularis*. L'analyse a été effectuée sur les espèces *in toto* séchées et broyées. Après minéralisation en utilisant l'acide perchlorique, l'acide chlorhydrique et l'acide nitrique, le dosage du cadmium a été effectué au moyen de la torche à plasma (JY2000).

Résultats et discussions

L'évolution de la concentration moyenne du Cadmium le long de la chaîne trophique est illustrée dans la figure 1.

Fig. 1. Evolution de la concentration du Cd dans les organismes de la chaîne trophique, exprimée en $\mu g/g$ du poids sec, affectée des intervalles de confiance (95%)

L'examen des concentrations en Cd montre une différence dans l'accumulation entre les compartiments en fonction des saisons.

Les valeurs enregistrées dans le sédiment ne dépassent pas 1 µg/g pendant les deux saisons, elles sont par conséquent inférieures à la norme présentée par la Commission Européenne (CE) [1]. Concernant les phanérogames, le Cd s'accumule plus chez la posidonie que chez la Cymodocée. La posidonie concentre plus le Cd au printemps résultant certainement de sa grande masse foliaire. En effet, ce métal se concentre plus dans les parties épigées (faisceaux foliaires) [2]. La posidonie pourrait être un bon indicateur de la pollution dans la zone. Nous remarquons que les concentrations du Cd entre les sédiments et la posidonie [2] (atteignant un maximum de $14.37 \pm 1.44 \mu g/g$ poids/sec en Corse), nos valeurs sont assez faibles et cette zone est modérément contaminée. Le gradient croissant automne printemps est justifié par le développement des feuilles et l'accumulation de ce métal à ce niveau. Chez *Ruditapes decussatus*, la valeur maximale mesurée ne dépasse pas les normes fixées par la CE. Cette variation peut être due à l'effet saison, fait d'ailleurs mis en évidence par

plusieurs travaux et particulièrement dans le golfe d'Annaba par Solttani et *al.* [3]. En comparant ces valeurs avec celles de la littérature, nous remarquons qu'elles suivent les mêmes intervalles de variation que celles du golfe de Gabès [4]. Le dosage du Cd chez le Sparaillon est $<0.2\mu g/g$ pour les deux saisons.

ORGANIC MATTER IN THE KOTOR BAY, SOUTH ADRIATIC SEA

Jelena Dautovic ¹*, Vjerocka Vojvodic ¹ and Bozena Cosovic ¹ ¹ Rudjer Boskovic Institute - jdautov@irb.hr

Abstract

Dissolved organic carbon (DOC), particulate organic carbon (POC) and surface active substances (SAS; NF – nonfiltered, dissolved and particulate, F - filtered, dissolved) were studied seasonally from April 2008 to March 2009 at three locations in the Kotor Bay, Montenegro. Concentrations of reactive part of organic matter displaying surface active properties were compared to the related DOC and POC contents. Temporal distributions are presented in the surface and the bottom layer. <u>Keywords: Organic Matter, Adriatic Sea</u>

	surface	bottom
Salinity	7.5 - 25.9	35.7 - 36.9
Temperature (°C)	11.40 - 27.30	12.93 - 18.53
SAS NF (mg/L)	0.069 - 0.219	0.055 - 0.098
SAS F (mg/L)	0.088 - 0.196	0.045 - 0.091
DOC (mg/L)	0.685 - 1.172	0.842 - 0.971
POC (mg/L)	0.187 - 0.541	0.048 - 0.127

Tab. 1. Ranges of average values obtained for different parameters

Introduction

Boka Kotorska is one of the best indented parts of the south Adriatic Sea. It is characterised by considerable precipitation quantities and is considered among the rainiest parts of Europe. Coastal Dinaric classical karst of Montenego is characterised by high degree of karstification and tectonic rupture of carbonate rocks and of flysh barriers [2] which swallow huge quantities of freshwater creating a permanent freshwater inflow to the bay leading to an increase in biological activity (phytoplankton blooms) and, hence, in organic matter content.

Methods

For determination and characterization of organic matter electrochemical method a.c. voltammetry with a nonionic model T-X-100 as a standard was used. DOC and POC analysis were done by high temperature catalytic oxidation (HTCO) method. Emphasis is given to the results obtained for surface and bottom samples since great differences are observed among them – bottom layer is monotonous and less variable in all studied parameters (Table 1).

Results

Permanent nutrient inflow and low salinity (permanent freshwater input) lead to an increase in biological activity (phytoplankton bloom) during 04/2008 confirmed by the highest average SAS NF value indicating presence of fresh, surface reactive organic material in the surface layer (Fig. 1a). With time, fresh organic material SAS NF is transferred in the dissolved fraction accompanied with an increase in average DOC concentration (Fig. 1b). In 07/2008 new surface active material is visible, indicating another increase in biological activity (Fig. 1a). DOC concentration reaches it's maximum average value in the summer period (Fig 1b). During autumn and winter average SAS and DOC concentrations continue to decrease (Fig. 1a, 1b). Average POC values increase from April to May reaching a maximum value, and then decrease slowly toward winter followed by an increase again in 03/2009 (Fig 1c). Interestingly, bottom average DOC values are higher than surface average DOC values in the spring (04/2008, 05/2008, 03/2009).

Fig. 1. Seasonal variations of average SAS NF, SAS F (a), DOC (b) and POC (c) in the surface and the bottom layer

Abstract

Evidences of the impact of desert dust deposition on the biogeochemistry of surface marine waters call for atmospheric dust transport models to provide deposition fluxes. Dust deposition observations are critically needed to constrain the models. Here we show a compilation of (i) past results on dust deposition in the western Mediterranean, (ii) new measurements from Corsica obtained in the framework of the project DUNE, and (iii) CHIMERE-Dust model results, compared with 1-yr measurements from the project ADIOS. We finally advertise for a new deposition monitoring network and model validation effort in the framework of the project ChArMEx.

Keywords: Atmospheric Input, Western Mediterranean

Results on total dust deposition (eventually based on Al used as a tracer based on an average content of 7.1 to 8.2%) in the western Mediterranean are relatively scarce in the literature. They are widely dispersed in space and time, spanning from October 1982 to May 2002 at various sites from Campo de Gibraltar in southern Spain to the French Riviera, including island sites in Sardinia and Corsica. Yearly deposition fluxes range from about 2 to 26 g m⁻². Since late March 2008 a new monitoring station has been operated with a weekly sampling time step at Galeria (42.44° N; 8.65°E) on the western coast of Corsica in the framework of the project DUNE (a Dust Experiment in a Low-Nutrient Low-Chlorophyll Ecosystem). Figure 1 illustrates that no event larger than 0.45 g m⁻² was recorded in one year so that the yearly flux is among the lowest ever observed in Corsica (2.9 g m⁻²).

Fig. 1. Weekly dust deposition flux (horizontal dashes) based on an average Al content of 8.1% in soil dust, and rainfall (vertical bars) at Galeria, Corsica.

A 12-yr time continuous record obtained in Corsica[1] shows that interannual variability is high and precludes integrating non coincident data from various stations for studying spatial trends. During the ADIOS programme a few deposition sampling stations were operated simultaneously on a monthly basis from June 2001 to July 2002. Results show a factor of 4 range in yearly dust deposition fluxes, with the lowest values near Gibraltar and the highest in Corsica [2] not only reflecting the precipitation distribution.

Preliminary simulations of African dust deposition with the transport model CHIMERE-Dust[3] are compared with ADIOS observations and indicate that deposition data are necessary to constrain the dust transport budget in addition to optical depth observations. To better constrain the spatial variability of dust deposition fluxes, in the framework of the project ChArMEx (the Chemistry-Aerosol Mediterranean Experiment; http://charmex.lsce.ipsl.fr), we shall set up from late 2010 a new monitoring network of 10 stations in the western Mediterranean (Figure 2) to be operated for a 3-yr period with a 2-wk time step based on a new autonomous sampler under development. We propose that the network is completed in the western basin and enlarged to the eastern basin thanks to international collaborations.

Fig. 2. Future network of total insoluble deposition measurement. Master sites on islands will include soluble and insoluble deposition fluxes of Fe, P, N, Si and C, and total flux of Hg.

DISTRIBUTION MÉTALLIQUE DANS LES EAUX ET LES SÉDIMENTS DU LITTORAL DE LA BAIE DE TANGER. RIF NORD OCCIDENTAL MAROC

A. El Arrim¹*, A. Raissouni¹, M. Wahbi¹, M. Maatouk¹, A. Afailal Tribak¹ and B. El Moumni² ¹ Faculté des Sciences et Techniques (FST) Tanger. Univ. Abdelmalek Essaidi - elarrimk@yahoo.fr ² Faculté Polydesciplinaire de Laarache

Abstract

La pression urbaine et la poussée industrielle sur le littoral de la baie de Tanger a conduit à l'augmentation de la pollution anthropique des eaux marines. L'évaluation de la pollution des eaux dans la baie de Tanger a été appréciée à travers cette étude qui porte sur l'analyse des eaux de surface et des sédiments superficiels. L'analyse a concerné essentiellement les éléments métalliques. Les résultats démontrent une pollution domestique et industrielle assez inquiétante. *Keywords: Sediments, Pollution*

Introduction

Ce travail porte, pour la première fois, sur l'étude des éléments métalliques dans les eaux de surface du littoral de la baie de Tanger et l'évaluation de l'état de contamination du milieu par les polluants métalliques. Il constitute également un complément important aux études sédimentologiques, minéralogiques et géochimiques effectuées sur le littoral de la baie de Tanger et les principaux oueds qui y débouchent.[1]. La baie de Tanger se situe au NW du Maroc, sur la rive sud du détroit de Gibraltar, entre 35°46' et 35°48' de latitude Nord, 5°45'20" et 5°49'00" de longitude Ouest.[2].

Méthodologie

L'étude a concerné l'analyse des eaux de surface et les sédiments superficiels de la baie de Tanger. Des prélèvements ont également été réalisés dans les principaux oueds drainant l'arrière-pays de la baie de Tanger : O. Mghogha, O. Souani, O. Mlaleh et O. Chatt ainsi qu'au niveau de la canalisation majeure des eaux usées : O. Lihoud et Rejet Port. L'analyse des eaux a porté sur la détermination des paramètres physico-chimiques (T°, pH, Conductivité, Oxygène dissous, saturation en Oxygène, MES), sur le dosage des éléments métalliques (Cd, Cu, Fe, Mn, Ni, Pb, Zn) et sur le dosage des éléments nutritifs (P, S, NO₃, NH₄).

Résultats et discussion

Les concentrations des éléments métalliques, (en ppb), enregistrées dans les eaux de surface de la baie de Tanger : Cd (2.3-2.6), Cu (71.3-74.3), Pb (99-105), Zn (3.5-22), Fe (16-40.3), Mn (0,11-3,01), Ni (4-18,7) sont en général élevées en comparaison à celles mesurées dans d'autres secteurs périméditerranéens similaires. Les teneurs moyennes sont plus faibles que celles enregistrées dans les oueds débouchant dans la baie. Les movennes des teneurs en éléments métalliques dans les sédiments superficiels de la baie de Tanger sont plus faibles que celles des oueds : Pb (99-105 µg/g), Zn (3.5-22 µg/g), Cu (71.3-74.3µg/g), Ĉr (67,8 µg/g), Ni (4-18,7µg/g), Mn (0,11-3,01 µg/g) Fe (16-40.3 µg/g) Cd (2.3-2.6 µg/g). Ces valeurs avoisinent et dépassent parfois celles trouvées dans d'autres secteurs méditerranéens, les valeurs maximales coïncidant avec des teneurs élevées de la fraction fine (<40 um) et en matière organique. Les faibles concentrations se trouvent dans le secteur Est de la baie, ou prédominent des sédiments sableux. Ces résultats indiquent une évolution décroissante des concentrations en métaux de l'ouest vers l'est et de la côte vers le large de la baie, subdivisant ainsi le milieu étudié en deux secteurs bien différenciés, le premier à l'est, soumis à l'action des houles NE dominantes et le deuxième, à faible régime hydrodynamique, bien protégé par les aménagements portuaires des courants engendrés par les houles du secteur NW. La distribution spatiale de ces teneurs en métaux lourds dans les eaux et les sédiments de la baie de Tanger se localisent dans le secteur ouest à proximité des principales embouchures des oueds (Souani et Mghogha) et du port de la baie. Les fortes variations des teneurs en métaux témoignent de l'existence de plusieurs sources de pollution.[3]et [4]. Conclusion

La concentration de ces éléments semble être liée :

- aux rejets des affluents domestiques et industriels (produits toxiques, détergents, métaux lourd...) qui arrivent directement dans la baie par les oueds (Souani et Mghogha) ;

à la dispersion du panache ; sortie du rejet, situé à 500 m au nord-ouest de la jetée principale du port, véhiculant une partie des apports et des eaux usées du rejet vers la baie par l'action combinée du transit littoral NW et NE ;
à l'activité portuaire (rejets d'hydrocarbures, produits chimiques,....).

Abstract

Les concentrations en hydrocarbures aromatiques et non aromatiques ont été déterminées au niveau de la matière particulaire des eaux de surface de la baie de Tanger. Les hydrocarbures totaux ont été extraits et fractionnés sur colonne de silice en hydrocarbures aromatiques et non aromatiques. Ces dernières analysées par des techniques chromatographiques, montrent des concentrations relativement importantes (HNA: 36-276 µg/l; HA: 49-133 µg/l). L'étude qualitative a permis de mettre l'accent sur la nature pétrogénique des apports avec une faible présence de la trace des apports biogènes liés aux plantes supérieures. *Keywords: Coastal Waters, Particulates, Pollution, Western Mediterranean, Geochemistry*

Introduction

La Méditerranée marocaine est une zone d'intérêt économique par excellence pour le Maroc. Elle est sous l'influence des évacuations industrielles et urbaines émanant des villes côtières. La situation est dangereuse étant donné le trafic commercial important. Plusieurs millions de tonnes d'hydrocarbures transitent par le détroit de Gibraltar chaque année. A cela, s'ajoute l'effet des événements en mer dont le nombre est d'environ 60 par an, d'où l'intérêt de mettre l'accent sur le bilan de la pollution des côtes marocaines par les hydrocarbures et notamment au niveau des sites potentiels de gisement halieutiques et des sites d'attraction touristique. Les eaux de la baie de Tanger, située à l'entrée de la Méditerrané, sont sujettes à toutes ces agressions, faisant ici l'objet de l'évaluation de la contamination par les hydrocarbures.

Matériels et méthodes

Huit échantillons d'eau ont été prélevés à la surface de la baie de Tanger en quantité de 10 litres et filtrés sur un filtre GF/F de 15 cm de diamètre et de $0,7\mu$ m de porosité. les filtres ont subit ensuite une extraction effectuée selon le protocole de Bligh and Dyer [1] modifié, où le chloroforme est remplacé par le dichlorométhane. L'extrait a été ensuite fractionné sur une colonne de silice en hydrocarbures non aromatiques (HNA) et hydrocarbures aromatiques (HA). Ces deux dernières ont été analysées par chromatographie en phase gazeuse (CG-FID) et chromatographie couplée (CG/SM). La quantification est obtenue à l'aide des standards internes deutérés.

Résultats et discussions

Les hydrocarbures non aromatiques montrent des concentrations qui varient de 36,3 ±0,4µg/l à 276,47±0,5µg/l. Ces valeurs restent élevées en comparaison avec d'autres endroits en Méditerranée [2,3]. Les hydrocarbures aromatiques montrent également des concentrations de 49,74 ±0,6µg/l à 133,62 ±0,4µg/l. L'observation de la distribution spatiale de ces concentrations révèle une étroite liaison entre les niveaux de concentration et la proximité aux sources de pollution (port et embouchure des rejets urbains) d'une part et d'autre part avec les mouvements des masses d'eau à l'intérieur de la baie. Les chromatogrammes des HNA (figure 1) montrent une distribution uni-modale centré sur n-C29 - n-C31. Certains échantillons montrent une légère prédominance des composés impairs n-C27 - n-C29 - n-C31 relatifs à une origine terrestre dérivant des cires des plantes supérieures [4]. Dans l'ensemble, les n-alcanes ne montrent aucune prédominance entre composés pairs et impairs, ce qui est généralement traduit par l'indice d'imparité CPI (Carbon Preference Index) au voisinage de l'unité. Ces valeurs avec la présence des doublets n-C17 pristane et n-C18 phytane et de l'UCM (Unresolved Complex Mixture) dans la majorité des chromatogrammes, mettent en évidence la contribution d'une source anthropique pétrolière. Cette dernière a été confirmée par la présence des composés hopanes en série C27-C35 ayant la configuration 17 $(H),\,21\beta$ (H) caractéristiques d'une contamination pétrolière [5,6].

Fig. 1. Chromatogrammes de la fraction "hydrocarbures non aromatiques" obtenus par CG/DIF pour un échantillon d'eau de la baie de Tanger

Les hydrocarbures aromatiques montrent un mélange de composés possédant des groupements phényle traduisant ainsi les traces d'une activité industrielle de teinture, de plastique etc.

RELATIONSHIP BETWEEN THE DISTRIBUTION OF ORGANIC MATTER AND NUTRIENTS IN THE NORTHEAST MEDITERRANEAN (MERSIN BAY)

Emine Erdogan ¹, Özden Bastürk ¹, Süleyman Tugrul ² and Fatih Sert ²* ¹ Mersin University, Faculty of Fisheries

² Middle East Technical University, Institue of Marine Sciences - fsert@ims.metu.edu.tr

Abstract

In the present study, 6 field studies were performed in the Mersin Bay during September 2008 – August 2009. Nitrate (NO₃+NO₂) concentrations varied between 3.6-10.8 μ M in the river-fed nearshore waters, whereas phosphate (o-PO4) ranged merely between 0.02-0.14 μ M, exhibiting higher N/P ratio (35-50) in the nearshore zone. Surface distributions of total phosphorus (TP), chlorophyll-a (CHL) and particulate organic matter (POC, PON, PP) displayed similar spatial patterens in the productive shelf waters. TP and CHL contents of the polluted nearshore waters were 0.43 μ M and 2.0 μ g/L, respectively,as the offshore values were as low as 0.02 μ M for TP and 0.02 μ g/L for CHL. Particulate-P ranged between 0.01-0.41 μ M in the bay waters. *Keywords: Nutrients, Organic Matter, Particulates*

Introduction

The Eastern Mediterranean is a typical example for the oligotrophic water masses of the world ocean system [1-3]. However, Cilician shelf zone of the northeastern Mediterranean have been polluted by discharges of the major rivers (Seyhan, Ceyhan) and domestic wastewaters of the Mersin and Iskenderun cities. In recent decades, eutrophication phenomena have increased in the riverfed shallow zone of Mersin Bay. This study aims to assess eutrophication and water quality of the Mersin bay, covering the region extending from Mersin city coastal zone up to the east of Seyhan river mouth (Fig. 1).

Results

Six field surveys were conducted by R/V BILIM during the September, 2008-August, 2009 period within the framework of the (TÜBITAK-106G66) project. Hydrographic data were obtained by a CTD probe coupled to a 12-bottle Rozette system. Chemical results were obtained by the conventional methods [1-3]. Concentrations of nutrients, organic matter (POM) biomass (CHL-a) were markedly high in the shallow nearshore zone during the year; light transparency was very low, due to large river discharges and limited ventilation of the nearshore zone by open sea (Fig. 1, 2). POC/PON ratio generally ranged between 7 and 8. Surface nitrate and PO₄ values were as low as 0.1-0.2 and 0.02-0.05 μ M, respectively, in the bay offshore waters, consistent with NE Mediterranean open water values [1-3]. The nitrate/phosphate (N/P) molar ratio increased from levels of 8-15 in offshore waters to 35-50 in the nearshore zone fed by nitrate-replete river discharges. Thus, the N/P ratio is mainly dominated by nitrate changes in the P-depleted surface waters. Surface CHL concentrations, as low as 0.02 µg/L in offshore waters, increased markedly up to 2 µg/L level in the river-fed nearshore waters. Particulate-P values were as high as 0.36-0.40 µM in polluted shallow zone, decreasing to very low levels of 0.01-0.02 µM in offshore waters of the bay.

Abstract

Concentrations of Zn, Fe, Mn and Pb were determined in biota, sediment and sea water samples collected seasonally from two stations in the Marmara Sea in Turkey. The levels of Fe and Mn in biota and Zn, Mn and Pb in sediment samples were higher than the previous studies. The order of heavy metal concentrations in all samples was: Fe > Mn > Zn > Pb. *Keywords: Metals, Bivalves, Sediments, Marmara Sea*

Introduction

Dil Iskelesi is located in the east of the Marmara Sea. Dil stream is one the most polluted streams of Turkey passing through Dilovasi and carries untreated effluent from its basin to the Dil Iskelesi (Izmit Bay-Marmara Sea). Besides the effluents of 34 (total of 171) heavy industrial plants located in the Dilovasi, the wastewaters of more than 400.000 people are discharged to Izmit Bay from Dil Iskelesi region via Dil stream. The objective of this study is to understand the biogeochemical composition of some heavy metals on Dil Iskelesi shore under different seasonal conditions.

Materials and methods

Two sampling stations were chosen on Dil Iskelesi inshore. The first station is located next to a huge metallurgy plant cooling water discharge at a distance of 50 m from the shore. Second station was chosen in front of the Dil stream at a distance of 250 m west from 1st station (Fig. 1).

Fig. 1. Stations at Dil Iskelesi (Izmit Bay-The Marmara Sea)

Ulva lactuca (macro algae), Mytilus galloprovincialis (bivalvia), Paracentrotus lividus (echinoderm), sea water and sediment samples were collected from these stations between summer 2008 and autumn 2009. For metal analysis in biota samples, whole soft parts of *M. galloprovincialis* and soft parts, Aristotle's lantern and shell of *P. lividus* were dissected and washed with bidistilled water. Biota and water samples were analyzed by flame atomic absorption spectrophotometer for Zn, Fe and Mn and by graphite furnace for Pb. The sediment samples were analyzed by ICP-MS. Other procedures of the methods were described previously [1, 2].

Results and Discussion

The maximum heavy metal levels were determined in autumn for both stations except Pb at 1st station in *U. lactuca.* Higher Zn, Mn and Pb levels were found in summer while Fe in autumn at 2nd station in *M. galloprovincialis.* In *P. lividus,* Zn and Pb levels were higher in soft parts while Fe and Mn levels were high in shell in lantern parts, respectively. In sediment samples, the metal levels in summer season were higher for all metals. All metal levels in the sediment samples were higher than those in biota samples. In the sea water samples metal levels close to each other. However Fe levels were higher in autumn while Mn in summer (Table 1). Among the biota samples, higher Zn and Pb levels were found in mussel while Fe and Mn in algae samples. While Zn levels were higher at 2nd station, Mn levels at 1st station both algae and sea water samples in summer and autumn seasons. Pb and Fe levels were higher at 1st station in summer and 2nd station in autumn season.

Compared with the literature data, our results in biota and sediment are

generally at the same level or higher than the other Marmara Sea studies [1, 3, 4]. The Fe and Mn levels in the present study are clearly higher than the biota samples collected from the different locations of the Marmara Sea. On the other hand, Pb levels in biota samples in the present study are slightly lower than those given in previous results. Zn, Mn and Pb levels in the sediment samples are higher than the levels observed in other Marmara Sea locations except for Mn in the Gulf of Gemlik. The Fe levels in the sediment samples are lower than those in Erdek Bay of the Marmara Sea [4]. Acknowledgements This study was funded by TÜBITAK (Grant No: 107Y261) and Kocaeli University (Grant No: 2008/017)

THE EFFECT OF WEIGHT AND CONDITION INDEX IN MUSSEL ON HEAVY METAL CONCENTRATIONS IN IZMIT BAY

Halim Ergül 1* and Betül Çayir 1

¹ Kocaeli University Science and Art Faculty Department of Biology, Kocaeli, Turkey - halim.ergul@kocaeli.edu.tr

Abstract

The body weight and condition index (*CI*) effect on concentrations of Pb, Zn, Mn and Fe were investigated in Mytilus galloprovincialis soft tissue at two different locations in the Izmit Bay. A negative correlation between soft tissue dry weight and metal concentrations was clear in Mn and Fe. On the other hand, Zn and Pb levels decreased with increasing *CI* value. *Keywords: Metals, Bivalves, Marmara Sea*

Introduction

It is well known that mussels are good bioindicators for heavy metals. Several internal (e.g. body size, body weight, shell size, age, filtering capacity) and external factors (e.g. waves, tidal exposure, salinity, temperature) effect the metal accumulation in mussel tissues. Literature data shows a relation between body size and metal accumulation in mussel soft tissue [1]. In general metal accumulation is negatively correlated with body size but some studies reported that metal concentrations in molluscs can be independent of body size [2]. The objective of this study is to evaluate the some metal concentrations in different sizes of *Mytilus galloprovincialis* soft tissues at the two different locations from Izmit Bay (The Marmara Sea) (Fig. 1).

Fig. 1. Station locations in Izmit Bay (The Marmara Sea).

Material and Methods

The mussels were collected on April 2009 from the coast line 100-200 m lengths from Vinsan, a stagnant area under the effect of untreated wastewater and from Hersek, a waving area located next to shipyards in the Izmit Bay (The Marmara Sea). At least 30 individual mussels in 5 different size (3, 4, 5, 6, 7cm \pm 2mm) were measured with Wernier calipers with 0,1 mm sensitivity, dissected, dried and weighed same as the shells. Condition index (CI) was calculated by dry tissue and dry shell weight. For metal analyses whole soft parts were analyzed by flame atomic absorption used for Zn, Fe and Mn and graphite furnace for Pb. Detailed method is described previously [3]. Power function was used for plotting graphics for the effect of body size on metal concentrations.

Results and Discussions

Pb, Mn and Fe levels were higher in Vinsan while Zn in Hersek station. A negative correlation between soft tissue dry weight and metal concentrations was clear in Mn and Fe at both stations, and for Pb at Hersek station. On the other hand, contrary to general literature, Zn levels increased with increasing body weights, same as Pb in Vinsan station. However comparison between condition index and metal levels for Zn and Pb showed that metal concentrations were inversely related to the condition index. A previous study has reported that for metals, tissue concentration is inversely proportional to the condition index [4]. For this reason correlation graphics were plotted CI versus concentrations for Zn and Pb and dry weight versus concentrations for Mn and Fe (Fig. 2). In general metal concentrations were higher than those observed in other locations of the Marmara Sea [3]. These results represent the first CI and metal concentration data from the region in the framework of a monitoring project in the Izmit Bay. Further researches are necessary to understand the relationship between metal accumulation and body size of mussels more clearly in the region.

PAH/PCB CONCENTRATIONS IN MUSSELS (MYTILUS GALLOPROVINCIALIS) FROM IZMIT BAY

H. Ergül¹, B. Pekey²*, A. Karademir², B. Telli¹, M. Terzi¹ and Ü. Ay³

¹ Kocaeli University Science and Art Faculty Department of Biology, Kocaeli, Turkey

² Kocaeli University Engineering Faculty Department of Environmental Engineering - bpekey@kocaeli.edu.tr

³ Kocaeli University Science and Art Faculty Department of Chemistry

Abstract

PAH and PCB concentrations were determined in mussel samples collected from Izmit Bay at the east of marmara Sea. The samples were taken from ten points in spring season and analyzed by gas chromatography after ultrasonic extraction. Total PAH concentrations varied between 2.5-13.9 ng.g-¹ wet wt., while the total PCB concentrations were between 4.2-140.7 ng.g-¹ wet wt. The results indicates a considerable pollution problem in the bay, especially with respect to PCBs. *Keywords: Pah, Pcb, Bivalves, Marmara Sea*

Introduction

Izmit Bay, located in Northeastern Marmara Sea, has strongly been affected by growing populations and industrialization since 1960s. The study presents the first results of PAH/PCB analyses in the mussel samples in the framework of a pollution monitoring project in Izmit Bay.

Materials and Methods

Mussel samples were taken from ten different points in Izmit Bay in spring season (April 2008). Ultrasonic extraction was used to extract the PAHs and PCBs from the mussels samples. At least 30 mussels were dissected and soft parts selected for analysis. The samples were cleaned up on an alumina–silicic acid column containing 3 g of silicic acid (deactivated with 3% water) and 2 g of alumina (deactivated with 6% water). After treatment with sulfuric acid, the final sample volume was adjusted to 1 ml by nitrogen blow-down. The two fractions containing PAHs and PCBs were analyzed using a Hewlett-Packard 7890 gas chromatograph equipped with an flame ionization detector (for PAHs) and an electron capture detector (for PCBs).

Results and Discussions

Results were summarized in Fig. 1-2.

Fig. 1. Average PAH concentrations in mussels.

Fig. 2. Average PCB concentrations in mussels

Mean mussel shell length were determined 5.26 cm among ten stations. Total PAH concentrations varied between 2.5-13.9 ng.g⁻¹ wet wt., with the average of 8.8 ng.g⁻¹ wet wt. Relatively dominant PAH compounds were found as phenanthrene, benzo(e)pyrene and benzo(ghi)perylene. The mussel PAH levels were generally similar (higher than 7 ng.g⁻¹ wet wt.) for the sampling points, with the exception of two points located on the north side of the Bay (with PAH levels about 2-3 ng.g⁻¹ wet wt.). These results are interesting, because these two points are close to the refinery and other possible PAH sources. This may be attributed to the effect of water circulation patterns in the Bay, as given in a previous study [1]. On the other hand, observed PAH concentrations are in the range of the levels obtained in the mussels from similar polluted water bodies [2].

Total PCB levels, on the other hand, were between 4.2-140.7 ng.g⁻¹ wet wt.,

producing an average of 42.1 ng.g⁻¹ wet w. For PCBs, PCB 90, PCB 153 and PCB 31 were the dominant congeners. The highest PCB levels were observed in the points on north and east side of the Bay, suggesting a clear effect of industrial discharges. Mussel PCB levels were relatively high as compared to other studies conducted in Izmit Bay and Marmara Sea [1, 3].

A general evaluation of total PAH/PCB data from all the stations indicates that the pollution levels are considerably high not only at the points close to possible sources, but also the points away from these sources, possibly due to the effects of oceanographic and meteorological factors.

ASSESSMENT OF THE BIOGEOCHEMICAL PARAMETERS IN NEMRUT BAY AEGEAN SEA

Esin Esen ¹*

¹ Dr. - esinsn@gmail.com

Abstract

The biogeochemical properties of the water column in Nemrut Bay showed that the anthropogenic influence is mostly detected in stations closer to the shoreline. The heavy metal content of the sediment revealed that the contaminant levels for most of the trace elements were heavily polluted throughout the Bay.

Keywords: Metals, Nutrients, Pollution, Coastal Waters, Aegean Sea

Introduction

Aliaga town located 50 km northwest of Izmir Municipality has been subjected to extensive industrial developments. Nemrut Bay, neighboring marine environment of Aliaga town was investigated to provide baseline information about the environmental conditions within the framework of an environmental impact assessment of a proposed Zinc Recovery Plant which aims to recover zinc oxide from waste material produced in the Aliaga Heavy Industrial Zone [1]. Nemrut Bay is a subsystem within the Candarli Bay ecosystem and opens up to the Aegean Sea.

Material and Methods

Field measurements were carried out by RV/K. Piri Reis during 2005. Seawater samples were collected from three depths in 15 stations. Dissolved oxygen was recorded *in situ*. Nutrient and total organic carbon analyses have been carried out according to the methods presented in [2]. Metal measurements were carried out in AAS using flame, graphite furnace and cold vapor techniques. Particulate phosphate (PP) contents were measured by the spectrophotometric method where the particulate organic carbon and particulate organic nitrogen contents were analyzed at CHN analyzer.

Results and Discussions

Nutrients : Dissolved oxygen values for July sampling varied between 6.29-7.20 mg/l that were found to be lower than the values measured for February sampling (7.50-8.28 mg/l). Nitrate and nitrite concentrations of Nemrut Bay were below the typical values determined in coastal waters in both periods (0.09-2.90, 0.01-0.29 μ M respectively). High ammonium and ortho phosphate concentrations were measured in February along coastal stations of the Bay (0.5-9.9, 0.1-4.6 μ M) where the same parameters varied between 0.2-1.6 μ M and 0.03-0.09 μ M, respectively in July. The values of chlorophyll-a varied from 0.07 to0.24 μ g/l in February and between 0.01-0.15 μ g/l in July. The results show similarity to those of the Aegean Sea. In winter season, the deacrease in primary production caused less consumption thus high values of nutrients in February were determined. In summer season, the primary production increased so that the nutrients were depleted.

Heavy Metals : The heavy metal content of the water column have been determined for February and September. Hg, Cd, Pb, Cu, Zn, Mn and Fe concentrations are below the unpolluted seawater levels (0.001-0.018; 0.001-0.0025; 0.8-2.8; 0.27-3.1; 2.1-5.8; 0.5-1.9; 3.3-7.7 μ g/l, respectively). Cr and Ni concentrations ranged 0.69-1.2 μ g/l and 1.1-1.8 μ g/l respectively and determined to be higher than typical seawater levels. The heavy metal content of the sediments in Nemrut Bay have been determined in February. Contamination Factors (CF) calculated for Nemrut Bay indicated that Pb and As had very high contamination levels where there were considerable Zn contamination in most of the sediment samples [3]. Hg concentrations that were measured in this study correspond to very high contamination and should be investigated in further studies (CF ranged 32.3-395 corresponding to a concentration range of 1.70-9.60 mg/kg). The elevated enrichment levels of Pb (2.03-16.06) and Zn (1.08-8.52) indicates anthropogenic pollution.

PAH and Phenols in Surface Water : Polycyclic aromatic hydrocarbon (PAH) and phenol concentrations were measured from surface water samples. The results indicated that there were no PAH and phenol pollution for the sampling area and the sampling period.

Conclusion

The biogeochemical properties of the water column in Nemrut Bay showed that the anthropogenic influence is mostly detected in stations closer to the shoreline.

Abstract

Total Suspended Solid loads (TSS) and associated natural and artificial radionuclides were monitored over the 2001-2008 period at the lower course of the Rhône River thanks to the SORA monitoring station located at Arles. The high frequency monitoring established affords to quantify TSS annual fluxes and TSS fluxes generated by flood events. Besides, the survey allowed registering two uncommonly high loaded events in 2008 partly due to dam management. 9.1 106 tons were thus exported in 2008 whose almost 70% during the two atypical events of may and December. Globally, artificial and natural radionuclide activities display a decreasing trend with rising liquid flow rates making possible to access to geochemical or anthropogenic background values. *Keywords: Radionuclides, Monitoring, Rhone Delta*

As described for many land to sea systems, the Rhône River inputs affect primary production significantly in the north-western Mediterranean area and plays a leading role on the marine ecosystem functioning in the whole Gulf of Lion [1]. The Rhône River also transfers to the Sea various Potentially Contaminating Trace Elements (PCTE) including heavy metals, poly-aromatic hydrocarbon and artificial radionuclides that are largely associated to solid compounds, i.e. particles. Radionuclides inputs from the Rhône River whatever from natural or artificial origin may generate radiotoxicity for man and its environment even though generally awfully low due to the extremely low level of contamination. The inputs of particle reactive radionuclides from the Rhône may be also of a particular interest to determine residence time of sedimentary mass from the coastal to the open sea. In this frame depending on the distance to the source term, i.e. the Rhône mouth, and the velocity of mass transfers, short to long-lived radionuclides may represent useful tools for quantifying sedimentary mass dynamics at various spatial scales. In this frame, Total suspended sediment (TSS) and associated natural and artificial radionuclides were monitored over the 2001-2008 period at the lower course of the Rhône River. Over this period of time high frequency samplings was gradually established for floods $> 3000 \text{ m}^3.\text{s}^{-1}$ as these events were shown to export the main part of the solid load towards the marine environment [2-5]. Our results underline several key points:

a- TSS loads follow a power function relationship with the liquid discharge that does not significantly differ from the relations established for previous period of time. The correlation is highly significant mainly due to the huge number of data Nevertheless, TTS concentrations may range over two to three orders of magnitude for a same liquid flow rate in some cases.

b- From 2001 to 2008 TSS annual fluxes ranged from $0.98 \ 10^6$ tons in 2005 to 9.1 10^6 tons in 2008, with a mean value of 4.7 10^6 tons.

c- Dam management during flood episodes and consecutive excess water and sediment deliveries may conduct to 'semi anthropogenic floods' characterised by moderated liquid discharges but abnormally high TSS concentrations. In 2008, 56% of the solid annual flux was transferred during such an event. The high frequency TSS survey at the lower course of the Rhône made possible to register for a first time such scare unusually heavy loaded floods that may largely supply solid fluxes to the sea.

d- The particulate concentrations of the various studied radionuclides show generally a decreasing trend with rising liquid discharges towards more or less constant values reflecting the geochemical or anthropogenic background levels.

e- 238 Pu and $^{239+240Pu}$ isotopes display a different trend as increasing particulate activities have been registered during rising waters due to the remobilisation of labelled sedimentary storages downstream of the Marcoule spent fuel reprocessing plant. Around 30% to 50 % of $^{239+240}$ Pu and 80% to 90% of 238 Pu transferred by the River downstream during flood events originate from sediment remobilisation, the residual coming from the soil erosion of the watershed.

f- ²³⁸Pu/²³⁹⁺²⁴⁰Pu activity ratio signatures during Rhône River floods may present an important variability (1) over a single flood event since hysteresis loops were observed and (2) between two different events depending on flood types and probably on the flood chronicles.

DIETARY SOURCES DOMINATE METAL UPTAKE IN MARINE FISH

Nicholas Fisher ¹*, Teresa Mathews ¹ and Jessica Dutton ¹

¹ Stony Brook University, Stony Brook, NY USA - nfisher@notes.cc.sunysb.edu

Abstract

The bioaccumulation of 10 metals in five fish species was experimentally evaluated following exposure to dietary or aqueous metal at environmentally realistic metal concentrations. A biokinetic model showed that, with few exceptions, >90% of a fish's metal body burden was obtained from diet. Regulatory bodies need to consider these findings in setting appropriate water quality criteria. Metal uptake from the aqueous phase was influenced by dissolved organic carbon and salinity, but no consistent patterns were evident for all metals.

Keywords: Bio-Accumulation, Fishes, Models, Metals

Like other aquatic animals, fish can acquire contaminants, including potentially toxic metals, from their diet and from the surrounding water [1]. Most water quality criteria for regulatory purposes are based on aqueous concentrations, as are most standard toxicity tests. However, because metals are concentrated in the food that fish eat by hundreds to thousands of times over levels in the ambient water [2], the dietary sources commonly represent especially enriched sources of metals. Here we present results of experimental studies in which diverse fish from coastal and estuarine environments were exposed to metals from both water and from their diet to assess the relative importance of these sources. We quantified uptake rate constants from the dissolved phase for diverse metals and assimilation efficiencies from ingested food, and determined the release rates of metals following different exposure pathways. We then used these kinetic parameters in a metal bioaccumulation model to compare the relative importance of diet and aqueous exposures as sources of metals for fish. We used gamma-emitting radioisotopes to determine the uptake, retention, and tissue distribution of Am, As, Cd, Co, Cs, Hg, monomethylmercury (MeHg), Mn, Se, and Zn in four teleosts (Fundulus heteroclitus, Sparus auratus, Menidia menidia, Psetta maxima) and one elasmobranch (Scyliorhinus canicula) exposed to these metals either from their food or the dissolved phase. The diets consisted of either worms, amphipods, brine shrimp nauplii, or juvenile fish. We also evaluated the influence of dissolved organic carbon (DOC) and salinity on the uptake of metals from the aqueous phase in the euryhaline F. heteroclitus, which is used as a bioindicator organism of coastal contamination. Assimilation efficiencies (AEs) from diet were determined using pulse-chase methodology [3]. A biokinetic model [4] to assess metal bioaccumulation describes metal concentrations in fish, at steady state (Css), as: $C_{ss} = [(k_u \ge C_w)/(k_{ew} + g)] + [(AE \ge IR \ge C_f)/(k_{ef} + g)]$, where $k_u = uptake$ rate constant from the aqueous phase, Cw = dissolved metal concentration, AE = assimilation efficiency of ingested metal, IR = weight-specific ingestion rate, C_{f} = metal concentration in food, k_{ew} and k_{ef} = efflux rate constants of metals following aqueous and dietary uptake, respectively, and g = growth rate constant (Wang et al. 1996). This model evaluated the relative importance of diet and aqueous phases as sources of metal for these fish. For modeling, values for AE, k_u, k_{ew}, and kef were determined experimentally, whereas C_w, C_f, IR and g were taken from the literature [5,6]. Metal uptake was predominantly from dietary sources for most metals and fish species (Table 1). DOC concentrations were generally inversely related to Cr, Hg, and MeHg uptake and positively related to As uptake from the aqueous phase [8]. Salinity, over a range of 0 -20 psu, was inversely related to uptake of Cd and positively related to uptake of As, Hg, and MeHg [8]. Although uptake of metals from the aqueous phase is not negligible in marine fish, clearly dietary sources predominate (Table 1), and must be considered in setting appropriate water quality criteria for coastal regions.

Tab. 1. Model-estimated per cent of metal body burden calculated for diverse metals in 5 fish species feeding on crustaceans using measured kinetic parameters [3, 6-8]. Model predictions assumed that g was negligible compared to $k_{\rm e}$ values and assumed a mean IR value = 0.05 g g⁻¹ d⁻¹. nd = not determined.

ORGANOTIN CONTAMINATION IN THE COASTAL ZONE OF THE EASTERN ADRIATIC (SIBENIK AREA)

M. Furdek 1* , M. Vahcic 2 , T. Zuliani 2 , N. Mikac 1 and J. Scancar 2 1 Ruder Boskovic Institute - mfurdek@irb.hr

² Jozef Stefan Institute

Abstract

Organotin compounds (OTC) were measured with two different analytical methods in sediment, mussels and seawater from the central part of the eastern Adriatic coast. Butyltin compounds were found in all analyzed samples, with the highest concentrations obtained in samples from the several investigated marinas. These results indicate that TBT is still in use in Croatia and that coastal area is contaminated with these highly toxic compounds.

Keywords: Adriatic Sea, Sediments, Pollution, Monitoring, Bivalves

Introduction

The extensive use of tributyltin (TBT) compounds in ship antifouling paints over last four decades has created a global pollution problem. The widespread use of organotin compounds (OTC) started in 1950s and already in 1970s the negative effects of TBT on marine organisms were discovered. TBT containing antifouling paints were banned first on the ships less than 25 m and from January 2008 the use of TBT is banned in EU countries. The use of TBT in antifouling paints in Croatia is still not regulated by legislative.

In addition, there is no data on the level of OTC in samples from the Croatian Adriatic coast. However, a high degree of imposex (widely used as a biomonitoring tool of TBT contamination), found in gastropoda H. trunculus from the eastern Adriatic coast in 2005 [1], suggested that Croatian coats might be highly contaminated with TBT. Here we present first data on the level of OTC (methyl, buthyl, octyl and phenyl species) in samples from the central Adriatic.

Sampling and methods

Samples for organotin analysis were collected at 7 coastal locations in the Sibenik area, central part of the Croatian Adriatic coast, in Septemper 2009. Sampling locations included 5 marinas (RO-Rogoznica: MN-Mandalina: SL-Solaris, SK-Skradin; V-Vodice), Sibenik port (L-Luka) and one referent station in the Sibenik channel (MA-Martinska) which is not heavily exposed to the ship traffic. At every location sediment cores, mussels and seawater were collected. Analysis of organotin compounds were performed with two different analytical techniques, GC-PFPD (Gas Chromatography Pulse Flame Photometric Detection) and GC-ICPMS (Gas Chromatography Inductively Coupled Plasma Mass Spectrometry).

Results and discussion

Distributions of butyltin compounds (MBT-monobutyl; DBT-dibutyl; TBTtributyl) in surface sediment, mussels and seawater at 7 sampling locations are presented in Fig. 1. Significant levels of all butyltin compounds are found at all sampling locations, especially in marinas Mandalina (MN) and Rogoznica (RO). The concentration levels in sediment and mussels are comparable with the ones determined in samples from the Slovenian coast in 2002 [2] and indicate that TBT is still in use in Croatia. TBT derivatives prevail in sediment and mussels which also suggests recent input of TBT into marine environment. More abundant concentration of DBT than TBT in water reflects instability of TBT in water and fast decomposition into lower butyl derivatives. At all location except referent one (Martinska), level of DBT in seawater was higher than 0,2 ng/l, which is permitted level of individual butyltin derivatives in water defined by Croatian and European regulative. Total concentration of butyltin compounds in analyzed sediment cores decreases with depth and DBT and MBT prevail in deeper sediment layers, both indicating TBT decomposition in sediment with time. From other butyltin compounds traces of some methyl and octyl derivatives are found in water and mussels.

Abstract

Trace metal dynamics in the stratified Krka River estuary (Šibenik bay, Croatia) has been studied by combination of different analytical and modelling tools for sampling campaigns 2007-2009. Results showed an increased metal content at the estuary surface layer in summer, especially for Cu due to antifouling paint release associated to strong boat traffic. Contrary to March-April period for which the organic ligands are sufficient to maintain the free Cu concentration at non-toxic level in the whole water column, in summer this limit is over-passed in the surface layer for at least one order of magnitude, particularly at locations close to nautical marina. *Keywords: Analytical Methods, Chemical Speciation, Estuaries, Metals, Organic Matter*

Experimental

The Krka River estuary water column is permanently stratified because of a sheltered geography and the low tidal range of the Adriatic Sea. Due to low anthropogenic activities, this estuary is oligotrophic with ultratrace levels of heavy metals. However, during summer touristic period, the total Cu concentration increases, mainly because of Cu leaching from the antifouling paints [1]. According to depth variations of physico-chemical parameters (T/S/pH/%O2), samples were collected by scuba diving in April-2007 and March-2008, at 4 depths in front of the scientific marine station Martinska (site M). Additionally, in March-2008, samples were collected in the Krka River and the Adriatic Sea to obtain the 2 end-members of the estuarine water mixing. These samples were studied to (1) characterize the dissolved organic matter (DOM) by dissolved organic carbon (DOC) content and 3-D fluorescence spectroscopy (with PARAFAC analysis), (2) determine the dissolved metal concentrations by DPASV, and (3) study the DOM/Cu interactions by logarithmic titration with analysis of the ASV-labile Cu fraction and further modelling to define the DOM binding parameters by the classical at-equilibrium approach and by an innovative kinetic approach [2]. Furthermore, 2 field campaigns were performed in July-2008 and 2009. Diffusive- and restrictive-DGT were deployed during 3-4 days at 6 depths (according to physicochemical parameters depth variation), at 2 distinctive sites: the "clean" site M, and a "polluted" one in a nautical marina (site S). DGT-labile metal levels were determined by HR-ICP-MS. In addition, water samples were collected 1-2 a day at each DGT-depth, leading to discrete and composite samples analysed for DOM, total/dissolved metal and DOM/Cu interactions by the previously described techniques.

Fig. 1. Salinity, DOC, total dissolved Cu and calculated free Cu concentration depth profiles of samples taken in 2008; marked area represents the depth range of fresh/marine water interface. Vertical dashed line: the Cu toxicity limit of 10 pM [3]. Insets: Same parameters in relation to salinity; Full and dashed lines represent conservative and parabolic variations, respectively.

Results and discussion

DOC and Cu concentrations measured in April-2007 and March-2008 showed non-conservative variations, with a clear enhancement at the fresh/marine water interface (Fig.1). The main source of fluorescent material in the estuary is due to terrestrial inputs, and the additional OM produced by biological activities did not show any specific fluorescent signature. The increasing Cu concentration at the freshwater/seawater interface seemed to be controlled by the organic ligands (probably produced by biological activity), leading to calculated free-Cu concentrations lower than the toxicity limit of 10⁻¹¹ M [3] (Fig.1). Our results validated the applicability/reliability of the kinetic approach in the determination of apparent stability constants and ligand concentrations, and additionally allowed the calculation of the association/dissociation rate constants, i.e. the dynamic of DOM/Cu interactions. In summer, important metal contamination of the estuary surface has been recorded, due to increasing boat traffic [1]. Under such conditions, predicted free-Cu concentrations overpassed the toxicity level in the whole water column, except at the bottom. Results obtained for the summer campaigns demonstrated that site S is more polluted than site M for Cd, Cu, Pb and Zn, but showed quite comparable values for Co, Cr, Mo, Ni and U (partly seen in Fig.2). Exception is for Mn which presented higher concentrations for site M, due to the vicinity of a former ferromanganese factory. Metal speciation could be directly determined by comparing DGT (diffusive/restrictive) and total/dissolved metal concentration profiles (Fig.2). Additionally, the binding parameters determined by the study of DOM/metal interactions allowed a more detailed definition of the metal speciation and the prediction of metal behaviour in different physico-chemical conditions.

Fig. 2. Salinity, DOC, total dissolved Cu and Pb (by DPASV) concentration depth profiles of composite samples taken in 2009 and diffusive DGT-labile Cu and Pb concentrations depth profiles at both sampling sites

THE D-EXCESS AS A CHARACTERISTIC OF THE MEDITERRANEAN PRECIPITATION: A CRITICAL REVIEW

Joel Robert Gat ¹*

¹ Dpt. of Environmental Sciences and Energy Research; Weizmann Institute of Science - joel.gat@weizmann.ac.il

Abstract

A value of the d-excess larger than 15‰ in atmospheric waters of the Mediterranean region has been attributed to the special air-sea interaction mode on the continental leeside and has been utilized as a characteristic identifying moisture originating from the Mediterranean. This review examines additional factors affecting the d-excess parameter and points to the importance of also considering the in-cloud processes and vertical motions and exchange of the air masses over the sea in this context. *Keywords: Air-Sea Interactions, Atmospheric Input*

Introduction

Following the recognition of elevated d-excess values in precipitation in the eastern Mediterranean Sea area and in adjacent marginal seas (such as the Adriatic,Black and Aegean seas) ([1], [2], [3]), this was attributed primarily to the large humidity deficit in the atmospheric waters on the leeside of the continent relative to the saturated vapour pressure at the sea surface, based on the Craig-Gordon Evaporation Model. This characteristic has been widely used to identify the contribution of the Mediterranean moisture source to precipitation in the region (e.g.[4]] and its paleoclimatic implications ([5],[6]).

Review of additional data sets of precipitation and atmospheric vapour:

Additional studies throughout the region, many of them as part of the IAEA sponsored CRP on the isotope composition of precipitation in the Mediterranean Basin [7], which included measurements of the isotopic composition of atmospheric vapour, suggested a strong dependence on the air mass trajectory into the area and on the seasonality [8]. These findings were generally in conformity with the basic premise of the Craig-Gordon model, but more detailed meteorological investigations [9], vapour measurements over the sea [10] and collection of orographic precipitation indicate that additional factors have to be taken into consideration before a reliable quantitative assessment can be made. Among them the changing isotope composition of the Mediterranean surface waters, addition of sea-spray and most notably, the non-equilibrium isotope fractionation in accompaniment of in-cloud and below cloud processes that occur en-route throughout the air column.

Model verification

Idealized model calculation of the isotopic composition of the evaporating flux (δ_E) for the range of expected values of the sea-water's isotope composition, of the atmospheric humidity parameters and temperature, all show a relative limited influence on the d-excess value of the resultant atmospheric moisture, beyond that predicted by the classical Craig-Gordon model. However the admixture of vapour that is the residue of non-equilibrium in-cloud and subcloud processes, as well as the vertical exchange processes over the ocean, are seen to perturb the isotopic signature of the atmospheric moisture significantly. These model predictions are going to be presented.

Conclusion

Due to the manifold factors contributing to the value of the d-excess in atmospheric waters, it is evident that a more detailed three-dimensional modeling of the air moisture's evolution throughout the region and its seasonal pattern is called for, augmented by appropriate vapour sampling and/or measurements.

BIOGEOCHEMICAL PROPERTIES OF ADRIATIC DENSE WATERS

Abstract

Distribution and characteristics of dense waters in the Adriatic Sea were monitored during their formation in winter 2008, and later, in autumn at the end of the seasonal stratification period in the Adriatic Sea. Different types of dense waters were identified on the basis of their physical features. In order to characterised their biogeochemical properties dissolved oxygen, nutrient, and particulate organic matter (chlorophyll a, particulate organic carbon, particulate nitrogen and phosphorus) were analysed. Keywords: Adriatic Sea, Particulates, Oxygen, Nutrients, Organic Matter

The Adriatic Sea is one of the few sites in the Mediterranean Sea where dense waters are formed. This process represents an important driving engine for the circulation and ventilation of deep waters of the Eastern Mediterranean. Though the physical properties and mechanism of formation are well described [1], the biogeochemical features are known only for the dissolved inorganic nutrients [2]. Even less information is available for the particulate organic matter [3] and its relevance in the carbon cycling in the Mediterranean Sea. The whole Adriatic Sea system responds significantly to climatic variability, which acts on the properties of the water masses originating in the Adriatic, as well as on the exchange with the adjacent basins. The state of the art presented in this work derives from two cruises carried out in February and October 2008 in the framework of SESAME-EU-FP6 and VECTOR projects. During the winter season, cooling and evaporation triggered mixing leading to dense water formation over the northern shelf, and deep convection in the Southern Adriatic. The biogeochemical characteristics of these dense waters depend on the site and timing of preconditioning and formation. The North Adriatic Dense water (NAdDW) formed in winter flows southwards partly refilling the Middle Adriatic Pit increasing the oxygenation degree of those bottom waters and partly flowing into the Southern Adriatic Pit. The NAdDW is cooler and well oxygenated, especially if formed in late winter. In some years the maximum density (σ_{θ}) can reach more than 29.8 kg/m³ [1], depending on frequency and intensity of northeasterly dry wind (Bora). In February 2008 maximum values observed in the northern Adriatic were 29.6 kg/m³ for σ_{θ} (figure 1)

Fig. 1. Vertical distribution of density along the NW-SE longitudinal section of the Adriatic Sea.

and 106% for oxygen saturation (figure 2), indicating the beginning of primary production processes. They were richer in particulate organic carbon and nitrogen with respect to the other dense waters present in the basin during winter. The dense waters near the bottom of the Middle Adriatic Pit were oxygen depleted (figure 2) and had higher nutrient concentrations. The increase of oxygen saturation (from 65% to 75%) and the decrease of inorganic nutrient concentrations from February to October indicated the advection in the Middle Adriatic Pit of new dense waters.

Fig. 2. Vertical distribution of dissolved oxygen along the NW-SE longitudinal section of the Adriatic Sea.

During this period the convection reached 700-800 meter depth in the Southern Adriatic (figure 1) bringing the nutrient rich undersaturated Levantine Intermediate Waters up to the surface, which just after the oceanographic cruise gave rise to a phytoplankton bloom within the Southern Adriatic cyclonic gyre, as observed from the chlorophyll-a distribution from MODIS AQUA satellite images. In autumn the SAdDW, which occupies the bottom of the Southern Adriatic Pit, got warmer, slightly less dense, more undersaturated than in winter. Contemporarily an increase in the concentrations of nutrients and suspended particulate matter took place due to the settling of particulate matter and degradation processes. The Adriatic Dense Water (ADW), is a mixture of deep waters formed in the Southern Adriatic, in the Northern and in the Middle Adriatic [1]. It flows out from the basin through the Strait of Otranto in depth along the western flank. The Ionian surface and Levantine Intermediate Waters flow into the Adriatic along the eastern flank. The ADW had similar concentration of suspended particulate matter both in February and October 2008. However, the saturation of dissolved oxygen decreased to 80% and the nutrient concentration increased in October 2008, due to the remineralization processes.

Abstract

Sedimentary organic matter (OM) provides a variety of proxies for the reconstruction of marine and continental paleoenvironments and paleoclimates. In this study, we compare biogeochemical proxies isolated from three sediment cores in the Eastern Mediterranean Sea (from the Aegean and Libyan Seas) during the last 20,000 yrs. The marginal Eastern Mediterranean Sea represents a 'natural laboratory' for paleoceanographic studies due to its sensitivity to oceanographic and climatological changes ([1], [2]). *Keywords: Aegean Sea, Eastern Mediterranean, Organic Matter, Paleoceanography, Sapropel*

Early Holocene sediment records collected in the Eastern Mediterranean Sea (EMS) bear witnesses for the formation of the most recent sapropel S1, closely associated with distinct minima in the orbital precession cycle and the insolation-driven monsoon maxima ([3]). The different scenarios of S1 deposition involve changes in marine productivity, organic matter preservation and circulation changes and are still under debate ([4], [5], [6]). Herewith, we present a high-resolution study of organic geochemical proxies in three gravity cores collected from the EMS, namely the cores SL152 and NS-14 collected from the Aegean Sea (north and southeast, respectively), and core HCM2/22 collected from the Libyan Sea. Our goal is to investigate the patterns of organic matter accumulation and preservation and reconstruct paleo-SSTs based on alkenone unsaturation index Uk'37 during the last 20,000 yrs with focus on the deposition of sapropel S1 along a north-south transect in the EMS. Depending on the water column depth, the sediment accumulation rates and the proximity to freshwater and water formation sources, S1 deposited in our records between ~9.8 to 6.4 kyr BP, with an apparent interruption in the S1 deposition that occurred from ~8.6 to 7.6 kyr BP. At the Holocene climatic optimum, SSTs increase gradually more than 4°C and reaches values as high as 21.2°C, 22.5°C and 23°C (in cores 152SL, NS-14 and HCM2/22 respectively). Our records also show a pronounced centennial-scale cooling that culminates from ~8.2 to 7.6 kyrs BP, coeval to the N. Atlantic cooling event ([7]), causing an interruption in the deposition of S1 in all sites. SST fluctuations are detected between 4.9 and 4.1 kyr BP in core NS-14, with a sharp positive shift to 24.9°C indicating the presence of a warm period in the mid Holocene ([8]). The higher accumulation rates of TOC and all marine biomarkers within the sapropelic layer S1a and less pronounced within S1b in the Aegean Sea compared to the Libyan Sea indicate the importance of productivity - OM reaches the shallower sites more effectively - for the intensity of S1 deposition period. Organic carbon stable isotopes values span a narrow range. The different types of δ^{13} Corg excursions associated with stronger fluvial delivery (terrestrial inputs) in the north Aegean Sea whereas the other two sites received most marine organic matter. The distributions of land-plant biomarkers are indicative of variable terrigenous organic matter supply and the concomitant transport of nutrients to surface waters. Furthermore, the distribution patterns and characteristic ratios of marine biomarkers exhibit differences in the paleoproductivity trends and ventilation changes over the last 20 kyr. Lighter values of $\delta^{15}N$ within S1 and Mid Holocene Humid (MHH) phases reflect a significant contribution of N-fixing organisms to the N-cycle related probably to higher demand for nitrogen (denitrification/ P regeneration) due to the established dysoxia in the water column/sediment interface.

MERCURY ACCUMULATION AND SPECIATION IN RED MULLET (MULLUS BARBATUS) AND ANNULAR SEA BREAM (DIPLODUS ANNULARIS) FROM IZMIR BAY (EASTERN AEGEAN)

Tolga Gonul ¹* and Filiz Kucuksezgin ² ¹ Phd. student - tolga_8135@hotmail.com ² Prof. Dr.

Abstract

Total mercury (THg) and methylmercury (MeHg) concentrations were investigated in two different species from the Izmir Bay. The levels of THg and MeHg in fish tissue, ranging from 4.4 to 221.4 μ g THg kg⁻¹ and 3.8-194.8 μ g MeHg kg⁻¹ (wet wt.), varied according to sampling point and season. The results indicate that none of the fish analysed was $\geq 0.500 \ \mu$ g g⁻¹ for THg and ≥ 0.300 $\mu g g^{-1}$ for MeHg and nor did they exceed the WHO limit [1]. Keywords: Mercury, Fishes, Aegean Sea

Introduction

Izmir Bay, which covers a large range of industries, is one of the great natural bays of the Mediterranean. Few published data are present on total mercury concentrations in organisms from Izmir Bay, but no data are available on mercury speciation in organisms from Izmir Bay. The aim of this study is to comparatively evaluate THg and MeHg concentrations in two fish species collected from different sites of Izmir Bay. Methodology Fish samples were collected at four locations (Foca-Gediz, Uzunada, Gulbahce, Guzelbahce) in 2005 seasonally. THg concentrations were measured in VARIAN AAS by cold vapour technique [2]. The MeHg analysis in the freeze-dried tissue was made by GC-ECD [3].

Results and Discussion

Among the two species, THg and MeHg were examined (Table 1). The percentage of MeHg was high and constant in muscle. The mean percentages of MeHg to THg for all fish samples were 91.0 \pm 0.77% (Mean \pm SE) with a range of 84-98%, indicating that organic mercury was the predominant form of mercury in the muscle tissue of fish (Table 1). The significant differences between sampling areas for THg and MeHg were not found in muscle tissue of M. Barbatus and D. Annularis while concentrations in muscle tissue of M. Barbatus and D. Annularis differed significantly among seasons for THg and MeHg.

Conclusion

The maximum Hg content was 221.4 μg THg kg^-1, corresponding to 194.82 μg MeHg kg⁻¹ (wet wt.) in D. Annularis. For a person eating 200-250 g of D. annularis daily, the maximum amount of MeHg ingested is of 39-49 µg daily (273-343 μg weekly), a value of the same order of magnitude as the $210\,\mu g$ permissible tolerable weekly intake (PTWI) for methylmercury proposed by USEPA [4]. Our results indicated that D. annularis exceeded this limit.

Abstract

Les possibilités d'utilisation d'échantillonneurs passifs pour l'évaluation de la contamination chimique des masses d'eau ont été testées dans le cadre du projet PEPS. L'objectif principal était d'évaluer à "grande échelle" et dans différentes conditions de terrain (20 masses d'eau côtières réparties sur l'ensemble de la façade méditerranéenne française) l'opérationnalité de ces systèmes en terme de réduction des coûts, fiabilité et rapidité d'obtention des résultats, mais aussi en terme de facilité de mise en œuvre (par du personnel non spécialisé, mais préalablement formé).

