COMMISSION INTERNATIONALE
POUR L'EXPLORATION SCIENTIFIQUE
DE LA MER MÉDITERRANÉE

RAPPORT DU 40e CONGRÈS DE LA CIESM

40th CIESM CONGRESS PROCEEDINGS

Marseille (France) 2013 Volume 40

Ce volume présente sous la forme d'articles synthétiques toutes les communications scientifiques présentées lors du 40ème Congrès de la CIESM. Les articles incluent chacun un résumé et des références bibliographiques. Comme ce sont plus de 900 chercheurs originaires de 40 pays qui se sont rassemblés en octobre 2013 à Marseille, l'ensemble offre un vaste panorama, très représentatif des recherches marines menées actuellement en Méditerranée et en mer Noire.

Les articles présentés dans le cadre des six comités scientifiques sont édités sous la responsabilité du Président de comité concerné. Seules les communications physiquement présentées par leur auteur lors du Congrès ont été retenues pour cette publication. Pour leur part, les rapports des modérateurs des sessions ont été édités par mes soins.

Biogeochemical cycles, past and present

Maria Triantaphyllou, Greece

Résumé

A short introduction to the subject was given by the moderator, mainly addressing a series of questions that are featured in current research on biogeochemical cycles, dealing with how the geosphere and biosphere have evolved through time and the role of humans in pushing the geochemistry and geobiology of the Earth Surface System towards a potential tipping point.

A 30 minute debate followed the interesting 3 min presentations of the participants. During this fruitful and frank discussion between speakers and audience, a series of questions were addressed focused on: the timing of Black Sea inflow in the Mediterranean, carbonate chemistry within sapropel S1 deposition, physics of anoxia during S1 deposition, productivity and preservation during sapropel times, amount of total organic carbon accumulated during the S1 anoxic event in various Mediterranean basin depths, carbonate chemistry effects and the role of possibly limiting factors (temperature, salinity, depth) on coral growth in Mediterranean sites, coccolithophore flux variability in Mediterranean basins and possible occurrence of different Emiliania huxleyi morphotypes in the Black Sea coccolithophore assemblages.

Deep Sedimentary Processes

Stéphanie Dupré, Ifremer, France

Résumé

The 'Deep Sedimentary Processes' session with 8 presentations covered a wide range of geological setting from lacustrine to marine environments. Challenges in studying deep sedimentary processes imply the best view of the depth window which is involved, and this from the seabed expressions to the deeper signatures. The time window of these processes is obviously crucial, and complex to approach when combining geological and human time scales, the case for climate issues. Most of the presented studies concern natural resources (water, oil and gas) and risks (water pollution, landslides). A key player in these processes, to be considered as the sediments are, is the fluid (e.g. water, gas). Some of the discussions focused on the importance of the deep -tectonic- control of seabed manifestations, e.g. the role of the Messinian salt layer in relation with fluid systems initiation and occurrence, namely the Eastern Mediterranean Sea (e.g. the Nile Deep Sea Fan) versus the Western Mediterranean Sea. The wide panel of geographic studied sites, the Dead Sea, Bafa Lake, the Black Sea, the Mediterranean Sea (Western and Eastern Mediterranean and Adriatic seas) did put in light the relevance to study deep sedimentary processes in 'enclosed' areas.

Geo-archeology and sea level change

Hulya Caner, Turkey

Résumé

Four speakers intend in the session of geo-archeology and sea level change . Name of speakers ;

Nathaniel Bensoussan, Stello Petrakis, Matteo Vacchi, Hulya Caner

First presentation is about potential impacts of climate change on coastal benthic ecosystems and developed an original strategy for the definition of warming scenarios in coastal habitats. At the same time their potential impacts on key benthic species.

Second presentation is about AKTAIA research project which aims to investigate the impacts of climate change upon the coastal zone.

Other presentation is about the MEDFLOOD project . Main objectives of this project are

- to forecast future climate trends
- to examine the climate change impact
- to develop new methods
- possible socio-economic change

The last presentation is about paleoenvironmental changes and the cultural sequence of the ancient Theodosius Harbor (Istanbul Marmaray tube tunnel) using palynology . Flash presentations admitted more time to discussions and efficiently.

Marine canyons

Sandro Carniel, CNR-ISMAR, Venice, Italy

Résumé

Following the communications, a general, active discussion started. About 50 people were present at that time, and about 10 participants were involved in the question time and discussion, which concerned the following topics :

- possible links between the cascading processes and the deep water formation in the Eastern Mediterranean basin;
- relations between small scale processes and larger scale phenomena in marine canyons (e.g. cascading processes);
- new concepts emerging from recent advances on sea technology (high-resolution measurements multibeam, ROV, AUVs?);
- availability of new coupled numerical models linking atmospheric-oceanic-wave processes and their capability in describing spatial-temporal scale of cascading events and depicting bottom features;
- need of more objective ways to measure bottom sediment resuspension;
- origin and evolution of marine canyons;
- canyons development speed during the Messinian period;
- case studies in the Med area and their peculiarities with respect to ocean regions;
- quantitative estimate of the transfer of organic matter to the deep sea:;role of measurements and modeling;
- link between physical/abiotic processes and biogeochemical/biotic aspects;

Marine Geohazards

Stéphanie Dupré, Ifremer, France

Résumé

The entire Mediterranean Sea from its western to eastern shores and to the Sea of Marmara is characterized by natural risks involving catastrophic tsunamis, earthquakes and major landslides. These phenomena are well known through the entire human history. Geohazards are the subject of numerous studies as attested by CIESM workshops - see CIESM Workshop Monograph n°42 (192 p.) "Marine geo-hazards in the Mediterranean?; or CIESM Workshop Monograph n°24 (152 p.) "Human records of recent geological evolution in the Mediterranean Basin - historical and archaeological evidence".

In order to better understand the geological processes that lead to these short-term duration risk-associated events and to better define the triggers, the analytical approach requires a multi-data and multi-parameter integration, e.g. including the meteorological input into the sedimentary system and cycle or questioning the role of fluid migration with regard to sedimentary instabilities and earth-shaking. Combining onland and offshore studies is definitively an asset as looking at past activity of risks-associated events together with most recent ones. Assessing natural risks is a very challenging issue.

Messinian salinity crisis

Johana Lofi, France

Résumé

About 6 million years ago the Mediterranean Sea was transformed into a giant saline basin. This event, commonly referred to as the Messinian salinity crisis (MSC), changed the chemistry of the global ocean and had a permanent impact on both the terrestrial and marine ecosystems of a huge area surrounding the Mediterranean area. Since the first MSC scenario has been proposed following DSDP Leg XIII in the 1970s the Messinian event remains one of the longest-living controversies in Earth Science. A few years ago a deep revision of our knowledge of the Messinian event was performed during a CIESM Workshop (The Messinian Salinity Crisis from megadeposits to microbiology - A Consensus report, 2008. N° 33 in CIESM Workshop Monographs (F. Briand Ed.), 168 pages, Monaco). A number of open questions were identified concerning the cause, nature, timing and consequences of the Messinian Salinity Crisis.

This session embraced several of these open questions through oral presentations. Thanks to a new multidisciplinary study on the DSDP Leg 23 cores, Caruso et al. proposed that the Red Sea and the Mediterranean Sea were still connected during the Late Messinian. De Lange et al. presented a mechanism in which gypsum formation and preservation occurred in shallow sedimentary settings while anoxic organic matter degradation processes in the deep basin formed dolomite. A series of presentations were also dedicated to the record of

the MSC event, thanks to seismic reflexion and borehole data. On the Egyptian margin, Abdel-Fattah et al. recognized downstepping fluvial terraces that can be used to reconstruct a relative sea level curve during the MSC. On the Eastern Sardinia margin, Lymer et al. mapped the MSC seismic markers, allowing to reconstruct the paleo-geography of the area ~5.6 My ago and to refine the timing of the rifting in this area. Driussi et al. also used these seismic markers to assess the post-MSC tectonic deformation of the Balearic promontory. Lofi presented the publication project of a second volume of a "Seismic atlas of the Messinian Salinity Crisis markers in the Mediterranean and Black seas?". The MSC session concluded by a presentation by Camerlenghi et al. of the DREAM project (Deep-sea Record of Mediterranean Messinian events) dedicated to the drilling of the MSC offshore records in the Mediterranean basin.

A general, constructive discussion followed the presentations, addressing the various topics presented and in particular the implications of a possible connection with the Red Sea during the Messinian, and the use of the MSC markers to assess the post-Messinian deformation due to tectonics.Since we are lacking at present stratigraphic and lithological control on up to 95% of the offshore Messinian records, the participants also discussed the critical need of offshore drillings in the deep basins (including the Black sea) to answer some questions still open concerning the Messinian event.

Metal distribution in sediments

Mohamed Bouhamadouche, Faculté des Sciences de la Terre, USTHB, Alger, Algérie

Résumé

The theme of the session was very well identified and nine communications presented the extent of metal occurrence (Cr, Mn, Cd, Al-, Co, Nor, Cu, Zn, Mb, and Pb) in various areas where they can reach worrying, if not alarming, levels, particularly in certain regions of Algeria, Turkey, or Egypt.

The contamination level of heavy metals was assessed by using the Igeo geoaccumulation index and metallic pollution indicators (MPI). A question particularly discussed was the particle size fraction of the marine sediment most affected by heavy metals pollution.

The debate that followed the communications was a good initiative as it has enriched several talks, concerning future methods and approaches such as the systematic study of metal isotopes, or metal contamination of major fouling species such as barnacles with interesting recommendations to be taken in future studies.

Shoreline dynamics

Muhammet Duman, Turkey

Résumé

This session on Shoreline Dynamics successfully unfolded, covering a diversity of topics that ranged from shoreline activities, modeling, hydrodynamics, Holocene deposits, deltaic structures, and seabed features. For young scientists this was a valuable and often the first opportunity to present their findings in front of an international audience.

The general debate saw specific questions and more general concluding remarks mainly on shoreline activities, hydrodynamics and seabed features.