Keywords: Monitoring, Western Mediterranean, Trace Elements, Sampling Methods

L'application de la Directive Cadre Européenne (DCE) [1] implique de mettre en oeuvre des programmes de surveillance de l'état écologique et de l'état chimique de l'ensemble des masses d'eau (de surface et souterraines). Le suivi en routine et à fréquence "élevée" de la contamination chimique est limité du fait que la plupart des contaminants sont présents à l'état de traces dans une matrice complexe (notamment dans le cas de l'eau de mer). Ainsi, l'analyse de la plupart des contaminants en milieu aquatique implique: l'utilisation de techniques d'échantillonnage "ultra-propres"; la mise en oeuvre de méthodes d'extraction/concentration et d'analyse complexes. De plus, l'augmentation importante du nombre de composés chimiques en milieu aquatique, notamment les substances "émergentes", ainsi que les modalités de surveillance des masses d'eaux fixées par la DCE, rendent pertinent le développement d'approches et d'outils "faciles" à mettre en œuvre sur le terrain et pouvant réduire le temps ainsi que les coûts des opérations d'échantillonnage et d'analyse. A ce titre, les échantillonneurs passifs sont des outils intéressants [2]-[7]. Certains ont été conçus pour les éléments métalliques (DGT); d'autres sont utilisés pour les contaminants organiques hydrophobes (SPME, SPMD, SBSE) et pour les molécules polaires (SBSE, POCIS).

Fig. 1. Exemple de concentrations en Cd (mesurées par DGT) et en certaines substances pharmaceutiques dans les masses d'eau étudiées. Les concentrations en Cd aux différentes stations sont comparées à la concentration moyenne calculée à partir de l'ensemble des concentrations mesurées (ligne rouge).

Ces techniques présentent aussi l'avantage de perturber au minimum la spéciation des contaminants échantillonnés (pas d'opérations de prélèvement d'eau, stockage, filtration) et présentent l'avantage de pouvoir être mises en œuvre rapidement. Cette présentation fera un bilan du test "à grande" échelle de l'opérationnalité de ces techniques (SBSE, POCIS, DGT) réalisé sur la façade méditerranéenne française. Une des originalités de cette étude a été de mettre en évidence l'opérationnalité de ces systèmes et leur facilité de mise en œuvre par du personnel non spécialisé, mais préalablement formé. Les résultats obtenus (Fig. 1) ont contribué à la caractérisation des masses d'eau par rapport à certains contaminants chimiques. Pour certains composés, les données acquises sont parmi les premières disponibles en milieu marin côtier [8].

Abstract

Barite is not restricted to reconstruction of paleoproductivity. If its sedimentary distribution underwent diagenesis, it can reflect changes in sedimentation rate, CH4 and SO4^{2²} fluxes. We present data from two cores retrieved in the Black Sea (BS). In contrast to Mediterranean sapropels, where Ba is used as tracer for organic matter accumulation, the primary Ba signal in the BS was lost in shallow sediment depths (>1.5 m). While Ba is inappropriate as a paloeproductivity proxy in the BS, it might serve as a tracer of the sulphate-methane transition (SMT). Migration of the SMT induced by the flooding of the BS was simulated using a numerical model. The results indicate that diagenetic BaSO4 redistribution did not affect the top ~0.8 m of the cores. Steady state could have prevailed since 3.8 ka after the first intrusion of seawater.

Keywords: Black Sea, Sediments, Geochemistry

The Black Sea has experienced severe changes after the last deglaciation concerning its hydrological and geochemical conditions. Due to the flooding by Mediterranean waters, conditions developed from a lacustrine setting with an oxic water column to the largest modern marine anoxic basin in the world. These changes affected the geochemical zonation within the sediment column, pushing the SMT downward and enhancing organic matter (OM) preservation. In ocean basins, barite Ba concentrations in the sediment can be used to reconstruct paleoproductivity [1]. Particularly in the Mediterranean Sea, Ba is a helpful indicator for the original extent of sapropels, which have been affected by postdepositional "burn-down" [2]. However, in zones of sulphate depletion, BaSO₄ is subject to dissolution. This diagenetic overprint is decisive for Ba cycling in Black Sea sediments, where the SMT is located at shallow depths of 2-4 m. The authigenic BaSO₄ fronts that form at (or slightly above) the SMT potentially record the movement of the SMT [3]. This study is the first to present solid phase Ba data of Black Sea sediments in combination with pore water data. The main questions are: 1) Do distinct Ba/Al variations appear in the sedimentary record? If yes - 2) Does the Ba signal reflect productivity or diagenetic redistribution of BaSO₄? And 3) Can relict fronts be used to trace the movement ot the SMT and thus changes in sedimentation rate or the upward methane flux? Two gravity cores 755 (501 m water depth) and 214 (1686 m water depth) were retrieved west of the Crimean Peninsula during RV POSEIDON cruise 317/2 (2004) and RV METEOR cruise M72/1 (2007). In addition to wet geochemical analyses, scanning electron microscopy (SEM) and energy dispersive spectrometry (EDS) were carried out on bulk sediments to identify the main Ba phases. Pore water profiles indicated barite dissolution below the SMT and precipitation of authigenic BaSO4 fronts at the base of the sulphate zone (Fig.1). By SEM-EDS, barite crystals with sizes $<3 \,\mu m$ were found in five samples above the current depth of the SMT. Most of those crystals were irregularly shaped and only a few grains showed morphologies characteristic of biogenic barites. The movement of the SMT since the Holocene flooding of the Black Sea was simulated using a numerical transport and reaction model. The results demonstrate that due to time constraints arising from sedimentation rates and the velocity of diffusion, the upper ~80 cm of the sediment column are not affected by diagenetic barite redistribution. A coupling of OM and Ba in these intervals can be recognised, although the correlation is still ambiguous. The sediments showed an opposite pattern to that in Mediterranean sapropels: OM is well preserved while BaSO₄ was efficiently remobilized. Ba is therefore not applicable for studying paleoproductivities in the Black Sea. These findings also suggest implications for the use of the Ba-proxy in analogue ancient settings.

SUBMARINE BAUXITIC TAILINGS DISPOSAL: A CASE STUDY IN CORINTH GULF, CENTRAL GREECE

Margarita Iatrou^{1*}, George Papatheodorou¹, Maria Geraga¹ and George Ferentinos¹

¹ Laboratory of Marine Geology and Physical Oceanography, Department of Geology, University of Patras, - iatroum@upatras.gr

Abstract

A Submarine Tailings Disposal (STD) system operates on the northern flank of the Corinth Gulf, discharging bauxitic tailings on the shelf of the Gulf. A deposit of three high relief mounds has formed at a water depth of about 100 m. The surface of the mounds suffers from instabilities and tailings are transported as slumps down-slope. The tailings are dispersed on the shelf floor and are directed through the channels and canyons of the slope, to the basin floor where they form thin intercalating layers. Tailings have increased significantly the level of heavy metals in the study area.

Keywords: Metals, Pollution, Sediment Transport, Eastern Mediterranean

Introduction

On the northern margin of the Corinth Gulf, in Antikyra Bay, is located a bauxitic processing plant, Aluminium of Greece, which has contributed significant amounts of bauxitic tailings to the marine environment through a submarine tailings disposal system (STD). Throughout 20 years period, four (1982-83, 1987, 1994, and 2007) multidisciplinary environmental surveys were carried out in Antikyra Bay and in the Corinth Gulf basin, in order to monitor the STD system [1,2,3] and study the dispersion and transport mechanism of bauxitic tailings as well as the distribution of heavy metals concentration. The STD system discharges red mud slurry as the by-product of the aluminum production. Though the STD system the tailings are piped out at water depth of 100 -120m.

Results-Discussion

On the shelf the tailings have formed three high-relief overlapping mounds at the mouths of the pipelines, modifying significantly the bathymetry of the seafloor (Fig.1).

Fig. 1. Morphologic map of the central Gulf of Corinth showing the spatial distribution of bauxitic tailings. Inset shows the bulk granulometric composition of the tailings.

The mounds have wedged down-slope margins. The high rates of accumulation at the mouth of the pipelines, in association with the high seismicity of the area facilitate the instability of the mounds and the initiation of gravitative mass movements (such as slumps) as it is indicated by the surficial patterns of arcuated scarps. The red-mud tailings disperse from the mounds on the shelf floor in a down-slope direction and form an elongated main surface deposit. The distal tailings deposit is distributed down-slope from the main deposit as far as the shelf-break and thins out to 1 cm. The bauxitic tailings are transported as gravity-driven mass flows through the numerous channels incising the slope, to the basin where they are being deposited, at a depth of 800 - 850 m on a smooth and flat seafloor. On the base of slope and the basin floor, the red bauxitic tailings have formed successive layers, which intercalate with natural sediments. The "red-mud" tailings and the intercalated natural sediment, consist of medium to fine-grained sediments. The tailing deposits are highly enriched in Fe₂O₃, TiO₂, Cr₂O₃, Ni, Co, Pb and Cu compared to the surrounding natural sediments, while the natural sediments are characterized by higher concentrations of Mn, Zn and CaCO₃. The concentrations of Fe₂O₃, TiO₂, Cr₂O₃, Ni, Co, Pb and Cu are highest the mouths of the outfalls in Antikyra Bay (Table 1) and they decrease towards the basin. Therefore the tailings during their transport as gravitational mass flows from the outfalls as far as their final deposition site on the basin are subjected to mixing with natural sediments.

TRACE METAL POLLUTION IN SEDIMENTS OF THE CATALAN COAST (NORTHWESTERN MEDITERRANEAN)

Marc Belzunces Ibañez ¹*, Albert Palanques Monteys ¹ and Mariona De Torres ² ¹ Institut de Ciències del Mar (CSIC) - marcbel@icm.cat

² Agència Catalana de l'Aigua

Abstract

A survey along the Catalan coast was carried out in 2007 to assess trace metals in sediments with a homogenous sampling and analytical strategy. The nine prodeltaic systems and adjacent areas of this coast were studied as sinks of polluted sediments in the continental shelf. Results show that North part of the coast presents background levels or low isolated alterations. South part of the coast, including the Ebro, Besòs and Llobregat prodeltas, presents high enrichment factors for several elements. Cadmium, and specially Mercury, presents very high enrichment factors around the metropolitan areas of Barcelona and Tarragona. *Keywords: Trace Elements, Pollution, Ebro Delta, Sediments, Mercury*

Introduction

The irregular regime of the small rivers discharging in the Catalan coast and also uncontrolled pollutant dumpings result in sporadic pollution. This produces anomalous trace metal contents in bottom sediments of active prodeltaic accumulation areas that are indicative of sedimentary systems affected by pollution.

Studies about trace metals in sediments of the Catalan coast have been carried out mainly in specifics areas, in different years and following different sampling strategies and analytical methods (Palanques et al. 1994). The present study provides homogeneity in sampling and analytical procedures in the study of trace metals in the sediments of the Catalan coast.

Material and methods

A total of 118 samples of surface sediment (first centimeter) were taken in the 9 prodeltas and adjacent areas of the Catalan coast (Figure 1). Transects of five stations perpendicular to the bathymetric isolines were established, taking surface sediment samples at 10, 20, 30, 40 and 50 meters depth.

Fig. 1. Study area with samples in black dots grouped in zones.

Grain size of all samples was determined by a sedigraph (fine fraction) and a settling tube (coarse fraction) according to Giró et al. (1985). For geochemical analysis, a total digestion technique was carried out, according to Querol et al. (1996). Pb, Cr, Cu, Cd, Ni and Zn content was determined by ICP-MS, Fe and Al content by ICP-OES and Hg content by a specific mercury analyzer. GIS analysis and representation of data were performed with ESRI ArcGIS 9.3.

Results and discussion

To obtain the enrichment factors (EF), samples were normalized by Al content. Results for every metal were compared to unpolluted samples of previous studies, including pre-industrial samples from sediment cores. Table 1 summarizes EF ranges for every area (Figure 1).

Samples from the northern of Barcelona metropolitan coastal area (Northern Maresme, Ter prodelta and Roses Gulf) presented natural or near natural EF, with some isolated pollution signals.

General high EF were present in the Barcelona metropolitan coastal area (Southern Maresme, Besòs and Llobregat prodeltas and Northern Central Coast), an area heavily populated and industrialized (4.9 million inhab.). In general, maximum EF were founded in Besòs prodelta, up to 38 for Hg (up to 2.5 μ g/g), up to 10 for Cd (1.4 μ g/g), up to 6.4 for Cu (up to 137 μ g/g), up to 7 for Pb (173 μ g/g), up to 4.9 for Cr (251 μ g/g) and up to 5.7 for Zn (450 μ g/g). In this area, pollution is associated to sewers and the Besòs and Llobregat rivers. Tarragona area, which hosts petrochemical industry facilities, showed the highest EF for Hg in the Catalan Coast (EF 126, 4.6 μ g/g). Hg pollution is associated to the several sewers in the area. Rest of metals showed natural levels (Ni and Pb) or EF below 3 (Cd. Cr and Zn).

The Ebro prodelta, the larger system, showed significant EF only near the river mouth (Hg up to 8) and in its Bays (Cd up to 3), probably due to retention of polluted sediment in the numerous dams throughout its basin and also to the higher dilution of polluted particles in a river with high water discharge.

FUTURE OCEAN ACIDIFICATION IMPACTS ON MEDITERRANEAN SEAFOODS: FIRST INVESTIGATION OF THE ECONOMIC COSTS

OF THE ECONOMIC COSTS Ross Jeffree ¹*, Nathalie Hilmi ², Denis Allemand ² and James Orr ³ ¹ IAEA Marine Environment Laboratories - R.Jeffree@iaea.org ² Centre Scientifique de Monaco ³ LSCE/IPSL, CEA-CNRS-UVSQ

Abstract

There is increasing concern with regard to future impacts of ocean acidification on marine biological resources, fisheries and aquaculture and the potential economic and social consequences. Here we give a summary report on the status of following sets of data required to evaluate the likely scales of future economic losses to Mediterranean fisheries and aquaculture; a) direct and indirect effects of reduced pH on Mediterranean species of socio-economic significance, b) effects of different global atmospheric carbon emission rates on future acidity of Mediterranean seawater, and c) the economic values of shellfish from both wild fisheries and aquaculture industries. The areas of uncertainty that warrant further investigation are also identified. *Keywords: Ph, Aquaculture, Global Change, Fisheries*

Ocean acidification (OA) refers to changes in ocean chemistry brought about by increases in atmospheric CO2 from combustion of fossil fuels, deforestation and cement production. Ocean acidification leads to an increase in hydrogen ion concentration [H⁺], which we refer to as acidity, and thus a decrease in pH (defined as -log[H⁺]) and carbonate ion concentration. The Mediterranean Sea is a semi-enclosed basin with different properties than typical seawater, including generally higher surface temperatures and salinities. However, the 21st-century reductions in Mediterranean Sea surface-water pH and carbonate ion concentration are expected to be similar to those in tropical waters of the ocean. Yet unlike the tropics, in the Mediterranean Sea there are large differences between winter and summer saturation levels (carbonate ion concentration). Combined effects from other peculiarities, including different marine ecosystems and intense anthropogenic pressures, necessitate distinct initiatives to study Mediterranean Sea acidification. For the Mediterranean Sea there is little scientific information on the likely effects of ocean acidification on marine food webs, fisheries and aquaculture species. However many of the taxonomic groups of organisms present in the Mediterranean are also found elsewhere where many of the ocean acidification studies are currently focussed [1].Our approach has been to first assess the current state of knowledge of the impacts of ocean acidification on seafoods and specifically for the Mediterranean, including potential indirect effects through disruption of food webs, and in combination with the effects of co-contaminants and increasing temperatures. Then we use this assessment to interpret biological and ecological impacts in the context of projected future acidification of the Mediterranean. We then present some macro-economic assessment of the value of Mediterranean seafoods at the regional and national scale to determine what is potentially at threat economically from ocean acidification in the future. By undertaking this preliminary cross-disciplinary study of the economic significance of ocean acidification for Mediterranean seafoods we have also better evaluated the inadequacies of the economic and scientific data for the Mediterranean that is currently available for such a purpose. We have also proposed what is needed to better assess the economic costs and risks. with a prioritisation of the requirements for new information to reduce the uncertainties in such an analysis. Ocean acidification is a recently identified phenomenon and the scientific assessment of its impacts on seafoods and underpinning biodiversity is still in its infancy, particularly for the Mediterranean. Its tentative nature has constrained the precision of our socioeconomic analyses. However, the scale of potential losses has been better clarified and detailed for Mediterranean countries, for the groups of seafoods that are currently identified as more at risk from OA. Moreover, the following questions have been better shaped through our collaborative analyses to indicate where the needs for further research and consideration lie, viz: i) the higher alkalinity of Mediterranean water mitigates the rate at which it will acidify, however the biological responses of organisms that have also evolved under these conditions need to be assessed experimentally, to discern the degree of their vulnerability, ii) such experimental assessments need to be undertaken within the ranges of pH values that are projected to occur, with longer-term exposures, and for those species that have been identified as of particular economic value for individual countries, iii) particular countries are also identified as being pre-disposed to greater socio-economic impact of OA due to both the value of calcifiers in their seafood production coupled with the narrow species base of their seafood industries, iv) assessment of the potential scale of socio-economic impacts of OA and the equity of their distributions among the Mediterranean countries, that represent a very broad range in their states of economic development. By its diversity among member states in their level of economic development and the resilience of their economies, the Mediterranean offers the unique opportunity to investigate the different scales of socio-economic impacts among countries of OA [2].

PHYLOGENETIC CONSISTENCIES IN RADIONUCLIDE AND METAL ACCUMULATION BY TELEOST AND CHONDRICHTHYAN FISHES OF THE MEDITERRANEAN

Ross Jeffree ¹*, Francois Oberhaensli ¹ and Jean Louis Teyssie ¹ ¹ IAEA Marine Environment Laboratories - R.Jeffree@iaea.org

Abstract

There is a need to explain why different organisms contrast greatly in their capacities to accumulate trace element contaminants. Such understanding will enhance predictive ecological risk assessment for these contaminants and permit better evaluation of the 'reference organism' approach to radiation protection [1,2,3]. More fundamental biological explanations of these differences in bioaccumulation between different organisms are yet to be achieved. Experimental investigations have shown consistencies within teleost and chondrichthyan fish in their patterns of bioaccumulation of multiple trace elements. Such patterns are indicating phylogenetically-based predispositions for elevated boaccumulation and internal exposures among these contaminants. *Keywords: Teleostei, Bio-Accumulation, Elasmobranchii, Metals, Radionuclides*

To test the hypothesis of taxon-based bioaccumulation patterns we had previously conducted a 14 day uptake/ 29 day loss experiment of uptake from seawater that compared the whole-body uptake and loss kinetics of seven radiotracers in a teleost (turbot- Psetta maxima) and chondrichthyan (lesser dogfish- Scyliorhinus canicula) . This experiment showed appreciable differences ($P \le 0.01$) between the two species in their rates of accumulation for multiple elements (eg. Am-241, Zn-65 and Cs-137) [4], which were great enough to warrant further assessment of the hypothesis, as described below. A set of nine radiotracers in seawater were used for an experimental exposure that compared their whole body: water concentration factors at 14 days in each of three teleosts and three chondrichthyans. Radiotracers included the anthropogenic radionuclides 54Mn, 60Co, 65Zn, 134Cs and 241Am that are typically released into coastal waters from nuclear power stations, and that could be expected to increase in the future due to enhanced nuclear power programs that are planned. Radiotracers of Cd, Ag and Se were also included as they are contaminants that are commonly elevated in coastal waters due to effluents from land-based sources. Teleost fish species were turbot Psetta maxima, Order Pleuronectiformes, Family Psettodidae, sea bream Sparus aurata, Order Perciformes, Family Sparidae and sea bass Dicentrarchus labrax, Order Perciformes, Family Serranidae. The chondrichthyans were dogfish S. canicula, Order Carcharhiniformes, Family Scyliorhinidae, undulate ray Raja undulata, Order Rajiformes, Family Rajidae and spotted torpedo marmorata Order Torpediniformes, Family Torpedinidae. Torpedo Discriminant function analysis was used to determine an equation to best separate between dogfish and turbot on the basis of their CFs among 7-9 radiotracers. This function could then be used to objectively classify individuals of the other chondrichthyan and teleost species used in this experiment, as being closer to the a priori chondrichthyan or teleost 'bioaccumulation model'. Hierarchical classificatory, multi-dimensional scaling (MDS) and similarity (ANOSIM & SIMPER) analyses were also used to further assess the hypothesis of different bioaccumulation characteristics for species of teleosts and chondrichthyans. These analyses also identified those trace elements that were most different between them in their bioaccumulatory capacities. Discriminant function analysis on whole body: water concentration factors (CFs) for 7-9 radiotracers separated dogfish and turbot in the two independent experiments. Associated classification functions grouped the teleosts, seabream and most seabass with turbot and the chondrichthyans, undulate ray and spotted torpedo with dogfish, thus supporting our initial hypothesis of taxon-based boacumulation patterns. Hierarchical classificatory, multi-dimensional scaling and similarity analyses also separated all three teleosts from all chondrichthyans that were more diverse amongst themselves compared to teleosts. Dogfish were the most distant from teleosts, followed by the undulate ray and then torpedo. Among the several multivariate statistical techniques that were used to compare between taxa there were trace elements that were repeatedly more prominent in determining the separations between teleosts and chondrichthyans, based on their CFs, viz. Cs-134 was consistently elevated in teleosts and Zn-65 was elevated in chondrichthyans. Chondrichthyans were also higher in Cr-51, Co-60, Ag-110m and Am-241, whereas teleosts were higher in Mn-54. Our results suggest that chondrichthyans may be more susceptible to contamination from exposures in seawater for a greater range of trace elements, compared to teleosts.

IMPACT OF AQUACULTURE ON NUTRIENT DISTRIBUTION IN AEGEAN SEA

Janset Kankus¹*, Nihayet Bizsel¹, Sezgi Adalioglu¹ and Sebnem Kuscu¹

¹ Dokuz Eylül University, Institute of Marine Sciences and Technology - jansetkankus@gmail.com

Abstract

To observe the potential impacts of the aquaculture site, the nutrient distirbution (ammonium, nitrite, nitrate, phosphate and silicate), and their ratios have been monitored as the indicators of water quality in a well-known aquaculture area in the middle of Aegean Sea during winter and summer period. In addition to the nutrients, the total suspended solids (TSS) and dissolved oxygen (DO) were also determined. The spatial variability in the nutrient distribution shows that the effect of fish farm and freshwater tributaries input flow throughout the agricultural areas on the water quality parameters have no differences. The nutrient ratios (N/P/Si=1:5:1 in winter; N/P/Si=1,5:2:1 in summer) indicate that nitrate and silicate are limiting.

Keywords: Aquaculture, Nutrients, Aegean Sea

Introduction

During last two decades, the intensification of marine aquaculture in the Mediterraneancoasts has been reacted by the other users. Among these users, the tourism entrepreneurs have been leading a competition based on the conflict of interest for coastal zones. Their main argument is the adverse impacts of fish farms on marine ecosystems. On one hand, the over sprawled fish farms in coastal zones, which Turkey is well behind in comparison with Greece with her ability to supply 60% of EC's demand for Mediterranean fish [1] and on the other hand, the sharp increase in world's demand for seafoods from 120 million tonnes towards to 160 million tonnes, display the conradictory nature of the issue. An effective monitoring programme for the fish farming activities is therefore important and essential. As the consequence of such a programme, the sustainability of marine aquaculture can be acquired by considering tourism, fisheries and aquaculture, and environmental protection via the perspective of integrated coastal zone management. The number of fish farms is relatively quite limited in Turkey, however, their adverse environmental impacts are highly speculated in spite of the highly restricted number of scientific monitoring researches on this issue.

Materials and Methods

Dissolved oxygen (DO) were measured by Winkler method. The filtered water samples were kept frozen for analysis in the laboratory. SiO and NO were analyzed using the Grasshoff, Ehrhartd and Kremling (1983) method, and (NO + NO), NH PO following Strickland and Parsons (1972) [2,3]

Results and Discussion

In the present study, the annual nutrient variations were given in the min and max ranges in Table1.

As expected, nutrients were higher in winter than ones in summer period. NO :PO ratios are almost stable during the two seasons. However, TIN:PO and Si:PO show changes. While TIN:PO is increasing, Si:PO is decreasing in summer period.

Abstract

Les teneurs de neuf éléments minéraux (K, Mg, Na, Ca, Fe, Cd, Pb, Zn et Cu) dans le muscle dequatre espèces de poissons de la pêche côtière du golfe de Gabès (le sparaillon *Diplodus annularis*, le gobie *Zosterisessor ophiocephalus*, le mulet *Liza aurata* et le saurel *caranx rhonchus*) ont été déterminés dans le mois d'avril 2008. La variation des teneurs en minéraux en fonction du sexe de poissons et des espèces a été examinée. Une grande variabilité entre les deux sexes est observée pour les éléments majeurs (K, Mg, Na, Ca). Pour les éléments mineurs (Cu, Cd et Pb) peu de variations.

Keywords: Mineralogy, Fishes, Chemical Analysis

Introduction

L'analyse des teneurs en éléments minéraux permet d'évaluer le degré de contamination dans les rejets industriels dans la mer. Le golfe de Gabès assure une production halieutique importante en Tunisie. Cependant cette zone est de plus en plus industrialisée. L'objectif de cette étude est d'analiser les teneurs en éléments minéraux majeurs et mineurs dans quatre espèces de poisons de la pêche côtière du golfe de Gabès (le sparaillon *Diplodus annularis*, le gobie *Zosterisessor ophiocephalus*, le mulet *Liza aurata* et le saurel *caranx rhonchus*).

Matériel et methods

Un échantillon de 4g d'extrait sec de la chair totale est calciné dans un four à moufle à 550°C jusqu'à minéralisation complète de l'échantillon. 15 ml de HNO₃ dilués (1+ 4) avec de l'eau désionisée est ajouté à l'échantillon minéralisé [1]. Le filtrat est analysé en éléments minéraux : Ca, Mg, Na, Fe, Cd, Pb, Cu et Zn par la spectrophotomètre d'absorption atomique (Z₆₁₀₀ polarized Zieman, Atomic Absorption Spectrophotometer Hitachi, Japon). Les résultats représentent le moyen (moyen ; n = 3).

Tab. 1. Teneurs en éléments mineurs et majeurs obtenus dans la chair des quatre espèces de poisons examinées.

Résultats et discussion

Le tableau 1 récapitule les teneurs en éléments mineurs et maieurs obtenus dans la chair des quatre espèces de poisons examinées. Pour toutes les espèces étudiées les femelles sont plus riches en éléments minéraux majeurs. Pour le calcium les femelles contiennent entre 2,3 et 19,93 mg/100g de matière fraîche contre 3,86 et 12,62 mg/100g pour les mâles. La teneur en Mg maximale est de 14,34 mg/100g pour les femelles du mulet contre 9,97mg/100g pour les mâles de la même espèce. La teneur en sodium est de 48,62 mg/100g pour les femelles contre 20,49 mg/100g pour les mâles du gobie. La teneur en K est de 117,69 mg/100g pour les femelles du gobie contre 51,64 mg/100g pour les mâles. Pour les éléments minéraux mineurs le fer présente une teneur égale à 0,11 mg/100g chez les femelles contre 0,09 mg/100g pour les mâles du sparaillon. Pour les deux sexes analysés, on observe une richesse des femelles en éléments majeurs surtout pour le sparaillon, le gobie et le saurel. L'inverse est observé pour le mulet. Pour le cuivre, le cadmium et le plomb les teneurs obtenues dans la chair des quatre espèces de poissons sont en traces. Ce résultat est concordant avec celui de [2] et [3] obtenu pour les poissons de la mer noire. Pour le zinc les mâles du sparaillon présentent la valeur la plus élevée avec une teneur égale à 0,18 mg/100g. Le zinc est un élément essentiel dans le métabolisme humain [4], ainsi le sparaillon présente une source riche en cet élément.

Conclusion

Les éléments minéraux majeurs sont les plus abondantes dans la chair des poissons, ce résultat est en accord avec [5], avec des teneurs plus élevées chez les femelles et ceci pour toutes les espèces étudiées. Le sparaillon et le gobie sont les espèces les plus riches en ces éléments alors que le saurel est le plus pauvre. Les teneurs en Pb, Cd et en Cu sont faibles dans la chair indiquant que

la consommation de ces poissons ne présente pas un danger. La même conclusion est mentionnée par [6] avec les mulets de la lagune ghar el melh (Tunisie).

Abstract

Seasonal variation of the global chemical composition of the annular sea bream species of the coastal catch fish of the Gulf of Gabes (Tunisia) was studied between October 2007 and September 2008. The period of reproduction of Diplodus annularis occurs from April to June. This sexual maturity (RGS, RHS) is in strong correlation with the fat content. The fat content is negatively correlated with moisture content R = 0.83, $P < 10^{-3}$). The variance analysis of moisture, protein, fat and ash in the whole muscle shows that only the factor months has significant effect on the muscles chemical composition ($P < 10^{-3}$). Keywords: Chemical Analysis, Fishes, Coastal Engineering

Introduction

The period of reproduction of the annular sea bream occurs from February to September. The size of Diplodus annularis at the first sexual maturity is equal for both sexes to 10.21 cm [1]. The aim of the present study is to report an assessment of the global seasonal chemical composition (moisture, protein, fat and ash) of the principal costal catch fish species of the gulf of Gabes and to determine the factors influencing chemical composition. Material and Methods The muscle of fish is divided in two parts: latero-dorsal and latero-ventral parts, whole muscle and organs (liver, Head, gonads, viscera). The gonado-somatic (GSI) and the hepato-somatic (HIS) indexes were calculated as follows: GSI= (Wg/Wev).100,HIS=(Wh/Wev).100, where Wg is the gonad weight and Wev is the eviscerated fish weight. Wh is the liver weight. Moisture content, Crude protein. Fat and Ash are determined. All statistical analysis were performed by using SPSS software® version 11.0 (Statistical Package for Social Sciences). Every factor presenting a p-value (p) inferior to 0.05 was considered significant.

Results

Figure 1 shows the comparison between the gonado-somatic and the hepatosomatic indexes, and the fat content.

Fig. 1. Comparison between thegonado-somatic and the hepato-somatic indexes, and the fat content.

The gonado-somatic and hepato-somatic indexes of annular sea bream female's present maximal values in May (RGS = 7.73 % and RHS = 1.73 %), and minimal values in April (RGS=0.30) and in Aout (RHS=0.37). The RGS and RHS values are inferior for males than females. The maximal of fat content coincides with the chute of RGS and RHS values from March to July. The maximal of fat content is observed in september and is accompagned with a minimal RGS values. The minimal of fat content corresponds to the highst value of RGS. Strongest negative correlation is shows between fat and moisture contents (R=-0.83; p<10-3). Moisture, fat and ash contents varied significantly as a function of month (p<0.001). Whereas the sex of the fish did not have any significant effect on the variation of the moisture, fat, protein and ash contents of the organs (p = 0.83 for the sex). The month haven't a significant effect on the protein content (p=.0.45).

Discussion

According to the classification of fishes [2] based on their fat content, Annular sea bream could be considered as high fat fish categories » 5 to 25 % (g fat/ $100 \mbox{ g}$ fresh fish). In the state of sexual maturity, the size of gonads increases and the fat content of muscle decreased. So the fishes use their muscle fat reserve for the maturation of gonads. After the spawning period, the fat content increases due to the conversion of the gonad tissue. Moisture content is usually inversely related to fat content [3]. This relationship has been observed generally in pelagic ?sh, which lay down oil in the muscle tissue [4], and it could be a consequence of the ?sh maintaining constant density. The effect of sex on the chemical composition was not significant (P<10-3). Whereas the effect of month is significant for moisture, fat and ash content of the muscle.

Conclusion

The seasonal variation of the fat content is inversely correlated to the RGS index. In fact, the maximal of fat content reached in September (11.47 for males and 10.76 for females) coincides with the minimal value of RGS index. Fat and moisture contents are negatively correlated. The effect of sex on the global chemical composition of the annular sea bream is not significant.

RADIOACTIVITY CONCENTRATIONS IN THE SURFACE SEDIMENT AND MUSSEL SAMPLES FROM THE BOSPHORUS AND THE GOLDEN HORN, TURKEY

Ö. Kiliç ¹*, M. Belivermis ¹, S. Topcuoglu ¹, Y. Çotuk ¹, A. Ugur ² and B. Özden ² ¹ Istanbul University, Science Faculty, Biology Department - kilic_onder@yahoo.com

² Ege University, Institute of Nuclear Sciences

Abstract

It is well known that sediment and mussel samples are commonly used for monitoring of radioactivity levels in marine ecosystem. In the present study, radioactivity concentrations of 137 Cs, 40 K, 232 Th, 238 U and 210 Po were measured in sediment and mussel (*Mytilus galloprovincialis*) samples. The results of the present study were compared with the similar studies. *Keywords: Bosphorus, Mollusca, Radionuclides, Sediments*

Introduction

Nowadays, the natural radioactivity levels in Turkish marine environment are gradually increased by the fossil fuel industry, phosphate industry and the using of fertilizers. On the other hand, anthropogenic radionuclides are decreased in the biota samples of the Turkish marine environment in the course of time [1]. Some papers have been published concerning anthropogenic and natural radionuclides in biota and sediment samples collected from the Bosphorus strait [2, 3].

Materials and Methods

Fig. 1. Study area and sampling stations

The surface sediment samples were collected using a Van Veen grab sampler in the stations. The size fractions (< 63 and > 63 µm) of each sediment samples were dried at 85 0 C to constant weight and homogenized prior to analysis. The mussel samples were cleaned any external material, dissected and then dried at 85 0 C to constant weight and homogenized. The measurements of 232 Th, 238 U, 40 K and 137 Cs activities were carried out using a gamma multichannel analyzer equipped with a HPGe detector (Canberra 2020). The concentrations of 210 Po in the samples were measured with an alpha spectrometer. Other procedures of the two methods were similar to that previously described [4, 5].

Results and Discussion

²¹⁰Po concentrations were not measured for the >63 μm fraction of sediment samples in all stations. In Balat station, >63 μm fraction of sediment could not be obtained for radioactivity measurements. ¹³⁷Cs concentrations in the mussels collected from the sampling stations were generally found to be at the similar level. The activity concentrations in mussel samples of the Bosphorus are slightly lower when compared with that of the previous study carried out in the same site during the period of 2004-2006 [6]. In a previous study, ¹³⁷Cs activity content significantly increased with the decreasing grain size [7]. ¹³⁷Cs concentrations determined in the <63 μm sediment fraction in the Bosphorus are significantly higher than those previously reported in this region [2, 4]. On the other hand, ¹³⁷Cs activity levels are significantly lower in the Bosphorus and the Golden Horn when compared with the eastern Black Sea sediment at the similar grain size.

LLD, Lower limit of detection

The highest concentrations of 210 Po in mussel and sediment samples were found as 166 ± 17 and 230 ± 11 Bq kg⁻¹ in R. Kavagi and Unkapani stations, respectively. 210 Po activity concentration in the R. Kavagi mussel has not changed significantly during the past ten years [3]. On the other hand, 210 Po level in the Golden Horn sediment is higher than the Black Sea sediment [1].

Abstract

L'étude de la variation saisonnière des teneurs en éléments minéraux et en métaux lourds (mg / 100g frais) de quatre espèces de poissons du golfe de Gabès, révèle qu'ils sont riches en éléments majeurs (calcium : 35,122-102,987, potassium : 179,474-309,447 et sodium : 105,154-179,788). Les teneurs en magnésium (44,402-80,324), en fer (16,123-22,628) sont plus faibles. Celles en zinc (0,489-1,622) et en cuivre (0,096-0,646) sont très faibles. Le cadmium (<0,04) et le plomb (0,076) sont présents en traces. L'analyse statistique montre que la saison et les espèces présentent des effets significatifs (p<0,05) sur les concentrations de quelques éléments minéraux.

Keywords: Analytical Methods, Chemical Analysis, Fishes, Gulf Of Gabes

Introduction

Les métaux lourds qui sont continuellement déchargés dans les écosystèmes aquatiques contribuent à la pollution de la mer. Les poissons peuvent être considérés comme des indicateurs les plus significatifs pour l'évaluation du niveau de pollution en métaux. Plusieurs espèces commerciales et comestibles ont été largement étudiées afin de déterminer leurs teneurs en éléments minéraux et en métaux lourds. L'objectif de cette étude est de déterminer la variation saisonnière des teneurs en éléments minéraux et en métaux lourds du rouget de vase (*Mullus barbatus*), rouget de roche (Mullus surmuletus), marbré (*Lithognatus mormyrus*) et pageot (*Pagellus erythrinus*) du golfe de Gabès.

Matériel et méthodes

L'échantillonnage des poissons a été réalisé durant l'année 2007-2008 par le chalut du golfe de Gabès. Au laboratoire, les échantillons de poisson frais ont été pesés puis éviscérés. Après éviscération, la chair des mâles et des femelles est analysée séparément. Les échantillons frais ont été déshydratés dans une étuve réglée à une température de 105°C jusqu'à poids constant. L'extrait sec obtenu a été calciné dans un four à moufle à 550 - 600°C pendant 3 heures. Les teneurs en éléments minéraux et en métaux lourds ont été dosés par spectrophotométrie d'absorption atomique (type Hitachi Z 6100) [1]. Une analyse de variance et une analyse en composante principale ont été appliquées pour étudier l'effet des facteurs (saison, espèce et sexe) sur les concentrations en éléments minéraux et les répartirent en différents groupes à l'aide du logiciel SPSS (15.0) (Statistical Package for Social Sciences).

Résultats et discussion

Les concentrations des éléments minéraux et des métaux lourds dans la chair du poisson sont dépendantes des saisons et des espèces étudiées. Les valeurs des teneurs en Ca, Na, K, Mg, Fer, Zn, Cu, Cd et Pb pour les deux saisons (printemps et été) et pour les espèces étudiées sont consignées dans le tableau 1.

Pb	±0.002	±0.002	±0.003	±0.003	±0.002	±0.002	±0.002	±0.001

Les valeurs minimales de Ca et K ont été obtenues en été, alors que pour les autres éléments minéraux (Na, Mg, Fer et Zn) et les métaux lourds (Cu, Cd et Pb), les teneurs maximales sont obtenues en été. L'analyse de variance montre

que les éléments minéraux et les métaux lourds (potassium, calcium, magnésium, fer et cuivre) différent significativement d'une saison à une autre pour les quatre espèces et sexe confondues (p<0,05). L'ANOVA de l'analyse des deux saisons ensemble, révèle que seul le zinc (Zn) varie significativement (p<0,05) selon les quatre espèces étudiées. Le sexe n'a pas d'effet significatif (p>0,05). Sur tous les échantillons analysés, pour la saison de printemps, les espèces influent seulement sur les teneurs en Ca, K, Fer et Zn (p<0,05). En été les concentrations en Ca, Na et Zn différent significativement selon les espèces (p<0,05). Cette dernière constatation est bien confirmée par l'Analyse en Composantes Principales (ACP). En effet, le calcium, le sodium, le zinc, le magnésium, le fer et le cuivre définissent l'axe 1 qui représente 47,38 % de la variance totale. La variable potassium détermine l'axe 2 qui représente 23,43 % de la contribution totale qui est 70,818 % (figure 1).

Fig. 1. Analyse en Composantes Principales des éléments minéraux des espèces des poissons étudiés en été.

VARIATION SAISONNIERE DES TENEURS EN EAU ET EN LIPIDES ET DE LA COMPOSITION DES ACIDES GRAS DU ROUGET DE ROCHE (MULLUS SURMULETUS) DU GOLFE DE GABES

Aida Koubaa¹*, Abdelwaheb Abdelmouleh², Abderrahmen Bouain¹ and Nourhène Boudhrioua¹

² Institut National des Sciences et Technologie de la Mer, 3018, Sfax, Tunisie

Abstract

Les teneurs en eau et en lipides des rougets de roche présentent une large fluctuation durant toute l'année. Le maximum de la teneur en lipides est atteint au mois de novembre (10,886 %) et le minimum est atteint au mois de mai (2,92 %). Durant toute l'année, la teneur en eau est inversement proportionnelle à celle en lipides. Le spectre des acides gras montre une richesse relative en acides gras polyinsaturés (l'acide linoléique, l'acide arachidonique et l'acide docosahexaenoique). Les concentrations des acides gras saturés et mono insaturés sont plus élevées pendant le printemps que l'hiver, le cas contraire est observé pour les acides gras polyinsaturés. *Keywords: Analytical Methods, Biotechnologies, Chemical Analysis, Fishes*

Introduction

La Tunisie est un grand producteur et exportateur de fruits de mer. Le secteur de la pêche a une grande importance économique, sociale et même environnementale. Les fruits de mer de la Tunisie incluent les mollusques, les crustacés, les poissons, etc. Plusieurs modes de pêche sont pratiqués en Tunisie, parmi lesquels on cite la pêche au chalut. L'apport national de ce mode de pêche a augmenté de 12 % entre les années 2007 et 2008 [1]. Le rouget de roche est une espèce benthique à haute valeur commerciale et très consommée en Tunisie ; elle est pêchée au chalut. C'est une espèce grasse, riche en acides gras polyinsaturés. De nombreuses études ont montré que l'huile de poissons a plusieurs bienfaits pour la santé comme la réduction des maladies cardiovasculaires [2]. Ce travail porte sur l'étude de la variation saisonnière de la teneur en eau et en lipides et de la composition des acides gras du rouget de roche du golfe de Gabès.

Matériel et méthodes

La capture des poissons a été réalisée à l'aide d'un chalut dans le golfe de Gabès. La variation de la teneur en eau, en lipides et en acides gras a été déterminée durant l'année 2008-2009. Les analyses ont été effectuées sur la chair de poissons frais. Pour la détermination de la teneur en eau, les échantillons ont été déshydratés dans une étuve réglée à une température de 105°C jusqu'à poids constant [3]. La teneur en lipides a été analysée par la méthode de Soxhelt en utilisant le chloroforme comme solvant d'extraction. Les acides gras ont été extraits selon le procédé de Bligh et Dyer [4], après méthylation, les esters méthyliques ont été analysés par CPG-SM (type ATTUMICAM 610).

Résultats et discussion

L'analyse de la teneur en lipides révèle qu'elle est très variable. En effet, la réserve lipidique est totalement épuisée pendant le mois de mai, les valeurs de la teneur de lipides chutent de 8,1 % (avril) à 2,92 % (mai). Durant cette période le poisson utilise beaucoup d'énergie : c'est la période de ponte. Contrairement à la teneur en lipides, la teneur en eau subit une diminution pendant les mois (octobre et novembre) et une augmentation pendant le mois de mai (figure 1).

Pour les mâles et les femelles de cette espèce, durant toute l'année, les lipides sont formés par les proportions suivantes des acides gras totaux (20 à 30 % saturés, 15 à 45 % mono insaturés et 15 à 60 % polyinsaturés). En ce qui concerne leur variation, les poissons capturés au printemps présentent une concentration plus élevée d'acides gras saturés et mono insaturés (tels que l'acide palmitique : C16:0, l'acide stéarique : C18:0, l'acide palimitoléique : C16:1n-9, et l'acide oléique : C18:1n-9) et une concentration moins élevée d'acides gras polyinsaturés essentiellement l'acide linoléique (C18:2 n-6), l'acide arachidonique (C20:4 n-6) et l'acide docosahexaenoique (C22:6 n-3) que ceux capturés en hiver.

PETOLA-STROMATOLITIC BASEMENT FOR MANUAL GATHERING OF SALT IN SECOVLJE SALINA

Nives Kovac¹*, Neli Glavaš¹ and Boris Šket²

¹ national institute of biology (marine biology station) - kovac@mbss.org

² Faculty of Chemistry and Chemical Technology, University of Ljubljana, Askerceva 5, 1000 Ljubljana, Slovenia

Abstract

In Secovlje Salina (Gulf of Trieste, northern Adriatic), the stromatolitic microbial mat named "petola" is a crucial element in old mediaeval manner of salt-production so the understanding of its chemistry is very important for the preservation and progress of this activity. The chemical study (FT-IR, ¹³C-NMR, elemental analyses) was performed to investigate the petola composition and its transformations during salt-making solt.

Keywords: Salinity, Mineralogy, Adriatic Sea

Introduction

In Secovlje solar salterns (northern Adriatic, Slovenia) the salt is still produced with traditional procedures by manual gathering of salt on the petola i.e. microalgal mat composed mostly of cyanobacteria, diatoms and other microalgae impregnated with minerals (gypsum, Mg-calcite...). Petola prevents sea mud from mixing with salt so this naturally produced salt is rich in minerals and purely white. This biological-chemical facet has a special role in the precipitation/dissolution processes so the understanding of its chemistry is very important for the preservation and progress of this activity. The presented results upgrades the previous chemical study of petola samples from 2006 [1].

Materials and methods

Sampling was carried out in the crystallizer pond on May 14th (Sample A), June 9th (Sample B), and July 30th (Sample C), in 2009. Surficial sediment samples (0-2 cm) were collected using 40 mm diameter gravity core sampler and then the tiny slice of surface sediment i.e. 2-3 millimeter thick layer of biosediment was cut offand frozen. The freeze-dried samples were grounded to a fine powder and used for elemental, ¹³C-NMR and FT-IR analyses.

Results and discussion

The FT-IR analyses of petola samples (Figure 1) confirmed the fractional crystallization of different salts according to the increasing evaporation and salinity. First to crystallize are carbonates and sadara (brine conc. >13 Bé), followed by NaCl (brine conc. ~25 Bé) and finally magnesium salts (brine conc. >26 Bé) [2]. Unfortunately, the NaCl is transparent to the infrared light and not introduce any lines onto the spectra. The alteration of organic fraction of petola was detected during its maturation and increasing brine salinity concentration. Cementation during petola cultivation contribute to its stabilization and a higher hardnes allowing the manual gathering of salt on this basin's base.

Fig. 1. FT-IR spectra of petola samples (Secovlje Salina)

Major FT-IR spectra bands could be assigned: 3625 cm^{-1} (clay minerals), $3000-3600 \text{ cm}^{-1}$ (O-H and N-H stretching band region), $2800-3000 \text{ cm}^{-1}$ (organic carbon i.e. CH₂ and CH₃ alkyl groups), $1653-1640 \text{ cm}^{-1}$ (proteinic component, water signals, aromatic and olefinic C=C groups), carbonates, (2514, 1795, 1420-1450, 876 and 713 cm⁻¹), silicates (1870, 1160, 1020, 799, 780, 696 and 534 cm⁻¹), sadra (3407, 1683, 1621, 1141, 1118, 669 and 602 cm⁻¹). Evaluation

of ¹³C NMR data will give us further insights into the composition and reactivity of petola organic carbon.

VERTICAL HYDROCHEMICAL STRUCTURE OF THE WESTERN BLACK SEA AREA IN 2007 – 2008 PERIOD

Anton Krastev^{1*}, Galina Shtereva¹, Ognyana Hristova¹ and Boryana Dzhurova¹ ¹ Institute of Oceanology - BAS, Varna, Bulgaria - antnkrstv@abv.bg

Abstract

The western part of the Black Sea is highly influenced by major rivers input. Through different periods its vertical hydrochemical structure varies in response of the hydrological conditions and the anthropogenic influence. The study is an attempt to estimate the stability of the chemical parameters content in the water body of the region in two seasons - early spring (cold upper layer waters) and late summer (well expressed termocline).

Keywords: Nutrients, Oxygen, Black Sea, Vertical Profile

Methods

The study is based on data obtained during the seasonal cruises (October 2007 and 2007 and April 2008) with RV "Akademik" in western Black Sea area. The samples are collected from 9 stations using Rosette Seabird system on the following depths: 1, 10, 25, 50, 75 and 100 m, depth of thermocline location and DCM and depths corresponding to σ = 15.0, 15.2, 15.4, 15.8, 16.0 and 16.2. The hydrological parameters are measured by Seabird CTD System. The hydrochemical parameters analyses are accomplished by standard methods [1]. Results

Hydrology. In October the Upper Mixed Layer (UML) is located in the water column beneath surface with temperature $18.5-20.3~^\circ C$ and density ($\sigma\theta)$ about 10.5 – 12.2. The thermocline is located in the depth range of 29 - 35 m and the Cold Intermediate Layer (CIL) - in 60 - 100 m. The thermohaline structure in April is typical for early spring without expressed thermocline. The upper surface layer is characterized with low temperature in range 9.3 - 11.2 °C and density 13.0 - 13.9.

Fig. 1. Filtered vertical distribution of DO, PO4, NO2 and NO3

Dissolved gases. High oxygen content in April (360 µM) (Fig. 1) corresponds to highest Oxygen Saturation (OS) in surface waters due to hydrological conditions. In CIL DO vertical distribution follows the same pattern for each season – decreasing gradient from about 250 μM to the redox zone. H2S is detectable from depths > 120 - 140 m. Its increase becomes steeper below 150

m ($\sigma\theta > 16.0 - 16.2$) (Fig. 1). The depth of the upper anoxic waters could be considered deeper for the distant stations but is not irregular during last decade [2].

Nitrogen. Surface, UML and CIL (oxygenated waters) NH4 concentrations are relatively low (0.5 μ M). From $\sigma\theta$ = 16.0 (135 – 145 m) its concentrations increase down to the anaerobic zone. NO2 and NO3 concentrations in UML in the end of summer are lower due to biochemical exhaustion and the NO2 maximums in the thermocline and in the oxycline are well expressed (Fig. 1). The maximum NO3 concentrations (~ 96 – 120 m, $\sigma\theta$ = 15.4) does not exceed 3 μ M, which is less than the values detected during summer (> $5 \mu M$) [3, 4] in the same region. Nitrates disappear at $\sigma\theta$ = 16.0 – 16.2 as it has been observed elsewhere [5, 6]. The Total Nitrogen (TN) varies around $10\,\mu M$ and is its content is relatively higher in April.

Phosphorous. PO4 content is low down to CIL both in warm and cold seasons. In CIL an increase is initiated with an upper maximum of 1.4 μ M in April and 0.8 μ M in October at $\sigma\theta$ = 15.5 and minimum at $\sigma\theta$ = 15.9 where the oxycline is located. The second maximum of $4 - 5 \,\mu M$ in the warm season is found at $\sigma \theta =$ 16.25 (150 - 160 m) (Fig. 1).

Silicates. SiO2 distribution is characterized by significant increase down to $\sigma\theta$ = 16.0 (Fig. 2). In UML its content varies in range $2 - 7 \mu$ M. The measured lower concentrations possibly are due to phytoplankton growth during both seasons in the euphotic zone. SiO2 concentration in near shore stations (coastal waters) is 2 times higher than in deep zone surface waters [7].

Suspended matter is higher in the upper layer - 0.7 - 1.0 mg/l and decreases steeply in the beginning of CIL. In thermocline SM is normally lower in the colder season.

Conclusions

- The vertical hydrochemical structure in Western Black Sea is generally specified by the hydrological conditions of the water column:

- The anoxic zone appears relatively low (140-150 m), the NH3 distribution, the NO2 specific variations and the NO3 reduction are well expressed, considering undisturbed stratification and hydrochemical stability of the water column in the investigated period;

- PO4 deeper maximum in October is specific for the warm part of year due to mineralization of the increased organic matter;

The measured surface lower concentrations SiO2 are possibly due to phytoplankton growth during both seasons in the euphotic zone.

Acknowledgements The study is supported by SESAME Programme and the BAS-RAS joint project - Black Sea Redox Layer Specifics.

POTENTIAL TOLL OF A DESALINATION PLANT: A) SEAWATER QUALITY

Nurit Kress^{1*}, Dror Dromi¹ and Yossef Z Yacobi¹

¹ Israel Oceanographic & Limnological Res, National Institute of Oceanography - nurit@ocean.org.il

Abstract

The potential impact the discharges of brine and backwash (containing the coagulant ferric hydroxide) on seawater quality was monitored at the area of the outfall of a reverse osmosis (RO) desalination plant. Preliminary results showed that water was warmer and more saline at the discharge area, and that the backwash tinted the water red, increased water turbidity and the concentration of suspended particulate matter, the influence reaching up to 1,500m. Nutrient concentrations were also higher at the discharge area and decreased with increased distance. While the effect of the backwash on a few parameters of water quality was obvious, the various discharges in the area make it impossible at this time to attribute a cause-effect to explain the findings of this research. *Keywords: Coastal Waters, Nutrients, Salinity, Monitoring, Levantine Basin*

Desalination has increasingly been seen as an important element in dealing with water shortage particularly by countries which border the sea. In Israel, increase in water usage and dry years prompted the government to set a goal of 600,000 million m³ desalinated water per year by 2013. To date, there are two operational seawater desalination plants at the Mediterranean coast of Israel, producing ca. 140,000 million m³ water yearly by reverse osmosis, a third plant almost operational (ca. 100,000 million m³ yearly) and two large plants at the planning stage. However, the impact of pumping large volumes of seawater into the plants and of concentrate discharges from the plants has yet to be fully assessed. Pumping large volumes of seawater into desalination plants can cause impingement and entrainment of organisms, in particular plankton, fish eggs and larvae, and depletion of those organisms. Moreover, ca. 50% of the feedwater is converted to concentrate that is discharged back to the sea. If the desalination plant operates in an area where water quality is already poor, the concentrate will contain also excess of the pollutants present in the seawater intake. In addition, the process of desalination utilizes chemicals in the pre-treatment of seawater entering the plant and during the desalination process such as ferric hydroxyde (coagulant) and polyphosphonates (antiscalants) that are discharged to sea with the desalination concentrate (1). In this work we monitored the effect of the discharge of ferric hydroxide on the water quality at the outfall of a RO desalination plant operating in Ashkelon, at the southern Mediterranean coast of Israel , the largest RO plant in the world. The brine and the backwash of preliminary filtration stage, the latter containing ferric hydroxide, are discharged at the shore, next to the discharge of cooling waters of a power plant adjacent to the RO plant. The brine is discharged continuously while the backwash is discharged in pulses, their frequency depending on the seawater quality of the intake. To complete the picture, brine from well's amelioration, containing nitrates, are also discharged in the same area. Three surveys (April and August 2008 and April 2009) were conducted in the area and seawater samples were collected before, during and after the pulsed discharge of the backwash, along a gradient from the more affected area to apparently clear (non affected) water area. Preliminary results showed that seawater temperature at the outfall area was higher by 4-6 °C due to the effect of the power plant cooling water discharges. Salinity was ca. 1% higher than the natural salinity in the area (39.5) due to the brine continuous discharge, it's influence traced up to 500 m from the outfall. Similar results were seen in SE Spain (2). The backwash increased water turbidity and tinted the seawater red as a result of the introduction of suspended particulate matter containing Fe. that increased in concentration from 6 to 14 mg/l. It's influence could be traced as far as 1,500 m from the outfall. The bacterial community was also influenced as described by Yacobi and Kress (Submitted abstract, CIESM 2010). Nutrient concentrations at the discharge area was higher than in the vicinity, in particulate nitrate, probably as a result of well's amelioration brine, with concentration decreasing with increased distance from the discharge area. While the effect of the backwash on water quality (turbidity, particulate matter) was obvious, the various discharges in the area make it impossible at this time to attribute a cause- effect to explain the findings of this research.

UNDERSTANDING WHY NUTRIENT CYCLING IN THE EASTERN MEDITERRANEAN (EMS) IS SO UNUSUAL?

Michael Krom¹*, Kay-Christian Emeis² and Phillippe Van Cappellen³

¹ University of Hamburg

² Georgia Tech Institute, Atlanta ³ Earth & Biosphere Institute, School of Earth and Environment, University of Leeds - M.D.Krom@Leeds.ac.uk

Abstract

The high N:P in the EMS is due to high N:P ratio in the external inputs combined with low denitrification caused by its ultraoligotrophic status. There is no evidence for N-fixation. The external inputs have increased by 2-5 times between 1960 and 2000 and yet there is no evidence of increased primary productivity. We suggest this is due to rapid export of excess nutrients through the Straits of Sicily.

Keywords: Eastern Mediterranean, Phosphorus, Pollution, Geochemical Cycles

The EMS is both P starved and unequivocally phosphorus limited with a nitrate:phosphate ratio in the deep waters of ~28:1 and similar high ratios in the dissolved and particulate organic matter (1). It is also unusual in being ultra-oligotrophic. This is despite the basin being surrounded by land with a resident population of ~ 120 million people and a further 120-200 million tourists yearly. As a result of this large population there are considerable external inputs of nutrients (N & P) from both atmospheric and riverine sources. Recent studies have shown that the high N:P ratio found in the EMS is due to a combination of high N:P ratios in the external inputs combined with low denitrification rates. This is because there are limited areas of anaerobic sediment due the ultra-oligotrophic nature of the basin. A total nutrient budget for the entire basin shows that the external inputs balance closely the outputs (Table 1) without any nitrogen fixation.

Tab. 1. Calculated nutrient inputs into and outputs from the Eastern Mediterranean basin. All values as given in 10^9 moles/y. The data for the total nutrient budget is from Krom et al., (2004) with subsequent data from Ludwig et al., (2009)

Source	N input/	P input/	Molar N:P
Atmospheric input (1996-1999)	111	0.95	117
Riverine input	63	2.4	26.3
Black sea	8	0	
Total inputs to basin	180	3.4	54
Straits of Sicily	142	4.4	32
Sediment deposition	27	1.0	27
Sediment denitrification	10	-	
Total output from basin	179	5.4	33
Atmospheric input (1960)	50.5	-	21
Atmospheric input (1996-1999)	111	0.95	117
Riverine input (1963)	10.8	0.51	21.2
Riverine input (1998)	51.0	1.04	49.2

A similar budget for the core of the Cyprus eddy found that the annual inputs of fixed nitrogen into the core of the eddy balanced by known exports (2). Both budgets were in balance without any significant nitrogen fixation. Previous explanations for the observed isotopically light δ^{15} N-NO₃ (2.4± 0.1‰) in the deep water which suggested extensive nitrogen fixation did not take into account the isotopic signature of the atmospheric input. Recent measurements have shown that this external input is isotopically light ($\delta^{15}N =$ -3.1‰) and together with the known atmospheric N flux is able to explain the isotopic content of nitrate in the deep water without any nitrogen fixation (5) Direct measurements of nitrogen fixation across the EMS have found rates at or below detection limits; (0.5-2 μ mol/m²/d; and ~1 nmol/l/d;. The exceptionally high nitrogen fixation rates in the Cyprus eddy (3) (129 nmol/l/d; 15 mmol/m²/d) are considered anomalous particularly since the only potential diazotroph observed within the system at the time of measurement were Synechococcus sp. and these were found in low numbers (3.3-4.3 x 10⁶ cells/l;. This explanation for the unusual N:P ratio in the EMS is entirely compatible with existing explanations for the global controls of the Redfield ratio as being a balance between denitrification removing N to below 16:1 and subsequent N

fixation adding fixed nitrogen. The EMS is simply unusual because there is almost no denitrification, even in the coastal sediments.

The low nutrient concentrations in the deeper water in the EMS, which is the cause of the observed ultra-oligotrophic conditions, is due to the anti-estuarine circulation with low nutrients being supplied by the in-flowing surface waters and significant nutrient export in the outflowing intermediate water. The external flux of fixed nitrogen in the atmospheric supply has increased by a factor of 2.2 since 1960 while the riverine flux has increased by a factor of 4.5 during the same time period (Table 1). The riverine P flux has also increased by a factor of ~2 (4). Despite these major increases in external nutrient flux, there is no evidence of a parallel increase in primary productivity or any other regional measure of eutrophication. We propose that this is because the nutrients are exported with the outflow at the Straits of Sicily with nutrients having a residence time of only <10 years in the EMS. These new understandings have important implications on our understanding of biogeochemical cycles within the EMS basin and need to be taken into account in any attempts to predict the effect of changing nutrient fluxes or ocean acidification on this sensitive ecosystem.

EVALUATION OF HEAVY METAL POLLUTION IN SEDIMENT AND MULLUS BARBATUS FROM THE **IZMIR BAY (EASTERN AEGEAN) DURING 1997-2009**

Filiz Kucuksezgin ¹*, Aynur Kontas ¹ and Esin Uluturhan ¹

¹ Dokuz Eylul University Institute of Marine Sciences & Technology - filiz.ksezgin@deu.edu.tr

Abstract

Izmir Bay (western Turkey) is one of the great natural bays of the Mediterranean. Outer and middle bays show low levels of heavy metal enrichments except estuary of Gediz River. Heavy metal levels were lower than the results in fish tissues reported from polluted areas of the Mediterranean Sea. Keywords: Metals, Sediments, Fishes

Introduction

Izmir is an important industrial and commercial centre and a cultural focal point. The Gediz River, which flows to the northern part of the bay, is the second biggest river along the eastern Aegean coast. Gediz River is densely populated and includes extensive agricultural lands and numerous manufacturing, food and chemical industries. A number of studies have been carried out on the concentrations of nutrients and heavy metals in the bay during a year, but no long-term and seasonal data are available. The main aim of this study was to monitor levels, temporal variability and distribution of heavy metals in edible fishes and sediments of Izmir Bay.

Materials and Methods

The study area located between the longitudes 26°30'-27°08' E and latitudes 38°41'-38°21' N. Sediment and fish samples were analysed according to UNEP [1,2,3]. Sediment (SD-MEDPOL-1/TM) and fish (MA-MEDPOL-1/TM) samples were used as a control for the analytical methods.

Results and Discussion

The highest concentrations of metals were found in sediments from the inner part of the bay where intensely industrialized (mainly iron, paper and pulp factories, antifouling paints, chlorine-alkali plants, chemical industries, textile industries, metal processing, timber processing, cement factories, food processing, beverage manufacturing and bottling, tanneries, oil, soap and a very busy harbour) compared to the middle and outer parts of the bay. The concentrations of Cd, Cu and Pb in the outer bay were generally similar to the background levels and mean concentrations from the Mediterranean and Aegean Seas except chromium, zinc and mercury. ANCOVA was used to compare the regional differences in the heavy metal concentrations of sediments. In consequences, the comparison of metal concentrations demonstrate that, there are significant (p<0.05) regional variations. M. barbatus, being bottom dwellers to a certain extent, are species that tend to concentrate contaminants to a higher degree than other species due to high mobility. For this reason it was recommended by FAO/UNEP [4] as monitoring species. The concentrations of heavy metals found in M. barbatus varied, with Hg ranging from 14-520, Cd from 0.10-10, Pb from 2.6-478, Cr from 22-270, Cu from 178-568 and Zn from 2157-3832 mg kg⁻¹ wet weight in The order of heavy metal concentrations bay. were: the Zn>Cu>Pb>Cr>Hg>Cd. The comparison of metal concentrations demonstrate that, there are no significant (p<0.05) regional variations during 1996-2009 except mercury (df=5, F=4.974, p=0.0005).

Conclusions

Most of the heavy metals concentrations in sediments were generally similar to the background levels from the Mediterranean and Aegean Sea, except delta of Gediz River in the outer bay. The high concentration of heavy metals is observed in the inner part of the bay. The levels of metals are lower in the inner bay than polluted areas of Mediterranean. Hg and Cd concentrations are higher than the reported mean values of heavy metals in fish organisms from the Aegean Sea and Mediterranean. Lead concentrations are similar to those reported in fish from Mediterranean countries.

MEDITERRANEAN SEA PRIMARY PRODUCTIVITY SIMULATED BY OPATM-BFM MODEL

P. Lazzari ¹*, V. Ibello ¹, A. Teruzzi ¹, S. Colella ², S. Salon ¹, C. Solidoro ¹ and A. Crise ¹ ¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS - plazzari@ogs.trieste.it ² ISAC CNR, Roma, Italy

Abstract

We present an analysis of the primary productivity estimation for the Mediterranean Sea carried out by the numerical tool OPATM-BFM. Annual budget of primary productivity is quantified and compared with other estimations based on satellite observations and insitu measurements. Model results are discussed and summarized considering the main biogeochemical properties and their inter-annual variability (period 1999-2004) at the sub-basins level with a particular interest to primary productivity (PP). <u>Keywords: Primary Production, Models, Pelagic</u>

Introduction

Scenarios analyses indicate that the anthropogenic pressure on the Mediterranean Sea environment will significantly increase in the next decades. Optimal management of this rapid change requires a quantitative knowledge of the Mediterranean Sea functioning based on an integrated view that may include in-situ remote measurements and modelling projections. Models represent the only system able to quantitatively estimate with high space/time resolution the biogeochemical processes at basin scale. We applied a model developed in the framework of the operational short-term forecast [1] for a multi-annual simulation of plankton productivity.

Model

OPATM-BFM is a three-dimensional transport-reaction model developed to simulate the evolution of the marine biogeochemistry. It is designed to resolve the seasonal cycle of primary producers on the Mediterranean basin spatial scale. The model in its current version has an horizontal resolution of 0.125 degrees with 43 vertical levels. The system is forced with physical parameters produced by an external high- resolution Ocean General Circulation Model (OGCM) according to the off-line approach. Advection, diffusion and sinking are implemented by a modified version of OPATM code, OPA Tracer Model version v8.1 [2]. The reaction term is implemented by the BFM model version 2.0 [3]. The physical parameters are computed by the MED16 OGCM forced by the atmospheric fields of the ECMWF reanalysis for the period 1998-2004. Photosynthetic Available Radiance (PAR) is modulated by a satellite-estimated extinction parameter. Initial and boundary conditions (for the Gibraltar Strait input) are obtained from the nutrient climatological dataset MEDAR MEDATLAS 2002.

Result and Discussion

Table 1 shows the annual averages (as arithmetic means) of PP estimated by OPATM-BFM model, SeaWiFS, and by data synthesis of in situ measurements for different sub basins of the Mediterranean Sea, Fig. 1. Overall there is a good correspondence among different estimations for all the sub-basins, with an average productivity around 94 $\,$ mgC m⁻² y⁻¹ for the whole Mediterranean Sea basin. The western Mediterranean is characterized by an higher average productivity level, around 127 mgC m⁻² y⁻¹, including Alboran Sea, while the eastern Mediterranean average productivity is lower and around 72 mgC m⁻² y⁻ . A seasonal cycle is evident for each year considered in the present simulations, both in the western and eastern sub-basins. The maxima of primary production occur always during the winter period while the minima occur in late autumn, as shown in the time series of the period 1999-2004, Fig. 1. In the ALB sub-basin, the seasonal cycle is super-imposed to the high frequency peaks related to the highly dynamical regime of this area. The NWM area has a dominant seasonal cycle with an evident maximum of the productive peak in 2003 (around 1 gC m⁻² d⁻¹). LEV area shows maxima of productivity in April and very low values during summer and autumn periods, even below 50 mgC m⁻² d⁻¹. In summary, our model gives full spatial/temporal coverage for the period considered, providing an estimate of the biogeochemical properties not measured experimentally.

Tab. 1. Horizontal averages of vertical integrated primary productions (gC.m⁻².y⁻¹) for the period 1999-2004. On parenthesis (average of the annual variance, variance of the annual average). Western basin includes Alboran Sea, North and South Western Mediterranean, Thyrrenian Sea. Eastern basin includes Ionian and Levantine sub-basins. Abstract

Samples were collected adjacent to the Island of Porquerolles in the Northwest Mediterranean Sea to study the distribution of natural and anthropogenic radionuclides in heavily oxygen-depleted sediments associated with the decomposition of organic carbon derived from the sea grass *Posidonia oceanica*. Elevated isotopic concentrations of uranium (²³⁴U and ²³⁸U up to 200 Bq/kg d.w.) were likely due to the high organic carbon and very low oxygen content of the sediment. *Keywords: Western Mediterranean, Sediments, Radionuclides*

Introduction

Coastal sediments are ultimate sinks for particulate matter in the water column and as such, represent important repositories of historical information on contaminant levels in the marine environment. The present study sought to obtain new information on the distribution of natural and anthropogenic radionuclides in coastal sediments and to investigate how their concentrations are regulated by diagenetic processes associated with the decomposition of organic carbon derived from *Posidonia oceanica*. In order to interpret the sedimentary processes and to study contamination over the last century, a dating method derived from the excess of ²¹⁰Pb was used together with ¹³⁷Cs horizon produced by global fallout and from the Chernobyl accident [1,2]. Samples and methods

Sediment samples were collected in 2002 near the Island of Porquerolles in the Northwest (NW) Mediterranean Sea by the Scientific Centre of Monaco [3]. Weapons tests conducted by the French navy had formerly disturbed both sea grass cover (Posidonia oceanica) and sediments in the study area, resulting in extensive growth of the green alga Caulerpa taxifolia [3]. Two sediment cores (100 mm in diameter and 0.8 long) were collected by divers at a region of overlap between two weapons-damaged areas (St. 1 and 2). A third core was collected by divers at a control site 6 km away from the damaged area (St. 3). A more distant reference core (St. 4) was collected offshore near Monaco. The St. 1 core was stored in a refrigerator and exposed to a sensitive photographic film for one week. The cores were freeze-dried and sliced transversely into 10 mm thick sections, and pulverized using an agate mortar and pestle prior to radiochemical analysis. Samples were analysed for anthropogenic $(^{137}Cs, ^{238}Pu, ^{239,240}Pu$ and $^{241}Am)$ and natural $(^{226}Ra, ^{210}Pb, ^{210}Po, ^{234}U, ^{235}U)$ and ²³⁸U) radionuclides and for organic carbon (OC). ²¹⁰Pb(excess) was derived from the measured ²¹⁰Pb (total) and ²²⁶Ra profiles, in order to date the cores by reference to their sediment accumulation rates.

Results and discussion

The sediment cores obtained at St. 1, St. 2 and St. 3 all bore the hallmarks of anoxia: dark-grey colour, strong H2S smell and the organic remains of Posidonia oceanica dispersed throughout. OC is oxidized by O2 and via the reduction of NO3⁻, SO4²⁻ and Mn/Fe oxides in sediments. The contribution of reduced species to O_2 consumption is effectively enhanced in coastal areas where anoxic conditions can be established even in surficial sediments due to high inputs of organic matter [4]. The sediments found at Porquerolles were highly anoxic, as evidenced by a lack of Mn peaks in the surface layers, whereas St. 4 showed a high concentration of Mn in the surface layer caused by the formation of MnO₂ (Mn analyses carried out by XRF). Organic carbon plays a critical role in determining the distribution of major elements and radionuclides in coastal sediments via its influence on diagenesis [5,6]. The surface OC content of Porquerolles sediments was much higher than previously reported (3.4 to 5.7 % versus < 1% in the western Gulf of Lions [4]) and could be attributed to the substantially greater density of vegetation cover. Fragments of Posidonia oceanica were found throughout the Porquerolles' sediment profiles following weapons tests that killed the sea grass beds and caused the rapid formation of new layer of organically rich sediment [3]. The OC content of the distant reference core taken at St. 4 was much lower (0.6 to 1.1 %) and was comparable with values determined in previous investigations [4]. The ²¹⁰Pb_(ex.) profiles of Porquerolles sediments revealed the impacts of weapon tests, which produced mixed sediment layers and high sediment accumulation rates up to 1.2 cm yr⁻¹, higher than have been reported elsewhere in NW Mediterranean [1,7]. The photographic film placed on the sediment core collected at St. 1 displayed evidence of exposure to radiation emitted from the sediment surface. A few "hot" particles were

isolated from the sediment at depths close to 40 cm from the surface, and analysed by SIMS. These analyses confirmed the presence of highly enriched U particles (AMS analyses of "hot" particles are still in progress). The origin of "hot" particles in the sediment is not yet known. Radiometric analyses of bulk sediment samples revealed U isotope concentrations at Stations 1 and 2 (²³⁴U and ²³⁸U up to 200 Bk/kg d.w.) well in excess of those measured at Stations 3 and 4. The peak U concentrations were observed at depths of around 40 cm, which coincided with a peak in OC concentration. High oxidation state of uranium (VI) dissolved in pore water tends to be reduced to immobile U(IV) and precipitate beneath the redoxcline. When the degradable organic matter in sediment is completely consumed, no further incorporation of U occurs in the sediment, and authigenic U is recycled to the ocean [6]. The high OC load and strong reducing conditions in the sediment at Porquerolles likely explains the high total U content. The average activity ratio of $^{234}\text{U}/^{238}\text{U}$ is 1.107 ± 0.018, consistent with the world's ocean value of 1.12 ± 0.01 [8]. The average activity ratio of $^{235}U/^{238}U$ is 0.038 ± 0.006, which is close to the natural level (0.047), but different from values characterising either an enriched U (0.091), or a depleted U (0.019). $^{239,240}\mathrm{Pu}$ and $^{241}\mathrm{Am}$ levels in surface sediments ranged from 1.0 to 5.7 Bq/kg and from 0.3 to 1.0 Bq/kg d.w., respectively. 137 Cs levels were between 0.3 and 6.2 Bq/kg. We may conclude: While high uranium content observed at St. 1 may be due to the high organic carbon and very low oxygen content of the sediment, the origin of uranium enriched particles in the sediment is not yet known, and further investigations are on the way to explain this anomaly.

INCREASINGLY DIFFICULT RESPIRATION OF AEROBIC ORGANISMS IN THE MESOPELAGIC LAYER: POSSIBLE ADAPTATION STRATEGY

Louis Legendre ¹*

¹ Laboratoire d'Océanographie de Villefranche - legendre@obs-vlfr.fr

Abstract

The provision of intermediate waters that are hospitable for aerobic life is a major service supplied by the sea, but respiration is becoming increasingly difficult for mesopelagic aerobic organisms: oxygen is decreasing in minimum oxygen zones in many regions, and increasing carbon dioxide contributes to lower the free energy from respiration. Reduction of this service calls for adaptation because the increasingly difficult mesopelagic respiration will be accompanied by a reduction of biodiversity that may progress so rapidly that many taxa may disappear before we know they exist. With them would disappear their potential services. The only possible adaptation strategy may be to accelerate the study of diversity in intermediate waters, which is more vulnerable to climate change than diversity in surface or deep waters.

Keywords: Oxygen, Biodiversity, Intermediate Waters, Global Change

INTRODUCTION

The long-term provision of intermediate waters (from 100 to 1000 m) that are generally hospitable for aerobic life is a major service that is presently supplied by the sea. However, respiration is becoming increasingly difficult for aerobic organisms in the mesopelagic layer (also called twilight zone) for two reasons.

METHODS AND STUDY SITES

Firstly, concentrations of dissolved oxygen are decreasing in minimum oxygen zones (OMZs, generally between 300 and 700 m) in many regions [3, 4], and are predicted to continue to decrease in coming decades and centuries [2]. The presently existing major OMZs with very low oxygen concentrations are located in the Eastern South Pacific Ocean, Eastern Tropical North Pacific Ocean, Arabian Sea and Bay of Bengal. A reduction of oxygen by 20-40% is predicted in deeper oceanic waters over the coming 700 years, but this should not lead to extensive deep-ocean anoxia [2]. Hence, climate change threatens dissolved oxygen more in intermediate waters than in surface or deep waters.

Secondly, the concentration of total carbon dioxide is progressively increasing in surface and intermediate waters. The energy from respiration that can be converted into work by organisms (called free energy) is related directly to dissolved oxygen and inversely to dissolved carbon dioxide [1]. Hence, the combination of decreasing oxygen and increasing carbon dioxide is presently reducing and will continue to reduce the free energy of respiration. This will make respiration of aerobic organisms in intermediate waters increasingly difficult.

RESULTS AND DISCUSSION

The combination of the above two processes will reduce a service that the sea had been providing to aerobic life for millennia. This serious environmental problem should be an additional incentive for governments to address the mitigation of global change internationally and without delay. However, even if mitigation policies were implemented efficiently and rapidly, the respiration of mesopelagic aerobic organisms would nevertheless become increasingly difficult in many areas. These respiration problems will lead to a reduction in the biodiversity of mesopelagic pelagic aerobic organisms. Hence, reduction of the above service calls for an adaptation strategy as discussed in the next paragraph.

On the one hand, diversity of the biota in intermediate waters is still largely unknown, and represents a nearly untapped reservoir of future services to humans. On the other hand, respiration problems may progress so rapidly in intermediate waters that many groups of organism there may disappear before we even know they exist, and with them would disappear their potential services. Hence, the only possible adaptation strategy available to human societies may be to accelerate the study of biodiversity in intermediate waters. The previous discussion has shown that mesopelagic biodiversity is more vulnerable to the strain exerted on aerobic respiration by climate change than biodiversity in surface or deep waters.

The above conclusion should reinforce the resolve of the international oceanographic community to target intermediate waters for priority studies in the coming years and decades (e.g. the international programme "Integrated

Marine Biogeochemistry and Ecosystem Research", IMBER). Mediterranean researchers should take part in this international effort.

Abstract

Concentrations of eight heavy metal (As, Cd, Cr, Cu, Hg, Ni, Pb and Zn) were determined in mussels (*M. galloprovincialis*) collected in September, 2006 from 5 locations in Dardanelles, Turkey. All measurements were carried out in Atomic absorption Spectrofotometer(AAS). The heavy metal levels determined for mussel were found to be 0.032-0.048 μ g As/g, 0.101-0.520 μ g Cd/g); 0.141-0.78 μ g Cr /g, 0.542-0.661 μ g Cu /g, 0.005-0.034 μ g Hg /g, 0.081-0.383 μ g Ni /g, 0.220-18.474 μ g Pb /g and 32.549-65.612 μ g Zn /g wet weight.

Keywords: Trace Elements, Bivalves, Dardanelles

Introduction

Heavy metal discharges to the marine environment are of great concern all over the world. Both essential (e.g., Fe, Zn, Cu) and non essential (e.g., Hg, Cd, Pb) metals are toxic to living organisms when subjected to high concentrations [1, 2]. Mussels of the genus *Mytilus* and related genera are useful as bioindicators because they have wide distribution on all continents from tropical to high latitudes. They are filter feeders extracting metals from water and particulate matter, and they store some metals at levels high above those in the abiotic environment [3]. *M. galloprovincialis* is wide-spread on the Dardanelles coasts and they collected from wild for human consumption in Turkey. The selected locations in the Dardanelles are especially suitable for its growth which makes it a good choice for a biomonitor of the researched area. The aim of this study was to use *M. galloprovincialis* as the biomonitor of the marine environment and bioindicator of the possible contamination.

Materials and Methods

The study was carried out in Dardanelles at five sampling sites (Kilye, Akbas, Suluca, Kepez, Karacaören) (Fig.1). Samplings were conducted from wild in September, 2006. About 25-30 mussels from each sampling site were selected and analysed for heavy metals. The soft tissue of samples was digested in concentrated HNO₃ in a commercial microwave oven. Following acid digestion, all samples were analyzed for 8 elements by atomic absorption spectrophotometry (Perkin Elmer AA 700). Zn was determined in an airacetylene flame. Cd, Cr, Cu, Ni and Lead were analysed in a graphite furnace. Cold-vapor for analysis of Hg and hydride generation techniques were used for analysis of As. The standard addition method was used to correct for matrix effects. All acids and reagents were: As, 0.002; Cd, 0.001; Cr, 0.002; Cu, 0.001; Hg, 0.005; Ni, 0.003; Pb, 0.001; Zn, 0.08 μ g/g. Results were presented as arithmetic mean values (μ g/g -wet weight).

Fig. 1. Mussel sampling locations in Dardanelles

Results and Discussion

To facilitate the analysis the results samples with a length shell of 60-70mm size, which is the most commercial mussel length, were analyzed. Metal concentrations (means \pm standard deviations) in the soft tissues *M. gallopovincialis* are presented in Table 1. Hg concentrations were the lowest for all stations while Zinc was the highest mean concentrations.

Tab. 1. Metal levels ($\mu g/g$ wet weight) in the tissue of *M. galloprovincialis* collected from 5 locations.

Metals									
(µg/g)	Locations in Dardanelles								
	Kilye	Akbaş	Suluca	Kepez	Karacaoren				
As	0.038±0.0079	0.032±0.0057	0.048±0.0217	0.046±0.0312	0.044±0.0298				
Cd	0.520±0.0400	0.457±0.0127	0.180±0.0178	0.101±0.0501	0.152±0.0453				
Cr	0.160±0.0478	0.174±0.0502	0.174±0.0523	0.178±0.0554	0.141±0.0357				
Cu	0.661±0.0421	0.621±0.0402	0.542±0.0252	0.626±0.0458	0.647±0.0423				
Hg	0.034±0.0057	0.005±0.0002	0.015±0.0054	0.009±0.0055	0.007±0.0048				
Ni	0.350±0.0362	0.298±0.0172	0.383±0.0388	0.346±0.0361	0.081±0.0188				
Pb	13.574±1.233	18.474±2.765	0.448±0.0406	0.220±0.0245	0.230±0.0333				
Zn	56.923±5.678	65.612±5.976	41.420±3.347	32.549±2.997	41.739±3.466				

Mussels and bivalves in general are known to be efficient accumulators of certain metals, particularly zinc, which can be stored against a concentration gradient of orders of magnitude. Other metals, particularly lead and mercury, are not bioconcentrated efficiently by bivalves [4]. In this study we observed similar results for the Zinc concentrations as the highest value in the mussel soft tissues collected from all sampling locations. By using *M. galloprovincialis* as a biomonitoring agent, the contamination of As, Cd, Cr, Cu, Hg, Ni in the Dardanelles was not found to be serious. However Zn and Pb levels in the samples collected from Kilye and Akbas were above the legal limits set by national Standards of Turkish Governments. Future studies should concentrate on the relative importance of water, sediment and food in the accumulation of metals by the mussels. From the human public health point of view, these results seem to show no possibility of acute toxicities of As, Cd, Cr, Cu, Hg and Ni if the edible mussels are consumed.

Abstract

In order to evaluate sediment contamination in six stations from Bizerta lagoon, a combination of *in vitro* bioassays and chemical analysis was applied to sediment organic extracts. By using 7- ethoxyresorufin-O-deethylase (EROD) induction in the fish hepatoma cell line PLHC-1 after 4 h of cell exposure, dioxin-like activities were detected in all analysed samples. Dioxin-like activities were higher in winter than in summer. A highly significant correlation was observed between bioassay- and chemical analyses-derived toxic equivalents (TEQs), but PAHs accounted for only a small part of the detected biological activities. Our results suggest the presence of unknown readily metabolised EROD inducing compounds, which will need to be further characterized. *Keywords: Lagoons, Pollution, Sediments, Ecotoxicology*

Introduction

Bizerta lagoon, situated in northern Tunisia, is an important ecological area implicated in various activities as fishing and aquaculture development. Unfortunately, this lagoon is submitted to many anthropic pressures, which led to chemical contaminations by various toxic compounds that may be biologically active. The aim of this study was (i) to evaluate the seasonal variations of dioxin-like chemicals, using in vitro bioassays, (ii) to compare bioassay data with PAHs analyses by using a toxic-equivalents (TEQ) approach.

Material and Methods

Superficial sediments were collected in January and July 2006 at six stations in Bizerta lagoon and at a reference station (GH) in the seawards entrance of Ghar el Melh lagoon. The sediment extracts were subjected to chemical and bioassays analyses. Then, the PAHs in sediment extract were quantified by gas chromatographic analysis. The EROD activity assay in PLHC-1 cells line was processed, as previously described by (1).

Dose-response curves were fitted by Hill equation model and the EC50 were calculated. Bioassay-derived benzo[a]pyrene- (BaP-EQ) and instrumentally derived toxic equivalents (TEQs) for PAHs were determined as described by (1).

Results and Discussion

As shown in Figure 1, all sediment extracts were able to induce EROD activity. The extract from Menzel Bourguiba (MB) site, which is subjected to intensive industrial activity, was the most active sample.

Fig. 1. EROD induction in PLHC-1 cells exposed for 4 h to serial dilution of sediment extracts sampled in winter (a) and summer (b). Results are expressed as percentage of maximal EROD activity induced by TCDD 1 nM. Values are means of triplicates \pm SD.

Regarding seasonal variations, it is noteworthy that, although similar site ranking was observed between summer and winter, higher activities were observed in winter in all stations, except for MB site, which was still highly potent in summer. This result suggests that the chemicals responsible for activation are metabolized in hot season, and support the hypothesis for a major role of PAH-like chemicals in EROD induction.

The regression analyses (Figure 2) showed highly significant positive correlation between biological- and instrumental-derived TEQs (R2 = 0.94). However, when comparing toxic-equivalent values the TEQ-chem values explained only a small part of the biological activities detected by the bioassay, suggesting that other EROD-inducing compounds than the 16 analysed PAHs are present in the extracts.

Fig. 2. Correlation between chemical analyses- and bioassays-derived BEQs determined in sediments extracts.

Conclusion

Seasonal variations were observed by both in vitro dioxin-like activities and PAHs concentrations in sediment extracts, which were lower in summer. Such variations probably reflect a higher abiotic and biological degradation of organic chemicals in the hot season. Furthermore, the dioxin-like responses observed in our study were thus likely to have been caused by other ubiquitous biogenic and anthropogenic PAH-like AhR ligands that were not taken into account by the chemical analyses.

Abstract

In the present study we propose a methodological approach for the early detection of macroalgae blooms in the lagoon of Venice. The approach basis on merging the pieces of information brought by a quasi real-time monitoring network and by a Reaction-Transport model of the lagoon. A case study is presented, where the relevant macroalgae standing crop observed in spring 2005 was satisfactorily estimated by constraining the model with continuous Dissolved Oxygen data collected at 7 lagoon sites. The results highlighted that the method is a valuable tool for the quasi real-time tracking of the primary productivity in the lagoon. That makes the approach a valuable tool for the early detection of threats to the ecosystem, such as the risk of anoxic crisis induced by macroalgae proliferation in coastal areas.

Keywords: Lagoons, Models, Monitoring, Blooms, Coastal Management

Introduction

Worldwide coastal areas are subjected to a composite ensemble of human pressures and evidences indicate that these ecosystems have increasingly become more stressed and dysfunctional [1,2]. In the last decades, monitoring, regulatory and management efforts have been carried out with the objective of improving the capability of these environments to recover their natural productivity and, thus, to contribute to the human welfare. The Lagoon of Venice is a valuable example of the complexity of the interaction between hydrodynamics, biogeochemical processes, and human actions aimed at counteracting the eutrophication processes [3,4]. Indeed, in the latest years, macroalgae standing crop have increased again in some lagoon areas were massive proliferations and critical anoxic conditions were observed in the eighties, despite anthropogenic loads of ammonia and reactive phosphorous have decreased. This sudden change in the decreasing trend of macroalgae population was promptly detected by the observing system set up by the Venice Water Authority [5]. The system integrates quasi real-time observations of hydrological parameters and periodical field surveys of trophic parameters. The aim of the present study is to propose a methodological approach useful for the early detection of macroalgae blooms in coastal areas. This approach integrates the continuous observations of parameter sensitive to primary production - in particular Dissolved Oxygen concentration (DO) - with a Reaction-Transport Model (RTM) of the ecosystem. A case study is presented, were the approach has been applied to the estimation of the relevant macroalgae standing crop observed in the some areas of the Venice lagoon in spring 2005.

Materials and methods

The RTM model of the Venice lagoon couples four modules: (i) a 2D transport module; (ii) a water temperature module, (iii) a pelagic biogeochemical module, and (iv) a benthic biogeochemical module, which describes the macroalgae dynamics. The Reaction-Transport equation is solved by means of an operator-splitting technique [6], i.e. the model solves the advective-diffusive processes at each time-step, while the reaction term is integrated using a larger time step. The model input data are current velocity fields, watershed loads of Nitrogen and Phosphorous, meteorological forcings, and the fluxes at the lagoon/sea boundary. The RTM model was applied to the estimation of macroalgae standing crop in spring 2005. To this aim, the model was firstly calibrated by exploiting monthly data collected in the lagoon in 2004 by the Venice Water Authority. The model was then applied to quantify the macroalgae standing crop in spring 2005 by using an "inverse" procedure. In this procedure, the model was iteratively run by varying the winter initial macroalgae biomass up to the value that lead a good fitting of the continuous DO observations in the spring months.

Results and Discussion

The model calibration for the year 2004, lead to a good representation of the observed fields of monthly nutrient and dissolved oxygen concentrations. The iterative model runs for spring 2005 lead finally to track satisfactorily the continuous dissolved oxygen data collected by the quasi real-time observing system, as one can see in Fig. 1. The figure shows that the maximum daily values of the dissolved oxygen observations rise to 180 % passing from April to May, providing an evidence of a rapid increase in the primary production. The model reproduced quite promptly the increase in the daily ranges of the dissolved oxygen observations. The estimated values of macroalgae biomass

leading to such a DO dynamic were in agreement with the results of field surveys carried out in spring 2005.

Conclusion

The case study demonstrated the usefulness of integrating the information brought by observing systems and Reaction-Transport models. Quasi-real time data can provide preliminary signals of macroalgae blooms, while their standing crop and biomass can be estimated by using the RTM model, opportunely calibrated by using the field observations. This integrated approach allowed us to investigate short and medium-term changes in macroalgae population in the lagoon of Venice. That suggests that the approach can support the efforts of early detection of threats to the ecosystem, such as the risk of anoxic crisis induced by macroalgae proliferation in coastal areas.

Fig. 1. Mean values and ranges of the i) field observations (dotted lines) and ii) model hindcast (continuous line and shaded area) of the Dissolved Oxygen concentrations in April-June 2005 at the Ve3 monitoring station.

DISTRIBUTIONS OF PHT. TOTAL ALKALINITY AND CO2 FUGACITY IN THE ADRIATIC SEA DURING THE SESAME CAMPAIGNS, WINTER AND LATE SUMMER 2008.

Anna Luchetta 1*, Giulio Catalano 1, Carolina Cantoni 1 and Stefano Cozzi 1 ¹ CNR ISMAR sede di Trieste - anna.luchetta@ts.ismar.cnr.it

Abstract

pH_T experimental data of good quality are still scarce in the Mediterranean as in theAdriatic Sea. Here are presented the results of two repeated surveys at basin scale, conducted within SESAME project, showing significant longitudinal and seasonal variabilities of the pH_T and other carbonate system parameters. Keywords: Adriatic Sea, Carbon, Global Change, Ph

The rapid response of the Mediterranean basin to the climate change [1] can be particularly true for the CO₂ induced acidification of seawater; as a consequence the Mediterranean area would already present significant pH drops [2] however there's still lack of good quality experimental data, witnessing such an occurrence [3], in particular in the Eastern Mediterranean Sea. The Adriatic Sea can play a very crucial role for the entire Eastern Mediterranean basin: as it issurrounded by industrialized regions, releasing carbon dioxide to the atmosphere, and during winter water mass can be so cold that CO2 solubility pump mechanism can efficiently work increasing the dissolved CO₂ amount pushing toward acidified conditions. In addition the basin is site of dense water formation, either on the northern shallow shelf [North Adriatic Deep Water (NAdDW), and by the deep Southern Adriatic Pit, Adriatic Deep Water (ADW). Adriatic dense waters after formation usually sink and outflow through the Otranto Strait sill (750 m), which controls the export to Ionian and Eastern Mediterranean Seas [4]. In this way Adriatic dense water masses have the possibility of sequestering acidified waters and spreading around through the Eastern Mediterranean impacting on biogeochemical cycles and ecosystems. We present and discuss two datasets (pHT. TA and other carbonate systemparameters) gathered during the surveys conducted in the frame of the SESAME EU project and providing two seasonal snapshots (February and October 2008). Methods pH has been measured by the spectrophotometric method as described by Dickson [5], values are expressed on the total $\rm H^+$ scale (pH_{T_{\rm v}} in µmol H^+/kg_{SW}), at 25 °C, with a precision of ± 0.001 pH units. To our knowledge the dataset is the first collected with such a precision. The total alkalinity was experimentally determined (potentiometric titration, precision \pm 1.0 $\mu\text{m/kg}_{sw}$), as reported by Dickson, Certified Reference Material has been used. From the experimental determination, the in situ pHT values and all the other parameters of the carbonate system (fCO2, TCO2, H2CO3, CO3= and HCO3-, Revelle, calcium carbonate solubilities Ω_{Ar} , Ω_{Ca}) can be derived (by CO2SYS program [6] Results and discussion Our results indicate that in winter 2008 the North Adriatic shelf, being shallow and exposed to cold dry winds (Bora), was involved in a dense water formation event on meso scale. The water column was cold (8< T < 12 °C), well homogenized and dense ($\sigma_t > 29.4 \text{ kg/m}^3$), T/S properties are in agreement with those of NAdDW. It appeared also well ventilated (Apparent Oxygen Utilization mean value ~ 0 µM), still rich of nutrients (1.00<DIN<7.00 µM; 1.20< SiO₂ <5.33 µM), while the values of pHT and allthe other carbonate system parametersexhibited a very low variability within the water column (7.917 < pH_T <7.973 pH_T units; 290.0 <fCO2<334.6 µatm, thus resulting much lower than the equilibrium value with atmospheric CO₂ =398 µatm, mean value on measurements conducted on board). In the remaining part of the section pHT and fCO2 values showed larger variabilities (fCO2 between 222.4 and 424.7 µatm; pH between 7.880 and 7.960) with the highest (fCO₂> 400 μ atm) and lowest (pH_T <7.880 pH_T units) values both at the bottom of the Meso Adriatic Pit, corresponding to AOU (> 65.0 μ M) and nutrients (SiO₂> 6.0 μ M, DIN> 5.0 μ M) maxima, thus suggesting the occurrence of an older water mass affected by remineralisation processes. Generally, NAdDW water mass flows southward and accumulates at the bottom of the Meso and Southern Adriatic pits (250 and 1250 m, respectively [4] as clearly indicated by density, higher than 29.3 and 29.2 respectively, at the bottom. For what concern the southern part of the section, in February 2008 a deep convection event was observed by the deepest stations, accompanied by deep mixing (σ_t around 29.15-29.16 kg/m³ down to 600 m) with a mean pH_T value of 7.947 ± 0.003 pH_T units homogeneously distributed from surface almost to the bottom. Total Alkalinity values varied between 2769 and 2613 $\mu MH^+/kg_{sw},$ with a mean value of 2661 $\mu MH^+/kg_{sw}.$ The highest TA values were found in the northern part of the basin, due to the influence of higly carbonatic rivers. At the beginning October '08 the situation appeared completely changed: vertical stratification of density, $\ensuremath{\text{pH}}_T$, TA and fCO2, was widespread over the whole Adriatic basin. Density, T, S, pHT, TA

and fCO₂ varied over a much wider range than in February, as expected in late summer season: 26.5 < $\sigma_t <$ 29.45 kg/m³, 13.0 < T < 21.0 °C, 37.250 < S < 38.800 psu, 7.850 < pH_T < 8.100 pH_T units; 2674<TA<2598 μ MH⁺/kg_{sw}; 319.2< fCO2 < 810.4 µatm, as the nutrients and AOU concentrations did (0.05<DIN<7.73 μM , 0.59<SiO2<10.48 μM). The northern shallow shelf region exhibited much warmer water (T>15.0°C, even at the bottom,) with higher pH_T values (7.960<pH_T<8.050 pH_T units), due to the influence of primary production, the highest fCO2 values have been observed (fCO2 >450 μ atm) there, such values were much higher than the equilibrium value (398 μ atm) with atmospheric CO_2 , thus indicating the whole northern basin was oversaturated with respect to atmospheric CO2. Very low pHT (<7.888 $pH_Tunits)$ and very high </br/>fCO2 values were still recognizable at the bottom of both the Meso Adriatic Pit. pH_T values within the upper euphotic layer were everywhere distinctly higher (>7.960 pH_T units) than in winter, as expected in warmer waters dominated by production processes. Again total alkalinity values (2674<TA<2598 µMH⁺/kg_{sw}, mean value 2623 µMH⁺/kg_{sw}) where higher in the northern part of the basin because of the discharging river loads. Concluding, the comparison between the two surveys at basin scale evidenced high spatial (longitudinal/latitudinal) and seasonal variabilities of the marine carbonate system parameters, largely exceeding the precision of the analytical methods. From a comparison of $\ensuremath{\text{pH}}_T$ values in the cold NAdDW water mass between 1983 and 2008, an acidification of 0.063 pH_T units turns out [7]. Such findings confirm that the Adriatic Sea is sensitive to the climate change and to atmospheric gas solubilisation (as CO_2) and should merit consideration in a discussion on the impacts of OA on the biogeochemistry of the marine carbonate system.

Abstract

In this work we present the results from a time series of sediment trap moorings located at 500 m in the pelagic Ionian Sea, focusing in particular on the biogenic calcareous and siliceous component. We quantify the fluxes of coccolithophores and diatoms, identifying a seasonal succession in the assemblage composition, as related to the environmental conditions. *Keywords: Coccolithophores, Diatoms, Particle Flux, Ionian Sea, Eastern Mediterranean*

Introduction

The understanding of present-day biogenic fluxes is of key importance in providing information on how the ecological signal is transferred from the surface waters to the sediment archives, in order to interpret paleofluxes. In the oligotrophic eastern Mediterranean, coccolithophores are known to play a major role as primary producers, while diatoms are subordinate, also due to the significant silica-undersaturation of the basin. Therefore, while there are some previous data on the present-day fluxes of coccolithophores at several locations in the basin [1, 2, 3], there are only a few data on diatom fluxes [4,5] and no detailed information on their specific assemblage composition in the sinking fluxes. We investigated the fluxes of coccolithophores and diatoms along three yearly intervals of a 7-year-long sediment trap deployment above Urania basin (35°13'N, 21°30'E) in the Ionian Sea, aiming at assessing the seasonality and interannual variability of the sinking biogenic fluxes.

Methodology

Sediment traps are PPS5/2, with 1 m^2 aperture and 24 collection vials. Each mooring was deployed for approximately one year, resulting in a sample resolution of 10 to 15 days. Coccolithophores and diatoms were analyzed on sub-samples (1/800-1/8000 and 1/40 respectively) processed following standard methods [6,7 respectively] and expressed as number per square meter per day.

Results and Discussion

Preservation of both coccolithophores (coccoliths and coccospheres) and diatoms was very good at all samples. The presence of delicate species (holococcolithophores,

Discosphaera tubifera among coccolithophores and weakly silicified taxa among diatoms) indicates that no dissolution occurred during either sedimentation through the water column, or sample storage and processing. Overall, the assemblages recovered at our sediment-trap site are typical of subtropical areas of the world's oceans. In fact coccolithophore species are those typically found in assemblages from subtropical and temperate settings, dominated by the cosmopolitan Emiliania huxleyi. Diatoms are ~70% tropicalsubtropical species, with a minor contribution from subtropical-temperate and temperate taxa and a very slight contribution from cold-water species. During the first year of observation (1999-2000), the total flux of coccolithophores and diatoms was maximum in late summer-fall, along with the total particle flux, decreased during the whole winter period and increased again in late spring. The combined fluxes of coccolithophores and diatoms allowed to identify three main periods within the annual cycle, characterized by different assemblage composition: a) late summer-fall period, characterized by highest coccolithophore species diversity, consisting of both surface oligotrophic and deep-dwelling taxa and warm water diatom taxa dominated by Nitzschia interruptestriata and Thalassionema bacillare; b) late fall-winter period, characterized by lower coccolithophore diversity, dominated by the cosmopolitan E. huxleyi and the deep-dwelling Florisphaera profunda and by the increase of cooler-water diatom taxa; c) spring period, characterized by highest relative abundance of E. huxleyi and decrease of F. profunda within coccolithophores and by an increase in abundance of major and minor diatom taxa. A similar seasonal pattern was identified in coccolithophore assemblage composition in the following years, although the pattern of total particle and coccolithophore flux was different. In fact maxima occurred either in late spring to summer (2000-2001) or in early spring to late spring (2005-2006). Nonetheless, the main changes in the relative abundance of the different coccolithophore species occurred in the same intervals. Diatom assemblages in these series are still under study. Overall, the variations identified in the coccolithophore and diatom fluxes in the investigated three-year time series testify the seasonal changes in surface water conditions, including the sea surface temperature cycle and the presence of stratification in the upper layers. The seasonal cycle of water column mixing and stratification results in fact in the development of a different production depth within the water column, with the increase of surface oligotrophic species from summer to fall, the prolonged persistence of a deep chlorophyll maximum from summer to late winter and a clear dominance of the most abundant r-selected species during periods of more extended water column mixing.

Abstract

L'analyse des résidus des polychlorobiphényles (PCBs) dans le sédiment côtier du golfe de Tunis nous a permis d'obtenir les premières données concernant la contamination de cette zone par ces composés organochlorés. Nos résultats ont révélé que les deux sites étudiés, Raoued et Radès, présentent des concentrations en PCBs non négligeables par rapport aux données de la littérature. L'hétérogénéité de la répartition des teneurs en PCBs est due essentiellement aux effets du courant qui a tendance à disperser les fines particules de sédiment vers le large d'où une accumulation plus importante des composés hydrophobes. *Keywords: Pcb, Pollution, Mediterranean Ridge*

A cause de leurs propriétés hydrophobiques, les polluants organiques persistants (POPs) ont tendance à s'adsorber à la matière particulaire de l'environnement marin et à se déposer dans le sédiment. Ce dernier est une matrice idéale pour l'étude et le suivi des polluants dans l'environnement marin. Dans le présent travail nous nous sommes intéressés à étudier l'état de contamination du sédiment du golfe de Tunis par les PCBs. Deux sites cibles ont été choisis : plage de Raoued qui reçoit les rejets des stations d'épuration par le biais du canal Khélij, et plage de Radès à proximité de l'embouchure de l'oued Méliane qui reçoit des rejets industriels. Une campagne d'échantillonnage a été effectuée au printemps 2004 pour le prélèvement du sédiment dans la zone d'étude. Le sédiment superficiel a été échantillonné au niveau des stations étudiées à l'aide d'une benne « Van Veen ». L'analyse des résidus de PCBs a été réalisée selon la méthode AFNOR [1]. Les échantillons ont subit une extraction au Soxhlet et une série de purification au florisil et au mercure. Les extraits ainsi obtenus ont été analysés par chromatographie en phase gazeuse avec un détecteur à capture d'électron VARIAN (CP3380). Dans la zone de Raoued 28 congénères ont été détectés dans les échantillons de sédiment des stations d'étude. Les teneurs en PCBs variant entre 7 et 175 ng/g PS avec une moyenne de51 ng/g PS.

Fig. 1. Répartition spatiale des teneurs en PCBs (ng/gPS) au niveau du sédiment superficiel de la zone de Raoued.

La concentration la plus élevée a été mesurée au niveau de la station R6 situé à l'Est de l'embouchure de canal Khélij (Figure 1). Dans le site de Radès, nous avons mis en évidence la présence de 25 congénères de PCBs. Les concentrations de ces résidus varient entre 13 et 2668 ng/g PS avec une moyenne de l'ordre de 621 ng/ g PS. En analysant la répartition des résidus de PCBs dans la zone de Radès, nous avons constaté que l'accumulation de ces composés est plus importante au niveau de la station M3 situé au nord de l'embouchure d'oued Méliane alors qu'elle est plus faible dans la station M8 localisée à l'Est de l'embouchure (Figure 2). Les auréoles de fortes concentrations en PCBs ont été ainsi mises en évidence au large des embouchures du canal Khélij et de l'oued Méliane. Ce profil de distribution est essentiellement dépendant des courants dominants dans cette branche de côte.

Fig. 2. Répartition spatiale des teneurs en PCBs (ng/g PS) au niveau du sédiment superficiel de la zone de Radès.

En interprétant nos résultats sur la base des PCBs totaux, nous notons que les niveaux détectés dans les zones étudiées sont comparables à ceux enregistrés dans d'autres travaux réalisés au niveau de la Méditerranée [2]. Toutefois les concentrations de PCBs enregistrées dans la zone de Radès sont significativement élevées par rapport à celles mesurées dans le sédiment de Raoued. Les rejets industriels véhiculés par l'oued Méliane sont probablement responsable de la forte contamination de la plage de Radès par ces organochlorés [3]. Le profil des PCBs selon le degré de chloration révèle que les pentachlorobiphényles sont prédominants dans toutes les stations étudiées, leur taux varie entre 22 et 41 %. Les octachlorobiphényles présentent les taux les plus élevés au niveau de la majorité des stations de la zone d'étude qui dépassent les 30% (34 - 51 %) sauf en M8 où leur taux est de l'ordre de 14 %. Cette dominance est due à la concentration élevée du PCB 200 dans presque toutes les stations de Radès. En conclusion, ce travail a permis de dresser un état des lieux de la contamination du sédiment du golfe de Tunis par les PCBs. Nous avons mis en évidence l'impact des rejets du canal Khélij et de l'oued Méliane chargés en micropolluants en provenance des stations d'épurations et des industries.

THE INFLUENCE OF SUBMARINE WASTEWATER SYSTEM ON CHEMICAL AND BIOLOGICAL PARAMETERS IN THE WATER COLUMN AND SEDIMENT AT THE MIDDLE ADRIATIC (CROATIA)

S. Matijevic^{1*}, G. Kuspilic¹, Z. Nincevic-Gladan¹, N. Krstulovic¹, N. Bojanic¹ and D. Bogner¹

¹ Set. I. Mestrovica 63, P.O. Box 500, 21000 Split, Croatia - dosen@izor.hr

Abstract

To eliminate the inadequate disposal of wastewaters in the middle Adriatic area, which created negative impacts and long-term changes of chemical and biological parameters during the second half of the last century, Republic of Croatia provided collection of wastewaters and discharge through submarine outlets. This paper presents results of investigations of oxygen, nutrients, chl <u>a</u> concentrations, microzooplankton, bacterioplankton and fecal bacteria in the water column, sediment redox potential, organic matter, organic carbon content and granulometric composition in the submarine wastewater outlet located in the Brac Channel, near town of Split.

Keywords: Adriatic Sea, Coastal Waters, Nutrients, Organic Matter

Material and Methods

Samplings and measurements were obtained at 11 stations located along the submarine wastewater outlet in the Brac Chanell during the period prior to (2002-2004) and after the activation of the discharge (2004-2009). Dissolved oxygen in seawater samples was determined by Winkler titration, while inorganic and organic nutrients were determined colorimetrically [1]. Chlorophyll *a* (Chl *a*) concentrations were determined fluorometrically [2], number of heterotrophic and fecal bacteria was identified using flow citometry and membrane filtration culture method, respectively. Sediment samples were collected by gravity corer and redox-potential was measured "*in situ*" by vertical penetration of a Pt electrode with Ag/AgCl reference electrode. Organic carbon content was determined using a Carlo Erba CHNS-O analyzer. Granulometric composition of the sediment samples was determined by sieving and the hydrometric method.

Results and Discussion

Oxygen saturation in the water column during the entire investigated period (2002-2009) at all stations ranged from 76% to 120% and it did not show significant difference depending on the outlet activation time, but rather followed seasonal cycle of oxygen at the middle Adriatic coastal area. Vertical and temporal distribution of total inorganic nitrogen concentration (range: 0.2-8.9 mmol m⁻³) were in accordance with values determined prior to activation of discharge and natural seasonal oscillations of nitrogen with ammonia as prevailing inorganic species. Distribution of orthophosphate concentrations (range: 0-0.77 mmol m⁻³) showed occasionally enhanced values, particularly at station nearest to the outlet which can be attributed to the input of wastewater in the area. While number of heterotrophic bacteria showed significant decrease in relation to period prior to activation, biomass of phytoplankton expressed as chl a concentration (range: 0.07-1.07 mg m⁻³) showed continually increase after the launching of the discharge. More obvious influence of the submarine wastewater input of organic matter was on sediment redox potential (Eh) and organic carbon content (C-ORG) in the surface layer (0-2 cm) (Fig. 1a,b). Prior to the outlet's activation, Eh at all investigated stations was mostly positive with short period of slightly negative values in 2003, which is probably part of the natural Eh oscillation as was reported for the middle Adriatic [3]. After the wastewater system's activation, from 2005 to 2009, medians of redox potential in the surface sediment layer of the entire investigated area were more negative (Fig. 1a), particularly at the stations nearest to the outlet (not shown on Fig.). C-ORG content at the all stations increased in relation to the period prior to activation (Fig. 1b) due to organic matter input and its accumulation in sediment. The observed changes in sediments are direct consequence of wastewater outlet and, considering the mechanical filtration of the effluents prior to discharge, the main impact to this marine environment occurs through dissolved inorganic and organic matter which can explain the observed delay in sediment response to anthropogenic input.

ISOTOPIC COMPOSITION OF NITROGEN IN SUSPENDED PARTICULATE MATTER OF THE ALBORAN

SEA

Jesús M. Mercado ¹*, Dolores Cortés ¹, Teodoro Ramírez ¹ and Esperanza Liger ²

Abstract

The ¹⁵N content of the particulate organic nitrogen (PON) suspended in the water column was determined during 4 seasonal surveys carried out in the northwest sector of the Alboran Sea (Mediterranean Sea). On average, the particulate matter in the mixed layer (ML) was enriched in ¹⁵N by about 1.5‰ in fall and spring with respect to summer and winter. In spite of this seasonal cycle, ¹⁵N relative content of PON in ML was correlated negatively with nitrate concentration suggesting that the mass-dependent isotopic fractionation associated to nitrate uptake by the phytoplankton was the main factor controlling the ¹⁵N signature of PON. *Keywords: Alboran Sea, Carbon, Nutrients, Primary Production*

Introduction

The $^{15}\rm{N}:^{14}\rm{N}$ ratio (usually expressed in per mil notation, $\delta^{15}\rm{N}$) of the algal material is determined by the isotopic composition of the source nitrogen used by the phytoplankton (NO₃⁻, NH₄⁺ and N₂) and the fractionation associated to the assimilation processes ($^{14}\rm{N}$ is preferentially taken up by the phytoplankton). The isotopic fractionation during NO₃⁻ uptake results in $^{15}\rm{N}$ depletion in the algal-N with respect to the source-NO₃⁻. The cyanobacterial N₂ fixation also lowers the $\delta^{15}\rm{N}$ of the algal material because of the lower $\delta^{15}\rm{N}$ of the atmospheric N₂ (0 ‰). The reduced forms of N resulting of organic matter and their consumption deals with decrease of the $\delta^{15}\rm{N}$ of the study area, differences in f-ratio have been documented thought the seasonal cycle [1]. The objective of this work is to research which process could be more important in determining the signature of 15N in the algal material of the study zone.

Materials and Methods

Hydrological data and seawater samples were collected in 6 stations located at the Alboran Sea, Western Mediterranean Sea, during four cruises performed in July-2003, October-2003, February-2004 and May-2004. Samples of seawater were collected at 6 fixed depths within the upper 100 m layer, in order to measure nutrients and chlorophyll a. Content of organic nitrogen (PON) and carbon (POC) and nitrogen stable isotope natural abundance in the organic matter lower than 0.2 mm were also measured by using a FlashEA1112 (ThermoFinnigan) elemental analyzer connected to a Deltaplus (ThermoFinnigan) continuous flow isotope-ratio mass spectrometer. The isotopic abundance in the samples were normalized by the isotopic abundance in the standard (atmospheric N₂) and expressed in per mil notation ($\delta^{15}N$).

Fig. 1. Profiles of ^{15}N : ^{14}N content of the organic mmater at the sampling stations during the four seasonal surveys

Results

Most of the profiles of POC and PON showed a maximum located within the upper 20-30 m layer. Contrastingly, the POC and PON maximums were situated in the surface during spring. In this upper layer, the spatial variability of POC and PON was remarkable, particularly in summer when the variation ranges for POC and PON were 300-50 and 50-10 μ g L⁻¹, respectively. The organic matter concentration trended to decrease below ML until to reach the lowest value at 75-100 m depth. POC and PON concentrations averaged for ML were significantly higher in summer and spring than in fall and winter. The relative abundance of 15 N in the particulate matter collected throughout the study period ranged from -0.1‰ to 13‰. In most of profiles, $\delta^{15}N$ decreased just below the surface until to attain a minimum roughly coinciding with the lower limit of ML (Figure 1). Below this minimum, ¹⁵_aN increased usually reaching the higher values at 75-100 m depth. The variation range of ^{15}N in ML was -0.1‰ to 6.5‰, with these low values being obtained in summer. On average, the particulate matter in this layer was enriched in ¹⁵N by about 1.5‰ in fall and spring with respect to summer and winter. The variability of ¹⁵₁N in ML was substantial during each survey, which was probably linked to the hydrological variability. In spite of that, δ^{15} N averaged for ML was negatively correlated with the nitrate concentration.

Discussion

The negative relationship between δ^{15} N of PON in the surface samples and nitrate concentration indicates that isotopic fractionation during N-uptake plays a major role in determining the δ^{15} N signature. The isotopic fractionation could also explain the vertical pattern of δ^{15} N of PON commonly observed in our study area, with values of δ^{15} N lowest at the base of the euphotic layer where NO₃⁻ is the highest, rising toward surface with decreasing NO₃⁻. The lower values of δ^{15} N of PON were obtained in winter. Note that our data precludes the possibility of significant N₂ fixation. δ^{15} N values from -2‰ to 0‰ have been described for N₂-fixer cyanobacteria. Most of the δ^{15} N values obtained in our study are above 2‰ and all the samples in which δ^{15} N was below this threshold were collected at stations where the NO₃⁻ concentration was relatively high (which inhibits the N₂ fixation).

Abstract

Sediment traps were moored at 1000m-depth at the DYFAMED time-series station (Ligurian Sea). 1990s and 2003-07 trace metal and mass flux data suggest that the transfer of atmospheric material is quantitatively driven by the magnitude and variability of biological production. Decadal trends are tentatively outlined, suggesting that the temporal variability of deep fluxes is modulated by the variability of external parameters that control winter convection and subsequent biological activity. *Keywords: Particle Flux, Trace Elements, Time Series, Ligurian Sea*

In NW Mediterranean marine environments mainly constrained by atmospheric forcing, the accumulation of sinking particles presumably mirrors the evolution of anthropogenic emissions. Automated time-series sediment traps (Technicap PPS 5, equipped with a programmable 24-cup collector, sampling rate 15 days) were moored at the DYFAMED time-series station (Ligurian Sea, 43°25'N, 7° 52'E, 2350 m depth), in the frame of the French project COMET (COnstructing MEditerranean Time-series, LEFE programme). Owing to its circulation (permanent cyclonic gyre), the DYFAMED site is sheltered from lateral inputs, apart from exceptional conditions [1]. Trace metal (TM: Al, Fe, Mn, Ni, Cu, Cd, Pb, V, Zn) and mass fluxes were measured from March 2003 to March 2005. Archive data from deployments in the 1990s were used to estimate a possible decadal evolution. The seasonal pattern of mass and TM fluxes are compared in Fig. 1 for the case of Al and Pb. An outstanding feature is the strong covariance observed between mass flux and TM flux, whatever the nature of the TM (e.g., anthropogenic or crustal). This suggests that, apart from convection episodes associated with dense water formation, the transfer of atmospheric material is almost totally driven by the magnitude and variability of biological production. This statement is in agreement with previous studies that pointed out the prominent role of biological activity in the removal of TMs [2, 3]. The comparison of 1995 and 1997-98 data with 2003-07 data suggests decadal evolutions linked to changes in land-based emission sources. However, these findings are slightly different of the decadal evolutions observed in the atmospheric aerosol in the same region [4]. This presumably results from the interannual variability of external factors (temperature, wind stress, etc.) that determine the intensity of winter convection and, therefore, that of biological production, i.e. the driving force of atmospheric matter downward transfer.

Abstract

Atmospheric deposition is a potential source of trace metals of continental origin to oceanic areas. Trace metals speciation (Fe, Al, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Cd and Pb) was studied in atmospheric deposition (wet and dry) collected at a remote location in the Eastern Mediterranean Sea. Elemental concentrations were measured using ICP-MS, while Dissolved Reactive Fe (DSRFe: Fe (II) and Fe(III)) was determined spectrometrically. Atmospheric deposition was also compared with long-term trace metals data in sediment traps.

Keywords: Eastern Mediterranean, Atmospheric Input, Sediments, Metals

Introduction

The atmosphere is a significant source, especially for oligotrophic oceanic areas and semi-enclosed seas, such as the Mediterranean, due to the relative proximity of land-based sources and densely populated shores [1]. Riverine inputs are limited and localized and will not affect offshore sites such as the Cretan or the Levantine sea [2]. Thus atmospheric input may play an important role in the supply of bioavailable nutrients to surface waters and hence marine biological productivity. Therefore a comparison between dry and wet deposition of metals would be noteworthy regarding the bioavailability and toxicity of metals in the marine system.

Materials and Methods

Atmospheric deposition samples, wet and dry, were collected at Finokalia $(35^{\circ}20?N, 25^{\circ}40?E)$, a remote coastal site in the Northeast part of Crete, in the Eastern Mediterranean over a two year period (January 2005–December 2006). After collection all samples were filtered through pre weighed 0.45 µm nitrocellulose filters. The sediment traps were moored for seven years in the Southern Cretan Sea (along 45°06?E, 500m and 1715m depth). The sediment trap samples were collected from 1999 until 2005, on a two–week basis and immediately after collection an aliquot was filtered through a precombusted and pre-weighted quartz fiber filters (Whatman QMA, diameter 47mm) for further analysis. An acid microwave digestion procedure followed by Inductively Coupled Plasma Mass Spectrometry was applied to measure metal concentrations in sediment trap and deposition samples.

Results and Discussion

Partitioning of atmospheric deposition between soluble and insoluble fractions demonstrated that Fe, V, Cr and Pb are mainly in the particulate form. For Cd, Zn, Mn and Cu, the dissolved fraction represents 60-68% of the total atmospheric input. Mean solubility for all metals in both wet and dry deposition appears to be related to pH and dust mass. More precisely solubility is decreasing with increasing pH values and increasing dust mass. For Pb, when the dust load is 0-70mg m⁻² solubility reaches up to 74%, whereas dust >500mg m⁻² leads to much lower Pb solubility is 0.3%. Cr, Mn and Cu are removed from the Eastern Mediterranean atmosphere by dry deposition, while Zn and Fe almost equally by wet and dry deposition whereas the rest of the studied metals via wet deposition.

In sediment traps, a significant correlation was observed between mass fluxes at 600m and 1715m indicating a quite good homogenicity in our system. Total mass flux presents two maxima: The first during spring, while the second one during autumn. Both are due to the increase in productivity and deposition of atmospheric dust. Similar seasonal trend was observed for Fe and Pb, elements characteristic of crustal and anthropogenic sources respectively, indicating similarity in transport mechanism independent of the trace metals origin. Dust is the main component of the sediment material as it accounts for about 40-44% of the mass. In addition a coherence between marine and atmospheric dust fluxes was observed. Annual deposition of atmospheric dust and dust in sediment traps are equal, in terms of fluxes, suggesting that atmospheric dust can be transferred in full down to 600 and 1715m.

Regarding the trace metals, our results suggested that atmospheric deposition is sufficient to balance their levels in the water column, indicating the predominant role of atmospheric deposition as external source of these elements in the area. Indeed DSRFe levels deposited were sufficient to account for the dissolved iron levels in seawater, therefore dissolved iron in the Mediterranean Sea could be exclusively attributed to atmospheric deposition. Cr, Mn, Fe, Zn, and Pb atmospheric deposition supplies 57- 84% of the amount collected in sediment traps. Total atmospheric depositions of Cu, Ni and Cd are equal to the fluxes from sediment trap deployment.

Abstract

The current study presents a complete data set of major and trace metals, organic and elemental carbon in sediment traps deployed in the South Western Black Sea. In addition data on atmospheric deposition of major and trace elements have been simultaneously obtained in a seaside resort on the Bulgarian Black Seas Coast. Atmospheric lithogenic mass fluxes accounts for 53- 65% of the lithogenic material in sediment traps. In general in sediment traps the lithogenic part was found to be the most abundant fraction (40%) followed by POM and carbonates (about 20-23% each). EC and others (probably opal material) accounted for the remaining %. *Keywords: Atmospheric Input, Black Sea, Sediments, Metals, Carbon*

Introduction

For the area under investigation, Black Sea, the chemical composition of atmospheric deposition and sediment trap samples will be discussed. In total 48 sediment trap and 18 atmospheric deposition samples have been collected and analyzed for the major and trace metals (Al, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Cd and Pb), while sediment traps have been in addition analyzed for organic and elemental carbon. The aims of this study are to evaluate the seasonal variability of atmospheric deposition and settling material in Black sea and moreover the role of atmospheric deposition on Black Sea major and trace metals levels.

Materials and Methods

The sediment traps were deployed in the South Western Black Sea (43°01,812N 29°28,498E) at two depths (930m and 1930m) during the period October 2007 to December 2008. The sediment trap samples were collected, on a two-week basis and immediately after collection an aliquot was filtered through a precombusted and pre-weighted quartz fiber filters (Whatman QMA, diameter 47mm) for further analysis. Atmospheric deposition samples were collected at a seaside resort on the Bulgarian Black Seas Coast in Varna close to the sediment trap area. The samples were collected on a monthly sampling interval from March 2008 to April 2009 using the technique described by [2]. After collection all samples were filtered through 0.4 μ m Millipore polycarbonate filters.

An acid microwave digestion procedure followed by Inductively Coupled Plasma Mass Spectrometry was applied to measure metal concentrations (Al, Ca, Ti, V, Cr, Mn, Fe, Ni, Cu, Zn, Cd and Pb) in sediment trap and deposition samples. In addition sediment trap filters were analyzed for Organic and elemental carbon (OC and EC), with the Thermal-Optical Transmission (TOT) technique [1].

Results and Discussion

The temporal variations of mass fluxes present a seasonal pattern: Lower fluxes occurred from January to March, whilst higher fluxes from November to December for both depths (Figure 1,2). The percentage of OC in sediment traps at the two depths (930m and 1930m) was found to be 10 and 11%, respectively. Carbonates have been also measured and they account for 22 and 23% of the total mass at the two depths. The lithogenic part was estimated using Fe as a crustal tracer and was found to vary between 40 and 38% at 930 and 1930m, respectively. A detailed comparison between atmospheric deposition and sediment trap fluxes of elements is presented and discussed in this work.

Fig. 1. Seasonal variations of total mass fluxes (mg $\ensuremath{\mathrm{m}}^{-2}$) and of lithogenic origin elements

Fig. 2. Comparison between the fluxes of Fe (in mg m $^{-2})$ for both deposition and sediment traps

Abstract

Within the framework of the MEDICIS programme, the regional project MYTIAD was undertaken in May-July 2008 to assess contamination along the coast of western and eastern Adriatic Sea. This research was a part of an interregional coastal water quality monitoring network in the Mediterranean basin based on active biomonitorig using caged mussels. In this paper, the distribution and levels of organochlorinated compounds (OCs) along Croatian part of the Adriatic Sea are presented. The possible influence of physiological parameters on OCs levels has been statistically examined.

Keywords: Adriatic Sea, Bivalves, Ddt, Pcb, Monitoring

Introduction

Since 1970s monitoring programmes were carried out to assess the quality of coastal environment. Therefore mussels have been successfully used as a good space and time-integrator of bioavailable contaminant fraction in the water. Active biomonitoring, i.e. transplantation of mussels from the same site and same population, provides comparable biological samples reducing possible sources of variation in the bioaccumulation process. Besides environmental parameters the resulting bioaccumulation in mussels is influenced by many physiological parameters such as lipid content and growth.

Materials and Methods

Using well-tested transplantation and caging technique [1], mussels of Italian origin, 16 month old and 50 mm length were immersed in plastic cages between 20 and 50 m at 12 locations along eastern Adriatic coast in May 2008 (Fig. 1). Mussel samples were collected after three months of immersion. Duplicate composite tissue samples (20 specimens) were freeze-dried, homogenized and Soxhlet extracted. The extracts were cleaned-up by concentrated sulphuric acid and passed through a florisil column for OCs separation. PCBs (IUPAC No. 28, 52, 101, 118, 138 and 180) and p,p'-DDTs were determined by GC-ECD.