SAPROPEL S1: BASIN-WIDE ISOCHRONOUS FORMATION AND PRESERVATION IN THE EASTERN MEDITERRANEAN

G. de Lange [1]*, C. Slomp [1], E. Erba [2], C. Corselli [3], J. Thomson [4], G. Anastasakis [5], A. Michard [6] and C. Vale [7]
[1] Geosciences - Utrecht University - gdelange@geo.uu.nl
[2] University Milano, IT
[3] University Milano Bicocca
[4] Southampton, UK
[5] University Athens
[6] CEREGE, FR
[7] Marine institute Lisbon, PT

Abstract
The occurrence of the most recent sapropel S1 appears predomoinantly controlled by its synchronous initial deposition and preservation at a basin-wide scale. A marked Mn-rich sediment bed formed basin-wide during the onset of reventilation at the end of sapropel S1. Its postdepositional preservation is dependent on organic matter and sulphide content and subsequent sedimentation rates, thus variable per investigated site.. Our basin-wide approach further elucidates that the watercolumn below ~ 1.8 km must have remained predominantly anoxic during sapropel S1 deposition.

Keywords: Paleoceanography, Sapropel, Redox, Geochemical cycles, South-Eastern Mediterranean

Clear cyclic compositional patterns occur in all Mediterranean marine deposits found on land and at the seafloor. These large-scale patterns appear related to Milankovitch astronomical variations [1-2]. The clear expression of these climate cycles in Mediterranean deposits in particular is partly related to restricted circulation in this semi-enclosed ocean basin. This restricted circulation results not only in a delicate oxygen balance, but also in a bottomwater formation and residence time that is very sensitive to Global climatic variations in past, present, and future. Variations in riverine fluxes concording with humidity-related climate cycles not only lead to variations in bottom water conditions but also in nutrient fluxes [3]. These variations have resulted in alternating organic-rich (sapropels) and organic-lean (marls) sediment intervals. This astronomical cyclicity serves as a perfect time-marker for Mediterranean Miocene to recent sediments, which permits an unprecedented comparison of samples in identical time-slices but from different locations. Some of these organic-rich units have a high degree of lamination [e.g. 4], thus permitting high-resolution studies, whereas the sedimentary expression of precessional cycles, volcanic ash layers and other time markers permit a high degree of age control. Potentially basin-scale reconstructions are possible for such time-slices, in particular for the most recent S1 period [5]. Such reconstruction may not only involve the oceanographic aspects of this model-ocean, but also the various land-ocean interactions, such as riverine and eolian inputs from various surrounding landmasses [6]. As a consequence, climatic variations are accurately recorded not only by giving variations in typical 'marine' signals, but also in typical 'continental' signals. The 'Monsoonal index' is strongly associated with the paleoclimatic conditions in the area around the Eastern Mediterranean, i.e. Sahara/ Africa, Middle East, Southern Europe. This association is clearly present in its sediments, mainly in a ~ 21 kyr precession-controled cycle: during 'humid' climatic periods organic-rich sediment (Sapropel) is deposited containing strong river and marine productivity signals, whereas during 'arid' climatic periods organic-lean sediment is deposited containing high dust input signals. As a consequence of the increased fresh water (monsoon) input between 10.4 – 5.0 ^{14}C ky BP, sapropel S1 formed basin-wide synchronously between 9.8 and 5.7 ^{14}C ky BP at all water depths greater than a few hundred metres [5]. Another effect of the increased precipitation over evaporation is water-column stratification, and the resulting restricted deep-water ventilation. This has caused predominantly anoxic water column conditions and as a consequence preferential preservation of organic matter has occurred below 1.8 km during 4,000 years of S1 formation (Fig. 1). Several diagenetic features are associated to sapropels, during their formation and during subsequent more oxic environmental conditions [7]. During sapropel formation the downward export of excess sulphide has resulted in an interval of reduced sediment immediately below S1 [8], whereas the post-depositional excess oxygen content has resulted in the downward removal of the topmost S1 interval [e.g. 9]. In addition, the deep-water reventilation thus re-oxygenation event has resulted in a marked MnO2 bed (previously referred to as Marker Bed; [5,10]). Using the S1 as a case study similar features can be recognized in older sapropel units.

GEOCHEMICAL AND PHYSICAL CONSTRAINTS FOR THE OCCURRENCE OF LIVING COLD-WATER CORALS

Sascha Flögel [1], Wolf-Christian F. A. Dullo [1]*, Andres Rüggeberg [1] and Mienis Furu [2]
[1] GEOMAR Helmholtz Centre for Ocean Research - cdullo@geomar.de
[2] Royal Netherlands Institute for Sea Research (NIOZ)

Abstract

Cold-water coral communities cover a wide range of possible habitats in terms of latitude, ocean basins, and depth. Ongoing studies and exploration are currently discovering additional occurrences in various regions of the global ocean. A range of factors determines the formation of cold-water coral reefs such as physical, hydrochemical, and biological (e. g. food supply) ones. Environmental niche factor analysis (ENFA) has been used to predict areas of suitable habitats. However, only few studies made an attempt to characterize the underlying suite of hydro –biogeo- chemical and physical constraints of cold-water coral reefs and to differentiate between pristine reef growth versus sites with reduced or no coral occurrences.

Keywords: Carbon, Cnidaria, Deep sea corals, Ionian Sea, Gulf of Cadiz

The analysis of physical and hydrochemical water mass properties from cold water coral (CWC) bearing locations in the NE Atlantic and the Mediterranean has revealed distinctive patterns. Firstly, the presented data compilation confirms the proposed control of temperature and [1] as well as sea-water density [2] on CWC growth. We found that DIC and desity of the sea water have a considerable influence on CWC in the investigated localities. Among all constituents of the carbonate system, DIC is one parameter that defines healthy, pristine, and large scale occurrences compared to just single colonies or even non-existent recent growth. The presented data indicate that DIC values below 2170 mmol kg^{-1} characterize healthy growth like in Norwegian, Irish, or Scottish waters while reduced abundances or even declined CWC reefs have higher values as seen in the Gulf of Cadiz, off Mauretania, and in the Mediterranean. This sharp separation is supported by the poor occurrences in the Oslo Fjord (2170 mmol kg^{-1}) and parts of the Bay of Biscay (Pagès Escarpment with 2170 mmol kg^{-1}). We speculate that CWCs are limited in their calcification process if DIC values in ambient sea water exceed 2170 mmol kg^{-1}. However, the carbon for calcification might originate from DIC of the ambient sea water. While it was suggested that CWCs can increase their internal DIC concentration [3]. it is possible that strongly elevated values cannot be regulated by metabolic/calcification processes. A closer look at the CO_2 system explains the overall reasons for changes in DIC.

Our data plot into two distinct clusters when plotted in a DIC-TA graph. The position of the Mediterranean data can be explained by the excess alkalinity. This likely reflects alkalinity inputs to coastal areas close to regions of deep and intermediate water formation. An alkalinity budget shows that main alkalinity inputs come from the Black Sea and from rivers, whereas the Strait of Gibraltar is a net sink [4]. The fast overturning circulation in the Mediterranean Sea has led to an overall invasion of the anthropogenic CO_2 in the basin. New results show that the Mediterranean Sea has taken up a large amount of C_{ant} on both a per-volume and a per-area basis, compared to estimates of the global oceans [5]. However, the position of the Gulf of Cadiz and Mauretanian samples can be explained by increased respiration rates at the sea-floor.

The results indicate that a DIC of 2170 mmol kg^{-1} represents a tipping point for the formation of pristine CWC reefs. This goes along with increasing knowledge of the present global carbon cycle. This is important for our ability to understand and predict the future carbon cycle and global climate. Because about 50% of the anthropogenic carbon released to the atmosphere from the burning of fossil fuels is stored in the ocean. The estimates of anthropogenic carbon (C_{ant}) in the oceans remain prone to error arising from (i) a need to estimate preindustrial reference concentrations of carbon for different oceanic regions, and (ii) differing behavior of transient ocean tracers used to infer C_{ant}. An empirical approach [6] revealed that more C_{ant} is stored in the deep ocean than shown previously. This has possible implications for future carbon uptake and deep-ocean carbonate dissolution. This approach showed that both, the DIC concentration and the aragonite saturation horizon increase and shoal continuously in the North Atlantic since preindustrial times. If the potential tipping point of 2170 mmol kg^{-1} is indeed a limit for healthy and pristine reefs, we can interpret the observed increase in DIC of about 20 mmol kg^{-1} over the past 20 years [7]] as an indication for an increase in the decline of CWC reefs and mounds during this period.

The presented data compilation of physical and hydrochemical parameters of the ambient water masses of CWC sites with *Lophelia pertusa* in the NE Atlantic and the Mediterranean sheds new light on the boundary conditions for pristine CWC growth and occurrences. We were able to extent and confirm existent data sets [2] regarding a potential density envelope. Furthermore, our new results of hydrochemical parameters reveal a distinct tipping point with respect to DIC. We show that pristine CWC occurrences are limited to bottom waters with DIC values < 2170 mmol kg^{-1}.

HIGH-RESOLUTION PALEOENVIRONMENTAL STUDY IN THE SOUTH AEGEAN SEA FOCUSING ON SAPROPEL S1 FORMATION

Amalia Filippidi [1]*, G.J. de Lange [1], Maria Triantaphyllou [2] and G. Roussakis [3]
[1] Institute of Earth Sciences-Geosciences Utrecht University - a.filippidi@students.uu.nl
[2] Faculty of Geology & Geoenvironment, University of Athens, Greece
[3] Institute of Oceanography, Hellenic Center for Marine Research, Greece

Abstract
The Aegean Sea is a semi-enclosed basin extremely sensitive to climate variability. Geochemical evidence from a high-sedimentation rate core from the South Aegean Sea demonstrates high frequency climate oscillations that were active prior, during and after sapropel (S1) deposition. These oscillations are thought to be linked to bottom water oxygenation, which in turn is strongly influenced by ventilation and climate change.

Keywords: Sapropel, Paleoceanography, Geochemistry, North-Central Mediterranean

Deposition of sapropels in the Mediterranean Sea, is associated with orbital climate forcing [3] and depicts the strong response of the basin to climate variability. The most recent sapropel (S1) was deposited between 9.8-5.7ka ^{14}C BP [4] and its formation is related to significant changes in the water circulation pattern. Despite the different mechanisms and processes described to be responsible for the formation of sapropels, elevated productivity as well as conditions favorable for the preservation of organic matter is widely accepted to prevail during sapropel deposition. The enhanced preservation of organic matter is thought to be related to restricted bottom water oxygenation and associated redox conditions at the water/sediment interface. In a high-sedimentation rate core (KN3) retrieved in 2008 (R/V Aegaeo) between Kos and Nisyros islands (Greece; 36^{o}40',636 - 27^{o}12',040, 607m depth) detailed (0.5cm resolution) geochemical and micropaleontological analyses have been performed. The results show that high frequency variability occurs in geochemical paleoproductivity proxies (e.g. C_{org} content and Ba/Al ratio) and trace elements. Fluctuations such as those in manganese content point to re-ventilation during S1 formation, at least in the Aegean Sea. The development of productivity in the deeper photic zone (high abundance of coccolithophore *Florisphaera profunda*) reflects increased stratification of the water column; although with several fluctuations. The practical absence of *Emiliania huxleyi* moderately calcified morphotypes implies elevated SSTs. Furthermore, this study provides evidence for more than one interruption during S1 formation, when the organic matter formation either was significantly reduced or the conditions were not favorable for its preservation. Trace elemental fluctuations used as indicators for anoxic/dysoxic conditions in surface sediments [1] advocate reduced oxygen conditions rather than a completely stagnant basin. High frequency cyclicity has been recorded also in micropaleontological and isotopic compositional data [2] implying restricted ventilation conditions but not a complete cessation of bottom water formation in Aegean Sea. Finally, the aforementioned proxies used for the reconstruction of the paleonvironmental conditions prevailing during S1 deposition in the South Aegean Sea, have been compared with results from other cores from within and from outside the Aegean Sea. Despite differences related to local environmental conditions, the general feature of variability within S1 as observed in Aegean core KN3 are confirmed. These observations strongly support the idea of the Aegean Sea not being a fully anoxic basin during S1 formation, but evolving under diminished oxygen conditions with potential episodes of re-ventilation. Additional studies are needed to more precisely set timing, distribution, and potential synchronicity of observed events.

MODELING THE BIOGEOCHEMICAL CYCLING OF NITROGEN AND PHOSPHORUS IN THE EASTERN MEDITERRANEAN SEA: 1950-2000

Helen R. Powley [1]*, Michael Krom [2], Philippe Van Cappellen [1] and Kay-Christian Emeis [3]
[1] Department of Earth and Environmental Sciences, University of Waterloo, Canada - hrpowley@uwaterloo.ca
[2] School of Earth and Environment, University of Leeds, UK

Abstract
The unusual nutrient cycling of the Eastern Mediterranean Sea (EMS) has been described by a coupled nitrogen and phosphorus mass balance biogeochemical model. The model is calibrated by independent nutrient measurements and is used to simulate changes in primary productivity and nutrient distributions within the EMS between 1950 and 2000. Despite threefold increases in the supply of nitrogen and phosphorus to the EMS during the second half of the 20th century the model only predicts a 22% increase in primary productivity, primarily due to efficient nutrient removal by the anti-estuarine circulation of the EMS.

Keywords: Nutrients, Ionian Sea, Levantine Basin, Geochemical cycles, Models

The unusual nutrient cycling of the Eastern Mediterranean Sea (EMS) is characterized by low nutrient concentrations and high nitrate to phosphate ratios. A coupled nitrogen (N) and phosphorus (P) biogeochemical model was developed for the EMS to describe and understand this cycling. The model domain consists of the EMS excluding the Adriatic and Aegean Seas. The water column is divided into three water layers; surface water (0-200m); Levantine Intermediate Water (200-500m) and deep water (>500m). The 1-D model accounts for fluxes between the water layers and for the anti-estuarine circulation of the EMS. It is assumed that the N and P cycles were at (near-) steady state in 1950 [1] and that annual primary production is phosphorus limited [2]. The N and P cycles are coupled together through the Redfield ratio (NO_3:PO_4=16:1) for primary production [3]. Estimations of the concentrations of soluble inorganic and organic forms, as well as particulate organic forms of N and P are based mainly on [4]. Inputs of nutrients to the EMS include atmospheric deposition, riverine supply, and inflows from adjacent basins (Adriatic, Aegean and Western Mediterranean Seas) whilst outputs include burial of particulate organic matter, denitrification and outflows to adjacent basins. Nutrient inputs between 1950 and 2000 were estimated using a combination of historical nutrient records from alpine ice cores [5,6], measured atmospheric deposition rates [7], and measured riverine concentrations [8]. The initial 1950 conditions were obtained by spinning up the model to steady state.

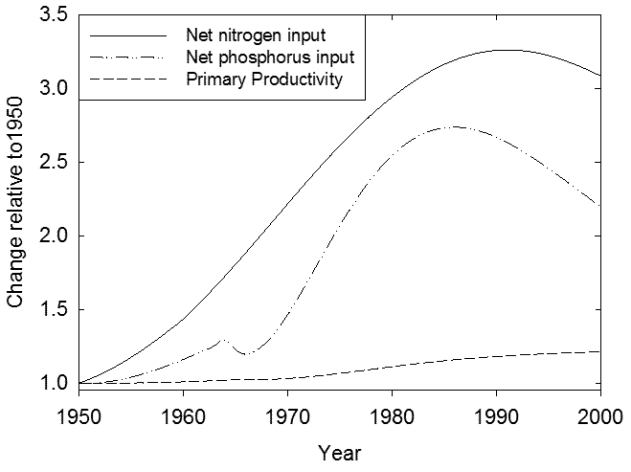

Fig. 1. Net nitrogen and phosphorus inputs to the EMS between 1950 and 2000, and the model predicted response of primary productivity, relative to 1950. Net inputs include the net flow of N and P between adjacent basins (Western Mediterranean, Adriatic and Aegean Seas), atmospheric deposition and riverine supply of N and P.

Despite major increases in the net supply of nutrients to the EMS, up to factors of 3.25 and 2.7 for N and P, respectively, modeled primary productivity during the 1950-2000 period only increases by 22% (Figure 1). The Western Mediterranean Sea (WMS) provides up to 67% of phosphorus input to the EMS, primarily as dissolved organic P. The model calculations indicate that 40% of nutrients supplied to the EMS between 1950 and 2000 are exported from the basin with over 25% to the WMS through the Straits of Sicily. Up to 20% of nutrient inputs are stored as inorganic nutrients in the deep water reservoir but the changes in deep water nitrate and phosphate concentrations between 1950 and 2000 are relatively small. The predicted nutrient concentrations in 2000 are consistent with the concentration ranges reported by [9]. The recycling efficiency of nutrients is very high with over 90% of phosphorus recycled within the surface waters. In conclusion, results indicate that the anti-estuarine circulation, exporting nutrients out of the EMS to the WMS through the Straits of Sicily, helps maintain the ultra-oligotrophic nature of the EMS and the phosphorus limited nature of the system.

Abstract
The export production of coccolithophores has been measured from Black Sea, North Aegean Sea, Cretan Sea, South Cretan margin and Ionian Sea, and compared in order to define the spatial and seasonal variability in their assemblage composition. Furthermore, the contribution of coccolithophores to the total carbonate flux is calculated.

Keywords: Biogeography, Coccolithophores, Black Sea, North-Eastern Mediterranean

A sediment trap mooring has been deployed for one year (10/2007- 9/2008) at 1000 m water depth, in western Black Sea. The maximum coccosphere fluxes, with almost monospecific assemblage of *Emiliania huxleyi*, have been recorded during May and June. The seasonally controlled coccolithophore patterns are strongly related to those of sea surface temperature and accumulated rainfall in the area, triggering riverine nutrient input.

Coccosphere fluxes in North Aegean Sea have been calculated from a sediment trap deployment at 500 m (1/2011-12/2011). *E. huxleyi* is the dominant species, followed by *Syracosphaera pulchra*, *Rhabdosphaera clavigera* as minor assemblage components. Maximum fluxes have been observed in between May-June.

A single mooring with two sediment traps (500 and 1700 m) was deployed at the southern margin of the Cretan Sea (1/2001-2/2002) [1]. The results obtained from 500 m depth show that the highest productivity season was recorded from January till late September with the highest flux values observed between late March to late June. During this period the pattern was characterized by three main phases that correlate well with the gradual increase in SST from January till September. Coccosphere sinking assemblages were characterized by high abundances of *E. huxleyi*, followed by *Florisphaera profunda*, *R. clavigera* and *Syracosphaera* spp.

Six moorings have been deployed at different sites along the south–west margin of Crete, providing a total of eight sediment-trap time series (6/2005-5/2006) [2]. Maximum coccosphere fluxes were recorded in between March to June, featured by dominance of *E. huxleyi* and subordinate *Helicosphaera carteri*, *Umbilicosphaera* spp. and *S. pulchra*; intermediate fluxes from June to November, with high abundance of the deep photic zone species *Algirosphaera robusta*, *F. profunda*, *Gladiolithus flabellatus*; and low fluxes from November to February, with high flux of *A. robusta*, *S. pulchra* and *Syracosphaera* spp. These three periods correspond to the seasonal changes in sea surface temperature and surface mixed layer depth.

Coccolithophore fluxes from the central part of the Ionian Sea have been studied from a sediment trap mooring (9/1999-6/2001) at 500 and 2800 m water depth [3]. Peak coccolithophore export production is observed in May, a secondary peak is observed in September-October. The assemblages is dominated year-round by the cosmopolitan species *E. huxleyi*, followed by the deep-dwelling *F. profunda* and by several minor species (*Syracosphaera pulchra*, *R. clavigera*, *A. robusta*, *G. flabellatus*, *Calcidiscus leptoporus*, *Umbellosphaera tenuis* and small *Syracosphaera* spp.) which are most abundant during the summer period of upper water column stratification.

A high seasonal pattern characterizes the coccolithophore assemblages from all the investigated areas of eastern Mediterranean and Black seas. The export production and biogenic carbonate fluxes are strongly dependent on the nutrient influx, the vertical mixing and sea surface temperatures of the water column, in a north-south and east-west transient.

Abstract
The paleoenviromental conditions during the high sedimentation rate depositional interval of sapropel S1 in the northeastern Aegean (gravity core M-4, length 2.53 m; south Limnos basin) have been studied, based on quantitative micropaleontological (benthic and planktonic foraminifera), geochemical (OC, δ^{13}Corg) and $U^{k'}_{37}$ sea surface temperature analyses. Our study points that sapropelic layer S1a has been deposited in more dysoxic conditions in respect to S1b. An interruption of the sapropelic conditions at 8.0 Ka BP, which is mainly characterized by the increase of agglutinated foraminiferal forms, confirms higher oxygen bottom conditions. From ~ 8.0 to 7.7 Ka BP, enhanced freshwater inputs along with the supply of terrestrial matter are probably associated with the inflow of Black Sea waters.