Fig. 1. Sampling locations of caged mussels along eastern Adriatic coast (Croatia).

Results and Discussion

The distribution pattern of OCs in the eastern Adriatic coastal waters (Croatia) was characterized by higher PCBs level in relation to DDTs (Fig. 2). PCBs concentrations ranged from 11 to 51 ng/g dw with the prevalence of congeners 153 (42%) and 138 (28%,) followed by PCB 118 (12%) and PCB 101 (8%). The elevated PCBs concentration was found near urbanized and industrialized centres (Dubrovnik, Split, Bakar, Rijeka) with high wastewaters input. The concentrations of DDTs were low, ranging from 2.3 to 6.0 ng/g dw, being spatially almost uniformly distributed. p,p'-DDE metabolite dominated with mean amount for 66% of total p,p'-DDTs followed by p,p'-DDD (23%), suggesting a lack of recent DDT input into the research area.

Fig. 2. Spatial distribution of p,p'-DDTs and PCBs concentrations at study area.

Statistical analysis revealed poor PCBs and moderate DDTs positive relationship with the percentage of hexane-extractable organic matter. Both PCBs and DDTs correlated positively and moderately with condition index of mussels. The OCs differences found in mussels were being primary influenced by local sources of contamination rather than physiological parameters. The ratio of the contaminant concentration in mussels after and before immersion was lower than 1, indicating an adjustment of contaminant levels during the 3 months experiment. Then, the levels of target organic contaminants found in caged mussels were generally lower than those published for native mussels on the coast, being within the range of values usually found in low to moderately contaminated marine coastal areas [2]. The mussel transplantation can be useful and reliable technique for large spatial monitoring. This study pointed out the importance of collecting the initial mussels from a relatively clean area in order to achieve optimal monitoring results.

THE EFFECT OF SHELLFISH FARMING ON THE WATER COLUMN NUTRIENT CONCENTRATION OF THE EASTERN MEDITERRANEAN

Nikos Neofitou¹*, Nikos Charizopoulos¹, Dimitris Vafidis¹ and Labrini Tziantziou¹

¹ University of Thessaly, School of Agriculture, Department of Ichthyology and Aquatic Environment - nikneof@uth.gr

Abstract

The effect of shellfish farming on the water column was investigated seasonally at a longline mussel farm (*Mytilus galloprovincialis* L.) of Maliakos Gulf, between October 2007 and July 2008. Nitrite and phosphate values showed significant differences among sampling stations and seasons (p<0.05 and p<0.001, respectively). Furthermore, in most cases concentrations of all nutrients and chl *a* at the farm site was lower than those observed at the control site. This indicates that shellfish farming contributes to the reduction of the primary production of Maliakos Gulf and consequently to the risk of eutrophication. *Keywords: Aquaculture, Mollusca, Coastal Waters, Nutrients, Aegean Sea*

Introduction

Annual world harvest of wild mussel stocks has increased during the past 20 years and has led to overexploitation of natural beds. Mussel aquaculture is consequently an expanding industry. The impact of aquaculture on the concentration of nutrients in the Eastern Mediterranean has been addressed in a number of studies [1]. The environmental effects of mussel farming, where no excess food is supplied, are supposed to be much less than those of caged fish farming. However, relatively little is known of the effects of longline mussel farming on nutrient dynamics [2]. The objective of this study was to assess the effects of longline mussel farming on nutrient concentrations of Maliakos Gulf.

Materials and methods

The study was carried out in the Maliakos Gulf, central Greece, at a shellfish farm (38°50'99" N 22°36'48" E) between October 2007 and July 2008. Mussel (Mytilus galloprovincialis L.) was intensively cultivated in this farm. Two stations were sampled. The first was located at the centre of the mussel farm and the second at a distance of 500 m from the mussel farm center. referred as farm and control site, respectively. Vertical profiles of temperature, salinity, dissolved oxygen (DO) and chl a were measured at each sampling station by means of a CTD (SEABIRD-19plus). For nutrient analysis, samples were collected by means of a 1 L Niskin bottle at the surface, 5 m and 20 m depth from the surface to the bottom. From both sampling stations, five replicate samples were taken during all seasons, in order to determine natural variability within replicates (120 total samples). The water samples were placed in 250 ml plastic vials where mercury chlorine (1 ml HgCl₂ per 1 L sample) was added in order to neutralize the bacterial and other photosynthetic organisms [3]. Samples were stored at -20 °C until analysis took place with a spectrophotometer (SHIMADZU UV-1700) according to the procedure described by [3]. The one-way nested analysis of variance (ANOVA) was used to analyze the effect of station and season on variations in chemical parameters.

Results and discussion

Physicochemical characteristics of both studied sites are summarized in Table 1. These results shows that almost in all cases the minimum, maximum and the mean concentration of the physicochemical characteristics was lower at the farm site compared to the control site. The above indicates the positive effect of shellfish farming on the water column nutrient concentration. The quantity of nutrients removed by shellfish harvest can be quite large [4]. Filter-feeding molluscs not only remove N from the water column, but also incorporate a high proportion of it into their tissues. When the molluscs are harvested, the N is removed from the system [5]. Shellfish feeding can also help to control or even prevent harmful algal blooms by removing the cells before the algae accumulate to environmentally detrimental levels [5]. During the course of this study, we concluded that shellfish farming is, by definition, a 'green' industry which plays a vary important role in the ecological system of Maliakos Gulf

Abstract

This research investigated the spatial distribution of chemical contamination and toxicity of marine surfacial sediments collected from six sites along the Turkish coast in Black Sea. Sediment toxicity to sea urchin (Paracentrotus lividus) embryonic development was evaluated with whole sediment specimens. Concurrently, sediment samples were analyzed for their chemical characterisation to evaluate toxicity data.

Keywords: Ecotoxicology, Sediments, Black Sea, Petroleum, Metals

Introduction

It is dificult task to make a desicion about toxicity of sedimentary contaminats to aquatic organisms. Bioassays are routenely used for sediment quality evaluation. Among these sea urchin embryotoxicity bioassays are recognized as reliable, sensitive and ecologically important tools for evaluating marine and estuarine environmental quality [1- 2]. The goals of this sudy were to determine concentration of metals and petroleum hydrocarbons in Black Sea sediments and relationships between contamination and biological effects.

Material and Methods

Sediment samples collected from six sites along the Turkish coast in Black Sea (Istanbul, Eregli, Inebolu, Sinop, Ordu, Trabzon) by using core sampler. Surface sediment samples were taken from upper 2cm. depth for chemical and toxicological analyses.

Determination of petroleum hydrocarbons were made by GC-FID according to UNEP [3]. 0.2g dry sediment samples were digested with HCl,HNO3,HClO4,HF acid mixture. Differantial Pulse Anodic Stripping Voltametry (DP-ASV) was used for Cu ,Pb and Zn by using Metrohm Voltammeter model 797VA Computrace according to Metrohm VAApplication Work AWUK4-0134-042002. C¹⁴ dating was made in Beta Analitic Inc.

The embryotoxicity test with sea urchin (Paracentrotus lividus) embryos was performed using the procedure reported in detail in before [1]. Bioassays were carried out in by evaluating the following endpoints: a) normal (N) pluteus larvae; b) retarded (R) plutei, with size <1/2 N, yet no evident abnormalities; c) malformed plutei (P1) exhibiting a number of skeletal or other abnormalities; d) developmentally arrested embryos (P2), i.e. unable to undergo larval differentiation (blastulae or gastrulae), and e) dead (D) plutei (D1) or early embryonic death (D2).

Results and Discussion

Bioassay with sea urchin showed that the highest embryotoxicity was exerted by the sediment from Istanbul (P1+P2 = 100 %) compared to controls (P1+P2 @ 3,5%). Sediments from Zonguldak and Inebolu displayed significantly higher developmental toxicity while the other sediment samples failed to show any significant difference compared to blank controls (Table1).

Tab. 1. Developmental toxicity of sediment samples collected from Turkish coast in Black Sea. % Developmental defects in P. lividus larvae, means ± SEM.

Sampling Site	N	P1	P2	P1+P2	value
Blank Control	96,5±0,9	2,7±0,7	0,3±0,2	3,0±0,8

Inebolu	78,3±3,1	20,8±3,2	0,3±0,3	21,2±3,1	,000
Sinop	89,5±0,4	10,2±0,5	0,5±0,5	10,5±0,4	,000
Ordu	92,7±1,3	7.3±1.3	0,0±0,0	7.3±1.3	,010
Trabzon	93,8±1,2	5.8±1.2	0,0±0,0	5.8±1.6	,076

The concentrations of petroleum hydrocarbons, metal and % organic carbon of sediment samples are given in Table2. Readman et al., [4] was reported 6,4 ng/g naphtalane concentration in Bosphorus (Istanbul) sediment samples. This result consistent with present data measured in Istanbul (7,0 ng/g). Σ PAH levels of all stations were much smaller than ERL value of 4122 ng/g. It has not been expected toxicity from **SPAH** value. The aliphatic hydrocarbon, n-C17 concentrations was significantly related to % developmental defects of sea urchin (R²=0,84). Bioaccumulation dynamics of aliphatic hydrocarbons in detritivoros fishes and codding feed crude oil controlled by an efficient molecular discrimination during intestinal absorbtion. Higher bioaccumulation factors has been found in the range of betwee $n-C_{15}$ and $n-C_{17}$ [5]. It was suggested that the correlations were probably related to hydrophobocity and bioaccumulation factors of n- alkanes like fishes. Trace metal concentrations was not correlated with toxicity data. The only station Zonguldak was not exceeded the ERL values according to metals. Suddenly drops of Cu and Pb in Zonguldak was due to the fact that surface sediment layer dated to 1780±40BP (calculated AD 130-350)

Tab. 2. Petroleum hydrocarbons and some metals concentrations in six sediment specimens from Black Sea and ERL guideline values (Effects-Range-Low). All HC values are as ng/g.

I-129 LEVELS IN MARINE ENVIRONMENT ALONG THE SLOVENIAN COAST

Andrej Osterc 1* and Vekoslava Stibilj 1

¹ Institute Jožef Stefan - andrej.osterc@ijs.si

Abstract

¹²⁹I is considered as a global pollutant and its role as a global tracer to follow the dissemination of radionuclides from a source point such as nuclear power reprocessing plants increases. A radiochemical neutron activation analysis method was developed to measure the concentration of ¹²⁹I in environmental and biological samples. The method was validated using the IAEA-375 Soil, FC98 Seaweed and NIST 4357 Ocean Sediment. The method was applied to analyze ¹²⁹I/¹²⁷I isotopic ratios in the marine environment of Slovenia. The results found were in the range from 1.3 to $55.4 \cdot 10^{-9} \,\mu q \, g^{-1}$ for seawater, from 104 to $127 \cdot 10^{-9} \,\mu q \, g^{-1}$ for blue mussel, from 334 to $471 \cdot 10^{-9} \,\mu q \, g^{-1}$ for alga *Fucus virsoides* and from 72 to $256 \cdot 10^{-9} \,\mu q \, g^{-1}$ for marine sediment. *Keywords: Algae, Coastal Waters, Fallout, Radionuclides, Sediments*

1 Introduction

The only stable natural iodine isotope is ^{127}I and the total amount of this element in the Earth's crust was estimated to be $8.6\cdot10^{15}$ kg of which nearly 70 % resides in marine sediments and 28 % in sedimentary rocks. The marine environment, i.e. the oceans, is the major source of iodine with average concentrations of around $60\,\mu g~L^{-1}$ iodine in seawater. The biogeochemical cycling of iodine is driven with its volatilization from oceans and soil to the atmosphere in the form of iodinated hydrocarbons of which methyl-iodide predominates. From the atmosphere the iodine is washed out to the marine and terrestrial environment by wet (precipitation) and dry (aerosol) depositions [1].

¹²⁹I ($T_{1/2} = 1.57 \cdot 10^7$ years) is the only natural radioactive isotope of iodine, which is formed in nature by two processes. The cosmogenic ¹²⁹I is produced in the atmosphere by the interaction of cosmic rays with xenon isotopes and the fissiogenic ¹²⁹I by spontaneous fission of uranium in the lithosphere. For the pre-nuclear era (no addition of anthropogenic ¹²⁹I to the environment) an ¹²⁹I/¹²⁷I isotopic ratio of about 1.5 · 10 ⁻¹² has been estimated. The quantity of ¹²⁹I in the pre-nuclear age ocean was ~100 kg. Since 1945 anthropogenic production of ¹²⁹I started which shifted the natural isotopic ratio for 3 to 6 orders of magnitude in favour of ¹²⁹I.

The main sources of ¹²⁹I are nuclear fuel reprocessing plants.

To our knowledge the ¹²⁹I level has not been measured in any biological or environmental sample from the Mediterranean area (Adriatic Sea). The aim of our work was to investigate the distribution of ¹²⁹I in the marine environment of Slovenia.

2 Methodology

2.1 Sampling and preparation

First sampling of alga (*Fucus virsoides*) and sediment was performed in 2005 and another sampling in 2009 including seawater, alga (*Fucus virsoides*) and blue mussel (*Mytilus galloprovincialis*). Alga and blue mussel were dried by freeze dryer to constant mass and homogenized. Seawater and sediment samples were analysed as collected.

2.2 Determination of ¹²⁹I and ¹²⁷I

Radiochemical neutron activation analysis method (RNAA) was used for the determination of ¹²⁹I [2] and ¹²⁷I [3] in environmental samples. Environmental samples contain very low amounts of ¹²⁹I therefore pre-concentration of iodine from up to 100 g of alga, blue mussel and sediment and up to 8 L of seawater are needed. Irradiation of sample, combustion in an oxygen atmosphere and extraction of iodine with CHCl₃ followed. Induced radioisotopes were measured on a HPGe detector. The chemical yield for the whole procedure was determined spectrophotometrically and by using the ¹²⁶I activity.

3 Results and Discussions

The method was applied to analyze ¹²⁹I/¹²⁷I isotopic ratios as well as ¹²⁹I and ¹²⁷I concentrations in the marine environment of Slovenia. The results found for analysed samples collected in 2005 and 2009 are summarised in Table 1. There are no literature dates for ¹²⁹I and ¹²⁷I concentrations in blue mussel. Values found in analysed seawater and sediment samples are in agreement with

values found in literature for areas that are not under the influence of direct liquid discharges of ¹²⁹I from nuclear fuel reprocessing plants. ¹²⁹I and ¹²⁷I concentrations found in analysed alga collected in 2005 and 2009 (Table 1) are in the same range. The ratio of ¹²⁹I/¹²⁷I found for alga *Fucus virsoides* is up to 10^{-9} , which is one order of magnitude higher than along the coast of China, up to two orders of magnitude lower than in the Baltic Sea, which is influenced by direct liquid discharges from La Hague and Sellafield, and up to four orders of magnitude lower than in the vicinity of the La Hague reprocessing plant.

Tab. 1. Range of ¹²⁹I and ¹²⁷I in marine environment of North Adriatic Sea

^apublish ed in 2008 [4]

The data of this study represent a survey of ¹²⁹I in the marine environment of Slovenia. The most likely source of ¹²⁹I are nuclear fuel reprocessing plants in La Hague and Sellafield, which are known to be the major sources of ¹²⁹I in the environment of North Europe. ¹²⁹I is transferred to the atmosphere and washed out to the marine environment of Slovenia by precipitation, so it is of atmospheric-precipitation origin.

THE DISTRIBUTION OF ZN IN SEAWATER AND SEDIMENTS OF A COASTAL MARINE AREA AFFECTED BY INDUSTRIAL ACTIVITIES (NW SARONIKOS GULF)

Vasiliki Paraskevopoulou¹, Emmanouel Dassenakis¹*, Styliani Triantafyllaki¹ and Nikos Giannikopoulos¹ ¹ Laboratory of Environmental Chemistry, Dept. of Chemistry, University of Athens - edasenak@chem.uoa.gr

Abstract

An oceanographic study of the coast of the North West Saronikos Gulf was carried out in the years 2006 and 2007. The area is affected by industrial and urban activities. Seawater and sediment samples were collected and various trace metals were determined. The present paper presents the results on the distributions and behaviour of Zn, which a metal of significant environmental importance, in this coastal marine environment.

Keywords: Aegean Sea, Coastal Waters, Zinc

INTRODUCTION

North West Saronikos Gulf is located 80 km west of Athens. This marine area is affected by industrial activities (oil refinery, cable manufacturer, soya mills, sulphur and fertilizers manufacturing), as well as touristic activity in the towns of Agioi Theodoroi and Isthmia. Furthermore the coastal zone of North West Saronikos is located on the Sousaki volcanic region therefore this area is characterized by a unique geological setting.

MATERIALS AND METHODS

The area was studied extensively from January 2006 to December 2007. There were 8 seasonal samplings in 9 coastal stations (MOT 1-MOT 9), in 7 off shore stations with depths ranging from 20 to 100m (MOT 10-16) and one off-shore station in the Megara Basin (UN6) with a depth of 200m. Dissolved and particulate Zn determinations were carried out using Chelex 100 preconcentration and nitric acid digestion respectively. Total Zn in sediments was extracted with strong acids (including HF) digestion [1]. The non lattice fraction of Zn was extracted with 0,5M HCl and with the BCR protocol [2]. All extracts from the above procedures were measured with Flame Atomic Absorption Spectrometry.

RESULTS AND DISCUSSION

The water column in both near-shore and off-shore stations was fully oxygenated in all seasons due to adequate water circulation. The theromocline started forming in June and was fully developed between 30 and 40m depth in August and September. The water column below 150m (UN6) has been isolated since 1992, therefore almost anoxic conditions prevail. Dissolved Zn ranged from 0,41 to 39,2 µg/L, while particulate Zn ranged from 0,11 to 4,1 µg/L. The dissolved Zn fraction comprised of more than 75% of the total concentration in all samplings. The average total Zn concentrations of coastal and off-shore stations were 2,7 and 5,1 μ g/L respectively and differed statistically (independent samples t-test). The off-shore stations exhibited a wider range of concentrations and some extreme values. The concentrations of total Zn below the depth of 20m were statistically higher than the corresponding concentrations at the surface and 20m. This was also depicted in the vertical profiles of total Zn in almost all sampling stations. The levels of total Zn in the off-shore stations of the study area were similar to the values of offshore East and South Saronikos Gulf but lower than the more polluted Elefsis Gulf which is characterised by more intensive industrial activity [3].

Fig. 1. Figure 1 Surface distribution of total Zn (mg/kg) in the sediments of the study area

The highest concentrations were determined in stations MOT5 (near a small shipyard) and UN6 (200m depth). The non lattice held (BCR1-3) concentrations of Zn ranged from 8,6 to 36,6 mg/kg and represented 17-53% of the total content. The highest percentages were determined near the main industries (stations MOT 2, 3 and 4). The non lattice held Zn was mostly found associated with Fe and Mn oxides (BCR2). The stations MOT5 and UN6 exhibited Sediment Enrichment Factors higher than 2 therefore the total Zn concentrations in these sediments could be attributed to anthropogenic pollution. The vertical distribution of total and non lattice held Zn in a small sediment core (10cm) of station UN6 also shows a marked increase in the surface layer which could be attributed to anthropogenic influence.

CONCLUSIONS

The study area of North West Saronikos Gulf is not a conventional hot spot due to increased depth and adequate water circulation and dilution. The levels of Zn in seawater and sediments were similar to other Greek marine areas and much lower than the most polluted part of the Gulf of Elefsis and East Saronikos. The significant pollution sources mentioned above and the neighbouring of populated and touristic towns suggest frequent monitoring of selected points to ensure that pollution levels remain fairly constant.

DISSOLVED OXYGEN AND NUTRIENT DISTRIBUTION IN NORTH AEGEAN SEA

Alexandra Pavlidou ¹*, Evagelia Krassakopoulou ¹ and Ekaterini Souvermezoglou ¹ ¹ HELLENIC CENTER FOR MARINE RESEARCH (HCMR) - aleka@ath.hcmr.gr

Abstract

In this work we present Dissolved Oxygen (DO) and inorganic nutrient (nitrate, nitrite, phosphate and silicate) distribution in the North Aegean Sea during April 2008 under the influence of different water masses. The Black Sea Water outcoming from the Dardanelles strait is not enriched in dissolved inorganic nutrients. On the contrary, the North Aegean Deep Waters carry higher concentrations of nutrients. According to DO data, formation of deep waters occurred at station NA2, but not at station NA7. *Keywords: Aegean Sea, Nutrients, Oxygen*

Introduction

The brackish, relatively cold and mestrophic waters exported from the Black Sea to the Marmara upper layer, reach the saline, oligotrophic waters of the Aegean Sea via the Dardanelles surface outflow. Thus, the Black Sea waters (BSW) are expected to contribute to the nutrient balances in the North Aegean Sea [1,2]. On the other hand, the salty Aegean waters enter the Marmara deep basin. The bottom layers of the North Aegean Sea contain one of the denser waters of the world ($\sigma_{\theta} > 29.5$ kg m⁻³), making it one of the principal dense water formation regions of the Mediterranean [3]. Below the surface layer there is a warm and highly saline water layer originating from the South Aegean and the Levantine, Levantine Intermediate Water (LIW), extending down to 350-400m depth [4,5]. The present work reports the Dissolved Oxygen (DO) and nutrient characteristics in the North Aegean Sea under the influence of the aforementioned different water masses.

Results and discussion

During the first week of April 2008, sampling was performed at 10 stations; among them, 4 stations were located close to the Dardanelles Strait, 2 northeastern of Lemnos Island and 3 northwestern of Samothraki Island (Fig.1).

Fig. 1. Bathymetric map of the study area and sampling stations

Mean concentrations of our data are presented in Table I. The DO vertical distribution seem to follow the salinity differences, showing maximum at the surface less saline light waters at the stations located near to the Dardanelles strait which indicate biological production. The significant decrease of DO which was observed at the bottom waters of station NA7 suggest a rather long stagnation period where bottom water formation has not occurred [6]. The BSW outcoming from the Dardanelles strait does not seem to be enriched in dissolved inorganic nutrients, but in organic nutrients [1]. Low inorganic nutrient concentrations have also been reported in other studies in the area, probably because of their exploitation by phytoplankton [7]. On the contrary, the North Aegean Deep Waters (bellow 400m depth, σ_{θ} > 29.35) carry higher concentrations of nutrients.

Tab. 1.	Mean	concentrations	of	DO	and	nutrients	in	North	Aegean	Sea

	n=20	n=7	n=5
σ_{θ} > 29.35			
DO (µM)	225 ± 3.82		
DIN (µM)	1.70 ± 0.39		
Phosphate (nM)	59.0 ± 10.9		
Silicate (µM)	2.21 ± 0.79		
DIN:P	26		
	n=6		

At the deep layer of station NA2 nutrients found to be lower than the ones measured at the deep waters of station NA7. More specifically, a decrease of 1.75 μ M for inorganic nitrogen, 117.9 nM for phosphate and 3.81 μ M for silicate is observed, while the accompanied increase of DO is 17 μ M. According to our results it is obvious that formation of deep waters occurred at station NA2, but not at station NA7.

HEAVY METAL CONTAMINATION IN CANDARLI BAY SEDIMENT: EASTERN AEGEAN SEA

Idil Pazi^{1*}, Filiz Kucuksezgin¹ and Dogan Yasar¹

¹ Dokuz Eylul University Institute of Marine Sciences & Technology - idil.erden@deu.edu.tr

Abstract

The accumulation of trace metals in sediments may cause serious environmental problems in the aquatic system. 8 sediment samples were collected using box corer in the Candarli Gulf in 2009 for a study on trace metal pollution. The concentrations of Hg, Pb, Cr, Zn and Al in the surface sediment layers were generally elevated when compared with the sub-surface layers. The metal levels were evaluated according to the enrichment factor analysis. The results revealed significant anthropogenic pollution of Hg and Pb in the surficial sediments of Candarli Gulf.

Keywords: Aegean Sea, Metals, Sediments

Introduction

Heavy metals are deemed serious pollutants because of toxicity, persistence and non-degradability in the environment [1, 2, 3]. Heavy metal contamination in sediment, soil and groundwater is one of the largest threats to environmental and human health [4]. Therefore, heavy metal contamination is still an environmental problem today in both developing and developed countries throughout the world. Few published data are present on metal concentrations from Aliaga Bay [5], but no data are available on metal levels in Candarli Gulf. The aim of this study is to comparatively evaluate Hg, Pb, Cr, Zn and Al concentrations in sediment, collected from different sites of Candarli Gulf.

Materials and Methods

In the framework of MEDPOL Phase IV Project, sediment samples were collected from 8 stations in Candarli Gulf using box corer to detect heavymetal concentrations by *R/V K. Piri Reis* (Institute of Marine Sciences and Technology). At each station surface and subsurface sediments (15-20 cm below the surface) were collected. Subsurface sediments were used as background levels for each element at all stations. Concentrations of Hg, Pb, Cr, Zn and Al were determined in the digested phase using ICP-ES/ICP-MS (ACME Analytical Labs, Vancouver, BC) in sediment samples.

Results and Discussion

Trace metal concentrations in sediments from the Station 6 (Sta. 6) are consistently higher than those from the other locations. The station near the PETKIM Complex has the highest values for Hg (6.3 mg/kg) Pb (138 mg/kg), and Zn (358 mg/kg). Cr level was measured as 44.6 mg/kg at Sta.6. This area is under the influence of the wastewaters and water-runoff from that industrial activity (rich in heavy metals). EFs present the identification and quantification of metal enrichment. Major population and industry in Candarli Gulf are located in Aliaga town. The relatively high trace metal enrichments in this region are therefore likely to originate from past and present day inputs. EF values tended to the greatest in Sta. 6. Enrichment factor of Cr are generally less than 1.5 (except Sta.6) suggesting that Cr contamination is not a problem at present. However, Candarli Gulf is severally contaminated by Hg, Pb and Zn as reflected by the enrichment factor values of these metals are all greater than 1.5. Enrichment factor results further indicated that these contaminants came from human impacts.

Conclusion

The metals contamination in sediment of studied locations may of anthropogenic origin with the exception of some local anomalies. When compared with the elemental background compositions, surface sediments were observed to be not contaminated with Cr. However, other elements, Zn, Pb and Hg with greater anthropogenic inputs, were observed to be enriched in the gulf sediment samples.

MODELING STABLE ISOTOPE RATIOS IN NEAR SURFACE WATER VAPOR IN THE MEDITERRANEAN: AN EVALUATION OF THE CRAIG-GORDON MODEL

Stephan Pfahl¹* and Heini Wernli¹

¹ Institute for Atmospheric and Climate Science, ETH Zurich, 8092 Zurich, Switzerland - stephan.pfahl@env.ethz.ch

Abstract

Stable isotope ratios in water vapor at Rehovot (Israel) are modeled with the help of the Craig-Gordon model, applied in a Lagrangian setup using backward trajectories. The comparison of the simulation results with measurements at Rehovot allows to infer about uncertain model parameters as the non-equilibrium fractionation factor. A new parameterization for this fractionation factor is suggested and applied in a first case study with a mesoscale dynamical model. *Keywords: Water Transport, Air-Sea Interactions*

Introduction

Stable water isotopes are widely used as diagnostic tools for investigating the global water cycle. An important step in this cycle is the evaporation of water from the ocean. The concurrence of equilibrium and non-equilibrium processes complicates a quantitative description and parameterization of isotope fractionation during evaporation. A linear resistance model, as introduced by Craig and Gordon [1], is commonly applied for this parameterization. In such a model, the isotope ratio in the evaporation flux can be expressed as follows: $R_E = k \cdot \frac{\alpha R_L - h R_A}{1 - h} (1),$

where R_L and R_A give the isotope ratios in the ocean and in atmospheric vapor, respectively; h denotes the relative humidity of the atmosphere, defined with respect to saturation at the sea surface, α is the equilibrium fractionation factor between vapor and liquid at the surface, and finally k denotes a non-equilibrium (diffusive) fractionation factor. This non-equilibrium fractionation factor is usually expressed according to [2], but its formulation is hardly constrained by atmospheric observations.

Methodology

This study addresses this issue by combining a recently developed Lagrangian moisture source analysis [3] with a Craig-Gordon fractionation parameterization (equation 1) in order to model isotope ratios in near-surface water vapor [4]. This technique is applied to 45 days of isotope measurements in water vapor at Rehovot (Israel) during the years 2001 to 2006 [5]. Different parameterizations for the non-equilibrium fractionation factor are tested in this setup. Finally, the mesocsale dynamical COSMO model [6] is equipped with the most successful parameterization and applied for simulating the spatial distribution of deuterium excess in water vapor close to the surface.

Results and Discussion

A comparison of the simulated deuterium excess from the Lagrangian approach with the measurements shows that a much better agreement can be achieved using a wind speed independent formulation of k (correlation coefficient r=0.80, RMSE=4.6 permil) instead of the classical parameterization by Merlivat and Jouzel [2] (r=0.53, RMSE=10.7 permil). The numerical values of k that lead to the best agreement of simulated and observed deuterium excess are k_{180} =0.9925 and k_{2H} =0.9961. These values are consistent with data from other studies. In future research, it should be tested if the empirically derived, wind speed independent parameterization also leads to an improvement of the performance of other models, including GCMs, in modeling deuterium excess. A first case study with the COSMO model verifies that the model is suitable for simulating spatial distributions of isotopes in water vapor in an event-based manner. The simulated deuterium excess of the new parameterization.

Abstract

The characterization of a new Reference Material (RM) for radionuclides in mussel (*Mytilus galloprovincialis*) from the Mediterranean Sea (IAEA-437) is described and the results of the certification process are presented. Four radionuclides (⁴⁰K, ²³⁴U, ²³⁸U, and ²³⁹⁺²⁴⁰Pu) have been certified, and information values on massic activities with 95% confidence intervals are given for nine other radionuclides (¹³⁷Cs, ²¹⁰Pb(²¹⁰Po), ²²⁶Ra, ²²⁸Ra, ²²⁸Th, ²³⁰Th, ²³²Th, ²³⁵U, and ²⁴¹Am). The IAEA-437 RM is intended to be used for quality assurance/quality control of radionuclide analyses of mussel samples using radiometric and mass spectrometry techniques (ICP-MS, AMS), for the development and the validation of analytical methods, for the development of reference methods and for training purposes.

Keywords: Radionuclides, Mediterranean Ridge, Pollution, Instruments And Techniques, Monitoring

Introduction

In collaboration with CIESM, an inter-laboratory comparison exercise using Mediterranean Mussel Reference Material was previously organised to test the performance of laboratories in analytical quality control [1-2]. More data from expert laboratories have been obtained during 2008-2009 allowing to assign the true values and the uncertainties of different radionuclides in this specific matrix of marine sample, and in consequence to permit to issue a new Certified Reference Material for Marine Environmental Study.

Experimental

The work was performed on a mussel tissue sample, which is commonly found and consumed seafood, and is widely used as bio-indicators in marine pollution studies. They were collected from the Mediterranean Sea in the framework of the CIESM (Commission Internationale pour l'Exploitation Scientifique de la Mer Mediterranée) Mediterranean Mussel Watch Program. About 1080 kg of mussel sample (Mytilus galloprovincialis species) was collected in Anse de Carteau, Port Saint Louis du Rhône (43°20'S, 5°10'E), France, by the Institut de Radioprotection et de Sûreté Nucléaire (IRSN, France) in June 2003. More detail of description of the material could be found in [1-2]. Of 34 laboratories received the sample, a total of 24 sets of results were received from participants and included in the evaluation report of the interlaboratory comparison exercise [2]. Because of very low-levels of radionuclide activities in the sample, 16 more samples were sent to 5 members of CELLAR (Collaboration of European Low-Level Underground Laboratories) and to 11 expert laboratories in 2007. High quality data from the interlaboratory comparison exercise, and additional data from the CELLAR and expert laboratories were included in the certification process, results of which are reported in the present paper.

Results and discussion

Homogeneity tests :The homogeneity of the sample was checked by measuring the activities of 40 K, 137 Cs, 235 U, 238 U, ${}^{239+240}$ Pu and 241 Am on 5-17 bottles taken at random. Gamma-spectrometric measurements were performed on 100 g of mussel. The activity concentrations of 235 U, 238 U, ${}^{239+240}$ Pu and 241 Am were determined by ICP-MS and alpha spectrometry on 0.5 to 100 g of mussel sample, respectively. Homogeneity was determined using one-way analysis of variance. The coefficient of variation was below 15% for gamma, alpha-spectrometrically determined radionuclides (with activity concentration less than 1 Bq kg⁻¹). The "between samples" variances showed no significant differences from the "within sample" variances for all analysed radionuclides. The material was thus considered sufficiently homogeneous for the tested radionuclides at the range of weights used.

Certification process: The certification process was carried out following the ISO Guide 35 [3] using the most precise and accurate data from interlaboratory comparison exercise and additional data from CELLAR and expert laboratories. For data sets comprising 5 or more accepted laboratory means, the median activities for the sets of individual data – after rejection of outliers – were chosen as the best estimations of the property values [4]. Evidence on metrological traceability to the SI units was provided by all laboratories in their reports.

Only 4 radionuclides ⁴⁰K, ²³⁴U, ²³⁸U and ²³⁹⁺²⁴⁰Pu were certified in the certification process. The mean, median values with 95 % confidence intervals, the number of accepted means which were used to calculate the certified activities are given in Table 1. Information values are given for 9 radionuclides: ¹³⁷Cs, ²¹⁰Pb(²¹⁰Po), ²²⁶Ra, ²²⁸Ra, ²²⁸Th, ²³⁰Th, ²³²Th, ²³⁵U

and 241 Am. The mean, median values with 95 % confidence intervals, the number of accepted means which were used to calculate the activities are given in Table 2.

DETERMINATION OF POLYMERIC ORGANIC MATERIAL CONTAINING "N-CATALYST" IN SEAWATER BY CONSTANT CURRENT CHRONOPOTENTIOMETRIC STRIPPING ANALYSIS

Marta Plavsic ¹*, Sladjana Strmecki ¹ and Bozena Cosovic ¹ ¹ Ruder Boskovic Institute, Bijenicka c. 54, 10000 Zagreb, Croatia - plavsic@irb.hr

Abstract

Catalytic properties and surface activity of nitrogen containing polymeric organic material (N-POM) were analyzed by constant current chronopotentiometric stripping analysis (CPSA) in seawater. CPSA proved to be a suitable method for determination of low concentrations of N-POM in seawater by measuring its "presodium" catalytic peak H. A protein human serum albumin (HSA) (15 % of N) was used as a model compound and the concentration of N-POM from natural seawater samples was expressed in HSA concentration equivalents.

Keywords: Electrochemistry, Adriatic Sea, Organic Matter

Introduction

Chronopotentiometric stripping analysis (CPSA) is an electrochemical technique in which preconcentrating step proceeds at negative potentials where amalgam is formed, followed by stripping step in which constant current is applied to strip the accumulated material. CPSA peak which appears is not due to the faradaic but to the catalytic reduction of hydrogen. That peak appears more positively on potential scale than usual hydrogen wave, preceeding the reduction of sodium ions. It is named peak "H" or catalytic hydrogen or "presodium" wave and a key organic molecule is called a "presodium" catalyst [1] already reported about CPS detection of peak H catalyzed by sulphur atoms in polysaccharides excreted from plankton cultures. A more negative peak H, at -1.7 V, was observed as well and a connection with the presence of polymeric organic matter containing N catalytic atoms was supposed [3]. Seawater samples were collected in the Northern Adriatic in 4 seasons: June and October 2008 and in January and March 2009, at surface (0.5 m depth) and bottom (~31 m depth), as well in some other areas in the Adriatic.

Results and Discussion

From peak H height measured in the seawater samples we could not characterize N-POM on molecular basis, as for that some specific separation techniques and characterization methods should be included. Macroaggregates found in the Northern Adriatic are characterized by high C/N ratio due to their low protein content having carbohydrates as a major component. Surface samples were richer in N- POM than bottom samples in all seasons. We calculated N-POM/SAS and N-POM/DOC and concluded that N-POM made a minor part of SAS and DOC in seawater samples comprising a few percent.

OLIGOTROPHICATION OF THE NORTHERN ADRIATIC, TRUE OR FALSE?

Robert Precali^{1*}, Tamara Djakovac¹ and Danilo Degobbis¹ ¹ Center for Marine Research, Ruder Boškovic Institute - precali@cim.irb.hr

Abstract

From 2003 to 2008 NA experienced a reduced input of freshwater and nutrients. In the second part of 2008, after five years, the Po River flow was higher than its average and in the whole NA the "oligotrophication scenario" (reduced trophic level) shifted to usual behaviour. The response to the change was immediate, indicating the fragility of the pelagic ecosystem. *Keywords: Chlorophyll-a, Nutrients*

Introduction

The northern Adriatic (NA) is mainly under the influence of the Po River (70 % of the inflow), one of the largest Mediterranean rivers. The last decade is characterized by a strong decrease in Chl *a* concentration in the whole NA and confirmed all over the basin (-0.11 mg m⁻³ a⁻¹) from satellite derived information [1]. A decrease in freshwater inflow and input of nutrients resulted in a reduced availability (greater limitation) of phosphorous (P), and accumulation of total inorganic nitrogen (TIN) in the ecosystem [2]. In this work we are trying to understand how fragile such an ecosystem is when freshwater input increases again.

Fig. 1. Northern Adriatic map and station locations

Methods

Sampling, parameters determination and calculation

Water samples for nutrients (amonium, nitrite, nitrate, orthosilicate and orthophosphate) and chlorophyll *a* concentration measurements were collected on a monthly scale from Jan 2007 to Dec 2008 at five oceanographic depths at station RV001 near Rovinj (Croatia, Fig. 1). Parameters were determined by standard oceanographic methods described in previous authors' publications. To understand the recent variability only residuals, after the removal of model values, are presented.

Model

Data collected from 1972-2002 on a monthly base were used to build an annual model. On annual scale through the data a Fourier smoother (with retained three harmonics) was passed.

Results and discussion

Station RV001 in the Istrian coastal area well represents the main processes in the open NA waters mainly because the local ones are not pronounced [2]. In the period 2007-2008 Chl *a* and orthophosphate (PO_4) concentrations were systematically lower than average confirming the overall trend in the wider area (Fig.2, [2]). On the contrary, TIN concentrations were higher than average over a great part of the investigated period, showing the coupling of greater P limitation and accumulation of TIN in the ecosystem. In 2008, more pronounced in the second part of the year (Fig. 2), the freshwater inflow increased and resulted in TIN consumption as more P was available in the ecosystem. The

increase of biomass (Chl a) was not observed probably due to a higher

The results show that the ecosystem rapidly responds to the input of fresh

nutrients and that is well adapted to such a type of stimuli. Oligotrophication of

the area is than only a measure to nutrient inputs, and controlled by the

efficiency of nutrients use by the phytoplankton community.

Fig. 2. Residuals (model – 1972-2002 removed) for chlorophyll *a* (Chl *a*), orthophosphate (PO₄) and total inorganic nitrogen (TIN) concentration (*c*), and Po River flow (*Q*) at Pontelagoscuro in the period 2007-2008. Thin line – residuals, thick line – running average

Abstract

The Rhone River exerts a major influence on the Gulf of Lions which is the largest river-dominated ocean margin of the Western Mediterranean Sea. The biogeochemical fate of the Rhone River inputs (dissolved nutrients, particulate organic matter and detrital particles) was investigated during a multi-compartment study (CHACCRA) by coupling simultaneous measurements on the river inputs, the river plume processes and the benthic deposition. A coupled physical-biogeochemical model was used to link the inputs and their fate in the Gulf of Lions and to investigate the sensitivity of the delta system to changes in climate and in river inputs. *Keywords: Deltas, Global Change, Gulf Of Lions, Organic Matter, Rhone Delta*

The Rhone River exerts a major influence on the Gulf of Lions which is the largest river-dominated ocean margin of the Western Mediterranean Sea. The biogeochemical fate of the Rhone River inputs (dissolved nutrients, particulate organic matter and detrital particles) to the continental shelf is largely influenced by primary production in the plume, deposition patterns of particles and transformation processes in the water column and sediments. We have designed a multi-compartment study (CHACCRA) by coupling simultaneous measurements on the river inputs, the river plume processes and the benthic deposition to elucidate the transport and transformation of Rhone River material in the Gulf of Lions. A coupled physical-biogeochemical model is used to link the inputs and their fate in the Gulf of Lions. First results from the river input monitoring show that the river input of organic material is highly variable in quantity showing intra and inter-annual variability. The largest change in quality of organic input is linked to the occurrence of floods in the Rhone watershed which may deliver either more reactive carbon (originating from the river bed and runoff on vegetated soils) or less reactive when delivered from erosion of soils. The benthic deposition and transformation of this material shows a spatial pattern with a focus of the deposition of river organic matter as tracked by $^{13}\mathrm{C}$ and $^{14}\mathrm{C}$ signature and an intense recycling of organic particles close to the river mouth. Oxygen demand values close to the Rhone River outlet are around 20 mmol m⁻² d⁻¹, remain high up to a distance of 10 km around the river mouth above 10 mmol m⁻² d⁻¹ (called the prodelta) and decrease to average continental shelf values further away [1]. This pattern is stable over the seasons but is disturbed by the occurrence of floods which, in the case of June 2008, spread low-reactivity material in the nearshore region and significantly decreased benthic recycling during a few months. The measurements performed during the three cruises dedicated to plume processes showed limited accumulation of Chlorophyll a in the Rhone River dilution zone, due to low flow rates during these periods. The structure of the pelagic food web was oriented towards recycling except on a single occasion where marine snow was recorded in the intermediate laver of the water column indicating benthic-pelagic coupling. Overall, a disconnection between river plume production regions occurring on the distant shelf (>30 km) and the hot spot of benthic recycling in the nearshore region is apparent. Biogeochemical modelling coupled to the Symphonie hydrodynamics model in the Gulf of Lion showed a first-order agreement with the timing and amplitude of the winter-spring bloom on the western part of the shelf. The Rhone River plume required specific parametrization, since its biogeochemistry is significantly different from the rest of the Gulf of Lion: stratification is stronger, nutrients are more abundant, the food web is oriented towards larger species. This specific model reproduced the succession of the different nutrients pools and planktonic groups along the Rhone freshwater dilution zone described by [2]. The model was used to characterize the biogeochemical functioning of the Gulf of Lion and to compute associated budgets during several years contrasted by their hydrological and meteorological forcing. The importance of floods and low flow rates on the delivery and fate of organic material to the Rhone prodelta points towards a

vulnerability of the ecosystem with respect to climatic change. Climate change should alter both river hydrography due to stronger extreme rains, dry periods and wind patterns in the Northwestern Mediterranean. These changes will be investigated, together with the human impact through the delivery of contaminants and nutrients, in the framework of the newly launched MERMEX programme.

Abstract

Trace metals and organic contaminants were analyzed in surface sediments of four sites of the Berre lagoon to determine their potential toxicity and genotoxicity for the benthic fauna. Bioavailable trace metals determined by chemical extractions were compared with bioassimilated contents in Hediste diversicolor as well as with the metallothioneine induction in these organisms. Genotoxic effects were observed for both trace metals and organic contaminants. *Keywords: Metals, Pah, Bio-Indicators, Annelida, Ecotoxicology*

In the last decade, numerous assays or indicators were proposed to define the toxicity or genotoxicity of contaminated sediments. They are mostly based on in vitro bioassays and generally refer to one type of contaminant: metal or PAHs. If some tests have been shown to be representative, it is still difficult to evaluate the toxicity associated to a multi-contamination combining organic and inorganic pollutants, and the in situ relationships between these mixtures and their effects on benthic organisms are still unknown.

To better understand such relationships, we conducted a preliminary work using a multi-tool approach on sediments from the Berre lagoon (south of France). This lagoon was impacted in the last century by industrial and urban development introducing large amounts of trace metals and organic contaminants. Their contents decreased in the surface of the sediments since the 1980's but large contents have been accumulated below the surface. These contents in the most impacted area (Vaine lagoon) are up to 160 μ g.Kg-1 for total PCBs, 2500 ppm for total PAHs, 80 ppm for Cr, 70 ppm for Ni, 45 ppm de Cu and 140 ppm for Zn.

Four sites characterized by various contaminants contents were sampled and surface sediments were analyzed for trace metals (Cr, Cu, Ni, Pb, Cd, Zn), 16 PAH's and 7 PCB's. The trace metal bioavailibility was studied in more details by comparing labile fractions obtained from Diffusive Gradient Technique (DGT) devices and from several chemical extractions including EDTA 0.1 M, or pH4 and pH6 as physiological pH prevailing in the digestive tract of organisms. In order to show if these various labile pools of metals are representative of the bioavailable form of metals for benthic organisms, we compared their concentrations to the bioassimilated metals contents in the deposit-feeder polychaete Hediste diversicolor (characteristic of coastal sediment) as well as to a metal specific stress marker: the metallothionein (MT) content in cells of the intestinal walls of these organisms. MTs (analyzed by ELISA method) were evidenced in only one site and no relation between MTs and trace metals in the sediment was observed (except for Cd extracted by EDTA). It confirms the rather large variation previously observed for MT induction that can be due to environmental parameters or supplementary detoxification processes [1].

Detection of acting genotoxic and mutagenic pollutants in sediment was tested by the vitro comet assay, the micronucleus assay and the Salmonella mutagenicity test (Ames test) performed on both organic and inorganic extracts of the sediment. The assays performed on organic extracts were conducted with and without metabolic activation (S9 mix) for the detection of both indirect and direct acting genotoxins. The two sites with the highest PAHs and PCBs contents revealed genotoxic and mutagenic effects with a positive dose-response relationship, but only when S9 metabolic activation was added. Furthermore, the strongest genotoxicity was not observed for the most contaminated site. Genotoxic effects associated to trace metals extracts were also observed for the two most contaminated sites, but as for MT there is no direct relationships with total or labile metal extractions.

The responses to the toxicity tests realized in this preliminary work are in rather good agreement with the multi-contaminants contents measured in the sediment. However, information on in situ xenobiotic effects onto organisms and their potential variations with time have to be gained from a future project that will be briefly presented.

Abstract

Nitrogen fixation, bacterial and primary productivity rates were measured along an 12 eutrophication gradient at two distinct provinces in the Levantine basin: the Shikmona 13 gyre (SG) and the Rhodes gyre (RG). Primary productivity in the euphotic zone ranged 14 from 0.37 mmol C m-3 d-1 for oligotrophic SG to 1.67 mmol C m-3 for moderately 15 mesotrophic RG. Bacterial productivity ranged between 0.08 μ g C L-1 d-1 at surface and 16 5.11 μ g C L-1 d-1 at the bottom depths of the SG, while the RG showed extremely high 17 rates, ranging from 6.3 to 87.8 μ g C L-1 d-1 at the surface and bottom, respectively. *Keywords: Levantine Basin, Nutrients*

The Levantine basin in the east Mediterranean Sea is one of the most oligotrophic, low nutrient low Chlorophyll (LNLC) seas especially during stratification periods. The deep waters of the Levantine basin have an anomalousy high nitrate to phosphate ratio (DIN:DIP) (28:1) and all its input sources, particularly atmospheric sources ([1]), show a high N:P ratios (>16:1) ([2]). In addition, its P turnover time (<5h, 26 [3]) is typical for P deficient water systems. Thus, it is expected that these properties do not favor significant N-fixation rates. Indeed, routinely monitored stations in the ultraoligotrophic waters of N-fixation (0-1.3 nmol N L-1 d-1) (Yogev et al., - in prep). Low N2 fixation rates were also recorded in the Gulf of Aqaba, Red Sea, during fall (stratified, oligotrophic) and spring (deep mixing, mesotrophic) seasons with maximum rates of 1 \pm 32 0.1 nmol N L-1 d-1 in the fall and 1.9 \pm 0.2 nmol N L-1 d-1 in the spring ([4]).

Theoretically, nitrogen fixers (i.e., large colonial cyanobacteria in the genus *Trichodesmium* and the heterocystous endosymbiont *Richelia*) could prosper in environments which supply phosphorus and iron to feed the energetic and enzymatic demands for the Fe-rich nitrogenase and N fixation process. Such conditions may occur along a eutrophic gradient in specific areas in the Levantine Basin. Indeed, an order of magnitude higher N fixation rates were measured in Haifa bay during May 2009 (8 nmol 40 N L-1 d-1) representing a more mesotrophic environment. To understand the factors controlling this process we explored N fixation rates, primary and bacterial production in two distinct water provinces in the Levantine basin, the ultra-oligotrophic Shikmona Gyre and the mesotrophic Rhodes Gyre.

The Shikmona gyre (SG), also referred to as the Cyprus eddy, is a warm-core eddy with an anti-cyclonic circulations patterns and is characterized with nitrate and phosphate values close to the conventional analytical detection limits in the surface waters (a few nanomolars during stratified period, [5]), development of deep chlorophyll maximum (125 m) and low values of primary productivity (0.37 mmol C m-3 d-1). TheRhodes gyre (RG) is a cyclonic feature of the eastern Mediterranean circulation and characterized with constant upwelling with relatively high nitrate and phosphate concentration at surface (0.2 μ M and 0.02 μ M, respectively), shallow chlorophyll maximum (60 m) and relatively higher rates of primary productivity (1.67 mmol C m-3 d-53 1).

Fig. 1. Depth profiles measured during July 2009 from the Shikmona and Rhodes gyres showing changes in water density (a), dissolved concentrations of nitrate+nitrite and orthophosphate (b) and concentrations of extracted Chlorophyll a (c)

Water was collected on July 2009 at the above locations onboard the R/V 55 Mediterranean Explorer, during the ISRLEV cruise. Rates of nitrogen fixation were measured on field samples using the 15N2 assimilation technique ([6]). Bacterial production was estimated using 3H-Leucine (Amersham, Specific activity: 160 Ci/mmol) incorporation method ([7]). Photosynthetic carbon fixation rates were estimated by means of the 13C technique ([8]).

EFFECTS OF THE HYDROLOGICAL CONDITIONS ON THE SPATIAL DISTRIBUTION OF CHLOROPHYLL A AND NUTRIENTS CONCENTRATIONS IN AN UPWELLING AREA OF THE ALBORAN SEA

Teodoro Ramírez¹, Dolores Cortés¹, Jesús Mercado¹ and Esperanza Liger²*

¹ Department of Applied Physics II, University of Málaga - eliger@uma.es

² Instituto Español de Oceanografía, Centro Oceanográfico de Málaga

Abstract

The coupling between the spatial distribution of Chla (chlorophyll-a) and nutrient concentrations and the hydrological conditions in the NW Alboran Sea is examined in the present study by using data from 12 seasonal oceanographic cruises carried out over three years period.

Keywords: Chlorophyll-a, Nutrients, Alboran Sea, Upwelling

Introduction

The Alboran Sea is characterized by a very high hydrodynamic activity. The Atlantic seawater influx through Strait of Gibraltar produces a system of two anticyclonic gyres which occupy almost all the central part of the basin [1]. With the aim of providing new insights on the coupling among biological structures and the hydrology in this area [2-3], four seasonal oceanographic cruises per year were carried out along the coast of Malaga.

Material and Methods

Samplings were conducted in coastal (20-30 m), neritic (80-100 m) and oceanic stations (210-540 m), situated in six transects located off the coast of Málaga (Fig.1). At each sampling station, continuous vertical profiles of temperature and salinity and seawater samples for Chla and nutrient analysis were taken. The mean values of these variables in the upper 20 m during each cruise were used to generate horizontal distributions maps for the whole period of study.

Results and Discussion

Salinity and temperature in the upper 20 m reflected the general circulation pattern of the zone as well as the influenced of different fertilization mechanisms. Thus the oceanic stations of the western transects (P, F and T) were frequently under the influence of the Atlantic jet, where lower temperature values coincided with the lowest average salinity, possibly due to the incursions of cores of North Atlantic Central Water (NACW) in these stations. The eastern transects (M. R and V) were usually affected by warmer waters from the East and with relatively low salinities and high dissolved oxygen values, suggesting the presence in the eastern transects of surface water with a high residence time. On average, salinity showed a strong gradient towards the coast on the whole area, mainly due to the wind induced upwelling events in the coastal stations. This gradient was even more pronounced in the westernmost transects due to the greater Atlantic influence in the oceanic stations. Nutrient concentrations correlated significantly with salinity, showing the potential fertilization associated to the saltier Mediterranean waters. However, no correlation was found with neither the temperature nor the depth of the AMI (Atlantic Mediterranean Interface). Chla was greatly affected by the hydrological conditions and showed significant differences between the western and the eastern transects (Kruskal-Wallis, H (N=24)=13.96, p<0.001). In the western transects different fertilization mechanisms (geostrophic front, incursions of NACW and advection waters from the Strait of Gibraltar) leaded to the highest Chla values found during the studied period, which on average were always higher than 1 µg L⁻¹. In the eastern sector, Chla concentrations were always lower than 0.7 µg L-1, coinciding with the presence in these transects of waters with a higher time of residence. In the Alboran Sea, the depth of the AMI (Atlantic Mediterranean Interface) has been frequently considered as an indicator of fertilization by different authors [1], as the Mediterranean waters are enriched in nutrients, and relationships between Chla and the AMI has been previously reported. However, the present study indicated that on overall the depth of the AMI was no good predictor of the vertical nutrient input towards the surface, though salinity did. In addition, no significant correlation was found neither between the mean values of Chla and salinity in each station, nor between Chla and the depth of the AMI. In contrast, Chla concentrations correlated significantly with the average temperature, dissolved oxygen and nutrient concentrations in the upper 20 m, indicating a close association between Chla concentrations and the thermal and biogeochemical features of the water masses. The lack of correlation between Chla and salinity was attributed to the existence of different fertilization mechanisms in the area of study, not only the upwelling of saltier Mediterranean of waters, as well as to the presence of water masses with different times of residence.

Abstract

In the framework of the MIRACLE project (Mercury Interdisciplinary Research for Appropriate Clam farming in Lagoon Environment), sediment cores were sampled in the Grado and Marano lagoon and in the tributary Aussa River in order to quantify and to characterize humic acids (HA) that are recognized to play an important role in complexing heavy metals, mercury included. Stable carbon isotopic composition was used to identify sources and contribution of organic matter from different environments to lagoon sediments.

Keywords: Organic Matter, Lagoons, Carbon, Chemical Analysis

Introduction

A substantial fraction of the so-called refractory organic matter in sediments is constituted by humic substances (HS) which are formed from the decomposition of plant, animal and microbial tissues and tend to be more recalcitrant than their precursors. HS can play an important role as electron transfer in the anaerobic environment [1]. HS they can bind both hydrophobic and hydrophilic species [2] and are electron donors in photo-oxidation reactions in marine environments [3]. The aim of the present work is to investigate the relevance and the origin of humic acids in the sedimentary organic matter of the Grado and Marano Lagoon.

Methodology

The sediments, surface layer (0-1 cm) and a sub-surface layer (5-6 cm), were collected in 16 stations in the Grado and Marano lagoon and in the Aussa River. Organic carbon (C_{org}) was determined in sediments and humic acids extracted by a CHNS-O elemental analyzer after removal of carbonates with HCI 1N [4]. Nitrogen (N) was determined following the same procedure, without acidification. The detection limit of the method was 0.4 micromole for C_{org} and 0.9 micromole for N. The stable isotopic ratio of organic carbon (${}^{13}C/{}^{12}C$) was determined by a CHNS-O analyzer coupled with an Isotope Ratio Mass Spectrometer. The analytical precision of measurements was 0.2%. The extraction of HA from sediments was performed following the methods of the International Humic Substance Society, modified by Moreda-Piñeiro et al. [5].

Results and discussion

The contribution of humic C to total C_{org} was high both in lagoon and riverine sediments (~ 30 %). The concentrations in riverine sediments were the highest and increased upstream from the river mouth. This relevant amount of humic acid to the sedimentary organic matter points out their important role in the transformation and accumulation of organic material in the lagoon environment. The ¹³C/¹²C ratios for the sedimentary organic matter showed a prevalently marine/lagoon origin whereas the riverine sediments appeared significantly more depleted in ¹³C/¹²C (more negative ¹³C) along with the highest C/N ratios, due to the fluvial and terrestrial origin of the organic matter [Fig. 1].

Extracted humic substances showed similar ${}^{13}C/{}^{12}C$ values of the corresponding sediments [Fig. 1], but higher C/N ratios, in particular in the subsurface ones. This increase with depth seems to indicate that different stages of transformation of the organic matter take place during early diagenesis.

Fig. 1. Stable carbon isotope ratios $({}^{13}C/{}^{12}C)$ of organic carbon vs C/N molar ratios in river Aussa, in lagoon surface and subsurface sedimentary organic matter and in corresponding extracted humic acids.

MUSSEL DNASE ACTIVITY AS A NEW BIOMARKER FOR ENVIRONMENTAL CONTAMINATION: RESPONSE TO MODEL POLLUTANTS

Sanda Ravlic¹*, Mirta Smodlaka¹ and Nevenka Bihari¹

¹ Center for Marine Research, Rudjer Boskovic Institute - ravlic@cim.irb.hr

Abstract

In this study the determination of pollutant effect on acid DNase activity was performed on mussel *Mytilus galloprovincialis* hemocytes and hepatocytes. The specific enzyme activity in unexposed mussels from mariculture area was higher in hemocytes than in digestive gland. Acid DNase activity response to detergent, gasoline and copper sulphate exposure was both pollutant- and tissue-specific.

Keywords: Mollusca, Ecotoxicology, Enzymes, Toxins

Introduction

Mussels adjust their function to environmental changes by reacting to various contaminants accumulated from the surrounding water and serve as bioindicators of coastal water quality. The aim of this study was to investigate the changes in the specific acid DNase activity in the mussel *Mytilus galloprovincialis* exposed to three types of model pollutants, a detergent as a surfactant, gasoline as a polycyclic aromatic hydrocarbon mixture and copper as a heavy metal. Digestive gland as a detoxifying organ and hemocytes as a major internal defense tissue were selected as target organs.

Materials and methods

The mussel *M. galloprovincialis*, average mass 10 ± 2 g and length 4 ± 1 cm were obtained from mariculture and served as a control group and reference sample. Mussels (30 specimens) were exposed in 201 tanks to ariel detergent (0.05, 0.5 or 5 mg/l), gasoline (0.05, 0.5 or 5 mg/l) or copper sulphate, CuSO₄x 7H₂O (2.5, 25, or 250 mg/l) for 3 days. DNase activity was measured fluorometrically by a method originally developed for neutral DNases [1] and adapted to acid DNases [2].

Results and discussion

Comparison of specific acid DNase activity in hemocytes and digestive gland of control mussels revealed hemocytes as a tissue with the higher enzyme activity. This result indicates that the requirement for enzyme activity is headed to restriction of DNA in the process of phagocytosis in hemocytes. Acid DNase activity response in hemocytes and digestive gland of mussels exposed to detergent, gasoline and copper sulphate is presented in Fig. 1A. In specimens exposed to detergent or gasoline the significant increase in enzyme activity was observed in both tissues. The highest enzyme activity was detected in mussels exposed to gasoline. A dramatic change in acid DNase activity was observed in the digestive gland of mussels exposed to gasoline and copper sulphate. Exposure to copper sulphate increased enzyme activity in the digestive gland but significantly suppressed it in hemocytes. Detergent and copper sulphate induced a fast response (24 h) of the enzyme activity in both tissues (Fig. 1B1, 1B3) while metabolic biotransformation of lipophylic constituents was probably the cause of the delayed enzyme response (48 h in hemocytes and 72 h in digestive gland) to gasoline (Fig. 1B2). Suppression of enzyme activity as a specific response of hemocytes acid DNase to copper sulphate is consistent with its effect on the cells of the immune system in bivalves [3]. Acid DNase activity response in hemocytes and digestive gland of mussels exposed to model pollutants was both tissue- and pollutant specific but the potential of acid DNase response in digestive gland of mussel to serve as an "all or nothing response" biomarker of contaminant exposure is promising.

Fig. 1. Dose (A) and time (B1, B2, B3) response of acid DNase activity of hemocytes and the digestive gland of the mussel Mytilus galloprovincialis to different pollutants. B1- detergent (5 mg/l), B2- gasoline (5 mg/l), B3- copper sulphate (250 mg/l).

METALS AND POPS IN SEDIMENTS ALONG THE ITALIAN ADRIATIC AND IONIAN COAST

S. Romano^{1*}, C. Mugnai¹, S. Giuliani¹, L. G. Bellucci¹ and M. Frignani¹

¹ CNR - ISMAR UOS Bologna - stefania.romano@bo.ismar.cnr.it

Abstract

Concentrations of inorganic and organic contaminants along the costal zone of the Adriatic and Eastern Ionian Seas in the centralsouthern part of Italy were obtained from the Ministry of Environment database and analysed to assess the quality of these areas, and understand their variability and its main causes. Peak values were found mainly in occasion of floods, which deliver land based contaminated materials to the coastal zone. To evaluate both contamination degrees and potential ecotoxicological effects, the values of metals, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs) were compared with sediment quality guidelines (SQGs). The mean concentrations are mostly below the lower SQGs, although maxima are higher, in some cases exceeding the limit above which adverse effects are expected.

Keywords: Metals, Pcb, Pah, Sediments

Introduction

The presence of urban areas, ports and industrial settlements is one of the main factors influencing the quality of coastal marine environments. This work aims to assess near-shore sediment quality and variability along the central-southern Adriatic coast of Italy, based on the data from Si.Di.Mar., web GIS of the Italian Ministry of Environment Marine Monitoring program, that stores information on contaminants in environmental matrices.

Material and Methods

We considered surficial sediments (0-3 cm) sampled every six months at 16 selected sites along the coast of Marche, Abruzzo, Molise and Puglia by Regional Environmental Protection Agencies in the years 2001-2006. Sampling areas, located within 1NM from the coastline, were selected among those subject to anthropogenic pressures, in general close to river mouths, ports and urban areas. In addition, a reference station, located inside a Protected Marine Area, was chosen for each region. The analysed contaminants include metals (Cd, Hg, Ni, Zn) and POPs (PAH and PCB priority congeners). Sediment characteristics, such as grain size composition, total (TC) and organic carbon (OC) contents, were also determined.