Keywords: Sapropel, Foraminifera, Geochemistry, Aegean Sea, North-Eastern Mediterranean

Gravity core M-4 has been recovered in South Limnos basin from water depth 216 m, at 39º 38.662'N, 25º 35.165'E. Sapropel S1 is very well exposed with overall thickness reaching 96 cm. S1a interval is characterized by the intense presence of anoxic/dysoxic benthic species, such as *Chilostomella mediterranensis*, *Globobulimina affinis* and *Cassidulinoides bradyi* together with *Bulimina* spp. (*B. aculeata*, *B. marginata* and *B. costata*), and the presence of *Bolivina spathulata*, *B. striatula* and *B. alata*. However, the presence of *Uvigerina mediterranea*, *Gyroidinoides* spp. indicates mesotrophic to eutrophic environments and higher oxygen conditions. Therefore, less severe dysoxia has been developed in South Limnos basin during the deposition of layer S1a, in respect to what has been documented before for other Aegean basins [1], [2], [3]. Higher values of OC during the deposition of S1a than those of S1b, indicate highest organic matter production and preservation in S1a, supporting previous results in the Aegean area [2], [4], [5]. The almost constant values of δ^{13}Corg, shifted towards marine end-member values during S1a, confirm the hypothesis that the deposition of sapropel S1 has been caused by enhanced primary productivity along with extended preservation of organic matter, when compared to the present-day levels in the north Aegean [5]. During S1a and S1b depositional intervals the dominant planktonic foraminiferal species are *Turborotalita quinqueloba* and *Globigerina bulloides*. Their abundant presence suggests the development of a low salinity sur?cial layer rich in nutrients over South Limnos basin during the deposition of S1a and S1b. The interruption of sapropel S1 at 8.0 Ka BP is probably associated with the northern hemisphere cold event at 8.2 Ka BP. During this interval, the increase of agglutinated forms confirms both higher oxygen bottom conditions and freshwater input. This is accompanied by decrease in OC and the presence of planktonic foraminifera assemblages (*Globorotalia inflata* and Neogloboquadrinds) which suggest stronger mixing of the water column at least during winter. The more negative values of δ^{13}Corg identified at ~7.7 Ka BP are indicative of terrigenous organic matter [5], that may caused high value of OC, during the interruption interval, probably associated with the inflow of Black Sea waters. Within the sapropelic layer S1b dysoxic foraminiferal species abundances are once more increased but to a lesser degree when comparing with S1a; in accordance with OC values. *U. mediterranea*, *Hyalinea balthica*, miliolids and agglutinants are increased, supporting even less dysoxia for S1b interval in respect to S1a. All acquired data records present rapid simultaneous fluctuations, suggesting short term paleoceanographic and palaeoclimatic changes in the studied area. Rapid palaeoclimatic changes during the discussed interval have been also reported in pollen records from N. Aegean Sea [6], [7].

Abstract

The Dead Sea is located on the boundary between the Sahara and the Mediterranean climatic zones. Its extension has substantially changed throughout time alternately expanding during ice ages and contracting during interglacials. The changing size of the successive lakes triggered changes in the chemical composition of their waters and, thus, their sediments are reflecting the climatic-hydrologic history of the region. The basin is located in an active tectonic region often affected by earthquakes that are preserved throughout the lacustrine sequence. Their identification and dating allows developing an event stratigraphy. Constraining the existing climatic and tectonic reconstructions for this area will help to disentangle the impact of these changes in the development and migration path of peoples from Paleolithic to modern times.

Keywords: Global change, Levantine Basin

The Dead Sea Basin (DSB) is the largest and deepest continental pull-apart basin formed along the Dead Sea Transform Fault, as well as along other continental transform faults [1]. During the Miocene (ca. 23 Ma), the basin was filled by fluvio-lacustrine deposits of the Hazeva Formation. Later during the Pliocene (ca. 5 Ma), the Mediterranean Sea intruded the basin forming the Sedom lagoon that deposited thick sequences of salts. After the disconnection of the lagoon from the open sea, terminal lacustrine bodies successively occupied the basin: the middle to late Pleistocene lake Amora (>740-130 ka), the last interglacial Lake Samra (~135-75 ka), the last glacial Lake Lisan (~75-17.7 ka), and the Holocene Dead Sea. The last glacial Lake Lisan and the Holocene Dead Sea have been widely studied during the past few decades providing significant archives of paleoenvironmental changes [2,3,4]. The Lisan Formation is comprised of up to ~40 meters of sediment deposited over nearly 60,000 years (~75 to ~17.7 ka), and records ice age conditions with seasonal time-resolution, due to regular deposition of thin (~1 mm thick) layers of precipitated inorganic carbonate during dry seasons (from lake evaporation) and detritus during wet seasons (from erosion of the marginal highlands and wind-blown dust) [2]. It also includes clastic layers associated with storms or lake level drops, gypsum layers associated with extreme dry periods and lake level drops, and jumbled "mixed layers" caused by earthquakes. The carbonate layers have been dated by U-series and ^{14}C, and the combination of radiometric dating and layer counting affords the opportunity to unravel the Near East hydrological-climatic and tectonic history at up to seasonal time resolution [2, 4]. The Lisan Formation overlies deposits from Lakes Amora and Samra, representing previous ice age high lake levels extending back at least 740 ka. But these past glacial and interglacial predecessors are fragmentary exposed along the shores of the current Dead Sea. Filling these existing gaps in the history of the basin is now possible with information obtained from cores retrieved from the central and deeper parts of the present lake. They improve our understanding of the behavior of the described water bodies evolving in the DSB as well unlock the climatic and tectonic mechanisms that shaped the region during past interglacial and glacial cycles [5] .

From November 2010 to March 2011 an international team of scientits (*) drilled the Dead Sea as part of an International Continental Scientific Drilling Program (ICDP) sponsored project [5]. The retrieved sedimentary cores are filling-in known (and estimated) gaps in the outcrop sediments and provide a nearly continuous and undisturbed record, that judging from changes in dominant lithology, are covering at least the past two glacial-interglacial cycles (ca. 200 ka). The sedimentary record can be divided into two dominant lithologies: salt layers interbedded with laminated mud, and massive and laminated marl interbedded with thin salt layers. Silt and sand (and gravel) levels indicate intervals of extremely low lake level (see slides). Additionally, a preliminary inspection of the material show spectacular sedimentary structures that are witnessing tectonic activity that has been registered in the lake sediments. Preliminary results indicate an average sedimentation rate more than double than the land deposits since salt deposition intervals (interglacials periods) are much thicker than the aragonite-detritus laminae that characterize the glacial intervals. In addition, the whole record becomes thicker due to the large thicknesses of the encountered slump sediments that have been most probably triggered by earthquakes of various ages. Once the chronology of these major events will be established, it may be possible to develop a regional event stratigraphy leading to an estimation of the frequency of earthquakes in this tectonically active area. The latter may help planning mitigation strategies of major societal impact.

A striking discovery is a mud-free layer of rounded pebbles more than 230 meters deep in the core taken from the deep basin, deposited at an age provisionally estimated to be the last interglacial. The pebble layer appears to be a beach deposit and nothing else like it has been found at other places in the cores. It overlies about 40 meters of mainly salt, and together they indicate an extreme lake level drop during that time. Today the Dead Sea level is falling fast because no fresh water is entering it due to the fact that most of the runoff is being used by the surrounding population. If the hypothesis that Dead Sea dry down is confirmed it means that in the geological past without human intervention, the runoff severely declined or almost stopped. This is critical since global climate models predict that in the near future this region will be more arid with higher mean temperatures implying that this precious resource, already fully used, will become scarcer.

DENSE WATER CASCADING AS DRIVER FOR SOUTH WEST ADRIATIC MARGIN RESHAPE

D. Bonaldo [1]*, A. Benetazzo [1], E. Campiani [1], S. Carniel [1], F. Foglini [1], M. Sclavo [1] and F. Trincardi [1]
[1] CNR-ISMAR - davide.bonaldo@ve.ismar.cnr.it

Abstract
Dense shelf waters nowadays originate in the northern Adriatic sea progressively move to the South, impacting the slope sea floor with velocities greater than 1 m/s and generating a wide variety of depositional and erosional features including muddy and sandy sediment waves. We merge the results of numerical runs, based on dedicated scenarios inferred from geological and paleoclimatology evidences - with most recent evidences from dedicated geological surveys - aiming at a detailed definition of the sediment fluxes driving the evolution of southern Adriatic mud waves.

Keywords: South Adriatic Sea, Continental margin, Bathymetry, Deep sea processes, Circulation models

After the end of the last glacial, the North Adriatic shelf was progressively drowned due to the eustatic rise generating a shallow shelf region which is now one of the Mediterranean key sites for the formation of dense shelf waters through wind-forced winter cooling. Once formed, the dense waters move to the south, along the western side of the Adriatic, and reach the South Adriatic slope across which they cascade generating a wide variety of depositional and erosional features such as muddy and sandy sediment waves. Moreover, several fields of dominantly muddy sediment waves have a patchy distribution and appear to reflect the interaction between the down-slope path of the dense water and the presence of both morphological constraints to accelerate the flows and mobile sediment to be casted into large-scale bedforms (Trincardi et al, 2007). Given the dominant role of seabed morphology in controlling such process, a detailed bathymetric characterization is necessary for an appropriate understanding of the hydrodynamic and geological processes. Recent advancements in geological survey technologies allow a very high-definition knowledge of the sea bottom geometry and sedimentology, providing a robust experimental basis for modeling inferences. At the same time, numerical models for ocean circulation have been developed and improved up to allow a refined description, at an adequate space- and time- resolution, of the formation and flow of dense water masses in the Adriatic basin until the South Adriatic slope (Benetazzo et al., 2013).