Results and discussion

The grain size composition indicate a predominance of sand at all sites, with significant fluctuations that can be attributed increases of system dynamics and/or significant inputs of coarse material from land. OC concentrations are relatively high (0.02-3.00%), which is rather peculiar in coarse sediments. Contaminant concentrations show a decreasing trend, except for PAHs (Fig. 1). Pattern of both sediment characteristic and contaminants are similar on the regional scale.

Fig. 1. Average values calculated annually for the whole study area for metals, Σ PCB and Σ PAH. The vertical bars show the maximum and minimum values.

Sediment quality guidelines (SQGs) are useful screening tools to asses the potential toxicity of contaminants in sediments in absence of direct biological effect data [1].

Table 1 shows a comparison of the contaminant data with different SQGs adopted for the Italian contest [2] and worldwide [3], [4], [5].

Tab. 1. Mean, minimum and maximum values for the whole study area on yearly basis for metals, \sum PCB and \sum PAH. The sediment quality guidelines used for comparison are listed above.

The annual mean values are mostly below the lowest benchmark, whereas maxima are usually higher, sometimes exceeding the upper limit above which adverse effects are expected (Table 1). This was observed for Hg (2003, 2004, 2005), Ni (each year except 2004), Zn (2001, 2003) and PAHs (2006). The main cause of the peak contaminant inputs recorded by sediment can be related to the particular rain regime in the last decades, which has been characterised by both a reduction of average precipitations and a higher occurrence of extreme events. These, apparently, have the capacity to mobilise contaminants stored on land and deliver them to the coastal zone.

PROPERTIES OF PERIODIC DYNAMICAL SYSTEMS MODELING: THE DIMETHYLSULFIDE(DMS)CYCLE

B. Rossetto ¹*, J. Ginoux ¹, N. Jean ¹, J. Jamet ¹, D. Jamet ¹, G. Boge ¹ and S. Richard ¹

¹ Toulon University - rossetto@univ-tln.fr

Abstract

The variables of a model of dimethylsulfide (DMS) cycle and their interactions are analyzed in order to fit Mediterranan sea data. The outcome is a class of dynamical systems with periodic coefficients. A method to determine some mathematical properties conferred by these systems to the phase space is proposed to extract some information from the complexity of the solutions. *Keywords: Models, Geochemistry*

Introduction

The dimethylsulfide (DMS) cycle of ecosystems may contribute to moderate anthropogenic forcing of climate. This field gives rise to a broad interest and to a large number of papers, but the magnitude of the DMS-climate feedback is difficult to appreciate.

Fig. 1. Manifold (dark) and solutions trajectories in the three dimensional phase space DMS (U), DMSP (W), zooplankton (z) $\,$

Fig. 2. Other perspective of the same phase space representation

Biologic study

The first part of this work is devoted to the construction of a model of the biogeochemical cycle of DMS based on works of A. J. Gabric & al.[1] and on experimental data from Mediterranean sea consisting in samplings of nutrients, phytoplankton, zooplankton and physical parameters such temperature,

salinity and photometry [2]. The variables of an eight-dimensional mathematical model are concentration of phytoplankton, bacteria, zooflagellates, large protozoa, micro and mesozooplankton, dissolved inorganic nitrogen, dissolved dimethylsulfonio-propionate (DMSP) and dissolved DMS. The air-sea exchange of DMS depends in a complex way on the wind velocity and on the sea surface temperature (SST), which is a function of time. So, the original model is an eight-dimensional dynamical system with variable coefficients. At first, a numerical study allows to determine what variables have a significant influence in the DMS cycle, according the environment, in order to reduce the number of dimensions of the dynamical system. It is shown that, under some conditions, the three variables zooflagellates, large protozoa, micro and mesozooplankton, can be merged. Then, the nutrients can be introduced are an external input. So, the dimensions

Mathematical study

Let us consider, for example, the dissolved DMS and DMSP concentrations. With some set of data, they autonomously oscillate with an irregular period of about one month. The high number of dimensions and this irregular oscillation contribute to the complexity of the solutions. The equation of an invariant manifold of an associated constant coefficient equivalent system (ACCES) is computed in a very simple way using differential geometry results [3]. This manifold plays an important role when the coefficients of the dynamical system depend on time [4]. When there is no wind, this manifold shows that the dissolved DMS and DMSP concentrations variations are almost synchronized. In the presence of wind, the manifold is periodically crossed by the solutions of the model as it is shown on the two figures, which are two perspectives of the projection of the same phase space on the (DMS, DMSP, zooplankton) tridimensional space. Then the DMS and DMSP respective influence is modulated by the sea surface temperature.

Conclusion

The respective influence of other set of variables could be studied by this method.

ASSESSMENT OF ZINC MOBILIZATION IN COASTAL SEDIMENTS

A. Sakellari ^{1*}, M. Plavsic ², S. Karavoltsos ¹, M. Dasenakis ¹ and M. Scoullos ¹

Abstract

The mobility of zinc in sediments of selected coastal microenvironments of the Aegean Sea (Greece) was investigated with the implementation of the DGT (Diffusive Gradients in Thin Films) technique. The various forms of zinc in sediments – together with those of iron and manganese –determined through sequential extraction schemes, their profiles in pore water and the impact of organic matter, including carbohydrates, were taken into consideration. A case of zinc flux from the sediment to the overlying water was investigated.

Keywords: Zinc, Sediments

Introduction

Heavy metals may be recycled several times through the sediment-water interface before being permanently stored in sediments or released to the overlying bottom waters. Pore water represents an important intermediate in this mobilization procedure, which is influenced by diagenetic reactions, prevailing redox conditions and microbial activity, with organic matter playing a major role via complexation [1]. Through the vertical profiles of metals' concentrations in pore water, the role of diagenetic reactions and the resupply of metals from sediments can be evaluated [2].

Methodology

The total metal content of sediment cores and their various forms according to the BCR sequential extraction scheme were determined by GFAAS. High resolution concentration depth profiles of metals were obtained by the *in situ* technique of DGT (Fig. 1). Organic carbon was measured by High Temperature Catalytic Oxidation and carbohydrates in sediments were measured colorimetrically by the phenol-sulfuric acid method, whereas in pore water according to Myklestadt et al [3].

Fig. 1. Concentration depth profiles of the DGT fraction of dissolved zinc in sediment pore water from Loutropyrgos site.

Results and Discussion

At the sites of Loutropyrgos (Saronikos gulf) and Kalamos (Evoikos gulf) the vertical distributions of total metals and organic matter in the solid phase of the sediment demonstrate similar fluctuations with metal profiles in pore water. On the contrary, this is not the case at Molos site (Maliakos gulf), probably due to prevailing turbation. Metal mobility in the cores studied is regulated by the forms under which metals occur in sediment and is significantly affected by diagenesis and the transformations of organic matter. These reactions are largely responsible also for the flux of metals from the sediment to the pore waters [4]. At the site of Loutropyrgos, located at one of the mostly industrialized areas of

the country, a flux of both zinc (Fig. 1) and organic matter from the sediment to the overlying water is likely to occur. Through the formation of a constant concentration gradient in the sediment-water interface an enrichment of the overlying water in zinc, dissolved organic carbon and carbohydrates takes place. This is confirmed by the higher concentrations of zinc, dissolved organic carbon and carbohydrates detected in seawater samples obtained from the area near the sediment-water interface, in comparison to those collected from upper layers.

GEOCHEMICAL STUDIES OF THE ENVIRONMENTALLY MOBILE METAL FRACTION IN BOX CORES FROM THE MESSINIAKOS GULF (GREECE)

Fani Sakellariadou 1*

¹ Professor in Marine Geochemistry, University of Piraeus, Dept of Maritime Studies - fsakelar@unipi.gr

Abstract

Eleven box core sediments collected from various sites of the Messiniakos gulf (SW Peloponnese, Greece) were analyzed for the determination of the environmentally mobile fraction of Mn, Cd, Cr, Cu, Ni, Pb, Zn, As. More significant inter-element correlation coefficients are presented. Enrichment factors were below 1 except of Pb ($r_{ef} = 2.6$) and Mn ($r_{ef} = 1$) at the central part of the gulf. Total enrichment values being much below 1 reveal a low degree of metal pollution. *Keywords: Metals, Pollution, Sediments*

Messiniakos gulf is located in the SW Peloponnese (Greece). Its seabed is dominated by very abrupt inclinations with depths often higher than 1000 m, resulting in extensive landslips and sediment transport. Eleven box cores were collected from various sampling sites of the gulf and divided into two sections each, corresponding to 0-5 (top, T) and 20-25 (bottom, B) cm depth. All samples were subjected to acid dissolution using microwave heating with a suitable laboratory microwave unit, applying the method EPA3051 [1]. All digests produced were analyzed using ICP-MS for the determination of the fraction of metals Mn, Cd, Cr, Cu, Ni, Pb, Zn, As [2] considered as mobile in the environment. This method does not accomplish total decomposition of the samples and therefore a few refractory sample matrix compounds may not be dissolved. However, it was applied as it deals with the non-residual metal fraction that participates in most aqueous transport mechanism of pollution, and consequently it is a good indicator of the metal biological availability. Minimum, maximum and mean values for top and bottom sections are presented in Table 1.

Tab. 1. Min, Max and Mean values $(\mu g/g)$ of the environmentally mobile metal fraction

		Mn	Cd	Cr	Cu	Ni	Pb	Zn	As
Т	Min	189	0.7	21.8	4.5	15.4	4.4	7.6	5.8
T	M ax	1518	3.0	77.8	43.4	81.7	48.3	74.6	24.6
Т	Mean	564	2.3	53.8	25.1	50.7	17.1	48.5	12.9
В	Min	207	1.5	40.8	19.5	28.9	11.0	35.1	8.4
В	M ax	3368	3.2	104.2	57.4	124.9	17.4	79.0	18.6
B	Mean	760	2.5	68.9	35.9	69.9	13.7	61.1	11.7

Studying the inter-element correlation coefficients at the two sets of data (top and bottom sections), it was found that there is strong correlation (>0.8) for the pairs (Cr,Ni), (Cd,Zn), (Cu,Zn), (Cu,Ni) (Cr,Cu), (Cd,Cu), (Cr,Zn), (Ni,Zn), (Pb,Mn) (Cd,Ni), (Cd,Cr). The same applies for (Cu,Pb) at the top section and (Mn,As) at the bottom one. In a following step, enrichment factors (r_{ef}) were calculated for the eleven top sediment samples by applying the formula

 $r_{ef} = (C_{sed} - C_{back})/C_{back}$

where, C_{sed} is the content of a metal in each surface sediment sample and C_{back} is the mean content of the same metal for all bottom sediment samples [3]. The enrichment factors were below 1 except of Pb (ref =2.6) and Mn (r_{ef} =1) at the central part of the gulf. Lead is a good indicator of urban metal pollution and can be used for the estimation of the relative pollution in surface sediments. Total enrichment factor values R, defined as R=(Σ ref)/n, were much below 1, revealing a low degree of metal pollution.

DOC EXPORT BELOW THE MIXED LAYER IN THE SOUTHERN ADRIATIC SEA

C. Santinelli ¹*, M. Ribera D'Alcalà ², G. Civitarese ³, R. Lavezza ¹ and A. Seritti ¹ ¹ CNR, Istituto di Biofisica, Pisa, Italy - chiara.santinelli@pi.ibf.cnr.it ² Stazione Zoologica "A. Dhorn", Napoli, Italy

³ OGS, Trieste, Italy

Abstract

DOC data collected in the Southern Adriatic Sea in three different seasons showed that the physical processes (thermocline, water masses circulation, deep water formation) strongly affected DOC distribution. In the surface layer (0-200 m) a clear seasonality was observed and it was mainly due to the occurrence of the thermocline. When the thermocline breaks the DOC accumulated in summer is transported below the mixed layer, from these data we can roughly estimate that the C export through this process is comparable to the export of POC.

Keywords: Carbon, Adriatic Sea, Deep Sea Processes, Organic Matter

Dissolved organic carbon (DOC) represents the largest, the most complex and the less understood reservoir of organic carbon on the Earth. The difficulty to describe and quantify marine DOC dynamics and cycles is due to the very scarce information on its numerous sources and sinks and to its variable and unknown composition. Although the bulk of DOC represents a continuum of biological lability, three fractions have been defined in the Ocean [1]: (1) a labile fraction, with a turnover time of minutes to days; (2) a semi-labile fraction, with turnover time of months to years; and (3) a refractory fraction, with a turn over time of centuries to millennia. DOC concentrations in oceanic waters are mainly the result of biological activity, whereas its distribution is driven by water mass circulation [2], such as has been previously reported for the Mediterranean Sea [3, 4, 5]. DOC data were collected in 9 stations, along the whole water column, in fall (November 2006), winter (February 2007) and spring (April 2007) (Fig.1), in the framework of the Italian Project "VECTOR" in the southern Adriatic Sea, an important site of deep water formation for the whole Eastern Mediterranean Sea, Main goals of this work were: (i) to evaluate the seasonal variability of DOC; (ii) to assess the processes mainly driving DOC distribution; (v) to estimate the role of DOM in carbon export at depth.

Fig. 1. DOC (mM) distribution along a section in the Southern Adriatic Sea (see the inset map), in three different periods.

In general DOC showed highly variable values (50-80 uM) in the surface layer (0-100 m), a decreasing until values of 42-48 uM at 300-500 m and concentrations ranging from 50 to 60 uM in the deep waters. In all the stations, the highest DOC values (> 63 uM) were observed in the mixed layer (< 50 m) after the summer, when the water column was well stratified (November 2006). In contrast, in winter, when the water column was mixed, almost homogeneous values were found until 200 m depth, without accumulation in the surface layer. These data suggest that the physical processes (thermocline, water masses circulation, deep water formation) strongly affected DOC distribution. In the surface layer (0-200 m) a clear seasonality was observed and it was mainly due to the occurrence of the thermocline. When the thermocline breaks the DOC accumulated in summer is transported below the mixed layer, from these data we can roughly estimate that the C export through this process is comparable to the export of POC. Considering the intermediate waters, in all the periods, DOC showed a minimum (42-48 uM) in the core of the Levantine intermediate water (LIW), recognizable by its salinity maximum (>38.77) and its oxygen minimum

(<210 uM). In contrast, the deep waters were characterized by an increase in DOC (>53 uM). This increase was attributed to the occurrence of young waters, recently ventilated (DO>228 uM). This water may be advected from the northern Adriatic sea or it may be formed by deep convection in the central part of the section. Assuming that the concentration of the refractory fraction of DOC in the Mediterranean Sea is 40 uM (like in the Ocean), in the LIW the semi-labile DOC should account for only the 5% to 17%. In contrast, in the young deep water, the high DOC concentration suggests the occurrence of a semi-labile fraction of DOC higher than 10 mM, this is transported at depth during deep water should contain an high percentage of semi-labile DOC (20-33%). This could represent a very important source of energy for deep sea ecosystem.

SPATIAL DISTRIBUTIONS OF NUTRIENTS IN THE NORTH EAST MEDITERRANEAN DURING 2008 – 2009

Fatih Sert ¹* and Süleyman Tugrul ¹

¹ Middle East Technical University, Institute of Marine Sciences - fsert@ims.metu.edu.tr

Abstract

North Eastern Mediterranen waters has been surveyed as two distinct basin in Turkish coasts in 2008 – 2009 period. Including Mersin Bay, Cilician Basin were examined with several cruises between March 2008 and October 2009. Moreover, we visited 10 stations (20 miles apart) on a south-north transect in Levantine Sea in March and September 2008. These studies aimed to assess spatial distributions of principal hydro-chemical properties (nutrients, DO, Chl-a) of these two basin with surface distribution and depth profiles.

Keywords: Nutrients, Levantine Basin, Oxygen, Chlorophyll-a, Eastern Mediterranean

The Cilicain basin of oligotrophic NE Mediterranean has a wide and shallow shef zone, so-called Mersin Bay receiving discharges of polluted rivers (Berdan and Seyhan) and domestic wastewaters of Mersin city [1],[2]. In order to sound understand hydrochemical dynamics of Cilician shelf zone, seasonal cruises were carried out between September 2008 and August 2009. Predefined stations on the shelf were visited for measurements of CTD, dissolved inorganic nutrient, total-P, DO, and chl-a concentrations. In September, when the upper layer was thermally stratified and river discharges remained at minimal levels, dissolved inorganic nutrient concentrations were very low in offshore zone of the basin. However, markedly high values of nutrients and Chl-a were recorded in the nearshore waters fed by the rivers. In the winter period, when the upper layer was well mixed and flushed by open sea, nitrate was at levels of $15 - 20 \,\mu\text{M}$ in near shore waters; it decreased to levels of 0.1-0.2 levels in the offshore waters. Surface PO_4 concentrations ranged between 0.02 and 0.4 μ M, with the largest values in the nitrate and silicate-replete nearshore waters. Total phosphorus (TP) concentrations displayed a similar trend, decreasing from $0.4 \,\mu\text{M}$ level to $0.08 \,\mu\text{M}$ in the offshore. High TP/PO₄ molar ratios (10-12) demonstrate that TP pool in the upper layer is dominated by organic P in the shelf zone. In summer of 2009, Chl-a concentration ranged regionally from 0.05-0.1 μ g/L levels in offshore to 2.5 – 3.0 μ g/L in the coastal waters of the bay. The NO3/PO4 (N/P) ratio was apparently high in the nearshore waters fed by nitrate and silicate rich river waters. The offshore N/P ratio declined to levels of 5-10 in the studied periods. However, surface Si/NO₃ ratios ranged between 0.5 - 1.0 in coastal waters of the Cilician basin, whereas the offshore ratio values were in the range of 5-8 for 2008-2009. DO concentration in shelf water exceeded the saturation values by up to 10-30% in the eutrophic nearshore zone having markedly high Chl-a values and low water transparency.

The SESAME cruises were carried out in the Cilician and Levantine basins of NE Mediterranean, in March and September 2008. In Cilician basin, relatively higher NO3 and Si and TP were recorded in the nearshore waters receiving discharges of nutrient-rich rivers and domestic wastes of Mersin city. Surface TP values steadily declined from $0.4 - 0.5 \ \mu\text{M}$ in the productive nearshore zone to levels of 0.08-0.10 µM in the offshore water colum. A similar spatial pattern was seen in nitrate and phosphate values and also in the N/P ratio. The N/P ratio in P-depleted offshore waters could be underestimated because PO4 values could be below the detection of the method (nearly 0.02 μM). The Levantine deep water contained 5-6.5 µM of nitrate and 0.18 - 0.22 µM of PO₄ below 350-400 m, with N/P ratios of 35 - 40. TP values increased from $0.1-0.12~\mu M$ in the upper layer to $0.25-0.30~\mu M$ levels in the deep layer. It appears that the TP pool in the deep layer was dominated by PO₄, whereas organic-P was the major fraction of TP in the upper layer. Surface silicate concentrations were lower in October-08 than in April-08; however, the euphotic zone values generally varied between 1.0-2.0 µM in the upper layer water, increasing up to 10-11 µM levels below 500 m. In the DO-saturated upper layer, Chl-a was relatively low (0.03-0.20 $\mu\text{g/L})$ in the near-surface waters, displaying its characteristic deep maximum (DCM) below 75m. DO declined to levels of 170 – 190 μM in deep layer. POM concentrations were as low as $2-4~\mu M$ for POC and 0.3 - 0.5 μM for PON in the euphotic zone of the oligotrophic NE Mediterranean. However; POC/PON ratio ranged merely between 6 and 8 in the water column.

TOTAL INORGANIC CARBON AND TOTAL ALKALINITY DISTRIBUTION IN THE AEGEAN SEA

Ekaterini Souvermezoglou¹*, Evangelia Krasakopoulou¹ and Catherine Goyet² ¹ Institute of Oceanography, Hellenic Centre for Marine Research - katerina@ath.hcmr.gr ² IMAGES, Universite de Perpignan

Abstract

Data of CT and AT were obtained in the Eastern Mediterranean in the frame of SESAME project. Preliminary results showed that Aegean Sea deep waters have the highest concentrations in CT and AT. Important differences on the concentrations of these two parameters, observed in the deep waters of the North and South Aegean during spring 2008 can be attributed to the dense water formation in the North Aegean Sea.

Keywords: Aegean Sea, Eastern Mediterranean, Carbon, Oxygen

Introduction

Total Inorganic Carbon (CT) and Total Alkalinity (AT) were determined in seawater samples collected in the Eastern Mediterranean (Aegean- Ionian-Levantine) during two cruises performed in the framework of the SESAME project during spring and late summer 2008, in order to provide both knowledge and reference for further investigation on the carbonate system.

The carbon dioxide system in the Eastern Mediterranean is very poorly studied. C_{T} and alkalinity values have been obtained at the 404 Geosecs station [1]. In 1983, [2] presented oxygen, CT and phosphate correlation in two stations in Central and South Adriatic waters. The distribution of CT and its relation with oxygen and nutrients in a dense grid of stations in the Northern Adriatic Sea were presented by [3]. Recently [4] published CT and AT data collected in Thermaikos Gulf (NW Aegean) in May 1997.

Results & Discussion

Preliminary results of the distributions of these two parameters in the Eastern Mediterranean, showed that the Aegean Sea deep waters have the highest C_T and AT, reaching 2340 and 2670 mmol kg⁻¹ respectively. Nevertheless our results revealed important differences between the North and the South Aegean Sea. In the surface layer the higher $C_T,\,A_T\,$ and oxygen values were recorded in northernmost part of the Aegean Sea in the 'less warm' and 'less saline' surface water of Black Sea origin (Figs. 1 & 2).

Fig. 1. Vertical distribution of C_{T} and A_{T} (µmol/kg) in the Northern and the Southern Aegean Sea

Our observations support the hypothesis of the major influence of the Black Sea to the Mediterranean water alkalinity, argued recently by some authors [5]. During spring 2008, the deep waters of the North Aegean Sea are richer in both CT and AT regarding those of the South Aegean Sea, indicating the existence of different sources of deep water and the limited communication between the two basins.

Indeed, the bottom topography of the region is characterised by an alternation of plateaux and deep troughs allowing water exchange above 400-m depth. Below 400 m, the deep basins of the North Aegean are filled with very dense water of local origin [6] and the deep basin of the South Aegean with Cretan Deep Water [7].

The C_T and A_T concentrations of the North Aegean Sea intermediate layer, reach the concentrations of the deep waters of the South Aegean Sea and the deep waters of the North Aegean are very well oxygenated (Fig. 2). Further examination of the oxygen distributions and the T-S diagrams showed that a dense water formation event occurred in North Aegean during winter 2008.

Fig. 2. Distribution of CT and dissolved oxygen (µmol/kg) plotted against sigmatheta in the Northern and the Southern Aegean Sea

Abstract

The Toulon bay (France), situated in the north-western part of the Mediterranean sea, was the object of an intensive investigation of its sediment contamination, in the framework of a multi-partners collaborative project. Surface and deep sediment sampling campaigns were performed, covering the whole Bay with spatial and deep resolutions allowing a very fine cartography. The obtained results attest its strong contamination, particularly in the small part of the Bay, were the water residence time is the longest with historic nautical activities and their associated pollutions (ex. antifouling paint release). For some pollutants, the measured values are in the order of the highest values recorded by the scientific community in the world. Study of deep sediment cores will allow investigating the history of these contamination episodes.

Keywords: Analytical Methods, Chemical Speciation, Metals, Sediments, Coastal Systems

Experimental

The Toulon bay is a semi-closed Mediterranean area, separated in two nonequal parts by a sea wall, submitted to various anthropogenic inputs, in particular to nautical activities (marina, industry, Navy). Because of this separation and the absence of regular freshwater inputs, associated to low tide, circulation of water in the small part of the bay is weak, leading to low water regeneration and so a possibly high contaminant accumulation in sediments. To map the surface contamination of this specific environment, sediments were sampled in the whole bay and chemically analysed for physico-chemical parameters, and metals, organic pollutants and radioactive elements. The first sampling strategy was dedicated to surface sediment, by specifically sampling the water/sediment interface, followed by a second sampling campaign aiming at defining the history of the sediment contamination. Surface sediment sampling campaigns were performed in November 2008, February and June 2009, with the help of French Navy boat and material, allowing the sampling of surface sediment cores (1m, in duplicate), preserving the water/sediment interface integrity. 50 points were sampled (Fig.1), covering the entire bay. Remaining water in the upper part of sediment cores was filtered and analysed to determine dissolved organic carbon (DOC) and dissolved metal (DPASV) concentrations of the water column. For each point, both sampled cores were sliced (0-5 and 5-10cm), pooled, frozen, freeze-dried, and sieved (2 mm). The obtained sediments were analysed to determine the following parameters: water content, granulometry (laser), organic and inorganic carbon contents (TOC-meter), metal/metalloid (acidic extraction under micro-wave, GFAAS) and mercury (combustion, AAS) levels.

Fig. 1. Location of the sampling points (cross: 1-m interface cores only; diamond: 1-m interface and 5-m Küllenberg cores, gray and black symbols: low/medium and high resolution respectively)

A fourth sampling campaign was performed in October/November 2009, using the BeauTemps BeauPré oceanographic boat from the French Navy, allowing the sampling of deep sediments by the way of a 5m-Küllenberg corer. 20 points were sampled (Fig.1). The obtained cores were sliced depending on the defined resolution: each 10, 20 or 50 cm respectively for the High, Medium or Low Resolution points. Additionally, at the HR points, 4 interface cores were also sampled. The first 2 were used for sedimentation dating (sliced each 2 cm) and pH/Eh measurements. The 2 other were treated as follow: slicing each 2 cm (under nitrogen conditions), pooling, interstitial water extraction by centrifugation, sediment freezing, freeze-dried, and sieving (2 mm). The obtained sediments were analysed as samples originating from the surface sediment sampling campaigns. On interstitial waters, the following analyses were performed: DOC, 3-D spectroscopic fluorescence, total dissolved metal concentration (DPASV) and metal speciation (pseudo-polarography).

Results and discussion

DOC values of water column are quite homogeneous (0.9-1.2 mgC $\rm L^{-1})$ in the entire bay, contrary to total dissolved metal concentrations which showed marked contamination in the small bay, particularly for Cu near the different harbours due to antifouling paint release (concentrations as high as 85 nM in the Toulon harbour). So, it can be suspected that the dissolved organic ligands will not be in sufficient concentration to maintain the free metal concentrations below the toxicity limit in the water column (ex. 10^{-11} M for Cu²⁺ [1]). Eh sediment depth profiles attests that sediments are under anoxic state from the first cm. Metallic contamination of surface sediments shows dramatically high levels, above the N2 level (French legislation on marine and estuarine sediment dredging [2], N2 levels for As, Cd, Cr, Cu, Hg, Ni, Pb and Zn respectively: 50, 2.4, 180, 90, 0.8, 74, 200 and 552 µg/g dw) by some order of magnitude, especially for the most enclosed parts of the small bay, where the water residence time are longer associated to strong nautical activities. It has to be pointed out that some specific points in the second part of the bay, directly open to the Mediterranean Sea, are also markedly polluted, signature of past anthropogenic activities and/or water circulation. Measurements on the Küllenberg cores will give information on the history of these different contaminations. Associated to measurements on interstitial water, such information will allow a better understanding of the contaminant behaviour at the water/sediment interface, influenced by diagenetic processes, which could partly control the contaminant remobilisation at the interface. This study will be completed by remobilisation experiments aiming at defining the possible contaminant remobilisation in natural events (ex. storm) or anthropogenic ones (ex. dredging) [3].

POLYCYCLIC AROMATIC HYDROCARBONS IN THE AREA OF A GREEK PETROLEUM REFINERY

Styliani Triantafyllaki¹, Emmanouel Dassenakis¹*, Vasiliki Paraskevopoulou¹ and Nikos Giannikopoulos¹

¹ Laboratory of Environmental Chemistry, Faculty of Chemistry, University of Athens, Panepistimioupoli 15771, Athens, Greece - edasenak@chem.uoa.gr

Abstract

Polycyclic aromatic hydrocarbons (PAHs) in coastal areas commonly originate from petroleum extraction, transport and refining processes. They may pose a risk to marine life, as they can be both carcinogenic and mutagenic.

In this study, the 16 PAHs on the EPA's priority pollutant list were determined in the wastewater of the petroleum refinery of Motoroil Hellas, as well as in the seawater of the nearby area.

Keywords: Pah, Aegean Sea, Petroleum, Coastal Waters

Introduction

The main sources of PAHs in the environment are natural and intentional combustion of organic matter and petroleum manipulation (extraction, transport and refining) [1]. Solid phase extraction (SPE) [2] and ultrasonic extraction [3,4] are frequently used for the pre-concentration of PAHs from environmental matrices, while high performance liquid chromatography (HPLC) is often used for the analytical determination of PAHs [2,3,4]. Motoroil Hellas, an important Greek refinery, is located on the NW coast of Saronikos Gulf, about 80 km from Athens. In this study, the 16 PAHs on the EPA's priority pollutant list were determined in the treated industrial effluent (IE), sewage effluent (SE), cooling waters (CW) of the refinery, as well as in the seawater of the nearby area (stations S1, S2, S3).

Methodology

The samples were collected in March and September 2007. They were filtered using glass fibre filters within a few hours of sampling for the separation of the aqueous and the particulate matter fractions. The filtered water samples were pre-concentrated by SPE using C18 cartridges. The filters were solvent extracted using an ultrasonic bath and SPE cleanup was performed. An internal standard was added to all samples before their respective extraction techniques. After elution from the cartridges and final concentration by nitrogen blowdown, the PAHs were determined by HPLC with photo-diode array and fluorescence detectors. Gradient elution was used, as well as fluorescence detector was acenaphthylene, which has a fluorescence close to zero.

Results

Some determined PAH concentrations for both sampling periods are given in the tables below:

March 2007						
Σ (water+part.matter)	S1	S2	S3	IE	SE	CW
naphthalene	19.5	19,0	$< \underline{LD}$	88.5	20.3	< <u>LD</u>
phenanthrene	24.6	25.4	21,0	73.8	11,0	< <u>LD</u>
fluoranthene	7.0	5.3	4.9	59.7	< <u>LD</u>	< <u>LD</u>
pyrene	8.0	7.0	24.0	4.7	9.0	< LD
benzo(b)fluoranthene	< <u>LD</u>	3.8	< <u>LD</u>	18.8	< <u>LD</u>	< <u>LD</u>
benzo(k)fluoranthene	< <u>LD</u>	< <u>LD</u>	< <u>TD</u>	< <u>LD</u>	< <u>LD</u>	< LD
dibenz(a,h)anthracene	< <u>TD</u>	< <u>TD</u>	< <u>LD</u>	24.1	< <u>LD</u>	< <u>TD</u>
	Sep	tember 2	007			
Σ (water+part.matter)	S1	S2	S3	IE	SE	CW
naphthalene	< <u>LD</u>	< LD	20.8	79.3	< <u>LD</u>	< <u>LD</u>
phenanthrene	18.9	13.6	18.6	62.4	16.5	8.4
fluoranthene	7.7	6.9	\leq <u>LD</u>	6.0	< <u>LD</u>	6.3
pyrene	13.6	25.9	5.3	15.0	5.4	< <u>LD</u>
benzo(b)fluoranthene	< <u>LD</u>	< <u>LD</u>	< <u>LD</u>	10.6	\leq LD	< <u>LD</u>
benzo(k)fluoranthene	< <u>LD</u>	< <u>LD</u>	< <u>LD</u>	3.9	< <u>LD</u>	< <u>LD</u>
dibenz(a,h)anthracene	< <u>LD</u>	< <u>LD</u>	< <u>LD</u>	9.0	< <u>LD</u>	< <u>LD</u>

Discussion

Individual PAH concentrations in the filtered water samples ranged from 2.9 ng/L for fluoranthene to 29.1 ng/L for phenanthrene, while in the particulate matter they ranged from 3.8 ng/L for benzo(b)fluoranthene to 88.5 ng/L for naphthalene. Two- to four-ring PAHs were more abundant; the highest concentrations were found for naphthalene (88.5 ng/L), phenanthrene (73.8

ng/L) and fluoranthene (56.8 ng/L) respectively in the particulate matter of the industrial effluent. Five- and six-ring PAHs were only detected in the particulate matter; the highest concentrations were found for dibenz(a,h) anthracene (24.1 ng/L) and benzo(b)fluoranthene (18.8 ng/L) respectively in the industrial effluent. The concentrations of individual PAHs as well as total PAHs for March in the seawater samples were overall slightly higher than those determined for September. Although concentrations of individual PAHs were generally low, it is essential to continue environmental monitoring in the area on a regular basis.

CONTAMINATION OF LEBANON COAST BY POLYCYCLIC AROMATIC HYDROCARBONS AFTER JIYEH **OIL SPILL IN 2006: THREE YEARS STUDY**

J. Tronczynski ¹, S. Azoury ¹*, K. Nakhlé ², G. Khalaf ² and B. Andral ¹ ¹ IFREMER - Sabine.Azoury@ifremer.fr

Abstract

The bombardment in July 2006 of the fuel tanks of the electric power plant in Jiyeh by the Israel military resulted in a major oil spill, polluting about 120 km of the Lebanon shoreline, as far as the border with Syria. The spillage estimates vary from more than 10,000 tonnes to almost 20,000 tonnes of heavy fuel oil released into the Eastern Mediterranean Sea [1, 2]. The prevailing currents, water masses circulation and wind trajectories in July 2006, favored oil slicks transport to the north from the Jiyeh plant. We report here an assessment into the chemical contamination of marine organisms (fish and shellfish) resulting from this oil spillage, as a complimentary part of scientific surveys carried out for the evaluation of the ecological consequences of this oil spill. Keywords: Petroleum, Pah, Mollusca, Bio-Indicators

Materials and methods

The intertidal mussel (Brachidontes variabilis) samples were taken in October 2006, in May 2007 and in April 2008 at 9 sampling stations along Lebanon coast, from the south (Itanieh, 33°21'298 N 35°14'846 E) up to the north, near the Syrian border (Qlaiaat, 34°35'663 N, 35°59'269 E). The temporal survey started in August 2006, and several mussel samples have been collected since that time in Batroun (northern coast). Caged mussels were also moored for three months in the water column at four Lebanon stations and three Syria stations in 2007. About 300 specimens of controlled shell sizes were pooled as a composite sample representative of each sampling location. Shellfish sampling was performed so as to avoid any contamination by coated fuel. The GC-MS analysis made it possible to identify and quantify parent unsubstituted PAHs, alkyl-substituted PAHs (C-PAH) and sulfur heterocycle unsubstituted and alkyl substituted compounds (SPAH and C-SPAH). Multivariate analysis and receptor modeling were applied for a better identification and apportionment PAHs originating from Jiyeh fuel oil in the mussel samples from the Lebanon coast.

Results and discussion

The spatial and temporal changes in the compositional patterns of PAHs and their levels in the intertidal mussel samples after the Jiyeh oil spill are reported. It appears that in October 2006 all intertidal mollusks sampled along the Lebanon coast north to the Jiyeh power plant were heavily contaminated by PAHs from Jiyeh fuel oil, and that this contamination extends at least to the Syrian border. This is clearly demonstrated by the increase in the concentration levels and by the drastic change in the distribution pattern of compounds in the shellfish inhabiting the northern part of Lebanon, compared to the mussel samples from the south. Furthermore, the strong spatial gradients in PAH concentrations in intertidal mollusks matches the extent of the shoreline contamination by the spilled fuel revealed by satellite images. Whereas PAH concentrations in the mussels from southern Lebanon (station Itanieh) are indeed very low and do not show, either by their levels or by their chemical fingerprints any significant contamination by PAHs from Jiyeh fuel oil. At that time, in October 2006, in this area, there were no visible traces of the spilled oil, and mussel samples collected south of the power plant probably came from an area outside of the influence of the oil spill. Indeed, the prevailing currents, water masses circulation and wind trajectories in July 2006 favored oil slicks transport to the north, away from the Jiyeh plant. The levels of PAHs found in caged mussels deployed offshore, in the water column, between May and August 2007 were also significantly lower than levels determined in the samples in intertidal mollusks. These results, as well as strong spatial gradients between stations, suggest probably weaker subtidal and benthic habitats contamination by PAHs from Jiyeh fuel. Furthermore, the concentrations of PAHs in subtidal oysters (Ostrea edulis) from Lebanon coast, reported elsewhere [3, 4], are definitely lower than PAH levels in the intertidal mussel samples. Consistent temporal decline (2006 to 2009) in PAH concentrations in intertidal shellfish were also distinguished, however in heavily contaminated locations such as Jiyeh and Byblos chemical fingerprints were still characteristic of Jiyeh oil induced contamination even three years after the disaster. Finally, in order to better scale the PAH levels and patterns determined in the mussels after the Jiyeh oil spill, the results were also compared with PAH data in mussels (Mytilus galloprovincialis) collected in the Western Mediterranean along the coast of France. These later data were obtained within routine chemical monitoring and provide external reference for the PAH chronic contamination in the Western Mediterranean Sea.

In conclusion, the PAH data in the intertidal mollusks from Lebanon represent both sensitive and accurate qualitative and quantitative indicator of the environmental impacts of the Jiyeh oil spill along the Lebanon coast.

LONG-TERM CHANGES IN THE HYDRO-CHEMICAL PROPERTIES OF BLACK SEA UPPER LAYER

Suleyman Tugrul ^{1*}, Gernot E. Friederich ², James W Murray ³ and Ilkay Salihoglu ⁴ ¹ METU-IMS - tugrul@ims.metu.edu.tr ² School of Oceanography, University of Washington ³ MBARI ⁴ Near East University

Abstract

Long-term hydro-chemical data, including pump-cast measurements obtained during the Knorr 2001 cruise, have been evaluated to assess spatial/temporal changes in distinct hydro-chemical features, lateral intrusions of Bosphorus plume and NW shelf waters to western basin of the Black Sea. The suboxic zone, having distict chemical features, remained enlarged since 80's. The upper layer silicate stock has decreased drastically as the phosphate and nitrate displayed opposite trends since late 60's. *Keywords: Nutrients, Anoxia, Black Sea, Eutrophication*

The Black Sea, a land-locked deep basin occupied with brackish waters, possesses distinctly different biochemical properties due to the presence of oxygenated in the upper layer and sulfide-bearing waters below a depth of 100-150 m and a transition zone in between [1-5]. The occurrence of hypoxia and anoxia in the Black Sea causes nutrients and other redox-sensitive elements to exhibit distinct vertical features in the Black Sea water column that are different from those profiles in the oxygenated basins of the world's oceans [1-5]. Though principal hydrochemical properties of the Black Sea system are known, spatial and temporal changes in the Black Sea and processes responsible for these variations are still poorly understood due to the lack of high-quality and high-resolution historical data and complicated biogeochemical reactions in the oxic/anoxic transition zone. Lateral and vertical oxygen influxes together with the catalytic reactions of manganese in the interface keep the sulfide-bearing waters in the deep basin at similar density surface over the basin for years [2-5]. Comparison of the new and historical data sets indicates long-term changes in Black Sea upper laver chemistry. Increasing inputs of nutrients by the polluted rivers with modified N/Si/P molar ratios have severely altered bio-chemical properties of the whole Black Sea [1-4]. Increasing load of DIN by the Danube and concurrent depletion of phosphate in the NW shelf euphotic zone and cold intermediate layer (CIL) in 80's, has led to markedly high N/P ratios in shelf waters down to CIL depths. In this period, the nitrate stock of the upper layer has increased by 2-3 times as silicate stock displayed an opposite trend in the upper layer down to onoxic intreface since the 60's [2-4]. Thus, nitrate/silicate ratio decreased drastically in the upper layer throughout the basin [4]. However, there has been a slow increasing trend in the surface silicate values in the last decade, suggesting progressive changes in the Black Sea ecosystem. It has been documented that oxygen and sulfide do not co-exist in the interface due to high rate of sulfide oxidation by oxygen [3-5].

Until the Knorr 1988 cruise, no integrated studies have been carried out in the Black Sea to provide real-time and near real-time chemical measurements and oxidation-reduction rates of redox-sensitive elements in the oxic/anoxic transition zone in the western basin. During the 2001 Knorr cruise, we have obtained high-resolution data of nutrients, dissolved manganese (and reduced iron at two stations) by both pump-profiling system and bottle-casts. The Knorr 2001 results demonstrate regional variability in vertical structures of nutrients and dissolved manganese in the western Black Sea Black Sea upper layer, depending on circulation patterns, particle influx from the surface layer and lateral intrusion of oxygen via Bosphorus plume. Lateral intrusions of partly oxygenated and nitrate-rich Bosphorus plume by mixing with cold intermediate layer (CIL) appear to ventilate and thus modify characteristic chemical structures in the oxic/anoxic transition layer of the rim current in the SW basin. Specifically, secondary broad nitrate peaks appears in the oxygen depleted transition zone, as well as to the co-existence of nitrate, ammonia, dissolved manganese and nitrite in the suboxic/anoxic interface. Silicate profiles also displayed undulating patterns with depth. Thus, the onset of sulfidebearing water shifts to greater density surfaces by about 0.2 density units in the SW region. Moreover, small undulating patterns of nitrate profiles in the suboxic zone of the northern slope and central gyre imply weak intrusions of CIL waters from western shelf with different chemical properties. Climatic warming in recent years seems to have decreased the nitrate content of CIL waters evolved in NW shelf, which flows towards SW coastal region via rim current system.

ASSESSMENT OF HEAVY METAL CONTAMINATION IN SURFACE SEDIMENTS OF THE HOMA LAGOON IN THE IZMIR BAY (EASTERN AEGEAN)

Esin Uluturhan¹*, Aynur Kontas¹ and Elif Can¹

¹ Dokuz Eylul University, Institute of Marine Sciences and Technology - esin.uluturhan@deu.edu.tr

Abstract

The heavy metal (Pb, Cr, Cu, Zn and Fe) concentrations in sediment were investigated in Homa Lagoon from the Izmir Bay. The surface sediments were collected from 8 stations at September 2005 - 2006. Homa Lagoon was polluted with Cr. On the contrary, Pb Cu, Zn and Fe values were smaller than those for average shale. *Keywords: Aegean Sea, Metals, Pollution, Sediments*

Keywords. Aegean Sea, Metais, I onunon, Sean

Introduction

Marine sediments provide useful information for environmental and geochemical research about marine pollution. Urban and industrial activities contribute to the introduction of significant amounts of pollutants into the marine environment and affect directly the coastal systems where they are quite often deposited. Also, heavy metals, pesticides and other toxic substances could be absorbed from the water column onto surfaces of fine particles and usually move thereafter with the sediments [1]. The study area Homa Lagoon is a coastal lagoon located in the Gediz Delta where agricultural drainage, water, industrial and domestic wastewater are transported by Gediz River. The lagoon is one of the 10 most productive lagoons in the Aegean Sea.

Materials and Methods

The surface sediments were collected from 8 stations in the Homa Lagoon in September 2005-2006. Sediment samples were taken using van-Veen grab. Immediately after collection, the sediments were placed in acid cleaned polyethylene bottles and frozen (-20°C). Thereafter, samples were dried in an oven at 50°C, and then sieved to pass 63 mm and homogenized. Samples were digested in microwave digestion system (Milestone 1200) with a HNO₃-HF-HClO₄-HCl acid mixture solutions were analyzed by flame AAS (Varian Spectraa-300 plus), using the manufacturer's conditions and with background correction [2,3].

Results

The mean concentrations of heavy metals in sediments and the average shale values were summarized in Table 1. Comparison of the metal concentrations with average shale values revealed that most of the samples from the Homa Lagoon were polluted with Cr. On the contrary, Pb Cu, Zn and Fe values were smaller than those for average shale, which indicated that there were no major sources of pollution for these elements in the Homa Lagoon. The highest Pb, Zn and Fe were measured at station E while maximum level of Cr was found at station C. Also the Cu content was high at station B. The statistical analysis of intermetallic relationship revealed that the high degree of correlation and significant regression relation among the metals indicate the identical behavior of metals in the marine environment. Sediment Pb showed positive correlation with Zn (r=0.81), Cu (r=0.93) and Fe (r=0.87). Also, significant positive correlations were observed between Cr- Zn (r=0.55), Cr-Fe (r=0.59), Cu-Zn (r=0.83), Cu-Fe (r=0.93) and Zn-Fe (r=0.80). Those correlations are probably indicating that these elements have the same source, possibly lithologic, characteristic of sediment was non impacted and therefore, of natural origin [1].

Abstract

Surface sediments collected from 33 stations along the Ambarli Harbor, the Sea of Marmara, were analyzed for petroleum aromatic hydrocarbons by UV-fluorescence. Higher concentrations of total aromatic hydrocarbons were found of all the samples collected during May 2009, with levels ranging 1860 and 72 μ g/g eq oil (205 and 7 μ g/g chrysene eq.). The spectra indicate dominant pyrolytic origins in some stations of pyrolysis reactions of fossil fuels where the 3-4 ring PAHs are dominant. The pyrolytic contamination of these stations could be attributed to fossil fuel oil particulates emission by commercial vessels, heavy maritime traffic, particularly involving petroleum transports and fishing boats, and the improper disposal of ballast and bilge waters. Keywords: Petroleum, Pah, Sediments, Marmara Sea, Pollution

Introduction

Sources of contaminants in the Harbor include municipal and industrial discharges, atmospheric inputs, non-point source runoff, hazardous waste sites, landfills, combined sewer overflows and accidental spills. The important sea pollutants originated from ship and seaport are as follows: oil-products, crew-disposals (i.e., shower, sink and toilet), bilge water, ballast, washing water for ballast, liquid-, and solid type poisonous materials carried by the ships and garbage of the ships. It is known that these anthropogenic pollutants arrive at the sediments, then, negatively affect the quality of the sediment.

Ambarli Harbor in Marmara region has an important position as a seaport especially for the city of Istanbul. It serves to the ships such as container-, cargo-, RoRo- and tanker types. Analyzing of the data from 2007 shows that totally 4959 ships has made use of the seaport.

The purpose of this study was to determine the concentration of the total hydrocarbons in the surface sediments in and offshore Ambarli Harbor to provide data for comparison by different reference materials and to get understand whether pyrolytic or petrogenic inputs come from anthropogenic processes.

Material and Method

Sampling

The sediments were taken by using the grab sampler, in May 2009 on board of R/V ARAR from 33 stations. The sampling depths were between 11 and 78m. The topmost 0-5 cm of the grab sample was carefully removed using clean spatula. The samples were stored in a freezer at -20°C until analysis. Analytical procedure

The methods used in this study have been described in detail [1] and will only be summarized here. TOC contents were measured by means of the Walkey-Black Method [2]. Extraction of samples with a Soxhlet apparatus and analyses by UV fluorescence spectroscopy (Jasco-6300, Shimadzu) were given in detail by Ünlü [1]. Considering spectrofluorometer conditions, excitation and emission wave-lengths were fixed to 310 and 360 nm for single measurement, respectively.

Results and Discussion

The TOC content of the sediment samples, which accounts for most of the variation in the uptake of contaminants by the sediment, is variable and ranges from 0.37% to 3.82%. Total aromatic hydrocarbon concentrations in samples varied between, 1860 μ g/g and 72 μ g/g equivalents of oil (205 μ g/g and 7 μ g/g chrysene eq.). An acceptable upper limit is 50 µg/g for clean sea floor sediments [3] and the concentrations higher than 100 (µg/g dry weight) are mainly related with terrestrial (riverine) inputs or port activities, on the basis of classification adapted by Readman [4]. According to fluorescence synchronous spectra of the sediment extracts containing >100 µg/g confirm the existence of a chronic oil pollution in the sampling region and suggest the presence of high potential hazards to aquatic organisms in the study area.

Although in general UV fluorescence technique has been replaced by more specific methods it is still being used for monitoring spatial and temporal concentration gradients of petroleum hydrocarbons in sediment. Because of its simplicity, sensitivity and easy application, UV fluorescence in synchronous excitation-emission technique constitutes a promising tool to be used in determination the polyaromatic structure of a compound since Lloyd has developed this method [5]. It simplifies the emission of each component of a mixture and gives a better-resolved spectrum for the whole of the mixture components [5]. According to the number of aromatic rings (spectral region from 220-700 nm), the USEPA priority PAH compounds were divided into three groups, representing two-, and three-, four-, and five-, and more ring PAHs.

Petroleum hydrocarbons in crude oil and light refined products are dominated by the lowest molecular weight PAHs with only trace levels of the penta- and hexa- aromatics present. However, 1-2 rings PAHs have not been encountered in the sediment samples. It appears likely that the more volatile PAHs are rapidly lost in this environment, through evaporation and photodecomposition.

Our results indicate dominant pyrolytic origins in all samples with small amount of pyrolysis reactions of fossil fuels at some stations (e.g. A1, A3, A7, A8, A12, A13, A18, A23, A27 and A28) where the 3-4 ring PAHs such as pyrene derivatives are dominant. The pyrolytic contamination of these stations could be attributed to fossil fuel oil particulates emission by commercial vessels

In sediment, the major problems are the land based and ship-based pollution. The sediments from the Sea of Marmara, show that the port activities are the most serious source of pollution in the around of Ambarli Harbor region. In this study area in which are determined the elevated contents of total aromatic hydrocarbons sediment is also polluted with larger amount of pyrogenic fossil fuel compounds. Therefore the marine sediments are very important in our estimating the degree of the damage given to the ecosystem by such inputs. The results deduced in this study, which for the first fundamental dataset for the region to be used as reference in future.

LONG TERM STUDY OF ORGANIC MATTER FLUCTUATION AND MUCILAGE EVENTS IN THE NORTHERN ADRIATIC

Vjerocka Vojvodic¹*, Jelena Dautovic¹ and Bozena Cosovic¹ ¹ Rudjer Boskovic Institute - vojvodic@irb.hr

Abstract

In the last fifteen years in the northern Adriatic the massive formation of organic aggregates reported as "mucilage phenomenon" occurred with increased frequency. The intensity of this phenomenon varied over the years: (1988, 1991, 1997, 2000-2004) > 1998, 1999. In the period 1998-2008 we have studied seasonal and spatial distribution of the content of dissolved organic carbon, and concentrations of the reactive organic matter with surface active properties. *Keywords: Adriatic Sea, Organic Matter*

Introduction

Most hypothesis proposed to explain the mucilage occurrence in the northern Adriatic (NA) recognize the accumulation of dissolved organic matter during the period of stratification as the main precursor of mucilage accumulation [1, 2]. We have undertaken the long-term study in order to see if the problems connected to the harmful mucilage events in NA are becoming worse or better.

Metodology

Dissolved organic carbon (DOC) and surface active substances (SAS) were analysed in the samples collected from the depth of 0.5 m along the transect between Rovinj and mouth of the River Po. SAS were determined by electrochemical method (a.c. polarography) using the calibration curve of model nonionic SAS, Triton-X-100 [3]. DOC was determined by using high temperature catalytic oxidation (HTCO) method.

Results

Over the whole period of investigations the concentrations of DOC and SAS showed regular seasonal patterns, with lower values in winter and higher values in the period from spring to autumn. A marked interanual variability of DOC and SAS values was observed as well. The mean concentrations of DOC (1.07-2.76 mg/L) obtained in the period 1998-2004, which is characterised by mucilage appearance), were up to 40% higher in comparison to the values obtained in 1994 and over the years 2005-2008 (0.82-1.60 mg/L) (Figs. 1a, 1b). No mucilage events were observed in this later period. Interestingly, the same trend of fluctuation was detected for SAS values, which were more than two times higher during mucilage appearance than those observed in the period 2005-2007 (0.025-0.405 mg/L and 0.006-0.151 mg/L respectively) (Figs.1c,1d).

Fig. 1. Fluctuation of DOC (mean values) in the period **a**) 1994, 2005-2008 (without mucilage occurrence), **b**) 1998-2004 with mucilage events as well as fluctuation of SAS (mean values) during **c**) 1994, 2005-2008, **d**) 1998-2004

Conclusion

The seasonal distribution pattern of DOC over the whole period of investigation clearly showed a decreasing trend from 1998 to 2008, in particular after 2002 (Fig. 2). The same decreasing trend, but less pronounced was detected two years earlier (2000) for reactive surface active organic matter (Figs 1c,1d). Reduced content of SAS, as well as the absence of the greater accumulation of dissolved organic carbon in recent years, probably have an important role on disappearance of mucilage events contributing to the improvement of the

northern Adriatic Sea ecosystem.

Abstract

Long-term monthly and short-term monthly and daily data on isotopic composition of precipitation together with meteorological data were used to trace spatial and temporal variations of isotopic composition of precipitation in Slovenia. A spatial distribution of stable oxygen isotopic composition in precipitation over Slovenia has been generated using temperature, latitude and altitude dependences. *Keywords: Hydrology, Monitoring, Adriatic Sea*

Introduction

Modern investigations of water cycle include determination of isotopic composition of precipitation, surface water and groundwater because isotopes of water molecule offer a broad range of possibilities for studying processes within the water cycle and thus became an important tool in isotope hydrology, as well as in studies related to atmospheric circulation and paleoclimatic investigations. As the recharge of groundwater is mainly due to precipitation, it is of utmost importance to know the isotopic composition of precipitation, and its seasonal and spatial variations. The Global Network of Isotopes in Precipitation (GNIP) organised jointly by the International Atomic Energy Agency (IAEA) and the World Meteorological Organization (WMO) in 1961 is a database that contains data on stable isotopic composition of hydrogen and oxygen, tritium activity, and relevant meteorological data on a monthly basis, and is thus extremely valuable for modelling climatic changes, as well as in hydrological and hydrogeological investigations. However, the need for a much more refined understanding of isotope variations was indicated in climatic studies and therefore the IAEA initiated a programme of collecting new data at a higher spatial density and temporal frequency in the Mediterranean basin, including the eastern Adriatic coast [1]. The aim of this paper is to present a review of isotopic results obtained since 2001.

Methodology

Monitoring of isotopic composition of oxygen and hydrogen in monthly precipitation has been performed at the continental sampling station in Ljubljana (Slovenia) since 1981 within the GNIP [2]. In the framework of an IAEA Coordinated Research Programme [1, 3] the monitoring programme was extended to two additional sampling stations on the coast of Northern Adriatic (Portoroz) and its near hinterland (Kozina) in the south-western, Mediterranean region of Slovenia in October 2000 during which monthly and occasionally also daily sampling was performed [1, 4]. Basic descriptive statistics, deuterium excess and local meteoric water lines were calculated. In addition, altitude effect and isotope - surface temperature relations were determined. Finally, modelling of spatial variations of isotopic composition of oxygen over Slovenia was performed.

Results and discussion

The highest precipitation amount weighted mean hydrogen and oxygen isotopic values are observed at Portoroz, while the lowest values are characteristic for the continental station of Ljubljana (Table 1). The orthogonal regression equations between the isotopic values of individual monthly samples representing local meteoric water lines (LMWLs) are:

- $-\hat{\delta}^2 H = (8.1 \pm 0.1)\delta^{18}O + (9.8 \pm 0.7)$ for Ljubljana (1981-2006)
- $-\delta^2 H = (7.7 \pm 0.4)\delta^{18}O + (7.3 \pm 2.2)$ for Portoroz (2001-2003)
- $\delta^2 H = (7.7 \pm 0.3) \delta^{18} O + (9.6 \pm 0.7)$ for Kozina (2001-2003)

Weighted mean d-excess values (Table 1) are close or above 10‰, showing the influence of Mediterranean air masses in south-western part of Slovenia. The altitude effect determined by vertical δ^{18} O gradient (-0.30‰ per 100 m) was calculated using the isotope data obtained for stations Portoroz and Kozina. Furthermore, the continental station Ljubljana shows higher correlation between oxygen isotopic composition and mean monthly surface temperature (r = 0.75) than the coastal station Portoroz (r = 0.36) indicating that temperature information can only be seen at continental stations and has less influence on the isotopic composition of precipitation at coastal stations.

Comparison of the monthly and daily isotopic composition of precipitation collected from October 2002 to September 2003 at Portoroz and Kozina showed profound differences between the two sets of data. It was shown that in investigated area during rain event of several days sources of air masses have changed during the course and mixing of air masses originating from the continent and from Mediterranean cyclogenesis appeared [4].

The spatial distribution of δ^{18} O in precipitation has been explained by a simple multiple regression models, based on the meteorological (temperature) and geographic factors (latitude and elevation). Continuous digital map of the d¹⁸O distribution over Slovenia has been generated using GIS tools (Figure 1).

Tab. 1. Weighted mean hydrogen and oxygen isotopic composition and deuterium excess values in %

Station	$\delta^{18}O$	$\delta^2 H$	Deuterium excess
Ljubljana (1981-2006)	-8.6	-59	9.5
Portoroz (2001-2003)	-6.3	-40	10.3
Kozina (2001-2003)	-7.8	-50	12.3

Fig. 1. Continuous digital map of the oxygen isotope distribution as a function of latitude and elevation

IRON(III)-ORGANIC COMPLEXES DISSOLVED IN SEAWATER: CHARACTERIZATION OF IRON(III)-SUCCINATE AND IRON(III)-MALATE COMPLEXES IN AQUEOUS SOLUTION

Petra Vukosav 1* and Marina Mlakar 1

¹ Ruder Boškovic Institute, Division for Marine and Environmental Research, Bijenicka 54, 10 000 Zagreb, Croatia -

petra.vukosav@irb.hr

Abstract

Iron(III), as an essential element and one of the most important element -for biochemical processes in the marine environment, is bioavailable only in dissolved form. By complexing with succinic and malic acid, intermediates in the citric acid cycle, iron(III) forms soluble complexes in aqueous solutions. Each organic acid form with Fe(III) several complexes, depending on acids concentration and pH (4.5 - 11). All investigated complexes showed stability for rather long period of time (weeks to years). *Keywords: Trace Elements, Phytoplankton, Electrochemistry*

Introduction

Dissolved iron(III) is very important element for marine organisms (for their biochemical and physiological functioning). Despite its abundance in the environment, dissolved Fe³⁺ in the oceans is present at low concentrations, <10⁻⁹ mol L⁻¹ (>99%), mostly in organic complexes. Low solubility of Fe³⁺ under oxidizing conditions is caused due to the formation of insoluble Fe(III)-hydroxides and oxides and that is why Fe(III) is a limiting factor for primary production [1]. Bioavailabile forms of iron(III) are, among others, complexes with succinic and malic acid [2]. Therefore, these complexes are possible candidates in the iron fertilization experiments in high-nutrient low-chlorophyll (HNLC) areas of the Oceans.

Results and discussion

Measurements were preformed by square wave voltammetry (SWV) and by UV-Vis spectrophotometry [3].

Iron(III) with different concentrations of succinic acid (0.04 - 0.5 mol L⁻¹) in pH range 5.2 – 7.4, measured by SWV, gave redox responses of two Fe(III)-succinate complexes (Figure 1. A). Within $C_{\rm suc}$ from 0.04 to 0.12 mol L⁻¹, Fe (III)-succinate (I) reduction peak at the potential \approx -0.22 V was registered, and with $C_{\rm suc} \geq 0.12$ mol L⁻¹, Fe(III)-succinate (II) complex at ≈ -0.37 V. The formation kinetics of both complexes was slow, Fe(III)-succinate complex (I) was equilibrated within 17 h, and Fe(III)-succinate complex (II) in about 15 h. However, after equilibration period, complex (I) was stable in the solution for about a week, and complex (II) for about 10 h. Analysis of UV-Vis spectra under same experimental conditions were processed by multivariate non-linear least-square fitting program Specfit [3]. The model, taking into account obtained iron(III) complexes by SWV, presumed that stoichiometry ratio of Fe(III):succinate complexs (I) and (II) was 1:2 and 1:3, respectively .

Three iron(III) - malate reduction peaks were detected in the pH range from 4.5 to 11, with malic acid concentration $C_{mal} = 0.1 \text{ mol } \text{L}^{-1}$. By SWV first complex reduction was registered at about -0.1 V (pH from 4.5 to 6.5), second one at about -0.35 V (pH = 6.5 - 9) and third at about -0.6 V (pH = 8.5 - 11) (Figure 1. B). Formation kinetics of this complexes was fast, and equilibrium was reached within 30 minutes. Fe(III)-malate complexes were much more stable than complexes with succinic acid, since they were detected in the solution even after one year. By UV-Vis spectrophotometry in the pH range from 1.5 to 8 three complexes were registered, as well, with two isosbestic points at 310 and 392 nm. Changes in spectra were detected in the pH range from 1.5 to 6.5, but at pH > 6.5 spectra remained almost unchanged. Principal Component Analysis (PCA) of spectra gave three spectrally distinguishable Fe(III)-malate complexes. Combination of voltammetric and UV-Vis results persumed stoichiometry of compexes: in the pH range from 1.5 - 3 exist complex Fe(mal) (with undisociated hydroxyl group at the second carbon atom in malic acid molecule); Fe(mal) and Fe(mal)₂ complexes (with dissociated hydroxyl group) in the pH range from 3.5 to 6.5 and these complexes gave reduction peak 1 in Fig.1B. In the pH range from 6.5 to 9 exists compex $Fe(mal)_2(OH)_x$ (peak 2) and in the pH range from 8.5 to 11 complex Fe(mal)₂(OH)_y (peak 3) is present.

Conclusion

Obtained results showed that succinic and malic acids form stable dissolved Fe^{3+} complexes in the pH range from 4 to 11 that remain in the solution for rather long period of time. The addition of relatively small amount of described iron complexes to the phytoplankton culture (*Dunaliella* sp.) in laboratory conditions resulted in incerased production of phytoplankton biomass.

Fig. 1. A) SW voltamograms of Fe(III)-succinate complexes in 0.55 mol L⁻¹ NaCl with C_{Fe} = 4 x 10⁻⁵ mol L⁻¹, pH=6.00 and C_{suc} : (1) 0.07 and (II) 0.5 mol L⁻¹.

B) SW voltamograms of Fe(III)-malate complexes in 0.55 mol L⁻¹ NaCl with C_{Fe} = 4 x 10⁻⁵ mol L⁻¹, C_{mal} = 0.1 mol L⁻¹ and pH: (1) 5.7, (2) 7.4 and (3) 10.1.

DOES POLLUTION THREATEN FETHIYE-GOCEK BAY (TURKEY) SPECIALLY PROTECTED AREA MARINE ECOSYSTEM AND ITS FUNCTIONING?

Aysen Yilmaz ¹*, Betil Ergev ² and Okan Taktak ²

¹ Institute of Marine Sciences, 33731, Erdemli-Mersin, Turkey - ayilmaz@metu.edu.tr ² Derinsu Underwater Engineering and Consulting, Nilgun Sk. 5/1 Kavaklidere 06680 Ankara, Turkey

Abstract

Fethiye-Gocek Specially Protected Area (SPA) is one of the 14 SPAs in Turkey and it is located in the south-west corner of the Anatolian peninsula - on the Mediterranean coast. Fethiye-Gocek Bay hosts more than double of the normal population in summers. Marinas exceeding the carrying capacity and pollution from land based sources threatens the marine ecosystem. The main aim of this project was to determine the biodiversity of this beautiful bay but main hydro-chemical, biological and pollution parameters were also determined in order to understand the ecosystem and the risks for its functioning. *Keywords: Marine Parks, Coastal Systems, Pollution*

Introduction

The coastline of Fethiye-Gocek SPA is about 235 km and it covers 817 km² area including coastal and marine areas of all figures (landscapes, bays, islands etc.). Total population of the area is 181,000 (2009) and this number is almost double during the high seasons (from April to November). Fethiye-Gocek bay is naturally protected from strong winds and less affected by the main current system (the Asia Minor current) even though the total depth at the large entrance of the bay is about 800m deep. This natural harbor has 5 marinas with totally 1210 yacht capacity and the marinas are almost full during summer months. Besides the in situ marine pollution, the input of pollutants from land-based sources threatens the area; since the level of almost all the critical pollution parameters exceed the limits especially in the Fethiye inner bay.

Results and Discussion

The data is obtained very recently (April and August 2008) and totally 15 stations were visited in the Bay. Sea surface temperature was relatively high in the summer (up to 29.4 °C) and seasonal thermocline was well established and generally observed at 20-60m. The surface salinity was measured in the range of 37.37 – 39.47 ‰ and it was reduced down to 31.86 ‰ at some coastal stations where there is fresh water input. The RDCP data revealed that currents were relatively weaker in summer months and stagnant water masses were especially observed near coastal zones. The reverse current system was characteristics of the Bay where surface and deep currents were in different directions and mainly directed towards to inside of the Bay at the surface.

The Secchi Disc Depth was measured in the range of 10-28 m in the Bay except a very low value (4.8m) recorded in Fethiye inner bay. It was assumed that the bottom of the euphotic zone coincided with the bottom of the shallow inner Bay. It seems this affected the bottom autotrophic production by bluegreen algae since scuba diving results showed that life was poor at this location. The high level of suspended sediment (16.8-29.6 mg/L) caused the extinction of the light at shallower depths with respect to those observed in the Mediterranean offshore. The level of oxygen saturation was determined in the range of 96-110% except some unacceptable values (47-59 %) obtained near the Fethiye and other inner bays. These extreme values were definitely far from the general picture, since the minimum level of oxygen saturation in the deep offshore waters were determined as of 70-80% due to effective vertical mixing and overturning [1]. The level and distribution of nutrients measured in the area showed similar patterns with the previous work [1] and low concentration of nutrients (PO₄: 0.7-8.5 µM; NO₃: 0.06-0.16 µM; NH₄: Below Detection Limits; Si: 4.74-18.1 µM) caused low level of autotrophic production. The average chlorophyll-a concentration representing the phytoplankton biomass was 0.3 µg/L (Range: 0.09-1.06 µg/L) in the surface waters and the primary production was dominated by regenerative production.

Heavy metal concentrations in the Bay were in the range of acceptable limits (e.g. Cupper: 3.00-9.50 μ g/L; Zinc: 14.00-47.6 μ g/L) and the highest concentrations were detected in the Fethiye inner bay. The same trends were observed for total phosphorus, nitrogen, organic carbon and heavy metals within the sediment samples and maximum concentrations were measured in the inner bay. Microbial pollution level were generally under the limits but they exceeded the limits over twice in the inner Fethiye bay (e.g. Total Coliforn: 930 individual/100 mL) causing unhealthy recreational waters to be present in the study area.

In summary, Fethiye-Gocek bay has very regular Mediterranean lower trophic level ecosystem. The level of pollution caused by heavy boating activities for leisure and input of pollutants by land based sources (e.g. municipal wastes) is

at the very sensitive limit. The biogeochemical cycling seems to be open to change due to the external strains like the input of additional nutrients from the land. Scuba diving between 0-55m in the same study showed that even though the area is under the risk of pollution, the biodiversity is rich (e.g. 24 taxonomic group and 1545 species were determined in the area where 44 of them were recorded for the first time along the Turkish coasts). The area is being one of the attractive tourist (both national and international) point with its marbles nature and its historical/cultural richness but everybody should note that sustainable development (e.g. in tourism sector) is only possible with the efforts for sustainable nature and effective environmental protection.

THE DETERMINATION OF ORGANOTIN COMPOUNDS LEVELS IN SEDIMENT SAMPLES FROM TURKISH AEGEAN SEA COAST

Aykut Yozukmaz¹, Fatma Sanem Sunlu¹, Ugur Sunlu¹* and Meral Özsüer¹ ¹ Ege University, Faculty of Fisheries, Dept. of Hydrobiology - ugur.sunlu@ege.edu.tr

Abstract

In this study, from the North tot he southern part of all the Aegean Sea coast line predetermined from 9 stations, the sediment samples were collected during summer-winter period in 2009 and organotin compounds (OTC) concentrations were detected at the ng g^{-1} Sn dry weight (d.w.) within sediment. In this way, effects of the most important organic tin contamination points of maritime activities in the Aegean Sea were try to determine in the coastal zone along the Turkish Aegean Sea. *Keywords: Aegean Sea, Coastal Waters, Sediments, Trace Elements, Pollution*

INTRODUCTION

The purpose of the present study is determined OTC levels and assess the hot spots at the most important maritime points along the Aegean Sea. There are considerable maritime activities along the Aegean Coast, relating the heavy maritime activities, e.g., fishing and yachting.

Hence their high atomic weights and low aqueous solubilities, OTC tend to adsorb onto particles and sink directly onto the sediment, here it accumulate and release into water column by re-suspension of particles. Although its extremely hazardous to aquatic ecosystem, there are very few data for OTC levels and its detrimental impacts on the marine environment of Aegean Sea.

Fig. 1. The Map of the Sampling Locations

MATERIAL AND METHOD

Aegean Sea is 380 miles (612 kms) long and 186 miles (299 kms) wide with 83,000 square miles (215,000 square km) total area. It is located between 41-45 N latitude and 23- 27/28 E longitude [1]. Sediment samples were collected from 8 predetermined stations from northern stretch of Aegean Sea, Ayvalik Marina to southern stretch Bodrum Marina along the coastal zone between March 2009 and August 2009 (Fig.1.). Reference stations determined relatively far from the maritime activity where human and marine environment engaged as in beaches and piers.

Sediment samples were collected by standard (6x6x6) stainless steel Ekman Grab. Sample analysis carried out GC/MS, HP Agilent 6890 coupled 5973N Mass Selective Detector [2] (non-detected-nd. limits for MBT, DBT, TBT were 0.003, 0.001, 0.001 ng g⁻¹ Sn respectively).

In order to quality control of the analytical results CRM-462 (Coastal Sediment for Butyltins) is provided from IRMM (Institute for Materials and Measurements) and analysis of CRM-462 proved that the method is able to accurately determine OTC.

RESULTS AND DISCUSSION

As a result of winter sampling the highest Σ butyltin level was detected from the station 2 (1752.4 ng g⁻¹ Sn). The lowest Σ butyltin level was measured from the station 5 (nd.). Mean concentration of Σ butyltin for overall stations was 1091.5 ng g⁻¹ Sn. The highest concentration of Σ butyltin was detected in station 1 (1464 ng g⁻¹ Sn) and the lowest was measured at the stations 7, 3, 4, 5 from the reference points (nd.). Mean concentration of Σ butyltin for overall

reference points was 495.9 ng g⁻¹ Sn.

At the end of the summer sampling, the highest total \sum butyltin level was seen in station 2 (4278.4 ng g⁻¹ Sn). The lowest \sum butyltin level was measured at station 5 (983, 6 ng g⁻¹ Sn). Mean concentration of \sum butyltin for all stations was 2691,2 ng g⁻¹ Sn. For the reference stations the highest and lowest levels of \sum butyltin was measured 2207,6 ng g⁻¹ Sn for station 4 and nd. for station 7 respectively. Mean concentration of \sum butyltin for all reference stations was determined as 1343.9 ng g⁻¹ Sn. High levels of tin compounds measured in summer-winter period along the Cost of Aegean Sea may be the results of the numerous marinas (operating 100% or more capacity almost all year long) and strong adsorption tendency of TBT. Additionally, high concentrations of TBT suggesting the illegal usage of TBT-based anti-fouling paints, on ships smaller than 25 m [3]. Furthermore, ongoing contamination of Aegean Sea could be consequence of leaching from the boat, painted before the ban, or the compounds' long-lasting effectiveness time (5-7 years).

Tab. 1. Reported OTC' levels from the world (ng g ⁻¹ Sn d.w.)
--

Sampling Areas	Levels of OTC (ng g Sn)					
Regions	MBT	DBT	TBT			
Marinas of the U.S.A.						
East-West Canada Coast	nd330	nd100	nd5100			
Crystal Lake, USA	21.3-320	59-350	1.5-14,000

Portuguese coast	5 2-78	5.3-65	3.8-12.4			
North coastline of Spain	860-2870	150-710	50-5480			
South-west of France	1.0-125	nd87	nd89			
Marinas of Turkey	cronikono.	1 10000 1000				
Aegean Sea (In this study)	nd2598	nd-1371	nd-3008			

Survey researches from all over the world reported that organic tin pollution is still a matter of concern. The two-way researches revealed that there are still significant TBT pollution along coastal zones of Pacific, Atlantic, Indian Oceans and of marinas and harbors. In conclusion; comparing the levels between measured OTC levels along Turkey coast of Aegean Sea and Mediterranean Marinas' former's levels are rather high (Table 1.). At the end of the results, we determined that the total TBT concentrations in the sediment samples showed the significant spatio-temporal changes.

DEEP BASIN TURBIDITES AS A PREVIOUSLY UNRECOGNIZED SINK FOR HYDROGEN SULFIDE IN THE BLACK SEA

Mustafa Yucel^{1*} and George W Luther¹

¹ University of Delaware, College of Earth Ocean and Environment, 700 Pilottown Road, Lewes DE 19958, USA -

mustyucel@gmail.com

Abstract

Speciation of sulfur and iron was investigated in the solid phase of Black Sea sediments (Unit 1 type and turbidites) collected during the R/V Knorr 2003 Black Sea expedition. Other than pyrite, solid phase sulfur in the upper Black Sea sediments existed as inorganic S(0) and acid-volatile sulfides (predominantly FeS) in the anoxic basin turbidites, and organic sulfur as humic sulfur in the uppermost 0-2 cm of the central basin sediments. A mathematical model was designed to simulate the temporal changes in the Fe-S chemistry in the anoxic basin turbidites, and successfully showed that turbidites were a previously unrecognized sink for sulfide in the Black Sea and ccan account for 14% of the annual burial of sulfur.

Keywords: Black Sea, Sediments, Geochemistry, Redox

Deep anoxic basin turbidites are a commonly reported feature of deep-basin Black Sea sediments [1, 2] but their chemical composition remained unexplored except for total elemental analysis. The recently found unexpected variability in the porewater chemistry [3] in the anoxic basin sediments could well be due to the differing solid phase compositions as a result of the presence of turbidites which were emplaced there after the 1999 earthquakes (mag. 7.4 and 7.2) in northwestern Turkey. In order to address these issues and to assess the impact of turbidites to Black Sea anoxic basin sulfur chemistry, detailed solid phase speciation of Fe and S will be reported and a mathematical model will be presented.

Pyrite - sulfur was the major phase in all anoxic basin cores [200-400 µmol (g dry wt)⁻¹]. However, zerovalent sulfur and humic sulfur also reached very significant levels: up to about 109 and 80 µmol (g dry wt)⁻¹, respectively [4]. Humic sulfur enrichment was observed in the surface fluff layers of the eastern central basin sediments where Unit-1 type depositional conditions prevail. Elemental sulfur accumulated as a result of porewater sulfide oxidation by reactive iron oxides in turbidities from the anoxic basin margin and western central basin sediments. The accumulation of elemental sulfur to a level close to that of pyrite-sulfur in any part of central Black Sea sediments has never been reported before and this finding indicates deep basin turbidites prevent the build-up of dissolved sulfide in the sediment. This process also contributes to diagenetic pyrite formation whereas, in the non-turbiditic parts of the deep basin, water column formed (syngenetic) pyrite dominates the sulfur inventory. Our study shows that the interactions between depositional patterns (Unit 1 vs. turbidite), redox state of overlying waters (oxic-suboxic-sulfidic) and organic matter content determine sulfur speciation and enable the accumulation of elemental sulfur and organic sulfur species close to a level of pyrite-S.

A time-variable mathematical model was constructed to further explore the nonsteady-state diagenesis of Fe-S species in a turbidite mud emplaced on normal anoxic-sulfidic deep Black Sea sediments. The turbidite layer was 20 cm thick and initially contained 80 µmol (g dry wt.)⁻¹ of Fe(III) in the form of goethite, which led to the rapid (1 day) oxidation and depletion of porewater sulfide and formation of solid phase sulfur intermediates such as S(0) and FeS. S(0) accumulated faster than FeS and was present in the sediment at high concentrations after 5-8 years following the deposition of the turbidite. Reduced iron was in the solid phase long after the consumption of all Fe(III), enabling the coexistence of S(0) and solid-phase reactive iron (which has not been sulfidized yet) for a long period of time. The porewaters had sub-micromolar concentrations of dissolved sulfide in the first 2 years after deposition with Fe (II) exceeding 1 mM. The turbidite layer served as a sink for the sulfide from the overlying waters for about 10 years after its deposition. These results agreed with the solid phase data for the western central station (30) and our suggestion that an earthquake-induced turbidity current could have transported iron oxides from the southwestern shelf/slope as far as 150 km in the western central Black Sea and caused massive oxidation of sulfide after the 1999 earthquakes in Northwestern Turkey.

Considering the ubiquity of the deep-basin turbidites found in the Black Sea and the dense tectonic activity on the Northern Anatolian Fault in Northern Turkey, an estimated 0.144 Tg sulfur / year could be buried as S_8 and FeS₂ due to the earthquake-induced turbidites. This value is about 14 % of the annual sulfur burial (as pyrite) and 3-5 % of the annual sulfide oxidation due to lateral injections of oxic Mediterranean waters to the anoxic-sulfidic Black Sea waters. It is highly likely that earthquake-induced turbidites and subsequent sulfide

oxidation in the deep basin represent a previously unrecognized sink in the budget of hydrogen sulfide in the Black Sea.

Fig. 1. Model output for the solid phase S-Fe species during the 8000 day simulation period. Time 0 indicates the deposition of the Fe(III) containing turbidite. Initially only dissolved sulfide and solid phase Fe(III) are present in the system. As the reactions progress sulfur intermediates, S(0) and FeS form in the solid phase. With time S(0), FeS and dissolved sulfide form pyrite, and the system reaches steady state after about 7000 days or 19.2 years.

SIMULATING THE INTERANNUAL VARIABILITY OF THE ADRIATIC SEA ECOSYSTEM DYNAMICS

Marco Zavatarelli ¹*, Emanuela Clementi ¹ and Paolo Oddo ² ¹ Bologna University Phys Dept. - Marco.Zavatarelli@unibo.it

² INGV

Abstract

The Adriatic Sea ecosystem dynamics has been simulated, under high frequency, interannually varying, surface forcing, with a coupled physical/biogeochemical modelling system composed by the Princeton Ocean Model (POM) and the Biogeochemical Fluxes Model (BFM). The high frequency forcing for the modelling system is from operational atmospheric circulation analyses. The preliminary simulations results relative to both the general circulation and the biogeochemical processes are assessed by comparing them with available and remotely sensed data. Particular emphasis is put on the analysis of the biogeochemical processes variability induced by the strongly inter-annually varying circulation dynamics (current systems, dense water formation etc.) and by the variability in the Po river freshwater and nutrient forcing. *Keywords: Models, Coastal Models, Adriatic Sea*

Introduction

The Adriatic Sea ecosystem is characterised by a strong spatial and temporal variability ([1] and [2]) due to the atmospheric forcing functions, the circulation patterns, the fresh water river runoff that strongly affects spatial and temporal variability and distribution of biogeochemical properties in the northern Adriatic Sea [3].

The objective of this research is to simulate with a three-dimensional coupled numerical model the Adriatic Sea ecosystem dynamics under high resolution and high frequency, interannually varying, surface forcing conditions; to analyse numerical results in terms of Nutrients, Chlorophyll, Primary and Bacterial production variability.

Model

The three-dimensional ecosystem numerical model used is a coupled hydrodynamic/ biogeochemical model.

The circulation model is the Princeton Ocean Model (POM), a threedimensional, primitive equation, time-dependent, sigma-coordinate, free surface, estuarine and coastal ocean circulation model [4].

The ecological model used in this research is the Biogeochemical Flux Model (BFM) [5]. The model describes physiological and population processes of lower trophic levels in the marine environment. Biota is described by means of three main functional groups: producers, decomposers and consumers, each one defined by internal constituents: Carbon, Nitrogen, Phosphorous, Oxigen and Silicon (in the case of diatoms).

The model has been implemented in the Adriatic Sea basin with a grid resolution of about 2.5 km in horizontal direction and 27 sigma vertical levels with a logarithmic distribution near the surface and the bottom; the minimum depth resolved is 10 m. The model is free surface with time step splitting: the two-dimensional external mode has a 5 sec. time step, while the three-dimensional internal mode has a 500 sec. time step.

Results and conclusions

Simulation results derived from a fully three-dimensional, coupled physicalbiogeochemical model implemented in the Adriatic Sea are analysed including Nutrients, Chlorophyll, Primary and Bacterial production. In particular, the monthly averaged numerical results of sea surface Chlorophyll-a concentration are compared with satellite remote sensing data derived from the MERSEA dataset.

The numerical results (Fig. 1) qualitatively agree with the main ecosystem dynamics of the Adriatic Sea. In particular the model is able to represent the high Chlorophyll-a concentration in the northern and western sides of the Adriatic Sea and its decrease towards southern and deeper areas. The seasonal Chlorophyll variability is also qualitatively modelled in comparison with SeaWifs data.

Fig. 1. Chlorophyll-a monthly mean concentration simulated by the model (up) and provided by MERSEA dataset (down) for May 2002.

THE MEDITERRANEAN SEA ECOSYSTEM DYNAMICS: HINDCAST AND SCENARIO SIMULATIONS

Marco Zavatarelli ^{1*}, Gelsomina Mattia ¹, Marcello Vichi ² and An Byuong ³ ¹ Bologna University Phys Dept. - Marco.Zavatarelli@unibo.it ² INGV-CMCC

³ INGV

Abstract

High resolution (1/16 degree) simulations of the interannually varying Mediterranean sea ecosystem dynamics are presented and discussed. The modelling system used is constituted by the on-line coupling of the BFM (Biogeochemical flux model) and NEMO (Nucleus for European Modelling of the Ocean). Hindcast for the period (1996-2000) were performed using two different sets of forcing functions: the ERA40 and the results of the ENSEMBLE atmospheric model coupling with the IPCC scenario of Co2 emission A1B. The main aim is to compare the influence that the use of different forcing functions might have on governing the ecosystem dynamics.

Keywords: Models, Circulation Models

Introduction

In the framewok of the EU FP6 Project SESAME (Southern European Seas: Assessing and Modelling Ecosystem changes) project, we performed a set of hindcast and scenario numerical simulations of the coupled ecosystem dynamics of the Mediterranean Sea. The atmospheric forcing functions used for the 1970-2000 hindcast simulations are derived from the ECMWF reanalyses (ERA40), while for the scenario (2070-2100) simulations the forcing functions are computed from atmospheric data originating from the numerical silulation of the global atmosphere carried out under the A1B IPCC scenario of greenhouse gas emission. The aim of the work is to study the impact of "green hous effect" related global change on the Mediterranean Sea ecosystem . The simulation performed for the periods 1970-2000 (hindcast), 2070-2100 (scenarios predictions).

Model

The used modelling system is based on the on-line coupling of a biogeochemical and a general circulation model.

The circulation model is NEMO (Nucleus for European Modelling of the Ocean)-OPA(Ocean PArallelise) version 9.0 [1] primitive equation model implemented in the Mediterranean Sea with an horizontal resolution of 1/16 degree (approximatevely 7 km) and a vertical resolution of 72 unevenly spaced vertical z-level.

The ecological model used in ths work is the BFM (Biogeochemical Flux Model) [2-3]. This model is an evolution of ERSEM (European regional sea ecosystem model) [4]. It is a generalized biogeochemistry model based on a biomass-based continuum description of lower trophic levels in the marine environment.

The initial conditions for nutrients and oxygen derived form SEADATANET project (http://www.seadatanet.org) merged with World Ocean Atlas climatology in the Atlantic box. In other hand, the initial conditions for biology are homogeneous guessstimates with vertically-distribuited analytical profiles.

Numerical simulations have been carried out oh a high performance parallel computer.

Results and conclusions

We focused on the temporal evolution of chemical and biological variables. In particular, we compared the monthly averaged numerical results of sea surface Chlorophill-a concentration (Fig.1) derived by simulation forced by ERA40 and satellite data.

The numerical results (Fig.1) show an overall tendency to overstimate phytoplancton biomass. The model is able to reproduce the interannual variability of Chlorophyll surface data. In particular, the relatively high march biomass in the Gulf of Lions and in the Sicily channel detected by the satellite are captured by the model, but with a positive bias particularly strong in the Sicily channel.

Fig. 1. Chlorophyll-a monthly mean concentration simulated by the model forced by ERA40 (up) and provided by SeaWifs (down) for March 1999

DOM STOICHIOMETRY IN THE MARMARA SEA DURING SEPTEMBER 2008

C. Zeri ^{1*}, S. Besiktepe ², A. Pavlidou ¹, A. Giannakourou ¹ and E. Krasakopoulou ¹ ¹ Institute of Oceanography, Hellenic Centre for Marine Research - chris@ath.hcmr.gr ² NATO Undersea Research Centre, La Spezia, Italy

Abstract

Dissolved organic carbon, nitrogen and phosphorus (DOC, DON, DOP) were measured in the Marmara Sea, the Dardanelles Straits and the adjacent North Aegean Sea, during September 2008. Additionally, surface waters at selected stations of the Marmara Sea were sampled for bacterial production (BP) and bacterial respiration (BR). The analysis and coupling of chemical and biological data showed that at least during September 2008 newly produced surface dissolved organic matter (DOM) was consumed in the Marmara Sea in times scales shorter than the surface water residence time and that the outflowing waters from the Dardanelles carry DOM of more refractory nature.

Keywords: Aegean Sea, Marmara Sea, Nutrients, Organic Matter

Introduction

The purpose of our study is to present new data on DOC, DON, DOP for the study system and investigate the processes which control their distribution. Also, we focus on the impact of the Dardanelles outflow on the North Aegean trophic status.

Results - Discussion

The Marmara Sea is a two layer counterflow system extensively studied in terms of its hydrography ([1] and references therein) but to a lesser extent in terms of its chemistry [2], [3]. Taking into consideration this specific flow regime we present our results in Table I.

Tab. 1. DOC, DON, DOP concentrations (µmol L⁻¹) and ratios in the studied area.

DOM in the overflow shows a 2-fold decrease in its DOC and DON content while DOP remains constant. DOM in the underflow shows stable DOC, DON, DOP concentrations. DOM stoichiometric ratios shown in Table I are indicative of the presence of considerable amounts of refractory material. The refractory character is more pronounced in the surface low salinity waters. In order to clarify to what extent the concentrations observed in the Marmara Sea reflect merely the mixing of rich in DOM low salinity Black Sea waters with poor in DOM high salinity N. Aegean waters, we plotted our DOC results along the mixing line of the two end members (Figure 1).

Fig. 1. Figure 1. Mixing line of low salinity high DOC BS waters with high salinity low DOC Aegean waters.

It was shown that in situ DOC production is also taking place in surface waters of the Marmara Sea. Deep waters of the Marmara and the N. Aegean Seas lie very close to the Aegean end member with a very good fit. Surface

Aegean waters also show a good fit to the mixing line with the exception of 2 points indicative of an extra DOC source. In systems such as the Marmara Sea with strong influence of terrestrial inputs and freshly produced organic material, it is very difficult to distinguish between refractory and labile forms of DOM. The two layer counter flow and the limited vertical mixing in the Marmara Sea does not allow us to consider bottom water DOC concentration as the refractory one, as it has been proposed for the open ocean. Therefore, in an attempt to get an estimate of DOM lability in the overflowing waters we considered that DOM found there is similar in nature as in surface waters of the Black Sea. In fact the similar nature of POM between the Black and Marmara seas has been reported [4]. The labile+semilabile component in surface waters of the Black Sea has been estimated to be 41% of bulk DOC and 50% of bulk DON [5]. Based on these percentages we calculated the amount of excess DOC and DON in the upper layer of the Marmara Sea and found 71 µmol/L for DOC and 4.1 µmol/L. DOC:DON ratio in this labile+semilabile material is 17.2, a value indicative of relatively fresher material compared to the DOC:DON ratio of the remaining refractory DOM (24.9). Mean depth integrated BP measured in Marmara surface waters was 1.25 µmolC/m3/h, and BR 0.7 µmol O2/L/h. Based on these data we calculated the bacterial carbon demand (BCD) and found that 15 µmol C/m³/h are consumed by the bacterial community. Since the source of this carbon is the labile+semilabile component of DOM, then the time needed for the bacterial community to consume this DOM was found to be ~30 days. This time is less than the mean residence time of surface waters (~ 4 months) in the Marmara Sea before they reach the N. Aegean [1], and implies that at least during September 2008 outflowing waters from the Dardanelles Straits carry DOM of more refractory nature. This is in accordance with the generally low BP values observed in the southern exit of the Dardanelles (0.25 µmolC/m3/h, present study) and in the N.Aegean (0.21-0.41 µmolC/m3/h) during the same period (Giannakourou unpublished data).

Abstract

The experiments made for the projet DYCOMED permit a better understanding of the natural organic matter (NOM) variation in seawater from surface to 2200m depth profile. Bisides the dissolved organic carbone (DOC) concentration, the NOM fluorescence gives an additional explication in sight of this particular ecosystem. The fluorescence data have been analyzed by the mathematic method PARAFAC. Four fluorescent NOM components have been found and have been compared. *Keywords: Organic Matter, Analytical Methods, Deep Sea Processes, Deep Waters*

Introduction

As a semi-enclosed sea which presents a particular aquatic ecosystem, the Mediterranean Sea is a special reservoir of dissolved organic matter (DOM). Following the study of B.Avril (2002)¹, a periodic series of samplings have been performed during one year (2008) in the central Ligurian Sea (DYFAMED site, 43°25'N, 07°52'E, NW Mediterranean Sea). The samplings have been made at 12 depths every month from 0 to 2200m-depth. Unfiltered samples have been collected in precombusted glass bottles (particulate organic matter represents les than 2%) and conserved with sodium azide (NaN₃, 1M) to prevent any biological development.

Methodology

DOC measurements were made by High Temperature Catalytic Oxidation Technique (Shimadzu TOC-V). The Excitation and Emission Matrix (EEM) spectra were obtained by spectrofluorimetry (HITACHI 4500) at excitation wavelengths from 250 to 500nm and emission wavelengths from 200 to 550nm, both wavelength slits for 5nm, scan speed is 2400nm/min. Analysis of fluorescent dissolved organic matter (FDOM) in the depth profile has been done with the help of parallel factors analysis (PARAFAC) software. It is a powerful statistical technique to treat the 3D-fluorescence spectra leading to the decomposition by a number of independent fluorescent compounds. In order to treat the Inner Filter Effect (IFE), 119 EEM of diluted samples have been made besides of 119 EEM spectra of original samples^{2,3,4}.

Results and Discussion

Two data treatments have been taken for this project according to the presence of FDOM components in the different depths. Treatment of all sample spectrums from the depth 0 to 2200m-depth gives 4 fluorescent components (Fig.1) that represent the fluorescence maxima of previously identified moieties : [Tyr] maximal excitation wavelength and emission wavelength 265nm/305nm (tyrosine-like) ; [Trp] maximal $\lambda_{\rm EX}/\lambda_{\rm EM}$ =280nm/340nm (Peak T, tryptophan-like group); [M] maximal $\lambda_{\rm EX}/\lambda_{\rm EM}$ =295nm/410nm (Peak M, marine humic-like substance) and a double maximum component [CA] with maximal $\lambda_{\rm EX}/\lambda_{\rm EM}$ =335nm/445nm (Peak C, visible humic-like group) and $\lambda_{\rm EX}/\lambda_{\rm EM}$ = 250nm/445nm (Peak A, UV humic-like substance).

Fig. 1. 4 Components: Component 1, Tyrosine-like fluorophore; Component 2, Peak T-Tryptophane-like fluorophore; Component 3, Peak M-Known as marine humic-like substances fluorophore; Component 4, Peak C and A-coupled humic-like substances fluorophore.

Fluorescence contribution of each component at different logarithmic depths (Fig. 2a) shows that the most concentrated fluorophores zone is deeper than 100m throughout the year, which is different from the results of DOC concentration of which the most concentrated zone is on the seasurface¹. It makes clearer the difference between living organism moleculars and NOM

because of the probable existence of some less or no-fluorescent substance (huge moleculars or longer chained protein, etc.) in the surface waters and more fluorescent substances like NOM in the deeper sea. This might be owed to 3 reasons: the better recycling of NOM by living organisms thanks to the sun rays at the water surface than deep sea; the deposition of no-bioactive NOM towards to deeper seawaters; the influence of photo bleaching on chromophoric compounds to the presence of FNOM. The fluorescence contribution of protein substances (Tyr and Trp) is important (+ and O, Fig.2a), this could be due to unfiltered sampling protocol. Humic-like substances are generally less fluorescent comparing to other compounds, particularly the M compound. An important peak contribution of marine humic-like substance has appeared in May at the depth from 100m to 2200m, although the other fluorophores kept their values reasonable. Moreover, the intensity maxima was associated to the mosopelagic layer (100~400m), while an increase of protein substances in the deep sea occured at 400 m followed by a sharp decrease at 600 m in July, August and September. This is probably due to the thermal stratification of water column. In the intensity comparison among minima, averages and maxima (Fig.2b), we have observed the averages close to the minimal data, which signifies generally the low NOM concentration throughout the year, besides of period of meosotrophy (spring bloom). In the deep sea, there is normally less NOM concentration because of lysis and low carbon production. But occassionally, an increase of FNOM is observed for a reason not yet explained, estimated could be brong by deep current (the third compound in Fig.2b). This project will be continued for several years. It permits us to study the variation of an ecosystem in a 2200m depth oceanic water column.

Fig. 2. Comparison of 4 components in depth profile. a): 4 components in each illusion with sea depths at Axis X and fluorescence intensity at Axis Y, totally 8 months from April to November. b): Fluorescence Minimal, Average and Maximal intensity in each illusion standing for each component.

PARAFAC TREATMENT IN 3D-FQ OF DOM-[M] COMPLEXATION

Huiyu Zhao^{1*}, Roland Redon¹, Cedric Garnier¹ and Stephane Mounier¹ ¹ Laboratoire PROTEE-Bt R, USTV 83957 La GARDE Cedex - hzhao@univ-tln.fr

Abstract

The DOM-Metal complexation propriety is accessible by fluorescence quenching (FQ). FQ spectrum can determine the fluorescent DOM composition by parallel factor analysis (PARAFAC) with excitation-emission matrix (EEM). [Cu²⁺] titration onto a river water sample from Brésil: [C] =5mg/L, initial [Cu²⁺]=1.68 nM, pH=4.5, [Cu²⁺]=10⁻⁹M \sim 10⁻³M is done with 50 Excitation and Emission Matrix (EEM) analyzed by PARAFAC, which has extracted 2 fluorescent components from all EEM: C1 (\lambda ex=235nm/\lambda ex=420-425nm) and C2 (\lambda ex=250-260nm and 345-355nm/\lambda ex=470-480nm) of which corresponding interatures were obtained by this new approach. It is confirmed that with PARAFAC FQ modification values fluorophores are better distinguished from the whole matrix.

Keywords: Organic Matter, Metals, Analytical Methods, Chemical Analysis, Surface Waters

Introduction

Dissolved Organic Matter (DOM) is a compled mixture existing everywhere in the environment. The studies of DOM in aquatic ecosystems enable us to obtain some information on its coming future and the importance of its role in the bio-geochemical processes. The fluorescence technique makes analyzes possible on the basis of the optical propriety of the DOM including its fluorophores composition and its complexation propriety face to face to certain metal¹. Recently for luminescence spectrum it is possible to determine the fluorescent component composition by the statistical analysis of parallel factor analysis (PARAFAC) with excitation-emission matrix (EEM)².

Methodology

The complexation propriety between DOM and metals is accessible by measuring the fluorescence quenching (FQ) functional to the metal additions. The EEMs in the FQ experiments contain maximal information as a whole of fluorescent DOM (FDOM). This work presents a quenching experience brought from copper ions titration onto a river water sample from Brésil of 5mg/L carbon concentration and 1.68 nano-molaire initial copper ions concentration (pH=4.5). A titration of copper ions (Cu(NO₃)₂) has been applied in copperions concentration range from 10⁻⁹M to 10⁻³M. Fifty EEM were obtained and gathered in order to analyze the FQ by PARAFAC. This statistical treatment permits us to extract 2 fluorescent components from the whole EEM (Fig.1): C1 (\lambda ex=235nm/\lambda em=420-425nm) and C2 (\lambda ex=250-260nm and 345-355nm/\em=470-480nm) corresponding to the peaks already described in the literature.

Fig. 1. Component 1 and Component 2 found by PARAFAC

Results and Discussion

Using the participation to the total fluorescence of these peaks, we have observed clearly that the fluorescence diminution was not uniform. The Fig.2 shows the relation between the Fluorescence Intensity Percentages (FI%)on function of logarithmic copper concentration (log[Cu]). The experimental points of Component 1 (C1, rhombus) show a stability near 100% at the begging of the copper ion titration just like those of Component 2 (C2, square) till to 10-⁷mol/L. From this concentration, the C1 FI% continues decrease till to the end of titraton. But instead of decreation, the C2 FI% increases sharply from 90% to 170%, which dues probablly to the Inner Filter Effect³ (While NOM concentrated in a sample, some of moleculars absorb the energy emitted by others, which shuts down the observed fluorescent light. This phenomenon is called "Inner Filter Effect", IFE)³. The current methods to correct IFE are unuseful in these continuous experimental measurements, although an other correcting idea is putting in the future trying. Anyway, C2 has shown its great fluorescent quenching characters by complexing with metal. The analysis of complexation propriety has found out two complexation compounds values: $K_1 = 10^{4.6}$; $L_1 = 10^{-7.8}$ et $K_2 = 10^{4.46}$; $L_2 = 10^{-9}$ all for the component C2 (Fig. 1).

These results signifies at least 2 complexation compounds giving by a same EEM component. The utilisation of PARAFAC has confirmed the presence of just 2 fluorescence fluorophores but more than 3 complexing sites obeying to the treatment conditions given by Ryan and Weber⁴. Meanwhile, PARAFAC permits to better observe the FQ values' modifications by decomposition of fluorophores contribution from a whole matrix. That is why C2 contains 2 peaks identified: Peak C and Peak A⁵. No fluorophore no-affected by the copper titration has been detected.

Fig. 2. Relation between fluorescence intensity and logarithmical copper ions concentration (FI%/log [Cu²⁺])

This new coupled approach organizing the optical fluorescence measurements (FQ), the mathematical data analysis (PARAFAC) and informatical modeling method (PROCESE) permits us to observe a macro image on FNOM composition and to link it to its own micro complexation characters. Application of this approach to mditerranean samples will be in the coming work.

Abstract

The levels of indicator and heterotrophic bacteria (HPC) and the frequency of antibiotic resistant bacteria with respect to the areas from which they were isolated were investigated and compared in the sea water samples taken from the coastal area of the Eastern Mediterranean (Turkey, Syria, Lebanon) and the offshore area (Northern Aegean Sea). While the highest levels of resistant bacteria were found in the samples taken from Syria, the lowest level of resistant bacteria was found in the samples taken from the offshore area of the Northern Aegean Sea.

Keywords: Bio-Indicators, Bacteria, Eastern Mediterranean

Introduction

In this study, bacterial studies were conducted with an aim to detect the level of indicator and heterotrophic bacteria and compare the level of antibiotic resistant strains in the coastal areas between Cesme and Cevlik (Turkey), Lattakia (Syria) and Beirut (Lebanon) and also the offshore area extending from the eastern part of Andros Island to the southern part of Gokceada -Thasos Island.

Material and methods

Two cruises were conducted with R/V YUNUS-S and sea water samples were collected during the months of August in 2007 and 2008 (Fig 1). Indicator bacteria analyses using the membrane filtration method [1] and HPC analyses using spread plate method with Marine Agar were carried out. Antibiotic resistance analyses were done according to NCCLS [2].

Results and Discussion

Faecal coliform, total coliform and HPC were found to be between<1,0-1,0 \log_{10} CFU/100 ml, <1,0–2,1 \log_{10} CFU/100 ml, 5,4–7,1 \log_{10} CFU/100 ml, respectively at 15 stations, during August 2007, in the Aegean offshore area ranging from the eastern part of Andros Island to the southern part of Gokceada-Thasos Island. Also in 2007, results of analyses conducted at 97 points between Cesme and Cevlik in the Eastern Mediterranean coastal area of Turkey were found to be between 1,7-4,7 \log_{10} CFU/100 ml for faecal coliform, 1,8-6,9 log₁₀ CFU/100 ml for total coliform, and 5,5-8,8 log₁₀ CFU/100 ml for HPC. Again in 2008, results of analyses conducted at 90 points between Cesme and Cevlik in the Eastern Mediterranean coastal area of Turkey were found to be slightly lower than in 2007. In 2007, results of analyses conducted at 6 points along the coastal area of Syria were found to be between 2,5-3,7 \log_{10} CFU/100 ml for faecal coliform, 3,1-4,5 log10 CFU/100 ml for total coliform, and 5,5-6,6 log10 CFU/100 ml for HPC. Once more in 2008, results of analyses conducted at 6 points along the coastal area of Syria were found to be slightly higher than in 2007 (2,7-3,8 log10 CFU/100 ml for faecal coliform, 2,9-4,1 log10 CFU/100 ml for total coliform, and 5,8-6,2 log10 CFU/100 ml for HPC). Also in

the year 2008, results of analyses conducted at 5 points along the coastal area of Lebanon were found to be between 1,0-3,2 \log_{10} CFU/100 ml for faecal coliform, 1,9-5,2 \log_{10} CFU/100 ml for total coliform, and 5,5-7,8 \log_{10} CFU/100 ml for HPC.

Fig. 2. Distribution of Antibiotic Resistant Strains

While the highest Multiple Antibiotic Resistance (MAR) was found in the bacteria isolated from the coastal area of Syria (48%), the bacteria isolated from Turkey (38%) and Lebanon (31%) respectively followed it. The bacteria isolated from the offshore area of the Northern Aegean Sea did not show resistance against antibiotics. The antibiotic derivates which were found to be resistant to bacteria were different in different regions. This situation shows that pollution input and the usage rate of antibiotics have differences related to geographic regions. In this study the first comparative bacterial data were obtained for these regions. There is a need for international long term monitoring studies for the purpose of detecting point pollution in these areas.

Acknowledgements We would like to thank Prof. Dr. Bayram OZTURK who contributed to our study by coordinating the cruises, and the crew of the R/V YUNUS-S.

DISTRIBUTION OF NUTRIENTS AND CHLOROPHYLL-A IN THE COASTAL AREA OF THE BOSPHORUS (TURKEY)

Abstract

The aim of this paper was to establish the annual variations in nutrient and chlorophyll-a concentrations. Samples were collected from June 2003 to May 2004 at five stations in the coastal waters of the Bosphorus. Nitrate+nitrite, phosphate and silicate concentrations in winter were higher than other sampling periods. Chlorophyll-a concentrations ranged between 0.54 and 6.13 μ g l . Keywords: Nutrients, Chlorophyll-a, Bosphorus

The Bosphorus is located at the northern part of the Turkish Straits System [1]. It is a narrow natural channel carrying the highly polluted waters of the Black Sea to the Sea of Marmara. Its upper layer waters have an average salinity of 16.5-18.5 ppt, and the lower layer an average salinity of 38 ppt. Such conditions are very likely to create density currents that can strongly affect the biogeochemical cycle of the system [2]. Nutrients are the essential chemical components of life in the marine environment. Phosphorus and nitrogen are incorporated into living tissues, and silicon is necessary for the formation of the skeletons of diatoms and radiolaria [1]. In the sea, most of the nutrients are present in sufficient concentration, and the lack of some of them limits the growth of phytoplankton [3]. The studies on this subject in the Bosphorus are still very limited. The aim of this paper was to establish the annual variations in nutrient and chlorophyll-a concentrations. This study was carried out in the coastal waters of the Bosphorus at five stations between June 2003 and May 2004 (Fig. 1). Nitrate+nitrite (NO3+NO2-N) concentrations were analyzed by cadmium reduction method on a Skalar autoanalyser [4]. Phosphate (PO4-P), silicate (SiO4-Si) and chlorophyll-a analyses were detected by the methods described by Parsons et al. [5].

Fig	1	Research	stations	in	the	Bosphorus

Nutrient and chlorophyll-a concentrations are shown in Table 1. The amounts of nitrate+nitrite, phosphate and silicate were 0.26 (November)-42.50 ug-at 1-1 (January), 0.24 (September)-7 µg-at 1-1 (December) and 1.97 (January)-84.26 µg-at 1-1 (December), respectively. Chlorophyll-a concentrations, as an indicator of phytoplankton biomass, ranged between 0.54 (September) and 6.13 µg l-1 (November).

In the present study, nutrient levels in winter period were generally higher than those in spring, summer and autumn. Especially, the highest values were recorded in the untreated domestic waste water discharge point. As Balkis [6] pointed out, there is an increase with time nutrient concentration of the Bosphorus. According to chlorophyll-a based assessments [7], chl-a values in this study showed that the area is generally eutrophic in nature.

FIRST RECORD OF OSTREOPSIS OVATA BLOOM IN THE GULF OF TRIESTE (NORTHERN ADRIATIC SEA)

O. Blasutto ¹*, M. Celio ¹, B. Zanolin ¹, C. Suraci ¹, M. Venuti ¹, A. Acquavita ¹ and G. Mattassi ¹ ¹ Regional Environmental Protection Agency - ARPA-FVG - oriana.blasutto@arpa.fvg.it

Abstract

In a shallow tidal pool in the Gulf of Trieste the first observed bloom of *O. ovata* occurred in September-October 2009. Water samples were collected for the light microscope analyses and nutrient analyses. Hydrological data were recorded using a multiparametric probe. *O. ovata* was observed by epifluorescent light microscope. Cell abundance was higher than 3 million cells per liter.

Keywords: Adriatic Sea, Dinoflagellates, Toxic Blooms

Introduction

O. ovata is an epiphytic potentially toxic dinoflagellate ([1] and references therein). Some Ostreopsis species can produce palytoxin that can accumulate in the trophic web, thus representing a potential although so far undefined sanitary risk [2]. Recently, Ostreopsis spp. produced blooms in the Tyrrhenian and southern Adriatic Sea. These blooms have been related to human health problems [3]. Monti et al. (2007) report the first record of O. cfr. ovata in the Gulf of Trieste and close to the town of Rovinj (Croatia) in October 2006. Up to summer 2009 in the Gulf of Trieste we have not been aware of any bloom in the water column though the presence of this dinoflagellate has been revealed by ARPA-FVG in several shallow coastal sites of the gulf (Bulletins of the Institute for Environmental Protection and Research - ISPRA). From June 2009 to July 2009 ARPA-FVG carried out a study in the Gulf of Trieste in order to investigate the hydrological and biological characteristics of the marine coastal water in relation to the presence of this potentially toxic microalgae. In early autumn the presence of a bloom of O. ovata was observed in a tidal pool in the coastal zone of the gulf. During this event some water samples were collected in order to study the composition and the abundance of the microalgal community and nutrient composition. Hydrological parameters were collected as well.

Material and Methods

On 29th September, 01st and 07th October 2009 water samples were collected in a tidal pool in the Gulf of Trieste. During sampling temperature, salinity and dissolved oxygen values were recorded using a multiparametric Idronaut mod. 316 probe. The hydrological data have been submitted to a quality control. Nutrients analyses were performed colorimetrically for ammonium, silicate, phosphate, nitrate and nitrite using standard autoanalyzer techniques [4]. The composition and the abundance of the microalgal community were analyzed following UNI EN 15204 (2006) [5].

Results and Discussion

From the onset of O. ovata in the Gulf of Trieste the coastal area most affected by the presence of this species has been a coastal zone known as Canovella De'Zoppoli (Duino-Aurisina). This area is characterized by the presence of a tidal pool well demarcated from the rest of the beach and in contact with the open sea only during high tide. The tidal pool is characterized by a pebbly bottom and it is sheltered from wind blowing and from wave actions by a natural reef; its depth ranges between 0.2 and $1.5\,$ m. Macroalgae are almost absent. During the microalgal bloom a mucilaginous brown pellet coated all the pebbly bottom and some brown macro-aggregates were floating on the water surface. Water surface temperature was 22.3°C and dissolved oxygen reached 142% of saturation. The high values of oxygen saturation were probably due to the elevated photosynthetic activity of the microalgal community. The microscopic analyses revealed the prevalence of O. ovata. The highest abundance of the dinoflagellate was 3076416 cells per liter in the water in contact with the pebbles previously rubbed, 2636928 cells per liter in the surface water of the tidal pool and 46800 cells per liter in the surface water picked up in a small dock adjacent to the tidal pool. The geomorphological characteristic of the tidal pool, its sheltered position from the wind and wave action, together with the good weather conditions with windless and cloudless sky that occurred for a period before the appearance of the bloom, have probably supported the development of O. ovata that found in this site the ideal conditions for its proliferation. As soon as weather conditions changed the bloom abruptly decreased. Fortunately swimmers usually attend the surrounding areas and very little this one affected by the phenomenon and thus the health risk appears to be reduced. Mussel culture are more than 200 m away from the site and sampling at the water column near the culture have detected insignificant abundance of O. ovata. Notwithstanding the site will be

monitored in the future considering carefully the health aspect.

Abstract

Our study investigated survival and virulence of *Escherichia coli* O55:B5 incubated in brackish water microcosms (Bizerte lagoon, northern coast in Tunisia). Thus, Microcosms were exposed to natural sunlight or maintained in darkness. Results showed survival time prolonged for strain maintained in darkness with modifications in biochemical profiles. Virulence, studied using vero cell test, was maintained during brackish water survival.

Keywords: Bacteria, Brackish Water, Pathology

Introduction

Survival of enteric bacteria reviews pointed out solar radiation and osmotic stress as the most alteration factors of bacteria (Rozen and Belkin, 2001). Else, enteric bacteria survival in seawater depends on their ability to retain their virulence characteristics (Du et *al.*, 2007). Here we tried to test the survival of virulent enterobacteria.

Materiel and methods

A cell suspension of *E.coli* O55:B5, washed three times, inoculated in microcosms ($\approx 10^6$ cells mL⁻¹) during the period from 18 to 30 April, where microcosms were exposed to sunlight (12 days) or maintained in dark condition (21 days). The total number of cells (TC) and the altered cells (AC) were counted by using respectively the DAPI (4', 6-diamide-2-phenylindole-Sigma) and the Live/Dead® *BacLight*TM kit. The virulence of *E.coli* was studied using the vero cell test (Al-Gallas et *al.*, 2002).

Result and discussion

In light conditions experiment (Fig.1a), TC abundances decrease was not significant. By the end of 12th day, abundances were lower than 10cfu mL⁻¹ on TSA agar and 1cfu mL-1 on DL agar. Else, the AC increased during at first of experiment and then stabilized. In darkness, TC abundances showed limited decrease (Fig.1b). Culturable counts decreased progressively and stabilized at a high level (10⁵ cfu mL⁻¹) by the 9th day, with slow increase in abundance of AC until the 4th day. The membrane alteration process appeared to affect the E.coli strain in light and in darkness (lower fraction of cell population) conditions. Membrane alteration involved the degradation of several vital processes linked to the role of cytoplasmic membrane and depended mainly on sunlight intensity (Fiksdal and Tryland, 1999). Nevertheless, we noted limited changes in carbohydrates assimilation, for darkness experiments. E.coli conserved its capacity to survive in non-host environment which can give to virulent serotype a competitive advantage compared to other E. coli serotypes and may have severe consequences for human exposed to potential contamination through shellfish consumption.

Fig. 1. Changes in culturable (CFU), total cell (TC) and altered cells (AC) of *E.coli* O55B5 exposed to sunlight (a) and in darkness (b). TSA: Trypcase-soy agar, DL: Desoxycholate Lactose agar

DEGRADATION OF HIGH MOLECULAR WEIGHT DISSOLVED ORGANIC MATTER BY DEEP-SEA PROKARYOTES ON PAP SITE (NORTHEASTERN ATLANTIC OCEAN)

Mehdi Boutrif¹*, Marc Garel¹ and Christian Tamburini¹ LMGEM, UMR6117, Centre d'Océanologie de Marseille - mehdi.boutrif@univmed.fr

Abstract

The aim of this work is to evaluate the capacity of deep-sea prokaryotes to degrade HMWDOM on the Porcupine Abyssal Plain site (Northeastern Atlantic) under in situ conditions.

Keywords: Bacteria, Deep Sea Ecology, Organic Matter

Deep oceans represent one of the largest reservoirs of organic carbon on the biosphere, mainly in the form of dissolved organic matter (DOM). DOM can be divided in high molecular weight (HMW-DOM > 1000Da, representing between 15 and 35% of total DOM) and low molecular weight (LMW-DOM < 1000Da) size classes. Study of the biogeochemical cycle of DOM must be improved in order to understand the interactions between marine prokaryotes (Archaea and Bacteria) and marine organic matter, since they play a central role in aquatic carbon cycle.

We synthesized tritiated exopolysaccharides (3 H-EPS) [1] and incubated them with natural deep-sea prokaryotes (2000m) at *in situ* pressure and temperature conditions. We also examined the assimilation of 3 H-Glucose and measured Prokaryotic Heterotrophic Production (PHP, with 3 H-Leucine). The number of cells taking up tritiated Leucine, EPS and Glucose were determined using microautoradiography combined with catalyzed reporter deposition fluorescence in situ hybridization (MICRO-CARD-FISH).

The first results shown that deep-sea prokaryotes are able to degrade ³H-EPS, assimilation rates being at the same range than in surface waters (assimilation measured between 1.6 and 2.81 pmol.L⁻¹ h⁻¹). Using our high-pressure retaining system [2], we found significant differences in assimilation rates for all the substrates used between *in situ* and atmospheric pressure conditions. In fact, assimilation rates of EPS, Glucose and Leucine were, respectively, 3.6, 3.4 and 2.3 times higher on samples under *in situ* pressure conditions than decompressed one, confirming previous results obtained in Mediterranean Sea.

FUNCTIONAL DIVERSITY OF PHYTOPLANKTON IN THE MEDITERRANEAN SEA: ENVIRONMENTAL FORCING ON CELL SIZE AND ECOPHYSIOLOGY

C. Brunet ¹*, V. Saggiomo ¹, A. Basset ², F. Conversano ¹ and V. Giovagnetti ¹ ¹ Stazione Zoologica Anton Dohrn - christophe.brunet@szn.it

² DisTeBa, University of Salento, Lecce, Italy

Abstract

Size is a crucial biological trait that determines the metabolism and energy fluxes in cells through resources requirement and acquisition, as well as the "susceptibility" of cells to environmental changes. The aim of our contribution is to do a synthesis of the relations between size – pico *vs* nano+microphytoplankton – and environmental forcings that have been investigated in different trophic conditions of the Mediterranean sea as well as from laboratory experiments. Different time and space scales are analyzed, from the large basin scale to mixed layer or deep-chlorophyll maximum. A strong discrimination between picoplankton and the rest of the community is highlighted both at the level of the ecological pattern and on their ecophysiological behavior. *Keywords: Phytoplankton, Pigments, Physiology, Biodiversity, Primary Production*

Phytoplankton size ranges between 0.3 and more than 100 µm, classified as picoplankton (<2-3µm), nanoplankton (3<20µm) and microplankton (>20µm). Body size is a key-parameter in community ecology and probably the most impacting functional trait for phytoplankton ecology. Both size and ecophysiological diversity could have their relevance in the paradox of plankton [1]. This adaptative character determines the efficiency of the algal community function - as photosynthesis [2] - and the food web structure. At a functional level, the broad range of sizes - resulting from adaptative evolution - determines a high diversity of behaviors and acclimative responses to environment forcing [3] and its variability over different scales. Tackling with the question of cell size community structure means to deal with the relation between ecosystem and cells at an energetic level [4]. The aim of our contribution is to investigate the relations between phytoplankton size community structure and environmental properties using a (photo-) physiological approach. The questions we address are: How does size affect the eco-photophysiological strategy developed by cells? and in which way does the size-related strategy fit with the environmental properties and variations? Data we are dealing with come from (i) experimental laboratory studies aiming to investigate the photoacclimation capacities relatively to light changes and the role of cell size on algal responses [3, 5], and (ii) from the Mediterranean sea field. The data we are analyzing cover a broad range of trophic states and relevant scales for phytoplankton ecology, from the large basin scale to the vertical distribution over the water column with emphasis on mixed layer and deep-chlorophyll maximum. Data has been collected during a trans-Mediterranean cruise carried out in summer 2007, mesoscale studies performed in the NorthWestern Mediterranean sea (spring 2003), Northern Adriatic sea (June 2003) and Strait of Sicily (1996) as well as from a seasonally sampled fixed station in the South Tyrrhenian sea (2006-2009) and over a daily cycle sampling program. Analysis mainly regards sizefractionated pigments (pico vs. nano+microphytoplankton), primary productivity, hydrological and light environment and nutrient concentrations. Contribution of picoplankton varied along trophic gradients over all the investigated scales. Our results highlight significant differences of ecological behavior between the two algal size classes (pico and rest of the community). Picoplankton cells are no- or little limited by nutrient concentrations and these cells appear to be much more able to cope with infra-diel light variations than the greater cell size. That means that photosynthetic function is strongly related to light field in the picoplankton group relatively to the greater cell size. Ecological implications are that picoplankton distribution would be mainly influenced by light (quantity and variability) and that is able to occupy niches characterized by relatively high stressful conditions, in relation to strong adaptation to these niches.

SEASONALITY OF DINOFLAGELLATES IN OLIGOTROPHIC ECOSYSTEM OF MIDDLE ADRIATIC

Marijeta Calic ¹*, Marina Caric ¹ and Nenad Jasprica ¹

¹ Institute for Marine and Coastal Research - marijeta.calic@unidu.hr

Abstract

This study presents the first data on dinoflagellates composition in oligotrophic Tela šcica Bay, and it is a part of complex hydrographical and biological investigation in the Middle Adriatic during 1999-2000. The relative contribution of dinoflagellates to microphytoplankton varied from 0 to 99.18%. Dinoflagellates dominated phytoplankton from late spring to beginning of autumn when water temperatures over 20 °C prevailed.

Keywords: Adriatic Sea, Dinoflagellates, Salinity, Temperature

Introduction

Telašcica Bay is situated in the central part of the eastern Adriatic coast, in the SE part of the island of Dugi Otok. It is 8200 m long and 150-1500 m wide, with the total coast length of 68.78 km. Owing to well-indented coastline and specific and diverse plant and animal life, this area was proclaimed the Nature Park in 1988. Based on the annual microphytoplankton abundance, Telašcica Bay may be classified as oligotrophic ecosystem [1].

Materials and methods

Phytoplankton samples were collected and hydrographic parameters were measured monthly between November 1999 and October 2000 in Telašcica Bay (except in February 2000). Surface samples were collected at three stations: inland (T1), middle (T2), and outer (T3). Temperature, salinity and oxygen saturation were calculated using standard oceanographic methods [2]. Phytoplankton counts were obtained at 200x and 400x magnification, using the inverted microscope method [3]. PRIMER v5 software was used to calculate the Margalef's species richness index [4].

Results

Water temperature in Telašcica Bay ranged from 10.3 °C (January) to 24.9 °C (July), with both the maximum and minimum at T1 (Fig. 1). Temperature rose from April to July and began to fall down in September at all tree stations. Salinity ranged from 37.9 in May to 38.9 in December, both at T2 (Fig. 1). Dissolved oxygen concentrations ranged from 4.9 cm³ L⁻¹ in September at T3 to 6.4 cm³ L⁻¹ in June at T2 (Fig. 1).

Fig. 1. Map of Telašcica Bay (left) and annual distribution (right) of surface temperature (A), salinity (B) and dissolved oxygen (C) $\,$

Microphytoplankton (MICRO, cells size > 20 μ m) abundances, varied from 1.2 x 10³ cells L⁻¹ in September at T3 to 2.5 x 10⁴ cells L⁻¹ in April at T1. Dinoflagellates were present in the Telašcica Bay throughout the whole investigating period, except in November at T2 (Fig. 2). The relative contribution of dinoflagellates to MICRO varied from 0 to 99.18% and from May to September they were the dominant group in MICRO at all investigated stations. Abundance of dinoflagellates ranged from 0 to 2.08 x 10⁴ cells L⁻¹ (Fig. 2), with the highest abundance encountered at station T2 (June2000).

Fig. 2. Annual distribution of dinoflagellates abundances (A) and their relative contribution to microphytoplankton (B)

Altogether, 59 taxa of dinoflagellates were identified in Telašcica Bay. The most abundant taxa (> 10^3 cells L⁻¹) were: *Gymnodinium* spp., *Gyrodinium* sp., *Oxytoxum variabile*, *Prorocentrum compressum*, *Prorocentrum micans*, *Prorocentrum minimum*, *Prorocentrum triestinum*, *Scrippsiella* sp. and unidentified dinoflagellates. *Prorocentrum compressum* was the most dominant species during the peak in June (1.7×10^4 cells L⁻¹). Margalef's species richness index varied from 0 to 3.6 at all stations, with the highest value found at the station T2 in August.

Conclusion

Dinoflagellates dominated the surface phytoplankton from late spring until beginning of autumn, when temperatures higher than 20 °C prevailed in the Telašcica Bay. In these months the contribution of dinoflagellates to total MICRO was 48-99% at all stations, with smaller dinoflagelate (cell size < 40 μ m), such as *P. compressum*, being the dominant taxa.

ANNUAL DISTRIBUTION OF NUTRIENTS AND PHYTOPLANKTON IN THE MARINE LAKE MIR (MIDDLE ADRIATIC)

Marina Caric¹*, Marijeta Calic¹ and Nenad Jasprica¹

¹ Institute for marine and coastal research - marina.caric-gluncic@unidu.hr

Abstract

Phytoplankton and physical-chemical parameters were investigated in the marine Lake Mir special geomorphological phenomenon of the Telašcica Nature Park. Nutrient limitation appears to have been important in defining the lakes' seasonal phytoplankton composition. There was a predomination of small diatoms in spring and autumn, while dinoflagellate dominance began in May and continued during summer. The phytoplankton abundance and biomass were similar those recorded in highly productive coastal Adriatic areas and in the Mediterranean.

Keywords: Adriatic Sea, Nutrients, Phytoplankton

Introduction

There are several marine lakes along the Croatian coast and on the islands of the eastern part of the Adriatic Sea. Phytoplankton succession and community composition reflect the environmental conditions of the ecosystem, among which the availability of nutrients play a significant role. Changes in nutrient supply are often reflected in their ratios. Deviations from nutrient ratios sufficient for a healthy growth of phytoplankton [1,2], either in the nutrient availability or uptake indicate a potential for nutrient limited phytoplankton growth. The present work reports the key environmental variables, particularly nutrient ratios, as predictors of phytoplankton abundance and structure.

Results and Discussion

Marine Lake Mir is landlocked marine environment, situated on the southern edge of Dugi Otok Island. The only communication with the adjacent sea is through the system of subterranean caves and siphons. Physical-chemical parameters and phytoplankton were collected monthly from November 1999 to October 2000. Parameters were determined by standard oceanographic methods [3,4].

Fig. 1. Monthly distribution of physical-chemical parameters, MICRO, NANO, and relative contribution of different taxonomic groups to MICRO abundance in Lake Mir

During the investigation period (Fig.1) the temperature ranged from $3.65 \text{ }^{\circ}\text{C}$ in January to $27.55 \text{ }^{\circ}\text{C}$ in June, with annual temperature gradient of $24 \text{ }^{\circ}\text{C}$. Temperature rose from April to May and were more or less constant from June to August. In September, the water column began to cool. Throughout the year, the most of salinity values are greater than 39. in the summer period the salinity values are extremly high (>40) with the maximal value of 44.36 in

September. In the water column doesn't exist thermal or haline stratification throughout the year. Oxygen saturation (O_2/O_2) ranged from 0.74 to 1.43. Regarding nutrients, nitrate (NO₃) concentrations were low from June to October. Despite the depletion of nitrate, nitrogen limitation was found only in Julv. because of relatively high ammonium (NH_4) concentrations. Phosphate (PO₄) ranged from 0.02 to 0.19 $\mu mol~L^{-1}$ while silicate (SiO₄) ranged from 0.17 to 7.87 µmol L⁻¹. Microphytoplankton (MICRO) and nanophytoplankton (NANO) abundance ranged from 0.9 x 10³ $- 6.8 \times 10^5$ cells L⁻¹ and 7.2 x 10⁵ - 1.8 x 10⁷ cells L⁻¹, respectively. Three peaks of MICRO were observed throughout the year (Fig.1). Domination of diatoms (mostly Actinocyclus sp.) was evident during the peaks in November 1999 and April 2000, when temperature and salinity were low and nitrate and ammonium were high. Dinoflagellates occurred in May and dominated the lakes' phytoplankton (65 - 95%) during the summer. Their dominance coincided with higher temperature, salinity, PO₄, and SiO₄, but lower NO₃. In July 2000, the MICRO peak was dominated by dinoflagellates (mostly Scrippsiella trochoidea). NANO was the dominant size fraction. The highest values of NANO were recorded in April and August 2000. Autumn, winter and spring provided an environment with low Si:N, while in summer Si:N, Si:P and N:P values indicated that no depletion of nutrients occurred (Fig.2).