In this work we merge the results of numerical runs, based on dedicated scenarios inferred from geological and paleoclimatological evidence, with most recent evidences from dedicated geological surveys carried out on R/V URANIA operated by the Italian National Council of Research (C.N.R.). The findings provides a sound background for a coupled hydrodynamic and sediment transport modelling effort, based on a complete in-situ sedimentological characterization and aiming to a detailed definition of driving processes and sediment fluxes involved in the evolution of southern Adriatic mud waves since the last glacial-interglacial transition, and in particular since the early Holocene, when stable-isotope studies suggest an enhanced bottom-water formation and circulation (Piva et al., 2008).

The modeling performed under different scenarios accounts for both the erosional and depositional features observed, assessing how the process of dense shelf water cascading can concur to a marked reshape of the sea floor landscape. The model results indicate that the downslope-cascading bottom currents are highly correlated with the orientation and spatial distribution of the observed bedforms.

The work done paves the way to new modeling efforts under past oceanographic scenarios and at a sub-feature scale, with the aim to investigate if and how the dense water cascading is consistent, by strenght and location, with the generation and evolution of the observed bedforms.

This work has been partially funded by the Flagship Project RITMARE - The Italian Research for the Sea - coordinated by the Italian National Research Council and funded by the Italian Ministry of Education, University and Research within the National Research Program 2011-2013.

Abstract

The Nile Deep Sea Fan hosts numerous active fluid escape structures associated with large gas emitting mud volcanoes, authigenic carbonates, pockmarks and briny mud volcanoes. During the MEDECO2 expedition (HERMES Program), some of these seeps were investigated with the research vessel *Pourquoi pas?*. Near bottom geophysical investigations were conducted with the use of the *Victor* ROV (Remotely Operated Vehicle). We present here, in the view of the seepage activity, the geophysical characterization of a large mud volcano caldera complex called Menes located in the Western Nile Province.

Keywords: Mud volcanoes, Tectonics, South-Eastern Mediterranean, Nile Fan, Brine pools

The Nile Deep Sea Fan hosts numerous active fluid escape structures associated with large gas emitting mud volcanoes, authigenic carbonates, pockmarks and briny mud volcanoes (Bayon et al., 2009; Dupré et al., 2007; Huguen et al., 2009; Loncke et al., 2004). During the MEDECO2 expedition (HERMES Program), some of these seeps were investigated with the research vessel Pourquoi pas? (Foucher et al., 2009). Near bottom geophysical investigations were conducted with the use of the Victor 6000 ROV (Remotely Operated Vehicle). Victor was equipped with 1) a Reson 7125 multibeam system operated at 400 kHz for high-resolution bathymetry and backscatter seafloor imagery and 2) an OTUS camera for long range optical black and white imaging. We present here, in the view of the seepage activity, the geophysical characterization of a large mud volcano caldera complex called Menes located in the Western Nile Province. Extending by 3000 m water depths with a diameter of ~8 km, the Menes Caldera contains several active mud volcanoes. Chephren and Cheops mud volcanoes located in the south and roughly in the centre of the caldera, respectively, are the most spectacular.

Chephren Mud Volcano

The Chephren structure is composed of two craters of 250 to 300 m in diameter each. The northern crater is filled up with muddy brine sediments. Within this brine lake, salinity reaches high values (120 to 145 psu). Gas analysis in the water column revealed high methane concentrations, 0.4 to 5.6 mmol/l. The temperatures within the lake indicate uniform values with depth, reaching ~60°C along a vertical profile of ~250m below the seabed. In contrast, the southern crater is relatively cold with thermal gradients similar to background values. This crater 10 to 20 metres deep corresponds to a former brine lake that is at present inactive in terms of brine seepage. Running outflows emitted from the northern brine lake are visible all around the mud volcano with the most recent activity located at the northern side. The seepage activity there corresponds to highly unstable seafloor environment. The fauna is mostly restricted within the close periphery of the brine lake. The small and narrow subcircular plateaus that composed the upper part of the crater attract many crabs and polychaete tubeworms. Within the brine lake, the less unstable areas appear to be characterized by dense accumulation of white filaments that correspond to sulfur associated with arcobater, sulphide oxidizing bacteria.

Cheops Mud Volcano

Cheops mud volcano, similarly to Chephren, exhibits high salinity values and methane concentrations (respectively 210 to 240 psu and 2.4 to 3.7 mmol/l). Cheops mud volcano, with an average diameter of ~250m, is composed of a brine lake surrounded by an almost continuous depression ring, covered in some places with recent outflows. This latter probably corresponds to a former edge of the lake. As previously suspected, the inner domain of this mud volcano correlates with an almost flat top where numerous muddy brine pools, decimetre to metre in scale and covered by whitish filaments, were observed at the surface of the lake. An average temperature of ~43°C was recorded from the surface of the lake down to 440m through a very unconsolidated material. The uniformity of the temperature profile with depth clearly supports the occurrence of first order active convection within a mud/brine/fluid conduit. The newly acquired geophysical dataset and high-resolution seabed photographic images brought more details, in particular, in the seabed morphology and spatial distribution of the seepage activity. The seepage activity is not restricted to the major mud volcanoes. The entire caldera is disturbed by fluids associated in depth with numerous faults and fractures and at the seabed with brine-related features. Acoustic anomalies were detected in the water column using the 38 kHz echosounder of the R/V Pourquoi pas?. An echo contiguous to the seafloor was recorded up to 600 m above the seafloor at the south-western border of the Menes. This acoustic anomaly is interpreted as a gas flare associated with a listric fault in relation with salt tectonics.

GEOPHYSICAL, GEOLOGICAL AND LYMNOLOGIC STUDIES OF BAFA LAKE, AN ANCIENT GULF OF THE AEGEAN SEA

Can Eytemiz [1]* and Erdeniz Ozel [1]
[1] Dokuz Eylul University, Institute of Marine Science and Technology - can.eytemiz@deu.edu.tr

Abstract
Lakes are perfect constituents of climatic, environmental and geologic changes and geophysical lake studies are exceptionally important to reveal their formation process. Lakes may record regional responses about some environmental processes and a combination of such records about origin of lake can contribute to a better understanding variations about shore studies. Bafa Lake in Mugla, Turkey is among the best examples of such an alluvial set lake in the Aegean Sea and it is one of the least spoiled watery areas at the shore, in Turkey.

Keywords: Geophysics, Hydrography, Aegean Sea, Sedimentation

Bafa Lake was one of the busiest bays of the Aegean Sea (Gulf of Latmos) in the seventh century B.C. [1]. The sediments brought to the lake is initially fed by the floods from the Big Meander River (Büyük Menderes) slowly pull away the bay from the Aegean sea by the first century A.C. [2]. From late antiquity, alluvials that brought by Big Meander River is closed the connection of the Latmos Gulf step by step and transformed the gulf to a lake (Fig. 1) [3]. Bafa Lake is one of Turkey's most important historical and protected area which also has cultural and archaeological resource value by having the ancient city of Latmos. So this area is under protection of the government as an open air museum and a nature park.

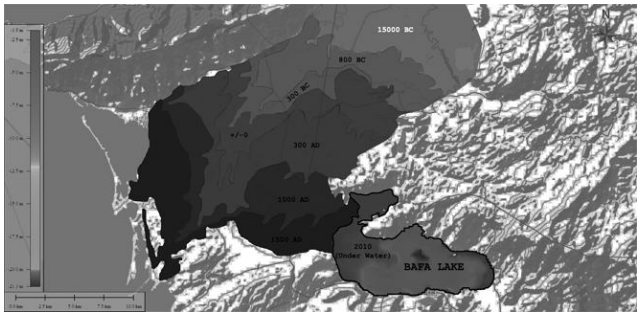

Fig. 1. Periodic progression of the Big Meander River Delta

We examined the Lake in geophysical, geomorphological and physico-chemical aspects. In this context, depth measurements and bathymetric mapping, side scan sonar studies which used to determined the morphology of the lake, water column physicochemical parameters and microbiological assays and sediment grab samples to determine bottom sediments were studied (Fig. 2).

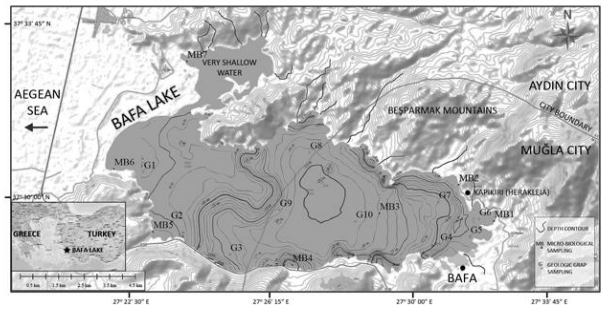

Fig. 2. Representation of Bafa Lake's location and depth contours with sediment sampling locations.

Results showed us how a river can transform a gulf into a lake by changing it's geology, morphology and echology and gave us a huge knowledge about similarly affected environments future, destinies.

THE DISTAL DANUBE DEEP-SEA FAN IS THE LAST "SINK" OF ITS EPONYMOUS RIVER BASIN:

Abstract
The Danube River Basin and the Black Sea represent a unique natural laboratory for studying source to sink and global change. In the last decade, many of the geosciences studies carried out in the Black Sea have focused on the Holocene marine transgression. This topic has been fully discussed and is still a matter of debate. Since the DSDP drillings, the lithology and mineralogy of deep sediments from the Black Sea have been well studied. However, only few recent studies have focused on the deep-sea morphology and turbidite sedimentation in the western Black Sea basin, where the main depositional feature is the Danube submarine fan. Recent oceanographic surveys demonstrate that the deep basin deposits bear the record of the Late Quaternary paleoenvironmental changes.

Keywords: Deep sea basins, Sediment transport, Canyons, Swath mapping, Black Sea

This study focuses on the deep water architecture of the western Black Sea deep basin and its sedimentological characteristics. The Late Quaternary Danube turbidite system (to the North) displays a well-constructed morphology, underlined by several channel-levee systems associated with distal lobe complexes, reaching the 2200 m isobaths. The adjacent deposits, onlaping the Danube Turbidite System distal lobes in the deep basin, show a linear, drape-like morphology, represented by thick continuous reflections on seismic profiles. They generally consist of distal turbidite deposits supplied from the Turkish margin. Most of these turbidite sequences show a thick upper unit composed by homogeneous clastic clays, thus forming thick mud turbidites. Following previous work in similar basin settings, we interpret these facies to result from large volume unchannelized turbidity currents generated by successive mass-wasting events. The abrupt break of slope at the bathyal plain transition enhances the rapid deposition of coarse-grained material and limits channel development in the bathyal plain. We relate the origin of these deposits with the very high seismic activity of the North Anatolian Fault on the Turkish margin. This work is based on data collected at the boundary of influence of the Danube Turbidite System and the Turkish margin, and provides a new record of the changes in sedimentary supply, climate and sea level that occurred in the Black Sea region since the last ~ 25 ka. The deep basin deposits bear the record of the Late Quaternary paleoenvironmental changes (Lericolais et al., 2012). The Last Glacial Maximum Period (~25 to 18 ka BP) was characterized by an important and relatively stable sediment supply with sediment transferred to the deep basin from both the northern Danube Turbidite System and the southern Turkish margin. The relative stable LGM period was followed by an increase of sediment transport to the deep basin, which is locally illustrated by progradation of lobe deposits from the Danube turbidite system in the deep basin, downlaping the Turkish deposits. Influx of meltwater to the Black Sea resulted in a early highstand sea level. The following Bolling Allerod Preboreal warm period and the Younger Dryas cold event have experienced alternative sea level lowstands and highstands that are not clearly underlain in the deep basin sediments (Lericolais et al., 2012). The onset of sea-level highstand after the Holocene marine invasion (~ 9 kyr BP) (Lericolais et al., 2012; Soulet et al., 2011) induced the end of the activity of the Danube Turbidite System whereas the gravity supply from the Turkish margin remained active throughout the Holocene. We conclude that the western Black Sea basin constitute an asymmetric subsident basin bordered by a northern passive margin with confined mid-size, mud-rich turbidite systems, and a southern turbidite ramp built in a tectonically active margin setting.

FLUID-ESCAPE STRUCTURES ON THE CENTRAL NILE DEEP-SEA FAN: RESULTS FROM INTEGRATED SWATH BATHYMETRY AND 3D SEISMIC DATA

Abstract
Fluid seepages are observed on almost every continental margin where detailed surveys have been conducted. They exhibit different morphologies at the seafloor, but pockmarks, mounds, and mud volcanoes are predominant. In the Central Nile Deep-Sea Fan (NDSF), an integrated approach, based on bathymetry and seismic investigations of the seafloor and of the sedimentary column reveal that pockmarks fields, mud volcanoes and shallow networks of cracks are associated with various geological features such as normal faults, faulted anticline, buried turbidite channels and mass-transport deposits.

Keywords: South-Eastern Mediterranean, Nile Delta, Bathymetry, Seismics, Mud volcanoes

Fluid emissions at the seafloor of continental margins have been recognized in a large range of settings. The most commonly described expression of fluid seepages are commonly pockmarks, carbonate mounds, mud volcanoes (MV) and/or gas chimneys; they may result from migration of thermogenic fluids along tectonic conduits, dissociation of gas hydrates and dewatering of turbidite channels or of mass-transport deposits (MTDs). Fluid seepages constitute thus a potential window on deep reservoirs and constitute part of geohazards affecting continental-slope environments. A great variety of fluid seepages have already been described over the NDSF. They are also recorded by patches of high acoustic backscatter indicating pockmarks and/or small carbonate mounds [1; 2]. Submersible observations have shown the high-backscatter patches to coincide with authigenic carbonate pavements [3]. Some of them were thought to be active during the Holocene. A new dataset used in this study includes multibeam bathymetry and backscatter data, as well as Chirp and seismic-reflection profiles (Géoazur laboratory) mixed together with the upper section of 3D seismic data (Total Company); it helps to better constrain the characteristics of already-known structures and to identify new ones within the central NDSF. Some 2000 additional pockmarks, identified between 300-1300 m water depths, appear either isolated or grouped in clusters. On seismic data, they are expressed at the seafloor as concave-up high-amplitude reflections lying on top of vertical pipes with incoherent facies at depth. Seven MV (conical, flat, circular in shape; 1.5-4 km in diameter; up to 70 m high) already identified between 100-1100 m water depths, are imaged in better details. The new observations reveal abundant mud flows at the seafloor, suggesting recent fluid activity. Newly identified emission centers consist of either low-elevation domes, with concentric ridges, or chimney-like structures merging in a large caldera. Such morphological differences may indicate variations in both nature and viscosity of fluid emissions. Radiating networks of lineaments, interpreted as small-scale fractures, are seen on the seafloor and at depth around some MVs and may indicate fluid intrusion processes within the pre-existing deposits. On seismic data, MVs exhibit either a "christmas-tree" pattern up to 300-ms penetration below the seafloor, or thinner construction lying at the seafloor, suggesting different fluid/mud emission cyclicity scales and initiation ages. Dendritic networks of curved cracks (0.1-3 km long, 5-10 m deep) are present at various locations between 800-1400 m water depths. They affect the first 50 ms below the seafloor and appear anchored on top of sub-vertical conduits with concave-up reflections. Over the studied area the spatial organization of pockmarks, MVs and cracks is constrained by several types of structures identified on the seafloor and at depth. In most cases, MVs are associated with networks of normal deep faults that in some case affect the present-day seafloor, for example Rosetta fault, as already indicated and which is therefore an active fault. Pockmark fields are superimposed to buried normal faults and on a faulted anticline, but can also be observed at the base of fault scarps affecting the seafloor. More surprisingly, some pockmark fields mimic relatively deeply buried turbidite channels and MTDs located up to 550 ms below the seafloor; and they likely result from dewatering processes strong enough to impact the seafloor; similar relationships were established in the Congo basin and on the Niger submarine delta [4]. Finally, shallow networks of cracks are located on top of buried MTDs. Their origin is still unclear but their orientation is nearly similar to the organization of MTDs internal thrust faults as shown on 3D seismic time slices. It is thus believed that dewatering of MTDs, guided by thrust faults, could generate overpressures within the overlying deposits and then extensional structures that propagate upward to the seafloor.

A MORPHOSTRUCTURAL AND GEOLOGICAL SYNTHESIS OF THE MEDITERRANEAN DOMAIN

Jean Mascle [1]*, Georges Mascle [2], Laetitia Brosolo [3] and Laurent Camera [4]

Abstract
A recently published morpho-bathymetric map of the Mediterranean Sea, constitutes the background support for the first morpho-tectonic map of the Mediterranean domain ever published. This compilation made under "Arcgis", includes a peri-mediterranean geological synthesis in which the various geological units have been assembled according to their implications with respect to the Alpine orogenic evolution. For the marine domain several characteristics, have been selected and successively mapped in distinct layers integrated to produce the final synthesis; among the selected layers: the nature and age of the deep basins, the distribution of messinian basins, of active tectonics and of large fluid seepage processes such as mud volcanoes.

Keywords: Bathymetry, Geomorphology, Swath mapping, Tectonics, North-Central Mediterranean

Onshore the map has been mainly constructed using the contours of the IGME 5000 Map [1], completed by information extracted from numerous publications The geodynamic evolution of the Mediterranean area being intimately related to the one of the Alpine realm, the various geological units have been assembled accordingly to their implications within the Alpine orogenic evolution; since the beginning of the Alpine history correlates with the end of the Variscan one, more or less at the limit between Carboniferous and Permian (300 Ma), all geological units older than Permian (Proterozoic and pre-Permian Paleozoic) have therefore been considered as basement; the Variscan magmatism (prior to 300 Ma) has however been distinguished to better highlight the Variscan basement. All others formations (younger than 300 Ma) have been characterized considering their implication within the Alpine structures and the different lithology, which constitute large tectonic units, are represented by a dedicated colour. Recent (Oligo-Miocene to Quaternary) sedimentary basins have been distinguished in two categories: flexural basins and others types (cratonic, rifts…). Oceanic-type rocks (i.e. ophiolites), that underline ancient suture zones, Neogene to Recent alkaline volcanoes (areas of crustal thinning or of hot spot activity) and subduction-related magmatism (former active margins), have been distinguished. All others formations, sedimentary, volcanic, or metamorphic (alpine metamorphism) dated from Permian to Oligocene (or to late Miocene depending of the area), have been grouped together, and shown by a single colour stressing their location within the Alpine realm. The compilation of a homogenous morpho-tectonic map of the Mediterranean Sea is still an unrealistic challenge. This is the reason why we selected a series of major characteristics and specificities, which appear common to the two Western and Eastern Mediterranean deep basins. These are for example the probable extension of the thick (up to 20km) continental crust, and of the different oceanic crust-floored deep basins whose age have also been indicated; similarly the various types of magmatism occurring in the basin are shown. The deep, and thick, Messinian basins, evidenced on seismic reflection grounds and on their impacts on the morphology of the sea floor, have also been mapped as well as the various halokinetic deformations resulting from the Messinian salt mobility such as diapirs (chiefly detected in the Western basin) and gravity tectonic related features (mainly evidenced in the Eastern basin); major brine lakes and mud volcano fields and belts, which constitute one of the specificities of the Eastern Mediterranean sea, are shown. The main active (or recent) tectonic features (faults, folds, thrusts, etc,..), induced by the geodynamic context of the Mediterranean Sea, are also indicated; their interpolated tracing has been made using their imprints on the seabed morphology as derived from details from swath bathymetric data, particularly in the Tyrrhenian Sea and in Eastern Mediterranean Sea. Finally the location of seism epicentres, from 1974 to 2011, and with magnitude between 4 and 8 (from the Us Geological Survey), is indicated since these earthquakes underline, offshore and onshore, one of the fundamental processes resulting from the geodynamic of the Mediterranean Sea The resulting synthesis map, constructed in an "Arcgis" digital environment, results from the superposition of more than twenty layers, each of them representative of a specific characteristic of the submarine domain and drawn from a compilation of numerous data extracted from many various publications. These layers are shown superposed on a general morpho-bathymetric background derived from the recent Morpho-bathymetric map of the Mediterranean Sea [2]. The various layers are syntheses made from numerous publications.

Abstract
Our main aim was to assess the potential impacts of climate change on coastal benthic ecosystems by the end of the 21st century at sub-regional scale: the North Western Mediterranean Sea. We developed an original strategy for the definition of warming scenarios in coastal habitats and their potential sub-lethal to lethal impacts on key benthic species. This was achieved by combining high resolution numerical simulations under IPCC scenarios with field observations and thermotolerance experiments. First, model validation for 2001-2010 was conducted in contrasted sensitive coastal areas. Forecasts run were performed under IPCC scenarios to explore changes in stratification. These simulations were qualified with species distribution and thermotolerance functions to explore present risk level and potential impacts by the end of the century.