Fig. 2. Si:N:P molar ratios in Lake Mir. Molar quotients between *in situ* concentrations of potentially limiting nutrients are delimited by Si:N = 1, N:P = 16, and Si:P = 16 lines

FIRST DATA ON THE BENTHIC ASSEMBLAGES OF HARMFUL MICROALGAL SPECIES IN THE GULF OF TARANTO (NORTHERN IONIAN SEA)

Carmela Caroppo 1* and Antonio Paride Bisci 1

¹ Institute for Coastal Marine Environment, National Research Council - carmela.caroppo@iamc.cnr.it

Abstract

The benthic assemblages of harmful microalgal species have been detected for the first time in the Gulf of Taranto (Northern Ionian Sea). The most abundant species was *Ostreopsis* cfr. *ovata*, which was present in all the samples collected. The microalgal association was mostly composed of *Ostreopsis* cfr. *ovata*, *Coolia monotis*, *Amphidinium carterae* and *Coscinodiscus* sp., and showed features typical of both the Mediterranean and tropical assemblages. *Keywords: Algae, Toxic Blooms, Ionian Sea, Phytobenthos*

Introduction

The biogeographical spreading of benthic dinoflagellates constitutes a major issue since the majority of them are capable of producing toxins [1], and raises questions about their origin and possible dispersal mechanisms [2, 3]. Among these dinoflagellates, the most known species *Ostreopsis* have today exceeded the biogeographical boundaries once considered for them (tropical and sub-tropical areas) and their presence in the Mediterranean Sea is actually well-documented [4]. In the tropical regions *Ostreopsis* genera are usually found in association with *Gambierdiscus*, *Prorocentrum* and *Amphidinium* species [5]. In the Mediterranean Sea, the assemblages of *Ostreopsis* with *Coolia monotis*, *Prorocentrum lima* and *Coscinodiscus* sp. [6, 7] have been detected. The aim of this study is to describe for the first time the benthic assemblages of harmful micro-algal species in the Gulf of Taranto (Northern Ionian Sea).

Material and mehods

In August 2008 samples of sediment were collected from three stations, located along the coastline of the Northern Ionian Sea (Mediterranean Sea) (1 = Mar Piccolo of Taranto; 2 = Mar Grande of Taranto; 3 = Lido Bruno) (Fig. 1). Samples of sediment (50–150 gr wet weight) were collected from depths between 0.5 and 1.5 m, placed in plastic bottles with filtered seawater and kept in the dark. In laboratory, sediment samples were vigorously shaken; the material was then passed through 250 and 100 mm mesh sieves to remove large particles, and was finally fixed with lugol's solution. The sediment was dried and then weighed. The fixed material was settled in 2–10 ml chambers for the appropriate time according to Utermöhl's sedimentation method [8]. Samples were examined and counted with an inverted microscope. The epiphytic abundance was expressed as cells gr^{-1} dry weight of sediment (dws).

Fig. 1. Map of the Gulf of Taranto with sampling stations.

Results and discussion

The microalgal assemblages of sediments was dominated by dinoflagellates, the most of them potentially toxic (Table 1). *Ostreopsis cfr.* ovata, which was present in all the examined samples, reached the highest concentration at the stn. 3. The harmful dinoflagellates *Coolia monotis, Prorocentrum lima* and *Amphidinium carterae* were also abundant. Among diatoms, the genera *Coscinodiscus* and *Nitzschia* were important components of the assemblage. The benthic microalgal association detected in the Gulf of Taranto (*Ostreopsis* cfr. ovata, *Coolia monotis, Prorocentrum lima* and *Coscinodiscus* sp.) was

similar to that found in other Mediterranean coastal areas, such as the Catalan [6], and the Northern Adriatic coasts [7]. Furthermore, the presence of *Amphidinium carterae*, typical of the tropical associations, and observed along the Southern Thyrrenian coast [9].has been confirmed also in the Nothern Ionian Sea. In conclusion, the establishment of tropical microalgal associations, besides the steady presence of "alien" species such as *Ostreopsis ovata*, seems to confirm the ongoing process of Mediterranean "tropicalization", even if the presented data must be considered only preliminary.

Tab. 1. List and abundances of the microalgal taxa detected in the sediments of the Gulf of Taranto.

ABUNDANCE AND DISTRIBUTION OF ACTIVELY RESPIRING BACTERIA IN A COASTAL-OFFSHORE TRANSECT OF THE TYRRHENIAN SEA(APRIL 2007)

G. Caruso^{1*}, M. Azzaro¹, G. Maimone¹, R. Caruso² and G. Zappalà¹

¹ National Research Council - Istituto per l'Ambiente Marino Costiero - gabriella.caruso@iamc.cnr.it ² A.O.U."G.Martino", Messina, Italy

Abstract

The abundance and distribution of actively respiring bacteria within the total prokaryotic community were estimated along the water column in a coastal-offshore transect crossing the Tyrrhenian Sea during spring 2007. Specific fluorochromes (SyBr Green and 3,5cyano-dytolyl-tetrazolium chloride, CTC) were used to detect by flow cytometry the total prokaryotic community and the fraction of actively respiring bacteria, respectively. Bacterial numbers were compared to those determined by epifluorescence microscopy. Respiratory activity rates, leucine aminopeptidase and beta-glucosidase activity rates were also analysed, in order to relate the abundance of living cells to their functional role in the ecosystem functioning. Keywords: Bacteria, Tyrrhenian Se, Analytical Methods

Introduction

The determination of cell viability is a critical issue in assessing the role of bacterial biomass in aquatic environments [1, 2]. Increased attention has recently been paid in determining the fraction of bacteria that are metabolically active and can be actively involved in biogeochemical cycles. Flow cytometry (FCM) with specific fluorochromes used allow us to discriminate bacterial cells according to their living attributes [2]. SyBr Green is a nucleic acid probe to stain the total prokaryotic community (TP), which fluoresces in the green range (maximum emission: 521 nm) of the light spectrum, when excited by a 488-nm wavelength light. The 5-cyano-2,3 ditolyl tetrazolium chloride (CTC) is a redox stain conventionally used as a marker of actively respiring cells, since in the presence of oxygen it is converted into formazan, which accumulates as red fluorescing granules within CTC+ cells [3]. The search aimed at evaluating, along a coastal-offshore transect crossing the Tyrrhenian Sea, the distribution of actively respiring bacteria within the prokaryotic community by FCM, in comparison with epifluorescence microscopy (EPI). **Materials and Methods**

During April 2007, 31 seawater samples were collected by R/V "Universitatis", at depths from 5 to 3250 meters, in an area of the central Tyrrhenian Sea (Lat. 39°30'00''N-Long. 13°30'00''E to Lat. 40°36'30''N-Long. 14°08'30''E). The study was carried out within the VECTOR (VulnErability of the Italian coastal areas and marine ecosystems to Climate changes and Their rOle in the Mediterranean caRbon cycle) Project. Three stations (VTM, 2 and 5) were sampled; VTM was the most off-shore station (maximum depth: 3450 m), about 80 nautical miles SW of Naples, while station 5 was the most coastal one (maximum depth: 700 m). Before FCM and EPI analysis, a 5-ml water sample was pre-filtered on a 100 µm-mesh size net to prevent clogging of the flow cytometer. A 2 ml volume of the filtered sample was stained with SyBr Green II (Molecular Probes, final concentration: a 10⁻⁴ dilution of a 5 mg ml⁻¹ stock solution) for 10 minutes in the dark at room temperature. A 1-ml aliquot of the SyBr Green-stained sample was added with a 5 mmol l⁻¹ solution of CTC (final concentration; Polyscience), and analysed using an Apogee 40 flow cytometer (Apogee Flow Systems). Green fluorescence was collected in the FL1 channel(515-545 nm, specific for SyBr Green); red fluorescence was collected in the FL3 channel (650-690 nm, specific for CTC). The remaining 1 ml of the SyBr Green- and CTC-stained sample was stored at + 5°C until EPI analysis, performed within 2 hours of sampling.For EPI method, the water sample was filtered on a Nuclepore black (0.22 µm pore size) polycarbonate filter; the filter was observed with a Zeiss Axioplan 2 epifluorescence microscope, equipped with specific filter sets (blue light: BP 450-490, FT 510 and LP 520, for SyBr Green+ cells; green light: BP 510-560, FT 580 and LP 590, for CTC+ cells). On the same samples treated for FCM and EPI,temperature, salinity, oxygen, fluorescence, extracellular enzymatic activities (leucine aminopeptidase, LAP, β-glucosidase, β-Glu, alkaline phosphatase, AP) and microbial community respiration by the Electron Transport System (ETS assay)[4], were measured. Results

Temperature ranged from 13.39 to 17.79°C; salinity from 37.56 to 38.73. TP counts obtained by FCM varied between 3.03 x 10⁵ cells ml⁻¹ (station VTM, 500 m) and 6.92 x 10⁶ cells ml⁻¹ (station 5, 100 m). CTC+ bacteria ranged from 1.94 x 10^4 to $1.19 x 10^6$ cells ml⁻¹, recorded at station VTM (500 m) and at station 2 (1000 m); on average, they accounted for 8.8 (station VTM) and 16.28% (station 2) of TP. At station VTM, a decreasing trend for both TP and CTC+ cells was observed; an opposite distribution was found at stations 2 and 5. CTC+ cells were particularly abundant at station 2, between 500 and 1500 m, where values of 32.8-38% of TP were reached. TP counts obtained by EPI varied between 8.25 x 10^3 (station 5, 50 m) and 1.79 x 10^5 cells ml⁻¹ (station VTM, 25 m). CTC+ bacteria ranged from 9.45 x 10² (station VTM, 500 m) to 2.39 x 10^4 cells ml⁻¹ (station 2, 1000 m); on average, they represented 40.88% of TP. Spatial distribution of TP and CTC+ cells found by EPI followed the same vertical patterns as FCM. CTC+ cells predominated at station 2, accounting for over 70% of TP between 500 m and 1500 m. Significant relationships were always found between TP and CTC counts by FCM (Pearson r: 0.975, 0.845, 0.881, P<0.01, stations VTM, 2, and 5, respectively), since CTC+ cells belong to TP. Analysis of variance performed on samples grouped according to the main water masses (surface Tyrrhenian waters: 0-200 m, intermediate mixed waters: 200-1000 m, and deep waters; > 1000 m), showed that CTC+ cells were significantly higher in intermediate mixed layers than at surface (F= 4.751, P<0.05 for FCM). On average, FCM counts were two orders of magnitude higher than EPI counts, although no statistical differences were found between both the methods. At station 2, TP and CTC+ counts by FCM correlated positively with temperature (r= 0.818 and 0.836, P<0.01, respectively) and negatively with salinity (r=-0.72 and -0.637, P<0.05, respectively); CTC+ cells correlated negatively with oxygen (r= -0.851, P<0.01), suggesting its consumption during respiration. No relationships between CTC+ cells and ETS activity rates was generally detected, while CTC+ cells were related to LAP, β-Glu and AP (station VTM, r=0.781, 0.702, 0.798, P<0.01).

Discussion

FCM method is a suitable approach to study the physiological state (i.e. active respiration) of specific microbial populations which are active in the organic matter biogeochemistry. Actively respiring cells in the examined Tyrrhenian transect ranged in the same order of abundance as other marine environments [3, 5]; they prevailed in the intermediate layers, suggesting their distribution could be affected by water masses, like the Levantine Intermediate Water. The lack of relationships between CTC+ cell numbers and ETS activity rates confirms that cell abundance and activity may sometimes be uncoupled, because CTC method detects only the most highly active cells [5]. FCM and fluorochromes could represent a powerful tool also for monitoring bacterial cells for their living properties (enzyme activity, metabolism, respiration) in clinical samples, helping to better assess their potential pathogenic role.

Abstract

The effect of *Caulerpa racemosa* var. *cylindracea* extract on ascorbate peroxidase activity and lipid peroxidation levels of *Oryza sativa* seeds were determined.

Keywords: Aegean Sea, Biotechnologies, Enzymes

Introduction

Caulerpa racemosa var. cylindracea is one of the well-known invasive species in the Mediterranean Sea. This seaweed showed invasive character and observed in 13 Mediterranean countries after 1990 [1]. Seaweeds have various vitamins, amino acids, trace elements and hormone-based compounds in their tissues which are important for plant growth. Therefore, seaweeds extracts can be evaluated as a natural organic fertiliser [2]. Reactive oxygen species (ROS) are by-products of aerobic cell metabolism. ROS play vital roles in various aging and disease processes. Unscavenged ROS can easily attack and damage the important components of cell such as DNA, lipids and proteins [3]. Ascorbate peroxidase (APX) transforms the hydrogen peroxide to water via ascorbate. The disordered balance between oxidants and antioxidants is resulted with peroxidation of polyunsaturated fatty acids of the cell membrane. In these cases, antioxidant supplementation is needed for healthy crops [4]. The aim of this study was to investigate the effect of Caulerpa racemosa var. cylindracea extracts on APX activity and LPO levels in root and leaf of Oryza sativa.

Material and Methods

C.racemosa was collected from Dikili-Izmir in May 2009. The seaweeds were transported to the laboratory immediately, washed and then stored at -20 0 C until used. Seaweed fertilizer was prepared according to Sivasankari et al.'s method [5]. *Oryza sativa seeds* were obtained from Ege Tarimsal Arastirma Enstitüsü (Aegean Agricultural Research Institute) Izmir, Turkey. After sterilization and soaked treatments, the seeds were watered with 15 ml 5%, 10%, 15%, 20% concentration of seaweed extracts every 24 h for 15 days in a growth chamber (Nuve ID 501). The conditions of growth chamber were 25 0 C and 55% humidity level. After 15 days, germinated *Oryza sativa* were collected and 0.10 g of wer root and leaf were homogenized by adding 50 mM 2.0 ml phosphate buffer (pH 7.0). The activity of APX was measured according to the oxidation of ascorbate in the presence of hydrogen peroxide [6]. LPO level was estimated according to Zhu et al. [7].

Fig. 1. The APX activities of *Oryza sativa* root and leaf. Different letters above the error bars indicate significant differences at p<0.05. The results are the means of three different experiments

Results and Discussion

According to Figure 1 maximum APX activity was found in root of *Oryza* sativa which was grown in the existence of 15% extract concentration (158.6 ± 1.9 IU/mg protein). As can seen from Figure 2 maximum LPO levels were observed in control groups root and leaf however the minimum LPO levels were found at 5% extract group. Abiotic factors are important sources of ROS. In these abnormal conditions, ROS are increased in plant metabolism and resulted in bad quality and low yield of agricultural product [8]. In the literature there are many reports on the effect of seaweeds extract to the plant growth. According to a recent paper, *Caulerpa chemnitzia* increases the biochemical parameters of *Vignia sinensis* [5]. This report was also well in line with the latter report. The present paper also revealed that *C.racemosa*

extract supplemented seeds showed lower LPO levels compared to control groups. Therefore, it could be said that *C.racemosa* extract could be applied as antioxidant booster in organic agriculture.

Fig. 2. The LPO levels of *Oryza sativa* root and leaf. Different letters above the error bars indicate significant differences at p<0.05. The results are the means of three different experiments

Abstract

Lactic acid bacteria (LAB) collection was identified from enteric organs of healthy sea bass and sea bream cultured in tunisia. Thus we charecterized mainly Enterococci group with predominance of E. faecium (53%) and E. faecalis (21%). E. sanguinicola, E. casseliflavus, E. mundtii, E. gallinarum, E. pseudoavium, lactococcus lactis, Aerococcus viridans and Carnobacterium sp. were also identified by 16S rDNA sequencing and comparing RAPD-PCR profiles. Further, we obtained clear discrimination within species which were sensitive to vancomycin and resistants to others antibiotics tested. Keywords: Aquaculture, Bacteria, Fishes

Introduction

LAB were described elsewhere as part of normal intestinal flora of fish and reported acting as probiotics since they can be harmless bacteriocin-producing bacteria and therefore may reduce the use of antibiotics in aquaculture [1]. The Enterococcus were LAB of primarily human and animal gastrointestinal flora which were introduced in farmed animals as biological control agents [2]. Here, we present investigation results of LAB isolated from healthy farmed sea bream and sea bass in Tunisia in order of to test their introduction as probiotics for the most valuable local cultured fish species.

Materials and methods

Sixty healthy fish specimens of sea bass and sea bream were collected from the greatest fish farm in southern zone of Tunisia (Monastir). Samples of skin patches and intestinal contents were sterily removed, homogenised and diluted in 0.9% saline solution and spread on MRS and M17 plates (Oxoid) before isolation and phenotypic characterization by mean of standard tests (colony and cell morphology, Gram stain, mobility, production of oxidase and catalase) and miniaturized API50CH biochemical tests (BioMérieux, France). Genetic characterization was performed using PCR-ribotyping of 16S rRNA sequences using universal primers p8FPL(5'-AGTTTGATCCTGGCTCAG-3') and p806R(5'-GGACTACCAGGGTATCTAAT-3'). Further genetic intra-specific characterization was performed by RAPD-PCR using M13 primer (5'-GAGGGTGGCGGTTCT-3'). In addition we test antibacterial sensitivity of all the strains by classical agar diffusion method [3].

Results and discussion

From eighty-four LAB strains isolated of fish samples : 32 strains were from skin and 52 from gut of both sea bream and sea bass. E. faecium was the most frequent (53%), followed by E. faecalis (21%). E. sanguinicola (8 strains), E. casseliflavus and Aerococcus viridans (each 3 strains) and E. mundtii, E. gallinarum, E. pseudoavium, Lactococcus lactis and Carnobacterium sp. (each one strain). The results obtained highlighted the first indigenous fish flora description of E. faecalis, E. faecium and other enterococci not previously considered [4]. Also, RAPD-PCR discrimination results were in agreement with phylogenetic analysis based on 16S rRNA sequences. From another view, Enterococcus isolates were sensitive to vancomycin and resistant to up to 10 ATB tested. Increasing use of antibiotics should be considered as principal cause of emergence for such resistance since supported by transfer of plasmids and transposable elements within marine ecosystem [6]. Present results should be considered in further to LAB investigation in fish both for probiotic assessments and antibacterial resistance treatment in aquaculture.

MICROFOULING COMMUNITY IN BAY OF CARTHAGE (NORTHERN TUNISIA) : PRELIMINARY IDENTIFICATION AND BIOACTIVE PROPERTIES

Wafa Cherif¹, Leila Ktari¹*, Ons Dali Yahya - Kefi² and Monia El Bour¹ ¹ INSTM: 28, Rue 2 mars 1934 Salammbo 2025 Tunisie - leila.ktari@instm.rnrt.tn ² INAT: 43, Avenue Charles Nicolle 1082 Cité Mahrajéne Tunisie

Abstract

Marine bio-fouling concerns any immersed structure. In order to specify fouling mechanism, we studied microbial communities and bioactive interactions for biofilms obtained from an experimental disposal.

Keywords: Fouling, Bacteria, Diatoms, Biodiversity

Introduction

In seawater, immersed structures rapidly accumulate colonising organisms that may range from microscopic bacteria to larger larvae or invertebrates. The first stage of this biofouling consists on a biofilm formed by unicellular organisms specially bacteria and microalgae [1]. Thus, we focused on these microfouling communities formed on an immersed experimental system to analyse biodiversity and potential biological activities.

Methods

Bacteria and microalgae were isolated from immersed steel and glass plates disposed in a shallow marine site (Bay of Carthage – northern coast of Tunisia) [2]. *Identification:* Bacteria strains were specified basically on cultural, morphological and biochemical identification while morphological identification of fouling microalgae was realised on the basis of microscopic observations. *Antagonism test :* Disc diffusion method [3] was used to detect the potential antagonistic effect of all isolates against 15 sensitive bacteria including fish and human pathogens.

Results and discussion

A group of thirty one bacterial strains were isolated with predominance of Gram negative (58%) mainly *Aeromonas hydrophila and Pseudomonas vesicularis* (Table1).

Tab. 1. Isolated microorganism from steel and glass plates.

Identified bacteria	Identified
	microalgae
Weeksella virosa;	Licmophora sp.; L.
Shezanella putrefaciens;	dalmatica; L. anglica;
Chryseobacterium	Nitzschia sp.; N.
maningosepticum;	frustulum; Ñ. palea; N.
Brevundimonas	dissipata; N.
vesicularis;	longissima; N.
Staphylococcus	angularis;
Epidermidis;	Synedra sp.; S.
Aaeromonas hydrophyla;	barbatula; S. pulchella;
Staphylococcus xylosus;	Grammatophora sp.; G.
Pantoea spp.;	oceanica;
Pseudomonas putida;	Peronia erinacea;
Chryseobacterium	Surirella sp.;
indologenes ;	Pleurosigma sp.;
	Fragilaria sp.;
	Navicula sp

Besides, 19 different species of microalgae, all diatoms, were identified with dominance of: *Licmophora* and *Nitzschia*.

Antagonism test revealed interesting activities for one specie: *Chryseobacterium indologenes* with large spectrum of activity mainly against *Staphlococcus aureus* (Table 2).

Tab.	2.	Antagonistic	activity	of	fouling	bacteria Chryseobacterium
indolo	gene	es against patho	genic strai	ns.		

Test strains	Inhibition zone (mm)
Escherichia coli O126B16	12
Staphylococcus aureus	35
ATCC 25923	
Salmonella typhylium	10
E. coli ATCC25922	7
Enterococcus fecalis ATCC	traces
29212	

Results obtained were in accordance with previous studies, particularly for the predominance of *Pseudomonas sp.* [4] in the bacterial community and *Licmophora sp.* for microalgae [5].

Further experimentations are in progress for molecular speciation of producers.

A STUDY ON THE DEGRADATION ABILITY OF THE BACTERIA ISOLATED FROM THE SEA OF MARMARA IN OIL HYDROCARBONS, TURKEY

Pelin Saliha Ciftci ¹* and Gulsen Altug ¹ ¹ Istanbul University - pciftci@istanbul.edu.tr

Abstract

In this study oil hydrocarbon degradation effect of 122 strains which were isolated from the coastal area of the Marmara Sea were investigated. The highest oil hydrocarbon degradation effect with respect to pH and oil layer thickness was observed in the single cultures of 112-*Enterobacter sakazakii*.

Keywords: Bacteria, Marmara Sea, Petroleum

Introduction

The fate of spilled oil in the marine environments depends on a number of factors such as evaporation, dissolution, microbial degradation and photooxidation. Understanding the degradation capability of bacteria and selecting of the most suitable oil degrading bacteria are important for bioremediation process [1] In this study the bacteria which were isolated potentially hydrocarbon polluted areas from the Marmara Sea were tested with respect to their oil degradation effect with an aim to detect the best candidate strains for furthers bioremediation studies.

Materials and Methods

The seawater samples were taken monthly from the four stations selected among ports (M1), oil stations (M2), marinas (M3) and fisherman shelters (M4) between July 2007 and June 2008. Isolates were identified [2] by API 20E and API 50 CHB (Biomereux, France). The single and mixed cultures of strains were screened using the Minimum Inhibition Concentration tests (MIC) with Batman crude oil (Figure 1). The isolates for which MIC values were determined were incubated in a shaking incubator at 150 rpm during 30 days and the ability of the isolates to degrade oil hydrocarbons was investigated by recording the oil layer thickness and the pH values in 72 hours intervals [3,4].

Results and Discussion

The differences of petroleum layer (cm) and pH values between the first and 30th days are shown in Figure 2. 112-E. sakazakii was recorded as the best candidate species between bacteria isolated from the studied area for bioremediation studies. The thickness of petroleum layer decreased from 1,2 cm to 0,2 cm in the single culture of E. sakazakii. In the single cultures of 111-E. corrodens and 109-P. aeruginosa, mixed culture I (P. aeruginosa+B. subtilis+E. coli), mixed culture II (P. aeruginosa+B. subtilis+V. fluvialis) the layer decreased from 1,2 cm to 0,4 cm. The petroleum layer thickness decreased from 1,2 cm to 1 cm in the single culture of 109-B. cepace. Oil degradation abilities of the mixed culture III (K. oxytoca+P. oryzihabitans+ P. mirabilis+E. sakazakii.e. corrodens) and the single culture of 108-K. oxytoca, 107-A. hydrophila,106-C. frenduii, 105-Providencia sp., have observed as low. The stocking of bacteria able to degrade oil hydrocarbons constitute basic data for our further studies intended to analytically determine which fractions of the oil was degraded by these bacteria.

MICROBIOLOGICAL QUALITY OF THE STRIPED VENUS (CHAMELEA GALLINA) AND WEDGE CLAM (DONAX TRUNCULUS) HARVESTED IN MARMASA SEA, TURKEY

Fatma Arik Colakoglu¹, Fikret Cakir¹, Hasan Basri Ormanci¹ and Çigdem Yigin^{1*}

¹ Çanakkale Onsekiz Mart University, Fisheries Faculty, Dept. of Fishing and Processing Technology - cyigin@hotmail.com

Abstract

Microbiological quality of the economically important striped venus (*Chamelea gallina*) and wedge clam (*Donax trunculus*) were investigated in the Marmara Sea. In this purpose, total coliform, fecal coliform, *E. coli*, *Vibrio parahaemolyticus*, and *Salmonella* spp. of the clams were examined. In *C. gallina* total coliform, fecal coliform, and *E. coli* were below the limits of the Turkish Fisheries Regulations and EC Shellfish Hygiene Directive. Similar results were obtained for *D. trunculus*, except for one station in summer where *E. coli* were at the limit value. Although no *Salmonella* spp. were observed in both of the clams, *V. parahaemolyticus* was found in clams during the summer season. As a result, *E. coli* and *V. parahaemolyticus* in the clams, regular microbial monitoring of these species should be conducted in the Marmara Sea. *Keywords: Bivalves, Bacteria, Marmara Sea*

Introduction

C. gallina and *D. trunculus* are the two most harvested and consumed bivalve species in all over the world that are more abundant in Marmara Sea and western Black Sea in Turkey. Bivalves are filter feeding and therefore tend to contain microorganisms in their body. Due to different factors that may contaminate the water column, pathogenic microorganisms may be harmful for human *fc. gallina* and *D. trunculus* were investigated for total coliform, fecal coliform, *E. coli*, *V. parahaemolyticus*, and *Salmonella* spp. between February 2008 and January 2009 in southern Marmara Sea.

Material and Method

Samplings were conducted between February 2008 and January 2009 seasonally from stations where natural stocks are found. *C. gallina* were sampled from five stations namely Sevketiye (SV), Kemer (KM), Karabiga (KB), Gelibolu (GB) and Bolayiralti (BA). *D. trunculus* were sampled from Karabiga (KB), Denizkent (DK) and Cardak (CR). The samples were collected along the littoral zone at 5 to 10 m depth using a mechanical dredge. Samples were stored at $+4^{\circ}C$ and transported to the laboratory. Microbiological analysis of total coliform (TC), fecal coliform (FC), *E. coli*, and *Salmonella* spp. (Sal) were conducted according to FDA (1998)(1) and the analysis of *V. parahaemolyticus* (Vib) were conducted according to FDA(2004)(2).

Result and Discussion

The results for C. gallina and D. trunculus are provided in Table 1 and Table 2. Because of the risks to human health, many countries developed regulations based on the microbiological analysis of the clams. According to the EC Shellfish Hygiene Directive (91/492/EEC) and Turkish Fisheries Regulation (Annex 7), tolerance levels for fecal coliform and E. coli in bivalves should be below 300 MPN/100g and 230 MPN/100g (3). According to FDA (US Food and Drug Administration) and EPA (US Environmental Protection Agency) regulations, the limit risk level for E. coli or fecal coliform is provided as 230 MPN/100g (4). Salmonella spp. and V. parahaemolyticus should not be any present in shellfish meat and fluid inside the shell. In this study D. trunculus had a E. coli value (230EMS/100g) which is exactly as the limit value during summer in Denizkent station and in the same station. Again, in summer, fecal coliform value (290EMS/100g) was close to the limit value. When considering the other seasons and bacteria groups, the bacteriological contents of clams were significantly (p<0.05) higher in Denizkent station. In all stations and seasons the indicator bacteria values in C. gallina were below the given limit values (3,4). Although the pathogenic bacteria Salmonella spp were not found in any of the samples, V. parahaemolyticus were found in D. trunculus speciesinthe Karabiga, Denizkent, and Cardak stations during summer. In C.gallina species V. parahaemolyticus was found in the Sevketiye and Kemer stations only once. As a result, in both clam species microbial values increased with the increasing water temperatures in summer. The reason of the increase during the summer season is due to the domestic and industrial sewages besides the increase of human activity on the shorelines. Although in most of the samples the increase of microbiological values are not reaching the critical limits for human consumptions, the E.coli and V. parahaemolyticus value observed at Denizkent for D. trunculus was reaching the critical limit and therefore regular microbiological monitoring of the species is suggested.

LUMINOUS BACTERIA CHARACTERIZATION IN MEDITERRANEAN SEA WATERS

M. De Luca¹, B. Caldarone¹, G. Ruggeri¹, F. Smedile¹, M. De Domenico¹ and E. De Domenico^{1*} ¹ Department of Animal Biology and Marine Ecology - University of Messina (Italy) - edd@unime.it

Abstract

To investigate luminous bacteria distribution in the Mediterranean Sea a multiyear study (2000-2009) was carried out in several areas from W to E (Gibraltar Straits - Crete Island), during several oceanographic cruises carried out in various seasons. By means classical identification pathways and molecular analyses (PCR, sequencing, etc) was carried out a taxonomic characterization from ca. 800 bioluminescent strains isolated in several sampling sites. *Photobacterium phosphoreum* was the more representative strain in the whole sampling area.

Keywords: Bacteria, Biogeography, Open Sea

Luminous bacteria (LB) are widely distributed and most abundant organisms light-emitting and are ubiquitous in the marine environment. LB interest several ecological niches: planktonic/free-living, parasitic, saprophytic, gut-symbiotic and light organ-symbiotic ([1],[2]). There are some studies describing the distribution and abundance of this group in the ocean ([3],[4]) but are very few data on LB distribution in the Mediterranean region. However are not yet perfectly known information regarding population dynamics, ecological function and role. According to molecular characterization and phylogeny, 11 species belonging to genera Vibrio, Photobacterium and Shewanella are reported to gather marine luminous bacteria ([5]) that can be divided in four groups: Shewanella group, Photobacterium group, Vibrio fischeri group and Vibrio harvey group ([6]). To understand better the distribution and ecology of luminous bacteria in the Mediterranean Sea, we examined over 3500 samples from about 210 sampling stations from the Straits of Gibraltar to the Island of Crete. Samples were filtered through a Millipore filter (0.47µm pore size), sewed on Petri dishes containing SWC agar medium and incubated in the dark at 20°C. Luminous colonies from plates of sampled depths (ca. 800 strains) were randomly selected, isolated and purified and 250, grown on replicates, were employed for taxonomic analysis. Total genomic DNA of each bioluminescent strain was extracted and PCR amplification of the 16S rRNA genes was performed using the primers 16F27 and 16R1492. Results were grouped into 7 areas: Gibraltar-Alboran, S-W Mediterranean, N-W Mediterranean, Sicily Straits, Tyrrhenian Sea, Ionian Sea, E Mediterranean. In the whole studied area P. phosphoreum (66.5%) was the most representative, whereas V. fisheri and V. harveyi presented values of 9,0% and P. leiognathi 8.5%. Other isolated strains belonged to S. woodyi (4.6%), P. profundum (0.5%) and unidentified strains (1.9%). Collected results (Fig.1) showed a significant geographical difference: the abundance of P. phosphoreum decreased moving from west to east, while V. fisheri and V.harveyi showed an opposite behavior. As far as vertical distribution is concerned, P. phosphoreum showed a wide distribution along the water column preferring the batypelagic layer (800m-bottom) while V. fisheri, did not found below 800m depth.

DISSOLUTION OF BIOGENIC SILICA IN ADRIATIC WATER MASSES

P. Del Negro^{1*}, A. Bergamasco², M. Celussi¹, C. Comici¹, E. Crevatin¹, C. Falconi¹ and M. Giani¹ ¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale - OGS BIO - pdelnegro@ogs.trieste.it ² CNR ISMAR

Abstract

Dissolution of diatom biogenic silica (BSiO2) and its control by prokaryotic activity were investigated in different Adriatic water masses.

Keywords: Adriatic Sea, Biokinetics

In the Adriatic sea, diatoms are the most important primary producers and represent the basis of pelagic and benthic coastal food chains. Orto-silicic acid [Si(OH)4] is an essential requirement in the formation of diatom frustules and its availability depends on both external inputs and internal recycling. Although the recycling of biogenic silica (BSiO2) at the sediment-water interface has already been quantified in different environments (1), very little is known about the processes of the silica cycle that occur along the water column, particularly below the euphotic zone. The silica cycle in Adriatic coastal ecosystem is now receiving much attention, because the increased P limitation conditions is changing the chemical composition of coastal waters. This may favour drastic modifications to phytoplankton community structure. Current biogeochemical models assume biogenic silica dissolution to be controlled by temperature, zooplankton grazing and diatom aggregation (2) but the role of prokaryotes has not been well established. Prokaryotes utilize the organic matter derived from primary production by varied strategies, including attack on dead and living diatoms by using hydrolytic enzyme, and could hasten silica dissolution by degrading the organic matrix which protects diatom frustule from dissolution. Here we report the results of experiments carried out on three Adriatic waters in which we measured BSiO2 dissolution kinetics and prokaryotic enzymatic hydrolysis. During an oceanographic cruise carried out during December 2007 on bord on Dallaporta CNR vessel, we sampled three different waters (surface -SW, Adriatic Deep Waters - AdDW, Modified Levantine Intermediate Waters -MLIW) in the southern Adriatic basin. 50 L microcosms were incubated under controlled temperature and BSiO2, POC, Si(OH)4 concentrations were analysed at different time intervals. Additionally, the diatom and prokaryotic abundances were detected. Since of the organic matrix is a key biochemical mechanism regulating diatom-silica recycling, we measured protease activity and calculated the enzyme kinetics in order to verify if different environmental conditions induce a variation in the conformation and thus in the efficiency of the enzymes produced. The results showed a fast increase in Si(OH)4 inside the deep and surface waters associated to an increase in enzymatic activity. Prokaryotes mediate potentially rapid but highly variable silicon regeneration rates enhancing the role of microbial loop on diatoms production and their biogeochemical fate in the Adriatic ecosystem.

ISOLATION OF HOT SPRING CYANOBACTERIA FROM IZMIR AND COMPARISON OF PYCOBILIPROTEINS

Zeliha Demirel^{1*} and Atakan Sukatar¹

¹ Ege University, Faculty of Science, Department of Biology - zelihademirel@gmail.com

Abstract

Cyanobacteria (blue-green algae) strains were isolated from hot springs area of Seferihisar, Zeytindali, Sifne-Izmir, Turkey. Filamentous cyanobacteria are rich source of phycobiliproteins. Phycobiliproteins located in the thyllakoid membranes of the cells, are functional light harvesting protein-pigment complexes, while the membrane-bound chlorophyll protein complexes were hardly impaired as demonstrated by SDS polyacrylamide gel electrophoresis. In this study, the filamentous cyanobacteria are isolation and cultivated crude extracts are obtained from phycobiliprotein after harvesting. *Keywords: Cyanophyta, Cyanobacteria, Pigments*

Keywords. Cyanophyla, Cyanobacteria, Figm

Introduction

Blue-green algae (cyanobacteria) are prokaryotic microorganisms and have many beneficial features; they are very nutritive and have therapeutic effects such as immuno enhancing [1], [2] antioxidant, antiviral [3], and antiinflammatory effects [4]. In this study, the phycobiliprotein of filamentous cyanobacteria, isolated from different hot spring area in Izmir-Turkey, was isolated and cultivated. In a previous study carried out with protein content of the extracts. After cultivation of cyanobacteria biomass, crude extracts were obtained from all species.

Materials and Methods

Isolation was done by plating on to Blue-Green Algae Medium (BG-11) containing 1.5 % agar. Individual cells were picked up and inoculated into the liquid medium. Protein contents of the extracts were determined by Bradford methods [5]. Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) was carried out according to Okadjima et al. (1993) using a 12.5% polyacrylamide gel and Brilliant Blue R was used for visualization the proteins.

Result and Discussion

The number of species of microalgae is estimated at 22.000 to 26.000, however only a little part of these organisms have been studied in detail with regard to their biochemistry and ecophysiology [7]. Cyanobacteria(blue-green algae) play an important role for being the only source of the blue pigment phycocyanin, and since Spirulina is a very rich source of valuable chemicals, particularly C-PC, commercialized for its use for medical purpose[8]. This is the first study on a purified from hot spring isolate of cyanobacteria. Isolation and cultivation of the cyanobacteria from these samples, three different media were tested. It was observed that isolated colonies from each medium grew best in BG-11 medium. Consequently, four different filamentous cyanobacteriae strains were isolated on BG-11 medium. The crude extracts (1-5) were confirmed by SDS-PAGE (Fig 1).

PHYTOPLANKTON ASSEMBLAGES AND DENSITY IN THE MONTENEGRIN COASTAL SEA

Dragana Drakulovic ¹* and Nenad Vuksanovic ¹

¹ Institute of marine biology - ddragana@t-com.me

Abstract

The Montenegrin coast is influenced by extensive use of the littoral zone and increasing development of tourism. All these changes cause increased eutrophication. We studied microphytoplankton assemblages from April to September 2009 in Boka Kotorska Bay and the Montenegro coast. The highest values of microphytoplankton density and some species indicators of eutrophication were found in the inner part of Boka Kotorska Bay.

Keywords: Coastal Waters, Plankton, Adriatic Sea, Eutrophication

Introduction

Boka Kotorska Bay is a part of the Montenegrin coast, located in the southeastern part of the Adriatic Sea. Due to its structure, values of some parameters indicators of eutrophication level are high enough to classify the region region as eutrophic.

Materials for investigation were collected from April to September 2009 in monthly intervals at 15 stations in the inner part (Kotor Bay and Risan Bay), middle part (Tivat Bay), outer part (Herceg Novi Bay) of Boka Kotorska Bay and outside the Bay, in the open sea (Fig.1). Samples were taken using 51 Niskin bottles on three depths (surface, middle and bottom). Microplankton abundance was determined using a Leica inverted microscope [1]. Chlorophyll *a* concentration was determined by measurement of absorbance with a Perkin-Elmer spectrophotometer and calculation according to Jeffrey et al. [2].

Fig. 1. Investigated area

Results

Oxygen saturation was positively correlated with microplankton abundances. Maximum values (from 115.7% to 125%) were found in July. The largest mean value of microplankton abundance was found in July (8.40 x 10^5 cells L⁻¹). Also in July we noticed two more peaks (3.86 x 10^5 and 3.08 x 10^5 cells L⁻¹). The fourth peak occurred in August (3.05 x 10^5 cells L⁻¹). All peaks were found in the summer period in the inner part of Boka Kotorska Bay. Outside the Bay values were lower, with maximum abundance of 7.84 x 10^4 cells L⁻¹ in the mouth of Bojana river. On the surface layer maximum microplankton abundances were on the order of 10^6 , as it is present in the other eutrophic region [3].

Fig. 2. Means values of microplankton abundance

Diatoms dominated the phytoplankton community throughout the study period period with maximum on surface $(2.51 \times 10^6 \text{ cells L}^{-1})$ in July. Abundance of dinoflagellates increased in summer, but diatoms were the most abundant. Some species appeared throughout the study. Some of them are: *Thallasionema nitzschioides, Pseudonitzschia spp., Prorocentrum micans, Gymnodinium spp.* Concentration of chlorophyll *a* in August was 2.675 mg/m³, when the fourth peak of microplankton abundance occurred. In July concentrations were lower (from 0.80 to 1.69 mg/m³). These changes can be explained by different photosynthetic activities, in different cell size fractions, and different phytoplankton composition [4].

Conclusion

Maximum values of phytoplankton abundance and diversity in the summer period were caused by untreated sewage waters. The change of environmental conditions due to human activities in the Montenegrin coast are rapid, and permanent seawater monitoring is necessary.

Abstract

Cette étude a révélé la présence de 18 espèces toxiques appartenant aux groupes des dinoflagellés et des cyanobactéries dans le golfe de Gabes. Les cyanobactéries toxiques sont composées d'une seule espèce "opportuniste" *Pseudoanabaena galeata* qui représente 11% du phytoplancton total et 74% du phytoplancton toxique. 17 espèces de dinoflagellés toxiques forment à elles seules 5% du phytoplancton total et 36% du phytoplancton toxique. L'espèce *Karenia selliformis* représente 18% du phytoplancton toxique. La dynamique de ces différentes espèces toxiques est fortement dépendante des conditions hydrologiques dans le golfe de Gabès. *Keywords: Gulf Of Gabes, Phytoplankton, Hydrography, Toxic Blooms*

Introduction

Le développement des blooms phytoplanctoniques contribuant à la formation des eaux colorées est en expansion tant par leur nombre que par leur fréquence et intensité [1]. Les eaux colorées sont nocives à la santé humaine, notamment lorsqu'il s'agit d'un développement d'espèces phytoplanctoniques toxiques [2], [3]. Les efflorescences d'algues toxiques ont été décrites en Méditerranée [4] notamment dans le golfe de Gabès depuis 1935 [5]. Dans cet écosystème, une prolifération excessive d'une cyanobactérie *Oscillatoria* sp. récemment appelée *Trichodesmium erytreum* a été observée au mois de juillet 1988 [6]. **Matériel & Méthodes**

Dans le cadre d'un projet intitulé "POEMM (LR02INSTM04" quatre campagnes d'échantillonnage à bord du navire de recherche océanographique et halieutique 'Hannibal R/V' ont été réalisées à différentes périodes de l'année (juillet 2005, mai-juin 2006, septembre 2006 et mars 2007) [7]. Durant chaque campagne, 30 stations ont été prospectées afin de réaliser une étude qualitative et quantitative des communautés phytoplanctoniques toxiques. L'étude qualitative et quantitative du phytoplancton a été réalisé en utilisant un microscope à phase inverse selon la méthode d'Utermöhl [8].

Résultats & discussion

L'étude qualitative et quantitative du phytoplancton total a montré la présence de 172 différentes espèces appartenant à 7 groupes [7]. Au cours de cette étude, nous avons identifié 18 espèces toxiques, appartenant essentiellement aux groupes des dinoflagellés et des cyanobactéries et qui représentent respectivement 5 et 11% du phytoplancton total. Les cyanobactéries toxiques, représentés par l'espèce Pseudoanabaena galeata, constituent 74% de la flore cyanobactérienne totale (Figure 1). Les dinoflagellés constituent 36% de l'abondance totale du phytoplancton toxique. Ils sont composés de 17 espèces toxiques dont la plus importante est Karenia selliformis qui représente 18% de la totalité des espèces toxiques (Figure 1). La thermocline (mai-juin 2006) est caractérisée par une nette dominance de Pseudoanabaena galeata représentant 88% des espèces toxiques (Figure 1). Cette espèce reste aussi dominante (71%) avec l'établissement d'une stratification thermique (juillet 2005) ; mais, suite à l'augmentation de la température, une stratification thermique s'est installée en septembre 2006, et nous avons observé une nette dominance de Karenia selliformis (74% des espèces toxiques). En revanche, Pseudoanabaena galeata montre une faible abondance ne dépassant pas les 0,5% des espèces toxiques. Le même résultat est observé dans le golfe de Gabès en octobre 2000, où 10 espèces toxiques sont présentes dont Karenia selliformis est la plus abondante [9]. Néanmoins, d'après Turki et al. [9], une faible densité de l'espèce toxique Karenia a été observée dans le nord-est du golfe de la Nouvelle Zélande. Lorsque la colonne d'eau est bien mélangée (mars 2007) on note une abondance excessive de Pseudoanabaena galeata (88% des espèces toxiques). Le même phénomène s'est manifesté dans différentes zones du golfe de Gabès durant les années 90 [5].

Fig. 1. Abondance relative des différentes espèces phytoplanctoniques toxiques au niveau du golfe de Gabès durant quatre campagnes d'échantillonnage (2005-2007)

DETECTION OF ANTIMICROBIA ACTIVITY IN SPONGE SPECIES FROM TUNISIAN COAST (CENTRAL MEDITERRANEAN)

Monia El Bour¹*

¹ National Institute Of Sea Sciences and Technologies - monia.elbour@instm.rnrt.tn

Abstract

To investigate antibacterial activities in sponges, we test 53 samples collected from different areas in Tunisian coasts. Three species (hymeniacidon sp, Fsciospongia sp and Aplysina aerophoba) shown antibacterial activities against several Gram neagtive pathogen bacteria. Sponge species represent source of several antibacterial compounds. *Keywords: Coastal Waters, Bacteria, Biotechnologies*

Introduction

Sponges were described as source of different bioactive compounds (antiviral, antitumoral, antibacterial..etc) with great benefit for pharmaceutical industry. Previous studies highlighted antimicrobial activity of sponges and pointed them as most significant invertebrate producers [1]. Here we report results of antimicrobial activities revealed from Tunisian sponge species.

Materials and methods

Sponges (53 samples) were collected in shallow coastal water (2 and 6m) from different Tunisian coastal areas. Their identification was based on morphology of spiculs and microscopic observations of their skeletal structures. Extraction of their bio products was realized using 2 solvents: acetone and methanol. All extracts obtained were tested by diffusion method against different bacterial species: *Vibrio alginolyticus, Pseudomonas aeruginosa, Aeromonas hydrophila, Escherichia coli* and *Salmonella Typhimurium*.

Results and discussion

Sponges collected (53 samples) belonged to order of Dictyoceratida and were subdivided in 4 families: *Irciniidae*, *Thorectidaes*, *Halichondriidae* and *Spongidae*. Three isolated species shown large inhibition of bacteria: *Hymeniacidon sp*, *Fasciospongia sp* and *Aplysina aerophoba* with strong activities on all pathogens tested.

Inhibition obtained was variable depending on bacteria species, category of solvent and sampling areas. Thus, most significant activity was reported for *Fasciospongia sp* on *Salmonella typhimurium* using acetone solvent extract. Such results were in agreement with [2]. Depending on sampling area, *Fasciospongia sp* from Kerkennah and *Hymeniacidon sp* from Salammbô have most significant activities compared respectively to those of Bahiret El Biban and Korbous. Since local sponge species seemed to harbour interesting bioactive components, we continue further investigations on the specific bioactive compounds and their eventual relation with epibionts.

Fig. 1. Identification of antibacterial activity of *Hymeniacidon sp* from Salammbô and Korbous against different bacterial species. **M**: Methanol extracts, **A**: Acetone extracts

Abstract

Salmonella enterica ser. Typhimurium a été identifiée par utilisation de la technique PCR Multiplex chez la palourde *Ruditapes* decussatus et comparée aux souches de référence C52 et LT2. Leur virulence a été mise en évidence par tests de cytotoxicité. D'après les résultats obtenus, un même sérotype présente deux profils différents de pathogénicité et le titre de cytotoxicité chez les Salmonelles Typhimurium isolées du milieu naturel demeure relativement élevé.

Keywords: Bacteria, Bivalves, Gulf Of Gabes

Introduction

Un nombre considérable de gènes (de l'ordre de quelques centaines) doivent être mobilisés par *Salmonella* Typhimurium pour échapper aux mécanismes de défense de l'hôte. Les facteurs de virulence spécifiques sont codés par des îlots de pathogénicité (un à plusieurs gènes associés à la virulence), en plus des îlots génomiques [1], [2]. Cette étude décrit l'identification de *S*. Typhimurium par des gènes de virulence, grâce à la technique de PCR multiplex.

Matériel et méthode

Extraction de l'ADN chromosomique: L'extraction de l'ADN génomique est effectuée selon le procédé de « boiling method » à partir de cultures bactériennes de *Salmonella enterica* serovar Typhimurium dont six sont isolées à partir de la palourde *Ruditapes decussatus* et deux sont des souches référence respectivement S. Typhimurium C52 et S. Typhimurium LT2 [3]. L'amplification génique par PCR multiplex : trois paires d'amorces ont été choisies, PhoP, Hin et Hli, donnant respectivement des bandes de 299 pb, 236 pb et 173 pb. Test de cytotoxicité : le surnageant des cultures bactériennes qui contient les toxines est mis en contact avec des Cellules Vero, cette suspension est incubée à 37°C dans une atmosphère à 5% de CO₂ pendant 48 à 72 h [3].

Résultats et Discussion

Les résultats de la caractérisation moléculaire de *Salmonella* Typhimurium sont résumés dans le tableau 1. L'amorce PhoP amplifie une région de 299 pb, cette amorce non spécifique des Salmonelles, caractérise également la présence de coliformes. Les amorces Hin et Hli, spécifiques des gènes impliqués dans le contrôle du système de variation de phase chez les Salmonelles, amplifient respectivement une région de 236 pb et 173 pb. Une seule de ces bandes suffit pour détecter une *Salmonella* Sp. (Figure 1). Ces résultats sont concordants avec les travaux de Ben Salem [4] et l'étude de Way *et al.* [5].

PHYTOPLANKTONIC COMMUNITIES IN EUTROPHIC COASTAL LAGOONS OF THE NORTHERN ADRIATIC SEA, ITALY.

Chiara Facca ¹*, Adriano Sfriso ¹ and Sonia Ceoldo ¹

¹ Department of Environmental Sciences, University Ca' Foscari, Venice, 30123, Italy - facca@unive.it

Abstract

Water column samples were collected in some coastal lagoons in the north-western Adriatic Sea (Italy) in order to evaluate the phytoplankton taxonomic composition and cell abundance. These areas are strongly affected by anthropic exploitation and impacted by industrial, agricultural and urban discharges. Except for the records of the Venice Lagoon, where monthly samplings were carried out in two sites from March 2008 to February 2009, in the other basins the samples were collected twice in several stations. Flagellates often represented the bulk of the community, whereas dinoflagellates were almost negligible. Diatoms were occasionally dominant in spring or summer. Cell abundance varied between 0.39 and 30.5 x 10^6 cells/L. *Keywords: Phytoplankton, Nutrients, Lagoons*

Introduction

The Italian coastline of the North Adriatic Sea displays a complex system of lagoons (Fig. 1), which receives the river discharges from a wide, densely populated and highly industrialized drainage basin. This determines high nutrients and pollutant inputs. Even though the most exploited basin is the lagoon of Venice, also the other wetlands present important anthropic activities; in particular extensive and intensive aquaculture installations are renowned in the area of the Po river delta lagoons. In order to describe and compare the environmental conditions in that basins water samples were collected to measure phytoplankton communities and nutrient concentrations.

Materials and Methods

Water samples were collected in 19 stations in July 2007 and in May 2008 in the Grado-Marano lagoon, which is characterized by high nitrate and mercury inputs. In the lagoon of Venice the campaigns were carried out in two sites from March 2008 to February 2009. The sampling stations were located between the Venice historical centre, where a sewage treatment plant does not exist, and the Porto Marghera industrial area. In the Veneto area of the Po river delta, water column was sampled in 17 sites in October 2008 and in July 2009. Phytoplankton was determined according the Utermöhl's method [1] and nutrients according the Strickland and Parson's procedure [2].

Fig. 1. Map of the study area. Circles marked the sampling basins.

Results and discussion

Phytoplankton cell abundance varied more or less in the same range in the lagoons of Grado-Marano and Venice with minimum of 0.23-0.39 x 10^6 cells/L and peaks of 17.5-22.1 x 10^6 cells/L. In the Po river delta lagoons, maxima values reached up to 30.5 x 10^6 cells/L. Even though the samples were collected in different periods and with different frequency, the results allowed to highlight some particular conditions. In the case of the Grado-Marano lagoon, the highest values was observed in July 2007 close to the river discharge, where nitrate

concentration was >50 µM and it was due to Cylindrotheca closterium and Nitzschia frustulum bloom. In a couple of basins in the Po river delta lagoon system, the phosphorus concentrations were comprised between 5 and 25 μ M during the October 2008 sampling campaign, but the phytoplankton community did not exceed 10⁶ cells/L, probably because of the low light availability. In the lagoon of Venice the community composition and cell abundance in the two sampling sites appeared to have some interesting differences, mainly due to the different depth and water circulation. The annual mean cell abundance was, in fact, higher in the site near the canal (4.43 x 10⁶ cells/L) than in the shallow bottom area (2.80 x 10⁶ cells/L). Moreover, both nanoflagellates and Skeletonema marinoi blooms were more marked near the canals than in the shallow bottoms, where Thalassiosira sp. and Cryptophyceae prevailed. In the Po river delta lagoons, the highest abundance was observed in July 2009, due to a equal contribute of flagellates and diatoms. Except for few cases, flagellates, in particular unidentified nanoflagellates, were always the dominant group. Dinoflagellates, on the contrary, never exceeded 2.4% of cell abundance, being negligible in most of the records. Diatoms displayed high variability ranging between 1.8 and 81.8%. It was observed that diatoms happened to be significantly abundant in summer in the lagoons of Grado-Marano and Venice, and in autumn in the Po river delta lagoons. Even though the species occurrence was quite similar in all the studied sites, small colonial centric diatoms such as Chaetoceros spp. prevailed in the Po river delta lagoons whereas in the lagoons of Grado-Marano and Venice benthic diatoms seemed to be more frequent.

MICROBIAL DESULFURIZATION OF EGYPTIAN CRUDE OIL BY A YEAST STRAIN ISOLATED FROM OIL POLLUTED SEA WATER

Laila Abdel Moneim Farahat ¹* and Nour Shafik El-Gendy ¹

¹ Egyptian Petroleum Research Institute, Nasr city-Cairo, Egypt - lailafarahat@yahoo.com

Abstract

Sulfides and thiophenic compounds specially Benzothiophene and Di-benzothiophene (BTs and DBTs) are the main sulfur types present in crude oil and its distillates (diesel) where their removals are very difficult by hydrodesulfuri-zation (HDS). As an alternative method is microbial desulfurization by *Candida parapsilosis* Nsh45, a locally isolated microorganism, from Egyptian hydrocarbon sea water. It was found that it is very efficient to remove up to 82% of 12.400 ppm sulfur content in diesel oil and \approx 75% from Belayim mix crude oil, respectively keeping the calorific value unchanged.

Keywords: Biotechnologies, Petroleum, Pollution, Red Sea

Introduction

In Egyptian crude oil, sulfur content ranges between (0.04- 4.19 wt.%) including DBTs and BTs and another thiophene compounds. The presence of sulfur has been correlated with the corrosion of pipelines, pumping and refining equipments. Hydrodesulfurization (HDS) is the current method used for sulfur removal, which is not only energy and capital intensive but also suffers from limitations in the removal of typical sulfur bearing aromatic compounds such as (DBT) and its derivatives. Microbial removal of organic sulfur from crude oil offers an attractive route because of the mild operating conditions afforded by the biocatalyst [1] offering significant cost and safety advantages. The first microorganism capable of S removal Rhodococcus rhodochrous (IGTS 8) that selectively cleaves sulfur from DBT through the 4S' pathway [2] In this work we study the BDS activity of a new isolated yeast strain *Candida parapsilosis* N.Sh 45 [3] on DBT. It is then applied to desulfurize diesel and crude oil comparing it with the standard strain *Rhodococcus erytrhopilis* (IGTS8).

Experimental work: The experiment was done using sterilized oil and basal salts medium (BSM) to study the ability of *Candida parapsilosis* NSh 45 to grow and desulfurize egyptian diesel of initial sulfur content (12,400 ppm) and Belayim mix crude oil (BX 2.76% sulfur). The desulfurization was carried here with the ratio of oil/BSM 1/3 (v/v) at pH 7 and inoculation size 10%. The cultures and the control oil were incubated at 30°c and checking speed 200 rpm. Diesel oil was subjected to GC-FID analysis. Sulfur removal was determined using x ray sulfur meter (ASTM, D4294). Calorific value and dynamic viscosity were also measured to determine the effective microbial treatment. **Results and discussions**

Identifications of the metabolites using GC-MS suggested that NSh 45 metabolized DBT trough the 4S pathway. This result is in agreement to that obtained by Baldy *et al* [4].

Biodesulfurization of Diesel oil: The effect of microbial treatment on diesel oil was studied after 7 days of incubation. The GC –FPD chromatogram of biodesulfurised diesel oil revealed extensive depletion of sulfur compounds (mainly BTs and DBTs) across the entire boiling range of the oil, with BDS potential of about 82% as shown in the figure.

Fig. 1. GC-FPD chromatogram showing OSC in diesel oil

Biodesulfurization of crude oil: The effect of microbial desulfurization treatment of belayim mix 2.76% was studied after 7 days of incubation. Gravimetric determination of asphaltene content showed a decrease in its weight percentage associated with the decrease in sulphur content of the crude oil. GPC data of the average molecular weight in the following table support the above results where there was a general decrease in the average Mwt of asphaltene fraction and decrease in the dynamic viscosity about 69.62% [5].

Tab. 1. Effect of crude oil BDS on; asphaltene and maltene ratios, asphaltene Mwt and viscosity

•				
Sample	Control	NCL45	ICTCO	
Parameter	Solutor	1101140	101 30	
S-content (%wt.)	2.76%	0.70%	0.99 %	
%BD S		75%	64.0 %	
% Maltene	92.00 %	94.64%	93.97 %	
% Asphaltene	8.00 %	5.36 %	6.03 %	
Asphaltene Mwt.	14,384	10,371	10.978%	
Miscosity (cp)	665	199	236	

Conclusion

It was found that *Candida parapsilosis* is very efficient to remove up to 82% of 12,400 ppm sulfur content in diesel oil and approximately 75% from Belayim mix crude oil with initial sulfur content of 2.76% compared to the standard strain *Rhodococcus erythopilis* IGTS8 wich removed up to 46% and 64% from the diesel and crude oil respectively.

PHOTOSYNTHETIC PIGMENTS IN MUCILAGE AGGREGATES AND SURROUNDING WATER IN THE NORTHERN ADRIATIC

Vesna Flander-Putrle^{1*} and Alenka Malej¹

¹ Marine Biology Station, National Institute of Biology - flander@mbss.org

Abstract

Massive amounts of mucilage aggregates have been observed in different marine environments worldwide but the northern Adriatic seems to be most severily affected. Our observations indicated that the phenomenon passed through a characteristic "life cycle" and variable phytoplankton composition assessed by pigment biomarkers (HPLC). The number of phytoplankton groups decreased as the aggregates aged and diatoms increased in relative biomass (up to 92.7 %). Phytoplankton biomass in seawater was similar in years with and without mucilage. Significantly higher contributions to the total biomass of 19 '-hexanoyloxyfucoxanthin-containing phytoplankton (prymnesiophytes) were found in the upper 10 m preceding the mucilage phenomenon, followed by prevalence of diatoms in summer.

Keywords: Adriatic Sea, Mucus Aggregates, Phytoplankton, Pigments

Introduction

Several types of aggregates are observed in the northern Adriatic. Occasionally, masses of mucilage remained suspended in the water column of the northern Adriatic for up to several months during the summer stratified season (from May to September). Calm weather favours aggregation, whereas intense mixing during strong north-easterly winds can cause a decay of the event during its early phase. Eventually, mucilage accumulates on the shores and bottom and generally disappears by autumnal vertical mixing although recently it was observed also in other seasons. The main goal of our research was to elucidate and quantify the composition of the phytoplankton assemblages in the different types of macroaggregates.

Methods

Samples of mucilage aggregates were collected in the eastern part of the Gulf of Trieste during summers 1997 and 2000, on the surface and in the water column. Seawater samples for a time course of pigments in ambient water were taken monthly (from May to September 1997 and 2000) at 6 different depths. Water samples were filtered through GF/F filters, mucilage samples were concentrated, and both immediately frozen until analysed. Observations of the evolution of mucilage phenomenon were carried out weekly by SCUBA divers, who recorded the phenomenon. Using HPLC (High Performance Liquid Chromatography) pigment analysis we determined the phytoplankton community structure.

Results

Several kinds of mucilaginous aggregates were observed during this study. Different forms of mucilage may co-exist in the water column. Phytoplankton biomass in the mucilage samples was very high (from 7.9 μ g/g to 390.8 μ g/g of chlorophyll a per unit of dry mass of mucilage). Generally, chlorophyll a per dry mass was lower in loose networks of mucilage in the layer above the thermocline compared to its concentration in the mucilage clouds and compact yellowish-brown mucilage found predominantly in, and below the thermocline layer. As the aggregates aged diatoms increased in relative biomass (up to 92.7 %). Cluster analysis of mucilage data indicated three, rather distinct mucilaginous groupings: (1) mucilage at the sea surface, (2) mucilage from the water column around the thermocline layer, and (3) "aged" mucilage samples collected deeper and later in the season. The surface group appears to be more similar to the deepest group than to the intermediate group located between the surface and deep groups. PCA performed with the contribution of seven phytoplankton groups in different mucilage samples from 2000, was used to determine the course of mucilage development. An ordination plot produced showed the progression of fresh mucilaginous aggregates (with prymnesiophytes and silicoflagellates), to intermediate mucilaginous stages (heterogeneous phytoplankton community), and to aged mucilaginous aggregates (with prevalence of diatoms). Comparisons of the succession of phytoplankton groups in the water column showed differences between mucilaginous and non-mucilaginous years. The former were characterised by a higher contribution of prymnesiophytes in spring, and the prevalence of diatoms in summer. The single pigment index, Fp, used to capture the trophic status of an ecological province [1], showed a clear difference between mucilaginous and non-mucilaginous years. In April-May (1997 and 2000), before the appearance of mucilage, Fp ratios were lower compared to the nonmucilaginous years. In contrast, when mucilage occurred in June-August, Fp ratios were higher than during non-mucilaginous years. A similar pattern was observed in year 2005, when the F_p index was very low (0.20±0.07) during April-May due to the high contribution of 19'-hexanoyloxyfucoxanthincontaining phytoplankton - prymnesiophytes. Later on (in June) we observed the beginning of mucilage formation, but due to the weather conditions that followed, with summer storms and strong winds, the mucilage phenomenon did not develop.