Keywords: Coastal systems, Global change, Biodiversity, Temperature, North-Western Mediterranean

Introduction
The Mediterranean Sea is extremely responsive to climate change and dramatic impacts are expected to occur in benthic coastal ecosystems which are among the most exposed to the current trends and extreme events [1]. In this semi enclosed microtidal sea with seasonal stratification up to 15°C, the influence of (sub)meso scale dynamics (eg. upwelling, downwelling) is crucial in modulating local thermal regimes and potential impacts of climate change at local scale [2,3]. Developing more precise/realistic scenarios of coastal habitats warming and potential impact on ecosystems is crucial for setting up sound management and conservation plans of the rich Mediterranean biodiversity and thus recognized as a priority theme of international programs (eg. CIESM, MEDPAN, MERMEX). Within the CLIMCARES project (http://climcares.medrecover.org), we specifically addressed the risk of mass mortality driven by thermal stress in rocky benthic ecosystems of the NW Mediterranean (NW Med) [4,5].

Materials and methods
We conducted a multidisciplinary approach combining hydrodynamic simulations at large geographic scale, physical and biological coastal observations, and thermo-tolerance experiments:
Temperature profiles (5-40m) have been monitored hourly over the past 10 years in different coastal areas of Spain, France and Corsica (T-mednet initiative, http://www.t-mednet.org). Observations from 10 contrasted stations were compared with simulations for the last decade for two different models: the high resolution hydrodynamical model addressing (sub) mesoscale processes MARS3D/MENOR (horizontal resolution 1.2 km) and NEMO-MED8 (ca. 13 km resolution) [6]. We evaluated statistically bias and errors to qualify the models and define local corrections. Forecast simulations were run under the IPCC A2 scenario and both models were considered for comparison.
Upper thermotolerance limits of key benthic species were compiled from *in situ* temperature records obtained during 1999, 2003 and 2006 mass mortality events, allowing correlation analysis of the degree of mortality and temperature conditions. Besides, thermotolerance experiments were conducted on some of the affected species. Finally, a data base on species distribution and upper distribution limit was also compiled.
The vulnerability scenarios were obtained by combining warming scenarios, biological responses to warming and upper distribution limit as fully described in [3].

Results and Discussion
Models comparison with coastal temperature series for 2001-2010 showed the good model performances of MENOR (bias, RMSD and correlation) even if extremes were underestimated in subsurface layers. The regional model also yielded good performances for monthly to seasonal statistics at these very near to coast stations. Thus both approaches - local correction of regional model and high resolution downscaling with MENOR - were considered complementary and used to explore respectively long term trends in stratification and extreme events by the end of the century. The thermotolerance response functions to warming compiled from field observations and experiments shared the same pattern for the sponges, anthozoans and cnidarians tested: mortality arose after sustained "moderate" increase in temperature (24-26°C) or stronger short overheating (27-28°C), at typical time scales from several weeks to day respectively.
The modeled temperatures were extracted along the NW Mediterranean coastlines and combined with thermo-tolerance and upper distribution limit of populations. This information was used to build risk and potential impact models. First based on hindcasts to evaluate species and areas of high conservation concern in the NW Med [3], highlighting the concomitant and/or repeated occurrence of a range of (sub)lethal conditions depending on the area considered during the past decade. Then on forecasts to explore potential impacts of climate change by the end of the century at specific, but also multi-specific level.

Abstract
As the capital of two world empires Istanbul is located at the crossroads of the waterway connecting the Mediterranean and the Black Sea. Project in due to build a tube tunnel under the sea between Asian and European parts of the city, an ancient Byzantium Harbor (Theodosius H. 4th century) was brought out at Yenikapi within the "historical peninsula". Geological and archaeological evidences in the sedimentary sequence exposed to daylight at the excavation site have revealed significant new data enabling for the first time to correlate the Holocene sea level change, paleoenvironmental changes and the cultural sequence of the region. This study include results of the polen analysis in the one of the sedimentary sequence which is collected from Marmaray excavation area.

Keywords: Paleoceanography, Marmara Sea

As the capital of two world empires Istanbul is located at the crossroads of the waterway connecting the Mediterranean and the Black Sea as well as the land route connecting Asia and Europe has contributed greatly to the cultural development and wealth of the city. It has been the setting for many civilizations since early times. During the preliminary construction works of a large scale Marmaray Tube Tunnel Project in due to build a tube tunnel under the sea between Asian and European parts of the city, an ancient Byzantium Harbor (Theodosius H. 4th century) was brought out at Yenikapi within the "historical peninsula". Geological and archaeological evidences in the sedimentary sequence exposed to daylight at the excavation site have revealed significant new data enabling for the first time to correlate the Holocene sea level change, paleoenvironmental changes and the cultural sequence of the region. This study include results of the polen analysis in the one of the sedimentary sequence which is collected from Marmaray excavation area. The sequence has a length of 270 cm. The litology of its consist of mainly blackish clay deposit (1) . It possibly formed in a small swamp. The interval between 220-222cm and 200 202 cm are yielded 7592-+44 BP and 7305-+47. 0.4–1 ml of sediments were sub-sampled from core 1 for palynological analysis. Sub-samples were treated with $Na_4P_2O_7$, HCl, HF, and HCl, then sieved through 125 and 10 µm screens. Numbers of microfossils per ml of wet sediment were calculated with the initial addition of *Lycopodium* tablets. Pollen residues were mounted in glycerol. Palynomorphs were identified at magnifications of 500X (routinely) and 1000X (special identification). All terrestrial and aquatic pollen grains were included in determining concentration. The pollen percentages are based on total pollen, excluding spores (2). The diagram of this sequence was divided into four local pollen assemblage zones.LPZ 4 (between 270-240 cm) was represented by low pollen values particularly *Sordaria* shows highest values (3). LPZ 3 (240-160 cm) , total pollen values increase (reaching 40%). Compositae *and* Chenopodiaceae appear in this zone and reaches highest values. . *Liquidambar oriantalis* L. exists on this zone. LPZ 2 (160-70 cm), pollen sum reaches its highest value in this zone. *Pterocarya* appeares whereas *Juglans*, *Juniperus* and Chenopodiaceae disappear.. LPZ 1 (70-10 cm) , *Acer, Olea, Tilia* and *Betula*disappaear upper part of this zone.

Abstract
The scope of the present contribution is to present the outlines of the AKTAIA research project that is currently implemented through the cooperation of the associated organizations. The project aims to investigate the impacts of the climatic change upon the coastal zone of eastern Crete with specific emphasis on beaches, developing new methodologies for continuous monitoring and a protocol for the mitigation of the anticipated sea level rise

Keywords: Aegean Sea, Shoreline evolution, Monitoring, Coastal processes, Coastal management

Introduction
One of the most significant impacts of climate change, both at a national and an international level, is the shoreline retreat, which is particularly intense in the case of beaches due to their low relief and composition (i.e. unconsolidated sediments). Climatic change induces coastal erosion through sea level rise, increased occurrence of extreme meteorological events and reduction of riverine sediment transport due to reduced rainfall. Moreover, erosion maybe related to human intervention (marinas, piers, coastal roads).

Scope and objectives
The on-going AKTAIA project investigates climate change manifestation and its influence on the stability and evolution of the coastal landforms along the shoreline of eastern Crete (some 757 km) (Fig.1), taking into account also the various aspects of human intervention.

Fig. 1. Location map of the study area.

The main objectives of the AKTAIA project are: (i) to forecast future climatic trends for the area of Crete (e.g. rainfall, wind, sea-level rise); (ii) to examine the climate change impact on the basis of collection of environmental data (meteorological, geomorphological, sedimentological and oceanographic) that are directly related to the climatic change; (iii) to develop new methods and indices for the assessment of Cretan coast's vulnerability; and (iv) to assess the socio-economic impacts and in particularly those related to the loss of coastal land. Project's materialization has been based on the synergy of four research groups established in Organization for the Development of Eastern Crete (Coordinator), the Institute of Applied Computational Mathematics (Foundation for Research and Technology in Crete), the Department of Marine Sciences (School of Environment, University of Aegean) and the Faculty of Geology & Geoenvironment (National & Kapodistrian University of Athens).

Methods and preliminary results
Aerial photographs, satellite images and orthophotomaps have been used to produce a detailed coastline map and to study the morphological characteristics of the coastal zone of Eastern Crete. More than 100 beach zones (with shoreline length >100m) have been visited during the three field campaigns, that have been conducted so far, including geomorphological and human intervention mapping, topographic, meteorological and oceanographic measurements and sedimentological sampling and observations. In addition, coastal video monitoring system accompanied by a meteorological station and a nearshore tide-wave gauge station have been installed in two pilot sites (Amoudara beach on the north and Koutsounari on the south) (fig.2); in these two sites coastal imaging [1] and nearshore oceanographic processes will be tested and adjusted to localised conditions, in order morphodynamic models to be calibrated.

Fig. 2. Monitoring system, meteorological station and D-GPS station, installed on-site.

Expected results
The coast of the eastern Crete consists mostly of rocky costs (71.5%), beaches (either sandy or pebbly) 18.2%, coastal landforms formed by wave erosion (2.5%), while the remaining 7.7% represents artificial coasts (e.g. marinas, groins etc). The development of a unified GIS-based environmental database incorporating all gathered data and existing information (i.e. coastal geomorphology, meteorological conditions, wave regime, beach material, human construction) will be then related to the forecasting climate trends (ENSEMBLE, http://ensemblesrt3.dmi.dk/) for the next decades in the area of Crete, in order the impacts of the climate change to be assessed, with respect to coastal zone evolution; this includes also the application of a coastal vulnerability index and an index suitable for beach zone vulnerability assessment. On the basis of the above, a protocol for the mitigation of the various impacts of climate change will be developed, towards a more successful management of Cretan's coast.

Acknowledgements
The project is supported by the Action "Cooperation 2007-2013" (09SYN-31-711 "AKTAIA") of the Operational Program "Competitiveness and Entrepreneurship" co-funded by the European Regional Development Fund (ERDF) and the General Secretariat for Research and Technology (Hellenic Ministry of Education).