Discussion and conclusions

The mucilage phenomenon shows an evolution [2]. Weekly or more frequent observations during the summers of 1997, 2000, 2002 and 2004 indicated that the phenomenon passed through a characteristic "life cycle". Phytoplankton composition in loose mucilaginous aggregates above the thermocline at different periods was very similar, indicating that fresh mucilage may form in the upper water column over a period of several weeks to months. The loose, web-like mucilage that developed earlier in the sequence of mucilage formation seemed, therefore, to be a favourable microenvironment for the development of autotrophs, resulting in higher chlorophyll a per dry mass in the more compacted mucilage clouds found deeper in the water column. Overall, the fucoxanthin concentrations revealed that diatoms were the main contributor to phytoplankton biomass in the mucilaginous aggregates. In contrast, phytoplankton biomass in seawater during a mucilage event did not significantly differ from years when mucilage did not occur. These findings indicate that the development of macroaggregates did not significantly affect the phytoplankton biomass in surrounding seawater. Our results suggest that the role of prymnesiophytes and other small flagellated forms in the initiating of mucilage development are crucial, and indicate the F_p index during spring as possible predictor of mucilage appearance.

SEM MICROPHOTOGRAPHS OF BIOFOULING ORGANISMS ON FLOATING AND BENTHIC PLASTIC DEBRIS

J. Fortuño ¹*, M. Masó ¹, R. Sáez ¹, S. De Juan ¹ and M. Demestre ¹ ¹ Institut de Ciències del Mar (CSIC). - jmanuel@icm.csic.es

Abstract

Results from the first electron microscopic observations of both floating a bentic marine plastics debris are presented. Plastics were collected near the marine protected area of the Cap de Creus(Catalan Coast). Floating plastics microphotographs showed fungi and bacteria as the first settlers and a high diversity community of microalgae mainly diatoms and some dinoflagellates. Benthic plastics are less colononized by microorganism and they are recovered by characteristic muddy sediment from the trawled fishing grounds .The results are discussed taking into account the paramount importance to improve knowledge of the marine plastic debris dynamics and consequently their impact in the marine environment. *Keywords: Algae, Biodiversity, Fouling*

Introduction

Marine debris is defined as any manufactured or processed solid material that enters the marine environment. Plastics account for the largest fraction of marine debris, which average proportion varies between 60 to 80% of total marine debris. In many regions, plastic materials constitute as much as 90 to 95% of the total amount of marine debris [1]. Apart from the widely evidenced negative effect of plastics on marine mammals, turtles and seabirds, plastics can also indirectly alter marine biodiversity by other less known actions, such as help in the introduction of alien species by floating plastics [2, 3]. Marine debris doubles the rafting opportunities for biota, assisting the dispersal of alien species [4]. This work aims to improve the knowledge of plastics debris effect both surface and bottom presenting images of the settler plastic microorganisms using the scanning electronic microscope (SEM) from areas subject to different levels of fishing impact.

Methods

Plastics were collected In the framework of the COMSOM project (CTM2008-4617).Samples were fixed in 2% glutaraldehyde. After dehydratation in etanol series, were critical point dried in liquid CO₂, sputtered with gold-palladium and examined with a Hitachi S-3500N operated at 5 kV.

Results and Discussion

SEM microphotograph of floating plastics debris shows the substrate covered by fungi and bacteria and a very diversity community of microalgae mainly benthic diatoms of the genus Thalasionema sp., Closterium sp., Tabularia sp., Navicula sp., Achnantes sp., Thalassiosira sp., Cylindrotheca. Dinoflagellates and resting cyst have been observed in some occasions. SEM microphotograph of benthic plastics shows, in general, a very distinct aspect. They are recovered by characteristic muddy sediment from the trawled fishing grounds and presented a less colonized substrate by microorganism. Diatoms are present but in rare occasions. It has been observed quite often spawns of unidentified organisms. This study of the microorganism attached to plastics debris show the high potentiality of SEM analysis to study plastic debris biofouling. SEM micrographs has been applied to study biofouling organism in different interfaces, but this is the first study of SEM microphotograph applied to marine plastics debris. Plastic accumulation in the marine environment represents an extra impact source for marine biodiversity that is already threatened by other factors like climate change, overfishing and many other anthropogenic activities. But evidences are still anecdotic, which implies an urgent need of increasing our knowledge on this subject.

ASSESSMENT OF THE ECOLOGICAL STATUS OF THE NORTHERN ADRIATIC COASTAL WATERS: TESTING AND ADAPTING TWO PHYTOPLANKTON INDICES

Janja France ¹* and Patricija Mozetic ¹

¹ National Institute of Biology, Marine Biology Station Piran - france@mbss.org

Abstract

As stated in the WFD, the response of phytoplankton to eutrophication of coastal waters needs to be assessed by evaluating biomass, composition and abundance, and blooms. We present the application of two indices (I_E , I_{SS}), which goes beyond the only metrics (Chlorophyll *a* concentrations) considered till now in the Mediterranean intercalibration group. *Keywords: Adriatic Sea, Phytoplankton, Monitoring, Bio-Indicators, Coastal Waters*

INTRODUCTION

Few classifications of the phytoplankton ecological status of European coastal waters that consider all parameters (biomass, composition, abundance, and frequency and intensity of blooms) listed in the Water Framework Directive (WFD, 2000/60/EC), have been tentatively described to date. All attempts to construct a useful index are from coastal waters of North-East Atlantic and Baltic Sea [1, 2, 3].

Phytoplankton biomass is the only parameter that has been calibrated in the Mediterranean intercalibration group (2008/915/EC), pointing out the difficulty of describing the phytoplankton community and its changes with proper metrics especially in the relatively oligotrophic Mediterranean Sea as compared to north-western European seas. This work presents the application of two still not fully developed indices in the northern Adriatic coastal waters (Gulf of Trieste).

MATERIAL AND METHODS

Phytoplankton data were obtained during Slovenian national monitoring program at five coastal stations. Reference conditions (RC) were determined on a data set of a site in the Gulf of Trieste with slight anthropogenic influence. Assessment period of two years only (2007-2008) was considered to estimate the recent trophic conditions of five sampling stations. Two indices described by Devlin et al. [3] were tested. 1. Index of elevated phytoplankton counts (I_E) is composed of frequency of elevated Chl-*a* records, frequency of high phytoplankton counts and frequency of high count of any single taxa. 2. Index of seasonal succession (I_{SS}) assesses the shift of the seasonal cycle of phytoplankton functional groups from RC.

RESULTS AND DISCUSSION

Values of $I_{\rm E}$ separate the five stations into two groups: stations F, MA and C4 with $I_{\rm E}$ lower than reference value, and stations K and DB2 with higher values (Tab. 1). We estimate that, subjected to additional analysis, this preliminary results could be used to set the boundary between very good and good ecological status.

The second index, $I_{\rm SS}$, needs an initial construction of reference standardized seasonal occurrence curves for the four functional groups. There is a difference between the values of the total $I_{\rm SS}$ among stations (Tab.1), but the results nevertheless offer no possibility to distinguish between ecological statuses of the stations.

We consider $I_{\rm SS}$ less suitable classification tool as compared to the $I_{\rm E}$ for at least two reasons. First, the stations are too similar as regards the phytoplankton community structure and, secondly, seasonal succession of phytoplankton species can be hardly assessed solely on monthly basis due to their fast generation times. There were several problems encountered during this initial phase of phytoplankton index testing. One problem is represented by the limited number of available data, e.g. two years of monthly data in comparison to 6 years assessment period foreseen in the WFD. The second and major problem relates to biomass and structural changes observed in the last decades in the phytoplankton community [4], which makes the establishment of the reference conditions a difficult task.

CELLULAR AND MOLECULAR ADAPTATIONS TO MEDITERRANEAN DEEP SEA HYPER SALINES

LAKES

Bruno Franzetti 1*

¹ Institut de Biologie Structurale. UMR 5075 CNRS - franzetti@ibs.fr

Abstract

Mediterranean Deep Halophilic Anoxic lakes (DHAL's) are unique ecosystems in which microorganisms have to face hyper salinity and high pressure as main stressor agents. To understand the origin and the environmental adaptation of these halophilic microbes it is important to specify their limits of viability and the molecular modifications of their proteins. A study combining microbiology, biophysical and electron microscopy will be presented as well as a preliminary work on the characterization of a DHAL enzyme isolated by metagenomic screening.

Keywords: Salinity, Anoxia, Bacteria, Biotechnologies, Deep Sea Basins

Cellular and molecular adaptations to Mediterranean deep sea hyper salines lakes Mediterranean Deep Halophilic Anoxic lakes (DHAL's) are unique ecosystems in which microorganisms have to face hyper salinity and high pressure as main stressor agents. To understand the origin and the environmental adaptation of these halophilic microbes it is important to specify their limits of viability and the molecular modifications of their In order to investigate the possibility that the endogenous proteins. halophilic Archaeal communities found in DHAL's could be the result of surface ensemencements, we have studied the effects of salt stress on the extreme halophile Halobacterium salinarium. Gene expression and enzyme activity studies combined with in vivo molecular dynamics measurements (neutron diffusion) showed that low salt conditions represent a stressor equivalent to high temperature for extreme halophiles. We found however that a large proportion of the halophilic cells can survive to drasic reductions in environmental salt concentrations, first by concentrating KCl inside the cytosol and then by undergoing dramatic morphological changes. The stressed archaea were studied by electron and confocal microscopy. The result revealed cellular ultrastructural modifications that differ from other known microbial survival forms such as sporulation. The Halobacterium survival form was found to be able to resist normal sea-water conditions for long periods. A esterase from DHAL was identified from metagenomic screening by Ferrer et al. It exhibited salt and pressure-dependent activation. The corresponding ORFs was cloned in expression vectors and purified as soluble material. Biophysical measurements showed that the protein is a monomer that exists is solution as two conformational states controlled by the redox conditions. The protein is thus activated in DHAL anoxic conditions. Ferrer et al. 2005. Microbial enzymes mined from the Urania deep-sea hypersaline anoxic basin. Chemistry and Biology. 12, 895-904

DEVELOPMENT OF A MICROARRAY-BASED ASSAY FOR THE DETECTION OF HARMFUL DINOFLAGELLATES

L. Galluzzi ^{1*}, A. Cegna ¹, S. Casabianca ¹, A. Penna ¹, N. Saunders ² and M. Magnani ¹ ¹ Department of Biomolecular Sciences, University of Urbino - luca.galluzzi@uniurb.it

Abstract

The high throughput, automation possibility and specificity of microarray-based detection assay, makes this technology very promising for qualitative HAB (harmful algal bloom) detection. In this study, we set up an assay based on the use of microarrays for the simultaneous detection of 9 dinoflagellate species/clades in Mediterranean Sea. The array format, hybridization and staining protocols were optimized, and the probe specificity and sensitivity were evaluated either with cultured microalgae or field samples, demonstrating the applicability of this assay for molecular monitoring of toxic microalgae. *Keywords: Monitoring, Dinoflagellates, Biotechnologies*

In the last years, several molecular methods having ribosomal DNA (rDNA) as target have been developed for monitoring HAB species (mainly dinoflagellates) [1]. In this context, the use of DNA microarrays represents a promising molecular approach, able to detect simultaneously a number of DNA sequences in an unknown sample. The application of microarray technology for the detection of HAB species has been illustrated by several recent publications [2, 3, 4, 5], in which the target DNA was represented by 18S and/or 28S rDNA genes and the length of the probes immobilized on a glass slide was between 18 and 25 nucleotides. It is also noteworthy that some authors, to reduce the number of false positives, adopted a hierarchical probe approach [2, 3, 4]. In this study, a microarray-based assay for the simultaneous detection and monitoring of 9 dinoflagellate species in the Mediterranean Sea was developed. The target dinoflagellates included Alexandrium andersoni, A. tamarense ME, A. tamarense WE, A. catenella, A. minutum, A. taylori, A. pseudogoniaulax, Protoceratium reticulatum and Lingulodinium polyedrum. The species-specific probes were 45-47 nucleotides in length, and were designed on the ITS1-5.8S-ITS2 rDNA region using the software Oligoarray 2.1. These probes were designed to identify selected dinoflagellate species in the Mediterranean Sea, plus several non-Mediterranean strains. Due to probe length and the rDNA region chosen, it was not possible to adopt a hierarchical probe approach. Then, to reduce the number of false positives, two specific probes were designed for each species. Moreover, a positive control probe and a negative control probe were included as microarray performance quality control. The microarray slide format consisted in 24 subarrays, each made of 18 columns and 22 rows. A single subarray contained 10 replicates of each probe (including positive and negative control probes) for a total of 200 spots, to maximize statistical significance of the results. The target rDNA region was PCR-amplified using conserved primers, and labeled by incorporation of dUTP-biotin. Detection of the hybridized PCR products was accomplished using Cy5-streptavidin. The hybridization protocol was optimized and the specificity and sensitivity of the method were tested using genomic DNA extracted from 20 cultivated strains. The value of mean background of the entire subarray plus three standard deviations was considered as threshold for a positive signal. The probe list and the hybridization specificity results are illustrated in Fig. 1.

Fig. 1. Summary of specificity tests for the microarray probes (on the left). Target DNA consisted in the PCR-amplified ITS1-5.8S-ITS2 rDNA region of strains indicated in the upper part of the figure. n.a.: not available.

It is noteworthy that, when amounts of PCR product ≥100 ng of A. andersoni

and A. pseudogoniaulax were used, a false positive signal appeared in probes cate/tama2, and tay2 / P_reticulat2, respectively. Nevertheless, concerning A. pseudogoniaulax, the false positive signals in probes tay2 and P_reticulat2 disappeared when amounts of PCR product ${\leqslant}10$ ng were used for hybridization. The false positive results observed in probes cate/tama2, tay2 and P_reticulat2 did not affect the reliability of the assay because the fluorescence on probes cate/tama1, tay1 and P_reticulat1 was below the threshold. The assay specificity was maintained also mixing different PCR products in the same hybridization mixture or amplifying genomic DNA extracted from 4 different Alexandrium species. Concerning the sensitivity of the microarray system, the species-specific probes allowed to detect up to 2 ng of labeled PCR product amplified from a DNA extracted from pure cultures. The microarray potential was tested with net samples from northern Adriatic Sea, unspiked or spiked with known amounts of target dinoflagellate species. Results confirmed the specificity observed with previous experiments and revealed the presence of A. pseudogoniaulax cells in Northern Adriatic (confirmed by Utermohl counts) (Fig. 2). Moreover, using spiked samples, it has been established that the sensitivity of the assay in net samples reached 1 cell/ml, with some variability from one species to another. The optimized procedure of the assay is rapid (1 working day) and allows the processing of up to 24 samples on a single slide, making microarray application attractive for monitoring programs.

Fig. 2. Microarray analysis results of PCR products amplified from a net sample. The PCR-amplified positive control DNA (10 ng) was added in all hybridization mixtures. Asterisks indicate values above threshold

Abstract

Knowledge of phytoplankton species composition is important to understand bloom events in the coastal areas; it is also crucial to have information on the presence of novel and potentially introduced taxa and to confirm the recurrent events of a species. In the case of dinoflagellates, the alternation between the life stages (vegetative and resting stage) has profound implications for population dynamics. Cyst assemblages in surface sediments represent a temporally integrated repertoire of species diversity. Therefore, cyst "seedbed" maps provide baseline information for monitoring purposes, to depict geographic patterns of harmful species, and to detect the introduction of new species.

Keywords: Biodiversity, Biogeography, Life Cycles, Toxic Blooms, Dinoflagellates

Introduction

The predictability of harmful algal blooms (HABs) is one of the most complex subjects of study and one of the major setbacks is improving our knowledge of life strategies of the species and their links to the surrounding environment. Dormant cells are well-recognized stages of the life cycles of HA species. The duration of the dormant phase is often much greater than that of the multiplicative vegetative one. The dormant cells are non-motile hence, during the resting period, dispersion and concentration are determined by the same forcing functions that control the dynamic of passive particles in the water. Due to these features, the dormant stages contribute to the persistence and expansion of harmful species. In the EU SEED project, one of the objectives was focused in the mapping of cyst beds and seed populations in surface sediments to obtain information of species at several Mediterranean areas. The maps were produced in a range of locations and habitats. The focus of those surveys has been to asses the present or past biogeographic distribution of HA species.

Study areas

Sediment cores were taken by a scuba diver using cylindrical plastic corers (20 cm long with a diameter of 5 cm) in different target areas: Arenys harbour (Spain), Olbia and Siracusa bay (Italy) covering different number of stations. Samples were stored in the dark at 4°C until analysed. The sediments were processed for cyst concentration and separation from the sediment using a modified sodium polytungstate density gradient method [1] and analyzed by molecular PCR method using taxa specific primers [2].

Results and discussion

The results of the different areas analyzed showed that a tight linkage exists between pelagic and benthic domains but we also found species that were never recorded as motile stages in the water column and were present in sediments as resting cysts. This was the case of the following dinoflagellate species: *Pentapharsodinium cf tyrrhenicum, Scrippsiella crystallina, S. lachrymosa, S. precaria, S. trochoidea, Protoperidinium avellanum, P. claudicans, P. compressum, P. conicum, P. cf minutum, P. oblongum, P. pentagonum, P. subinerme, Zygabikodinium lenticulatum, Gyrodinium instriatum and Gymnodinium nolleri (Figure 1).*

We found that mapping the distribution of benthic stages of HA species (e.g. dinoflagellates) in superficial sediments it would allow the establishment of a baseline for the monitoring of spreading events, such as introduction of new species, and human-assisted dispersal. Embayments and hydrographically confined areas in the Mediterranean Sea act as reservoirs for planktonic dinoflagellates. During stagnant conditions, fluxes towards the sea bottom are favoured. Organic matter, cysts, and other substances accumulate in the uppermost layer of the sediments which is continually modified by addition of newly settled particles and by subsequent degradation of the accumulated material. Under these conditions, the formation of a cyst bank occurs [1, 3 and 4]. These seed banks have a high biodiversity, hosting more and/or different species of those that constitute the diversity of the vegetative population ecologically active in a present moment. Knowledge of the geographic distribution and density of cyst beds of harmful algae can help to identify risk areas under different ecological and hydrographical scenarios, providing useful information for the management of coastal areas

Abstract

The main problem in making an appropriate description of spatial and temporal cycles of phyto and bacterioplankton is the lack of long-term studies and a wide spatial distribution. We analyze data from samples collected under RADMED monitoring program implemented by the Spanish Institute of Oceanography. Stations distributed along the Spanish coast are sampled four times a year (one per season) (fig1), from the Straits of Gibraltar to Barcelona, including Balearic islands. The seasonal cycle and time evolution of phytoplankton communities are analysed to the light of environmental information provided by this multidisciplinary program. *Keywords: Western Mediterranean, Phytoplankton, Bacteria, Monitoring, Time Series*

Material and methods

The samples collected were fixed with lugol, and analyzed by inverted for identification microscony and taxonomic composition of microphytoplankton. We focus on the study of large groups (diatoms, dinoflagellates and small flagellates). To study the smaller fraction of the phytoplankton, pico and nanoplankton and cyanobacteria (Synechococcus and Prhochlorococcus) samples were fixed on board with glutaraldehyde and immediately frozen in liquid nitrogen. The determination of the abundance of picoplankton organisms was conducted with a FACSCalibur flow cytometer (Becton & Dickinson) with a laser emission of 488 nm. At each station, samples are taken at standard depths (0, 10, 20, 50, 75, and 100). In the case of microphytoplankton, which analysis requires a strong effort, samples were only taken in areas of platform, while cytometry samples were analyzed both on platform and slope.

Fig. 1. RADMED monitoring program statios

The number of samples considered varies depending on the region, since there are data from previous monitoring programs to RADMED included in this study. In all stations studied, we have picoplankton cytometry and microscopy data in the period RADMED (2007-2009), while the series for microphytoplankton microscopy are longer in some areas as Alborán, in which we also have microphytoplankton data for the periods 1994-2002 and 2002-2009 and in Balearic islands from 1994 to 2000.

Results and Conclusions

Preliminary results show an increase in picophytoplankton concentration from platform to slope, reflecting offshore oligotrophic conditions. Picophytoplankton maximum abundances deepen with higher latitudes. In all the regions studied, the annual maximum is in autumn-winter, coinciding with the end of the stratification period. Regarding to microplankton composition, in all the regions we observe a dominance of diatoms and small flagellates, being more abundant in southern regions such as the Alboran Sea (fig.2), with a maximum in spring, when nutrient concentration is higher. They also describes south-north gradient with the highest abundances in the Alboran Sea area and a decrease northward accompanied by greater depth of the peak of maximum abundance.

Abstract

Comparison of the heterotrophic bacteria and cyanobacteria (*Synechococcus* sp.) abundance and biomass in highly contrasting water bodies composed primarily of the Eastern Mediterranean (Cilician and Levantine basins), the Sea of Marmara including Bosphorus and Dardanelles and the Black Sea were made within the framework of SESAME (Figure 1). Changes in picoplankton abundance and biomass in contrasting environments were investigated in relation to their unique physical, chemical and biological properties. Seawater samples were collected from the SESAME cruises carried out during spring and fall 2008. *Keywords: Marmara Sea, Eastern Mediterranean, Cyanobacteria, Bacteria*

Picoplankton including photosynthetic picoplankton and heterotrophic bacteria, are important members of marine microbial food webs [1]. They are also important because of their sensitivity to environmental factors. The Mediterranean Sea, the Sea of Marmara and the Black Sea, which are connected to each other via the Turkish Strait System have very distinctive physical, chemical and biological properties. Heteretrophic bacteria and cyanobacteria (*Synechococcus* sp.) components of the picoplankton of these highly contrasting water bodies were studied (Figure 1).

Fig. 1. Map of the stations

Seawater samples were fixed with gluteraldehide, stained with acridin orange and filtered through 0.2 μ m pore sized nucleopore membrane filter. Filters covered with immersion oil were counted using an epifluorescent microscope. The Image-Pro Plus V 5.0, image analysis program was used for calculating cell volume. 77 fgC/1 [2] and 120 fgC/1 [3] carbon conversion factors were used for heterotrophic bacteria and cyanobacteria (*Synechoccus* sp.), respectively.

Maximum heterotrophic bacterial and cyanobacterial abundance and biomass were observed in the Sea of Marmara during fall, with the values ranging between 2.6×10^6 cells/ml and $14.4 \,\mu$ gC/l for heterotrophic bacteria and 2.1×10^5 cells/ml and $25.3 \,\mu$ gC/l for cyanobacteria. In contrast, lowest levels were attained during fall in the Levantine Basin with the values ranging between 4.1×10^4 cells/ml and $0.24 \,\mu$ gC/l for heterotrophic bacteria and 2.5×10^1 cells/ml and $0.02 \,\mu$ gC/l for cyanobacteria. Both the surface bacterial and cyanobacterial abundance and biomass averages peaked in fall compared to spring in all regions with the exception of the Sea of Marmara where an apparent decrease in heterotrophic bacterial abundance and biomass was detected.

The Sea of Marmara held the highest bacterial population during both seasons followed by the Black Sea and the Eastern Mediterranean. The Mediterranean Sea is oligotrophic and the high bacterial abundance and biomass observed in Cilician Basin is due to the sampling of productive coastal shelf waters during the cruises. Both populations were more homogenously distributed with depth during spring when the water column was mixed thoroughly.

SEASONAL AND SPATIAL PATTERNS OF BACTERIAL PRODUCTION, RESPIRATION AND GROWTH IN THE E. MEDITERRANEAN AND THE MARMARA SEA.

Abstract

Bacterial production (BP), respiration (BR) and growth efficiency (BGE) were investigated in the upper 150m along a transect from Ionian to the Marmara Sea including the Dardanelles, during the SESAME cruises in early spring (March 2008) and late summer (September 2008) and the Alliance_TSS08 cruise (September 2008). Bacterial growth efficiency was highly variable, suggesting that several factors (DOC and inorganic nutrients) control BGE. The largest amount of carbon taken up by bacteria (85-99%) was not used for biomass production and was respired as CO2.

Keywords: Bacteria, Eastern Mediterranean, Marmara Sea

Bacterioplankton play a central role in the biological transfer of carbon in the ocean through the microbial loop [1], however bacterial processes have poorly been studied in the E. Mediterranean. In this study we report results from bacterial production (BP), respiration (BR) and growth efficiency (BGE) along a transect from Ionian to the Marmara Sea, including the Dardanelles straits. North Aegean is the area where Black Sea waters (BSW) of low salinity and low temperature enter the Mediterranean through the Dardanelles straits and intense interaction of different water masses, within a relatively small area, takes place [2]. Samples were taken on board the R/V Aegaeo and Alliance, in early spring (March 2008) and late summer (September 2008) covering 15 stations at the oligotrophic seas of the E. Mediterranean (Ionian, Cretan, Libyan and Aegean Sea), 2 stations at the Dardanelles straits and 4 stations at the Marmara Sea. BP and BR were measured by 3H-leucine incorporation, conducted at saturating (20nM Leu) concentrations [3] and by an automated Winkler titration method respectively. BGE was calculated using the formula BP/(BP+BR), assuming RQ=1 [4]. BP ranged 0.13 - 52.82 ngC l⁻¹ h⁻¹ in the E. Mediterranean and increased in March at the Aegean stations, with peak values at the surface layers of North Aegean, as influenced by the Black Sea water. In September BP values varied between 0.79 to 73.08 and 0.5 to 97.42 ngC l⁻¹ h⁻¹ at Dardanelles straits and the Marmara Sea, while the increased surface values were not detected at the N. Aegean water (Fig 1).

Fig. 1. Mean depth integrated values of bacterial production (BP) along the transect from Ionian (1), Libyan (2), Aegean Sea (3), to Dardanelles straits (4) and the Marmara Sea (5), in March and September 2008

Dissolved organic carbon (DOC) ranged 50-155 µmol l⁻¹. High values of DOC were encountered in Black Sea waters outflowing the Dardanelles Strait and occupying the surface layer of North Aegean (92-155 µmol l⁻¹ in March and 81-132 µmol l⁻¹ in September). Simultaneously in September increased values of DOC were recorded at the surface layer of Dardanelles straits and Marmara Sea (162-213µmol/l) (Zeri C., unpublished data). Bacterial respiration ranged 0.40 – 36.56 µM O₂ h⁻¹, the amount of carbon respired was 0.23 – 9.97 µM C d⁻¹. Using both these BR and BP values, we calculated the BGE and it ranged from 1%– 19% (Fig 2).

Fig. 2. Bacterial Growth Efficienty (BGE) at selected stations and depths from Ionian to Marmara Sea. S=September, M=March, 1=Ionian Sea, 2= Aegean Sea, 3=Dardanelles Straits and Marmara Sea

Bacterial growth efficiency was highly variable, suggesting that several factors (DOC and inorganic nutrients) control BGE. The largest amount of carbon taken up by bacteria (85-99%) was not used for biomass production and was respired as CO2. Thus bacteria act more as a 'sink' of organic carbon to higher trophic levels. E. Mediterranean is a complex marine environment and bacteria biomass and growth are controlled by several factors. Studies which used BGE values of 30% would have significantly underestimated the carbon flux through bacteria.

Acknowledgements The present study was conducted within the framework of the European IP project FP6_Sesame EC contract No GOCE-036949. The data collected during the NRV Alliance cruise to the area was made possible by the TSS Protocol, including as Participants the NATO Undersea Research Centre (NURC) and Turkish Navy Office of Navigation, Hydrography and Oceanography.

REMINERALIZATION PROCESS IN A NUTRIENT-PHYTO-ZOOPLANKTON-BACTERIA MODEL

Jean-Marc Ginoux ¹*, Bruno Rossetto ¹, Jean-Louis Jamet ¹ and Dominique Jamet ¹ ¹ Université du Sud - ginoux@univ-tln.fr

Abstract

Seasonal variations of plankton communities in the Toulon Bay (Var, France) have been studied since 1995 [1, 2] and samplings have been carried out regularly. The abundance of phytoplankton (P), zooplankton (Z) and nutrients concentration (N), *i.e.* average concentrations of nitrates and orthophosphates have lead to a three-trophic model [3]. Since 2005, bacteria average concentrations (B) have been also evaluated to take into account their influence on plankton communities in the remineralization process. Thus, the aim of this article is to propose the most simple and consistent Nutrient-Phyto-Zooplankton-Bacteria model transcribing this process. Then, regarded as a dynamical system its mathematical features are highlighted. *Keywords: Population Dynamics, Nutrients, Phytoplankton, Zooplankton, Bacteria*

The biological point of view

The classical three-trophic food chain [6] can be modelled by interactions of predator-prey type which consist of a top-predator (Z) which can graze on phytoplankton (P) which on its turn can predate on nutrients (N). But, bacteria can break down into utilizable nutrient, a process known as remineralisation [4]. Then, zooplankton can graze either upon phytoplankton or bacteria or both. Many models have been already developed in order to transcribe such behaviour [4] but the functional responses that involve make their mathematical study and biological interpretation difficult. So, starting from such seminal works the most simple and consistent NPZB model is proposed.

Modelling

Let's consider the classical Volterra predator-prey model [5, p.88] for a three trophic level interaction involving nutrients (N), phytoplankton (P) and zooplankton (Z) and let's include bacteria (B). This NPZB model does not include any functional response with limitation such as Holling type II or type III [4] since it can be considered that bacteria are playing the role of limiting factor in the evolution of this system. By considering that the remineralisation process can be modelled by an interaction of predator-prey type two terms are added to the nutrients growth: PB and ZB which correspond to the transformation of phyto and zooplankton losses into nutrients by the bacteria. Of course such terms represent an uptake for the bacteria. The most simple and consistent NPZB model is thus built with a parameter set chosen in a biological range.

Mathematical aspects

The behaviour of such dynamical system transcribes the evolution of each of its components. And since for certain parameter values this singularly perturbed system has three times scales the rates of change for the prey (N), the predator (P), the top-predator (Z) and the bacteria (B) range from fast to intermediate to slow, respectively [7]. The slow manifold analytical equation on which the trajectory lies (limit cycle or chaotic attractor) is provided according to a new method developed in [8]. Then, a state analytical equation involving the four variables is established.

PHYTOPLANKTON COMMUNITY STRUCTURE AND SUCCESSION ALONG THE EASTERN PART OF THE NORTHERN ADRIATIC SEA

J. Godrijan ¹*, D. Maric ¹, M. A. Pfannkuchen ¹, T. Đakovac ¹, D. Degobbis ¹ and R. Precali ¹ ¹ Centre for Marine Research, Rudjer Boškovic Institute, Rovinj, Croatia - jelena.godrijan@irb.hr

Abstract

Biological and hydrochemical properties were investigated monthly on seven stations in the coastal waters of the eastern part of the northern Adriatic Sea for the period 2008/2009. The characterization of phytoplankton community revealed apparent growth periods. *Keywords: Phytoplankton, Adriatic Sea, Coccolithophores, Diatoms, Dinoflagellates*

Introduction

The phytoplankton abundance and seasonality in the eastern part of the northern Adriatic (NA) are well described, and directly depend upon input of nutrients (related to the annual regime of the Po River discharge), and distinct physical processes ([1], [2], [3]). The eastern part of the basin is characterised by a different hydrological regime thus showing exceptions to the described trends of phytoplankton succession.

Materials and Methods

The study was performed along the Istrian peninsula, eastern NA, one mile from the coast (Fig.1). Samplings were performed monthly during the 2008/09 period on seven stations. Water samples were collected with a 5-1 Niskin bottle sampler at surface, 10m and 2m above the bottom. Subsamples for nutrient concentrations were analyzed by spectrophotometric methods [4]. Subsamples for phytoplankton community characterization were analyzed microscopically with the inverted microscope method [5] using a Zeiss Axiovert 200 model. A Total of 210 samples were analysed. For statistical analysis Systat 12 was used.

Fig. 1. Map of the investigated area

Results and Discussion

Recognisable microphytoplankton comprised 165 taxa; 97diatoms, 50 dinoflagellates, 16 coccolithophorids, and 2 silicoflagellates. A seasonal cycle was determined, together with several distinct periods which were characterized by high counts of major phytoplankton groups (Fig. 2).

Annual structure of phytoplankton succession was as follows:

January: coccolithophorids (up to 60%). The most dominant species at all stations was *Emiliania huxleyii* (max $4.4x10^5$ cells/l). An early bloom of *Skeletonema marinoi* (max $5.9x10^5$ cells/l - JPI01 surface) was observed on the two northernmost stations.

February-April: nanoplankton (up to 76% in April). Dominant species: Emiliania huxleyii and Pseudo-nitzschia delicatissima complex. In March a bloom of Prorocentrum minimum (max 1.9x10⁴ cells/l) occurred.

June-August: diatoms (up to 68%), coccolithophorids (up to 30%). A rich composition of dinoflagellates in both nano and micro fraction was observed. In July a diatom peak included *Chaetoceros sp.* (max $3.6x10^5$ cells/l), and *Pseudo-nitzschia delicatissima* complex (max $1.5x10^5$ cells/l).

September–November: diatoms (up to 80%). Dominant species were *Pseudo-nitzschia delicatissima* complex and *Chaetoceros sp.* complex. Through the whole profile *Chaetoceros socialis* prevailed in the bottom layer.

Fig. 2. Contribution of the major phytoplankton groups (N=nanoplankton, H=coccolithophorids, C=silicoflagellates, D= dinoflagellates, B= diatoms)

Although a monthly sampling strategy does not offer the best temporal resolutions to appreciate the actual annual cycle of phytoplankton, the seasonal blooms were apparent. The noted exceptions to the western part of NA [3] were: (i) a significant portion of coccolithophorids in the community throughout the whole investigated period, and (ii) absence of the diatom bloom usually noted in spring.

DEVELOPMENT OF NEW BIOASSAYS TO ASSESS THE QUALITY OF COASTAL AND ESTUARINE ENVIRONMENTS: THE POTENTIAL OF THE COSMOPOLITAN MARINE PROTOZOA EUPLOTES CRASSUS

Abstract

Estuarine and coastal sediments represent the final destination of thousands of organic and inorganic pollutants which are continuously discharged into the environment as result of industrial, agricultural and domestic activities. Due to the complexity of this environmental compartment sole chemical characterization often fails to correctly estimate the toxicity of such complex matrix. In such a context, a multi-disciplinary, chemical-biological approach can overcome this lack providing useful information for identifying those situations which require a close investigation at an early stage. In this work, the possibility of utilizing the interstitial marine ciliate *Euplotes crassus* (Dujardin, 1840) was examined for the screening of polluted estuarine sediments, pore and interstitial water by laboratory and field experiments.

Keywords: Bio-Indicators, Ecotoxicology, Sediments, Pollution, Monitoring

Contamination of the aquatic environments by pollutants has become a serious problem in the recent years. Furthermore, it has been observed that the pollutant concentration in sediments and sediment's interstitial water can be more than 10-100 times higher than the one present in the overlying water column. Hence, the interest in the toxicity of pollutants occurrence in these matrices and their biological effects, has increased during the last decades as they enter waterways by runoff, atmospheric deposition etc., and may be transported to estuaries and coastal sites potentially causing harm to a large variety of non-target wildlife organisms. On this context, it is generally agreed that in the field of environmental biomonitoring biomarkers can provide useful information for pointing out those situations requiring a close investigation at an early stage [1]. From this point of view, it is of increasing interest to identify a panel of organisms displaying sensitive responses to sediment and pore water from coastal environments under anthropic pressure.

Thus, the possibility of utilizing E. crassus, an interstitial single-cell marine protozoa, was examined by applying a battery of tests including cell viability and growth as typical ecotoxicological high-level endpoints. This study was also addressed to detect more sensitive sublethal early-warning responses utilising biological parameters such as lysosomal membrane stability and endocytotic rate, which are typical stress biomarkers in eukaryotic cells [2]. The sensitivity of E. crassus assay has been assessed within a range of organic and inorganic chemicals concentration and mixtures of them. Two heavy metals species were selected, one essential (Cu) and a non-essential (Hg), since it has been suggested that heavy metals may block enzyme systems of microorganisms or interfere with some essential cellular metabolites of bacteria and protozoa [3]. Furthermore, benzo(a)pyrene was involved as organic pollutant model. A field application was also performed aiming to validate the proposed bioassay. Four sampling sites within the Venice Lagoon were chosen according to previously reported differences in both environmental conditions and level of anthropic pressure [4, 5].

Results of laboratory studies indicated that estimated sub-lethal index of stress presented significant differences between reference and treated animals even after exposure to nano/micro molar trace elements concentrations. The endocytotic rate data showed a particularly strong decrease of predation capability in organisms treated with Hg. Sub-lethal tests, like endocytosis rates and lysosomal membrane stability, were able to detect biological effects of $n/\mu M$ concentrations of toxicants. Furthermore, a significant synergic effect was observed on lysosomal membrane stability and replication rate of ciliate protozoa exposed to binary mixtures of selected toxicants. The results of field samples were in agreement with the laboratory responses. The overall results confirmed the suitability of using *E. crassus* as sentinel organism for monitoring sediment toxicity and provided an ecotoxicological protocol based on cellular biomarkers for the early detection of biological disturbance [6].

PHYTOPLANKTON CARBON-BIOMASS IN THE MEDITERRANEAN SEA

Olympia Gotsis-Skretas¹* and Lydia Ignatiades² ¹ Hellenic Center for Marine Research - ogotsis@ath.hcmr.gr ² National Centre for Scientific Research "Demokritos", Institute of Biology

Abstract

In this study, we defined the phyto-carbon derived from 63 phytoplankton samples (216 species) collected from 9 stations and 7 depths located along a large scale (3188 Km) east-west longitudinal area ($4^{\circ}95$ 'E - $32^{\circ}67$ 'E) of the Mediterranean Sea, in summer 1999. Species identifications and cell dimension measurements for cell bio-volume calculations [1] were performed in an inverted microscope. Conversion of cell bio-volume to cellular carbon-content was made with the application of equations found in the literature [2], [3].

Keywords: Phytoplankton, Carbon, Biomass

Quantifying the carbon content of phytoplankton cells is essential, because carbon is the main parameter used in models and in flux and budget studies for understanding the structure and dynamics of marine ecosystem and for evaluating the role of the ocean in global carbon cycles. A synopsis of the results of the present investigation are given in Tables 1 and 2. The average cell concentrations (Table 1) did not differ among the three dominant phytoplankton taxa since they were for diatoms: 4.45×10^3 cells.L⁻¹ (30.7%); for dinoflagellates: 4.67×10^3 cells.L⁻¹ (35.9%); and for coccolithophores: 4.17×10^3 cells.L⁻¹ (33.3%). However, the average cell carbon content among these taxa (Table 2) showed significant differences because dinoflagellates contributed the maximal cell carbon content (average:18.71 µgC.L⁻¹; 71.3%), the coccolithophores the minimal carbon content (average:0.38 µgC.L⁻¹; 2.2%) and the diatom's relevant average was 6.15 µgC.L⁻¹ (26.5%).

Tab. 1. All stations' means and ranges of phytoplankton abundance (cells.L⁻¹ and % of total) for the three main phytoplankton groups along the east-west Mediterranean.

Таха	Mean	Range	Mean	Range
	(Cells.L ⁻¹)	(Cells.L ⁻¹)	(%)	(%)
Diatoms	4.45×10^3	3.29 x 10 ² - 1.17 x 10 ⁴	30.7	3.2 - 54.2
Dinoflagellates	4.67 x 10 ³	2.97 x 10 ³ - 7.82 x 10 ³	35.9	22.2 - 52.2
Coccolithophores	4.17 x 10 ³	2.04 x 10 ³ – 6.15 x 10 ³	33.3	9.5 - 51.8
Total Phytoplankton	1.33 x 10 ⁴	1.03 x 10 ⁴ – 2.15 x 10 ⁴		

Tab. 2. All stations' means and ranges of cell carbon (μ g,L⁻¹ and % of total) for the three main phytoplankton groups along the east-west Mediterranean Sea.

		1 0		
Таха	Mean	Range	Mean	Range
	(µg C.L ⁻¹)	(µg C.L ⁻¹)	(%)	(%)
Diatoms	6.15	0.72 - 18.81	26.5	6.2 - 64.6
Dinoflagellates	18.71	5.68 - 64.02	71.3	34.4 - 89.1
Coccolithophores	0.38	0.20 - 0.58	2.2	0.4 - 4.7
Total phytoplankton	25.24	11.71 - 75.54		

These data show that dinoflagellates were more carbon dense than diatoms and coccolithophores because of their bigger cell volume and confirm the information from the literature on the positive relationship of biovolume and carbon biomass in phytoplankton. The results also demonstrate the importance of dinoflagellates in the foodweb chain and the carbon cycle of the oligotrophic Mediterranean Sea during summer.

Abstract

Dans le Golfe de Gabès, les travaux effectués sur le phytoplancton et l'ultraphytoplancton en particulier, sont assez récents et peu nombreux [1], d'où le manque d'informations et de données. L'application de nouvelles techniques telles que la cytométrie en flux nous permet d'étudier l'action des facteurs physico-chimiques sur la distribution des populations bact ériennes et ultraphytoplanctoniques.

Keywords: Cyanobacteria, Gulf Of Gabes, Phytoplankton, Nutrients

Matériel et méthodes :

La cytométrie en flux est une technique d'identification permettant de mesurer les paramètres de diffusion, de diffraction et de fluorescence de cellules individuelles dans une population en suspension monodisperse. Cette technique est caractérisée surtout par sa rapidité d'analyse (jusqu'à plusieurs milliers de cellules par seconde), sa sensibilité, sa précision, ainsi que par sa simplicité. Cette étude de la distribution spatiale des populations bactériennes et ultraphytoplanctoniques par cytométrie en flux entre dans le cadre du projet intitulé « POEMM » (Planktonic and Oceanographic Ecosystem Monitoring and Management), fondé par l'Institut National des Sciences et Technologies de la Mer en Tunisie. La zone d'étude est située dans le Gofle de Gabès (Sud de la Tunisie), entre 33°N-36°N et 10°E-13°E et comporte 23 stations d'échantillonnage. La campagne a été effectuée à bord du navire de recherche océanographique et halieutique « Hannibal R/V », en juin 2008. Le prélevement d'eau de mer a été fait à 3 niveaux de la colonne d'eau (surface, milieu de la colonne d'eau et fond) pour les stations côtières, d'une profondeur inférieure à 50 m, et à 5 niveaux (surface, -10 m, -20 m, thermocline et fond) pour les stations de profondeur supérieure à 50 m.

Résultats et discussions :

L'analyse de l'ultraphytoplancton montre la présence d'eucaryotes (picoeucaryotes et nanoeucaryotes). En ce qui concerne les cyanobactéries, Synechococcus est présent de façon importante, alors que Prochlorococcus est moins abondant. Toutefois, une nouvelle population de cellules prédatrices de grandes tailles se distingue des autres groupes cellulaires. Ce groupe semble original et caractéristique du Golfe de Gabès. L'analyse du bactérioplancton montre la richesse du milieu en ces cellules hétérotrophes, avec présence de deux groupes cellulaires (HNA : High Nucleic Acid) et (LNA : Low Nucleic Acid), la distribution de ces deux populations est variable en fonction de la profondeur. Ces résultats de distribution des différentes populations bactériennes et ultraphytoplanctoniques sont discutés en fonction de la distribution des facteurs physicochimiques au niveau de la zone d'étude.

TROPICAL HARMFUL PHYTOPLANKTON SPECIES ALONG ABRUZZO COAST (W ADRIATIC)

Cristina Ingarao^{1*} and Tommaso Pagliani¹

¹ Mario Negri Sud Institute - Via Nazionale 8/a - 66030 Santa Maria Imbaro (CH), ITALY - ingarao@negrisud.it

Abstract

The presence of tropical harmful species along the Abruzzo coast (Western Adriatic Sea) belong to 2007 when it was revealed the first appearance of *Prorocentrum lima* species. After that summer, other tropical toxic species such as *Ostreopsis ovata*, *Coolia monotis* and *Prorocentrum concavum* were observed. Besides, the ichtyotoxic species from Japan sea (*Fibrocapsa japonica*) has been detected before 2007. These species are known to produce toxins that could be dangerous for human health. In this study four coastal rocky points have been monitored during the summers 2007, 2008 and 2009. Chemical - physical parameters of sea water have been measured in order to understand their relationship with the presence/absence of tropical harmful species. *Keywords: Algae, Toxic Blooms, Toxins, Phytoplankton, Species Introduction*

Introduction

O. ovata is a common species of tropical areas. Its occurrence in coastal areas of the Adriatic Sea (Gulf of Trieste, Conero Riviera and Abruzzo coast) has probably been favoured by the increased water temperatures of the last decade [1]. It clearly poses increasing risks for human health and effects on benthic communities. In most cases *O. ovata* was present in association with other potentially toxic dinoflagellates such as *P. lima* and *C. monotis*, belonging itself from tropical areas [2]. Blooms of *F. japonica* in the Adriatic Sea, instead, have been regularly observed since 1997, above all in summer periods (July - August). Among the 5000 species of marine phytoplankton, almost 300 species can occur in such high numbers that they obviously discolour the surface of the sea, while only 80 species have the capacity to produce potent toxins dangerous for humans [3].

Methods

This work underlines the presence of tropical harmful species of the Abruzzo coast. The investigations were carried out in four confined areas such as harbors and rocky banks during the periods of June, July, August and September of 2007, 2008 and 2009 years. These stations have been selected above all to localize epiphytic species like *P. lima, C. monotis, O. ovata* and *P. concavum* due to their behavior to live on macroalgae, on sediments and inside stagnant environment with absence of water movements. At each station, one seawater sample was taken at 0.5 m from the surface by means of a pump. Algae observations were effected by the use of the light microscope (ausJENA Telaval 3) at 200x, 400x and 1000x magnification (Fig 1). Cells abundance concentrations were all expressed as cells · L⁻¹, reading the entire well using a volume of 50 ml. Chemical - physical parameters of seawater were measured by a multiparametric probe.

Fig. 1. 1000x magnification, scale bar 10 μm: a) *F. japonica*; b) *C. monotis*; c) *P. lima*; d) *P. concavum*. 200x magnification, scale bar 50 μm: e) *O. ovata*

Results

The first appearance of *P. lima* was recorded on summer 2007 only inside Ortona harbor. Its cellular abundance has been detected for the entire season

(June, July, August and September) with a mean concentration of 1.9×10^5 cells · L⁻¹. The first appearance of *O. ovata*, instead, was at the end of August 2008, at Ortona harbor and Fossacesia rocky bank. Its mean abundance was 3.4×10^5 cells · L⁻¹. *P. concavum* and *C. monotis* have been detected for the first time during this last summer (August and September 2009) always at Ortona harbor, with 1.5×10^3 and 3.0×10^2 cells · L⁻¹ mean concentrations respectively. *F. japonica*, at last, has always been detected for the entire coast of study (6.8 x 10^4 cells · L⁻¹ mean abundance).

Discussion and Conclusions

The increase of sea water temperature and the expand of ships traffic and their ballast waters have caused the entry of several tropical harmful microalgae. In fact, the Ortona harbor point, characterized by a major ship traffic, has revealed the entire community of the species in study among the four sampling stations. Besides, the highest temperature values of the three years of monitoring were always measured on August. During these periods, the contemporary presence of the 5 tropical harmful species has been registered.

Abstract

Seventeen marine bacteria associated with the green alga *Ulva intestinalis* (northern coast in Tunisia), were isolated and tested for antibacterial and antifungal activity. None of the 17 isolates displayed antifungal activity whereas two isolates displayed antibacterial activity with different antibiotic spectra. These two isolates (U1 and U5) belonged to Alpha-proteobacterial genus *Stappia*. Strain, U5, showed the strongest activity against pathogens especially *Staphylococcus aureus* and *Aeromonas salmonicida*. Algae like *U. intestinalis* may benefit from epiphytic bacteria such as *Stappia* as potential resources of natural antibiotic production and concomitant protection against undesirable prokaryotes.

Keywords: Algae, Bacteria, Biodiversity, Antibiotics

Introduction

Bacteria surviving on marine algae live in highly competitive, nutrient limited environment. This competition for both space and nutrient inflict selective pressure on the marine microorganisms that may result in the production of bioactive compounds of possible medical and biotechnological value [1]. In Tunisian coast, the green alga *U. intestinalis* is abundantly present but little is known about their epibionts and the ability of these to produce bioactive compounds. Here we investigate the culturable bacterial fraction, colonizing *U. intestinalis* and focus on their antimicrobial activity against pathogens bacteria and yeast.

Materials and methods

Marine green algae U. intestinalis were collected from coastal waters, north of Tunisia in Cap Zebib (37° 16.2' N, 10° 3.6' E) between January and November 2007. Seaweed samples were washed and epiphytic bacteria were isolated [2, 3]. Identification of isolates was realized by PCR amplification of 16S rRNA gene. In vitro antibacterial tests were performed against fifteen sensitive bacteria including fish and human pathogens (*Aeromonas hydrophila*, *Pseudomonas cepacia, Vibrio anguillarum, Vibrio tapetis* CECT 4600, *Aeromonas salmonicida, Salmonella typhymurium, Streptococcus sp., Staphylococcus aureus, Vibrio alginoliticus, E. coli* O126B16, *E. coli* ATCC 25922, *Pseudomonas fluorescens* AH2, *Pseudomonas aeruginosa* ATCC 27853, *Staphylococcus aureus* ATCC 25923, *Enterococcus feacalis* ATCC 29212) and *Candida albicans* ATCC.

For the bioassay, drops of $10\mu l$ of the algae-associated bacteria suspension were spotted on the agar plates swabbed with the test strains and allowed to dry at room temperature. After incubation for 24 h, antibacterial activity was evaluated by measuring the inhibition zone (in mm) from the edge of the colony to the edge of the clear zone.

Results and discussion

Seventeen morphological distinct isolates were selected from U. intestinalis surface and tested for potential antibacterial and antifungal activities. Ten isolates were identified by PCR amplification and 16sRNA gene sequencing. Among them, nine were gram-negative, assigned to Proteobacteria (Gamma (one strain) and Alpha subclasses (seven strains)) and Bacteroidetes (one strain). Only one strain was gram-positive. Gamma-Proteobacteria subclass was represented by the genus Vibrio. This isolate appears to be not closely associated to its host since it was found inhibited by U. intestinalis extracts (unpublished data). Only two strains U1 and U5 showed antibacterial activities. These isolates were closely related to Stappia sp. Strong activity was detected for U5 against gram-positive pathogens:S. aureus and S. aureus ATCC 25923 and gram-negative A. salmonicida (Table 1). Similar antimicrobial activity of epiphytic seaweed bacteria was reported previously [3]. These authors described U. intestinalis as the main source of antibiotic producing bacteria that were identified as Pseudomonas-Alteromonas. Here we isolated antibiotic producing strains of Stappia sp. from U. Intestinalis, a promising result in the discovery of novel antibacterial compounds. Further analyses and characterization of the antibacterial compound is in progress.

Table.1. Antibacterial spectra of the *U. intestinalis* active strains U1 and U5.

	Active strains			
Test strains	U1	U5		
S.aureus ATCC 25923	-	13		
S.aureus	-	13		
A.salmonicida	4	12		
Streptococcus.sp	3	-		
P.auruginosa	4	-		
A. hydrophila	4	-		

Zone of inhibition (mm) measured considering the spot diameter, -: No activity.

EVALUATION OF PESTICIDES TOXICITY USING BIOSENSORS OF THE MARINE PHOTOSYNTHETIC PICOEUKARYOTE OSTREOCOCCUS TAURI

Fabien Joux ¹*, Fanny Leroy ¹, Sophie Sanchez ¹ and François-Yves Bouget ¹

¹ Laboratoire d'Océanographie Microbienne, CNRS, Université Parisé, Observatoire Océanologique - joux@obs-banyuls.fr

Abstract

Biosensors expressing the firely luciferase driven by specific genes were developed in the marine photosynthetic picoeukaryote *Ostreococcus tauri* and used to measure the toxicity of different pesticides (diuron and its metabolites DCPU and DCPMU, irgarol 1051, glyphosate, chlorpyrifos). Results were compared to the conventional assay of growth inhibition. Our results demonstrate that the use of luminescent biosensors can constitute a sensitive, high-throughput and non-invasive approach to assess the toxicity of pesticides. The gene encoding the cycling-dependent-kinase A (*CDKA*) implicated in cell cycle appeared to be the most sensitive to the pesticides tested.

Keywords: Ecotoxicology, Phytoplankton, Pesticides, Biotechnologies, Physiology

Introduction - Coastal ecosystems are exposed to various pollutants including pesticides. These pesticides can come from agricultural activities or from the leaching of biocides used as marine antifouling agents. These different pesticides may affect non-target organism including phytoplankton. There is a great interest to develop new approaches to detect the toxicity of theses pollutants for marine organisms and to perform ecotoxicological tests considering the interactions between different pollutants or the interactions of pollutants with environmental parameters. To resolve this complexity a highthroughput and sensitive assay is required. We propose here the use of the marine photosynthetic picoeukaryote Ostreococcus tauri for which biosensors expressing the luciferase under specific gene control have been developed [3]. O. tauri belongs to the Prasinophyceae and is reported as a globally abundant in Mediterranean coastal lagoons and in the oceans [1,2]. The most striking feature of O. tauri is it minimal cellular organization (a naked, 1-micron cell, lacking flagella, with a single chloroplast and mitochondrion), and a small genome (12.56 Mb) completely sequenced [4]. This is the first eukaryotic algal model where stably transformed luciferase lines accurately report gene expression [3].

Material and methods - For the growth inhibition assays, *O. tauri* strain 0TTH0595 was grown in 96-wells microplate at 25°C with Keller media under constant illumination at 56 µmole.quanta. cm^{-2.} sec⁻¹. Cells were introduced at 5 x 10⁶ cell/ml and the pesticides were added 24 h after inoculation. Growth of cultures was measured by flow cytometry (Cell Lab QuantaTM MPL, Beckman Coulter) over 72 h. For the luminescence assays, four different transformed luciferase lines were used in this study (Table 1). The different modified genetic lines were grown in 96-wells white microplate at 20°C with Keller media and luciferin (10 µM) under constant illumination at 13 µmole.quanta. cm^{-2.} sec⁻¹. Cells were introduced at 10 x 10⁶ cell/ml and the pesticides were added 24 h after inoculation. Luminescence was acquired every 2 h (Berthold LB Centro automated luminometer) and over 72 h to follow *in vivo* expression of genes of interest.

Results and discussion - Based on the growth inhibition assays it was possible to classify the toxicity of the pesticides as follow: irgarol > diuron > DCPU > DCPMU > glyphosate > chlorpyrifos. The use of luminescent biosensors gave the same order of toxicity but the effective concentration of each pesticide leading to a decrease of 50% of luminescence was most of the time lower than the concentration leading to 50% of growth inhibition, suggesting a more sensitive assay. Moreover, the automated, non-invasive and highly reproducible measurements of luminescence give additional advantages to the use of the biosensors compared to the growth inhibitions assays, promoting this new assay as a method of choice to monitor pesticide toxicity in the marine environment. When the different biosensors were compared we observed that pesticides tested had a stronger inhibitory effect on the expression of cell cycle-regulated genes (CyclineA and CDKA) compared to the photosynthesis (CAB) and the circadian clock (TOC1) regulated genes. The CDKA:Luc reporter gene was the most promosing biosensor since it had high basal level of luminescence and yielded highly reproducible results. The results are very promising for the design of a fast and automated ecotoxicological test based on O. tauri luminescent biosensors, which could constitute a useful tool for studying i) the impact of environmental parameters influencing the sensitivity of microorganisms to toxic compounds and ii) the interactive effects of different pollutants.

Fig. 1. Effect of different concentrations of diuron on the gene expression of *CDKA* in *O. tauri* as measured with the luminescent biosensor. The luminescence data are expressed in percentages relative to control cultures and are the mean of three independent wells. The dashed line indicate 50% of inhibition of *CDKA* gene expression

Tab. 1. The different luminescent biosensors used

Gene	Function	Luciferase gene reporter system
Chlorophyll a Binding protein (CAB)	Photosynthesis	Transcriptional fusion
Dependant Kinase A (CDKA)	Cell cycle	Translational fusion
CyclineA	Cell cycle	Translational fusion
Timing Of CAB expression (TOC1)	Circadian clock	Translational fusion

VIRIOPLANKTON DISTRIBUTION RELATED TO BACTERIAL METABOLIC STATUS DURING AN AUTUMN SURVEY IN THE NORTHERN ADRIATIC SEA

Ana Karuza¹, Erica Crevatin¹ and Paola Delnegro^{1*}

¹ Istituto Nazionale di Oceanografia e di Geofisica Sperimentale, Department of Biological Oceanography - pdelnegro@ogs.trieste.it

Abstract

The study was performed during November 2004 in order to detect spatial distribution of marine viruses in the surface waters of the Northern Adriatic Sea, to assess their interaction with bacteria as their most common host, and to investigate the influence of bacterial metabolic status on viral proliferation. Our results confirmed the numerical prevalence of viral fraction within the microbial community and showed that not only the highly active but also less active or dormant bacterial cells can sustain viral proliferation, the latter resulting particularly intense at the mouth of the River Po.

Keywords: Adriatic Sea, Bacteria, Coastal Waters, Po Delta

The importance of viral infection for overall bacterioplankton mortality tends to increase with increasing bacterial abundance and/or productivity [1] with the evidence that more active bacterial cells may be more susceptible to viral infection and that a more active bacterial community may sustain higher viral abundance [2]. Since the detection of highly active cells by using CTC method [3], only partially explains the activity of bacterial community the discrimination of non-viable (dead) bacteria could further help in understanding viruses-bacteria interactions. The marked trophic gradient of water masses in the Northern Adriatic represented suitable study area for investigating differences in microbial interactions. Surface water samples were collected from 18th to 21th November 2004 along 5 transects for a total of 25 stations (Fig. 1).

Fig. 1. Sampling stations in the Northern Adriatic Sea. Contour map indicates distribution of virioplankton abundances

Temperature, salinity, oxygen saturation and fluorescence data were obtained using CTD multiparametric probe (Idronaut Ocean Seven 316). Samples for biological analyses were collected using a Carousel water sampler carrying Niskin bottles. Viral abundance was determined using SYBR Green I protocol [4]. Total bacterial abundance was determined using DAPI staining method [5] while non vital cells were distinguished using PI nucleic acid stain and processed according the manufacturer (Molecular Probes). Metabolically active bacteria were detected by CTC incubation technique [6]. Bacterial Carbon Production (BCP) was determined by [3H]-Leucine incorporation [7] only along C and E transects (for a total of 9 stations). Seawater temperature ranged from 11.3 to 16.6°C. Minima values were found in the coastal area, increasing towards the central part of the basin. Salinity ranged between 29.7 and 38.4 with rather opposite pattern to the seawater temperature (p<0.01). Dissolved oxygen, ranging between 82-93%, also resulted significantly but positively correlated with temperature (p<0.05). These suggested the presence of a large amount of freshwater in the coastal belt, which matched with the highest fluorescence values. In the entire area fluorescence remained low ranging between 0.1 and 0.8 µg Chla 1-1. Virioplankton abundances (Fig. 1) ranged between 3.8 and 19.9×109 1-1. Higher values were found near the Po River mouth (coastal stations of the E transect) and offshore the lagoons (A3 and A5 stations). Bacterioplankton displayed quite narrow variability, ranging within 0.9 and 1.8×10⁹ cells l⁻¹. The abundance of highly active bacteria varied from 1.4 to 5.9×10⁷ l⁻¹, thus remaining below 5% of total bacterial abundance. A clear coast to offshore decreasing gradient was observed with the highest CTC+ abundance and the

maximum VBR ratio of 14 near the Po River mouth. In that area also bacterial production rate was the most intense (0.485 µg C l⁻¹ h⁻¹), gradually decreasing along the C transect, whether the minimum rate of 0.026 µg C l⁻¹ h⁻¹ was found in the offshore stations of the E transect. Non vital bacteria ranged between 0.1 and $9.5 \times 10^8 l^{-1}$ and their proportion within total bacterial community strongly varied from 0.4% up to 91%. It was found quite similar but opposite distribution pattern of virioplankton and non vital cells (p<0.08). Our results evidenced wide spatial variability of virioplankton and confirmed its numerical prevalence within the microbial plankton community of the N Adriatic surface waters. It is plausible that the riverine inflow increasing the trophic status of the system largely influenced viral distribution and the intensity of virus-bacteria interaction. Contrary to the results reported for the entire Adriatic [2], we found that virus-bacteria interaction can not be explained by the distribution of total bacterial community itself. Viral distribution matched quite well with bacterial production and the abundance of active bacteria, but only in the area proximal to the Po River mouth, suggesting that bacteria in this area shifted their metabolism to highly active status. The possibility of the copious enrichment in viral abundances from outside sources was also considered, but was less plausible since viruses in the sea are generally from within the system [8]. The large proportion of non vital cells was found also by other authors [9], even if they put under discussion the reliability of the PI method to indicate non active or dead bacteria. The relationship between viruses and active, non vital and total bacterial community suggests that viral proliferation is not only due to the highly active but also dormant bacterial host while the infection of non vital bacterial cells is not productive, thus further confirming the key role of bacterial activity in controlling viral dynamics.