ASSESSING VARIABILITY OF MEDITERRANEAN FUTURE SEA LEVEL SCENARIOS USING RELATIVE SEA LEVEL DATABASES

Matteo Vacchi [1]* and Alessio Rovere [2]
[1] OT-Med Labex, Europole de l'Arbois, batiment du CEREGE, Aix-En-Provence, France - matteo.vacchi@gmail.com
[2] Lamont Doherty Earth Observatory, Columbia University, NY, USA

Abstract
Relative Sea Level databases have proved useful to assess coastal vulnerability to sea level rise and to quantify the coastal vertical displacement. In the Mediterranean, much greater amounts of SL published data exists and such literature, still rapidly growing, has led to the obvious consequence of fragmented information. The importance of a standardized review of Mediterranean SL data was recently raised by the Medflood project (www.medflood.org). With this study, we tried to organically review the sea level data available in two complex areas of the Mediterranean with respect to tectonic setting.

Keywords: Sea level, Aegean Sea, Ligurian Sea, Geohazards, Coastal processes

Introduction
The reconstruction of past relative sea levels (RSL) has several implications, ranging from the investigation of crustal movements to the calibration of earth rheology models and ice sheet reconstructions. Recently, INQUA has funded a 4-years multidisciplinary project, named MEDFLOOD aimed at build a spatially explicit database of relative sea level markers for the Mediterranean and to use this resource to model risk and help project future flooding in and around the Mediterranean basin We contributed to the MEDFLOOD project with the construction of RSL database in two Mediterranean areas [4] . In Liguria (NW Mediterranean) we created a database of the Late Quaternary (i.e. last 125.0 ky BP) RSL changes in order to assess their spatial along the two rivieras. In NE Aegean Sea (Eastern Mediterranean), we analyzed the role of the North Anatolic Fault in controlling the RSL sea level changes in the last 12.0 ky BP. In addition, we presented our best estimates for the late-Holocene sea level rise. These data are essential in order to verify if relative sea level fluctuations were superimposed on the general rising trend, which is in turn central to predict the patterns of future sea level change.

Methods
The database included a wide range of geological RSL indicators (geomorphological and biological markers as well as marshy organic material and peats derived from sediment cores) as well as geo-archeological sea level data [1]. In the cases where a sample indicated formation or deposition in freshwater or marine environments, it was classified as a limiting date [2]. Therefore, reconstructed RSL must fall below freshwater limiting dates and above marine limiting dates. Ages of geological samples were estimated using radiometric dating of organic material of salt and fresh water marshes or marine shells.

Results and discussions
In Liguria, shorelines attributed to MIS 5.5 are present along the entire region, but dated shorelines occur only in the westernmost or easternmost part. This affects the interpretation of the neotectonic setting, but the analysis of the altimetric distribution of shorelines attributed to MIS 5.5 (Fig.1) allows to extend to the entire region the conclusion of several authors, who hypothesized that the western part of the region is in stable to slowly uplift, while the eastern part is to be considered in moderate uplift during Late Quaternary.

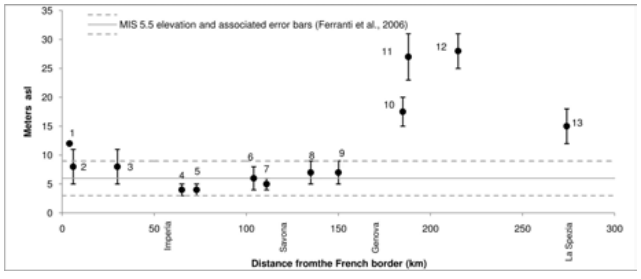

Fig. 1. Spatial variability of M.I.S. 5 shorelines along the Ligurian coast.

In NE Aegean, the analysis of the database brings a contribution to the open debate about the mid-Holocene RSL highstand in this sector of the Mediterranean Sea [3].
Even if with different rates, data provided by our database are consistent with a continuous RSL rise in the last 6.0 ky BP in the whole NE Aegean Sea (Fig. 2). Thus, our results do not support the hypothesis of a relative mid-Holocene sea level highstand, which partly reached or even slightly exceeded present MSL. The short records of tidal gauge RSL trends in the area did not allow a fair comparison between late-Holocene RSL and 20th century rising trends. We made an attempt in Izmir bay defining an acceleration of rising rates by ~0.6 mm/y-1 in the past century.

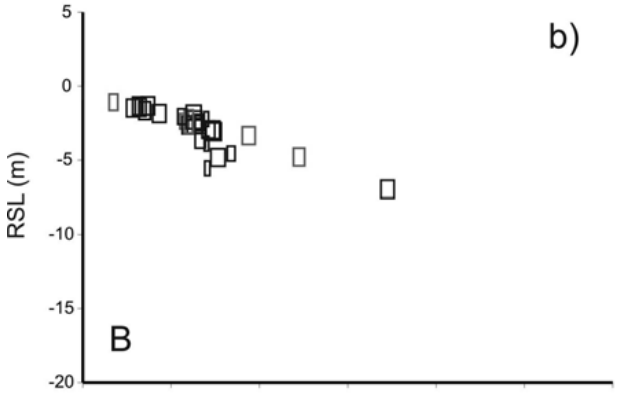

Fig. 2. RSL history along a part of the NE Aegean coast plotted as calibrated age against change in sea level relative to present (m). RSL data are plotted as boxes with 2s vertical and calibrated age errors. Grey boxes are virtually incompressible samples.

DENSE WATER CURRENTS AND SEDIMENT TRANSPORT IN THE SOUTHERN ADRIATIC SEA DURING THE COLD WINTER 2012

S. Carniel [1]*, L. Langone [2], A. Benetazzo [1], A. Bergamasco [1], D. Bonaldo [1], M. Borghini [3], F. Falcieri [1], S. Miserocchi [2], A. Russo [4], K. Schroeder [1], M. Sclavo [1] and J. C. Warner [5]

Abstract
During the exceptionally cold winter 2012, dense shelf waters originated in the northern Adriatic sea progressively moved into the southern region, where they impacted the local complex canyons bathymetry with a series of deep-reaching cascading pulses.This complex dynamics was investigated using a coupled wave-current-sediment numerical modeling approach (COAWST), validated by means of observations acquired during two dedicated cruises (CTD, XBT and currents) and by data resulting from five moorings deployed in deep hot-spots of complex bathymetry, that allowed to build upon an existing time series of temperature, salinity, currents and downward particle fluxes.

Keywords: South Adriatic Sea, Water transport, Deep sea sediments

Northern Adriatic Sea is an area where dense shelf waters (NAdDW) form during winters characterized by favorable conditions: high salinities, mainly deriving by low river water discharge (Po *in primis*) during previous months, and low temperatures, mainly deriving from violent, cold and dry Bora wind events blowing from NE (Carniel et al., 2009). Resulting dense waters progressively move away and then sink in the southern regions by successive cascading events. Both NAdDW favorable conditions characterized the winter 2012, when, following several months of low Po River runoff, a very cold Bora blew long (from end of January until mid-February). Consequently, the temperature of northern Adriatic Sea waters dropped to about 6° C and exceptional densities (exceeding 1030 kg/m^3) were reached (Mihanovic et al., 2013). The production and spreading mechanisms of dense water in the Adriatic Sea have been modeled by means of the COAWST (Coupled-Ocean-Atmosphere-Wave-Sediment-Transport system) system. It builds upon an eddy resolving, high-resolution (1 km), fully 3-D hydrodynamic model (ROMS), the wave model SWAN (Simulating Waves Nearshore) and the CSTMS (Community Sediment Transport Module System) sediment routines, driven by atmospheric forcings provided by the meteorological model COSMO-I7.

The dataset used to assess model outputs encompasses three fixed observational sites in the northern Adriatic and part of the measurements taken during the sea-truth campaign "Operation Dense Water (ODW)" (a set of two rapid response cruises carried out in southern Adriatic and which hot-spots measurement in terms of CTDs, L-ADCP and XBT measurements were acquired according to an adaptive sampling strategy "model-driven"). Moreover, in the region of open slope in front of the Gargano Cape, in the moat area north of the Dauno seamount (1200 m deep), in the Bari canyon and in the sediment wave field down-current of the canyon, where the occurrence of very energetic currents were inferred by depositional and erosive bedforms, five mooring arrays were maintained and/or deployed in order to allow the continuous acquisition of temperature, salinity, currents and downward particle fluxes, providing a rather thorough description of the intense hydrodynamic events and suspended sediment transport that characterized the winter-spring 2012. Results from the integrated data-model approach allow to suggest new insights on dense waters propagation and fate and how, triggered also by tidal forcing, can be constrained by bathymetric features and cascade into the Southern Adriatic Pit area (Figure 1). Additionally, COAWST capability to couple different numerical models allowed to disentangle the relative importance of different aspects on dense water generation and propagation (e.g. the role of continental runoffs, the effect of deep energetic pulses on movable bottom sediments, the wave forcing terms on ocean circulation, mixing, and bulk fluxes). In addition to this, additional light was shed on the transport pathways on the shelf and to determine the different steps characterizing the sediment transport dynamics in the area (e.g. related to storms, cascading pulses, currents), in this benefiting from unprecedented spatial resolution and a new bathymetry reflecting very high resolution data acquired via multi-beam techniques.

Abstract
High-resolution multibeam data, sub-bottom seismic profiles and sediment samples have been acquired in the Murcia continental shelf (Western Mediterranean Sea) to characterize a field of subaqueous dunes observed in the middle to outer shelf. Bedforms are composed of sandy sediments and display asymmetric morphology, with crest to crest spacing ranging from 20 to 1400 m and an estimated height up to 1 m. Dune asymmetry and orientation reveal unidirectional along-shelf currents that are consistent with the regional circulation of the margin. This suggests that these bedforms could be formed by the action of the predominant geostrophic current flowing southwards along the shelf break and slope.

Keywords: Continental shelf, Swath mapping, Sediment transport, North-Western Mediterranean

Large subaqueous dunes have been observed in continental shelves worldwide, mainly in response to strong tidal [1, 2] or geostrophic currents [3, 4]. In the Murcia continental shelf (Western Mediterranean Sea), a large field of subaqueous dunes was observed in the middle to outer shelf off Águilas [5]. To further analyze this dune field, a cruise was carried out on board the R/V Angeles Alvariño in 2013. Swath bathymetry was collected using the Simrad EM 710 system (Fig. 1).

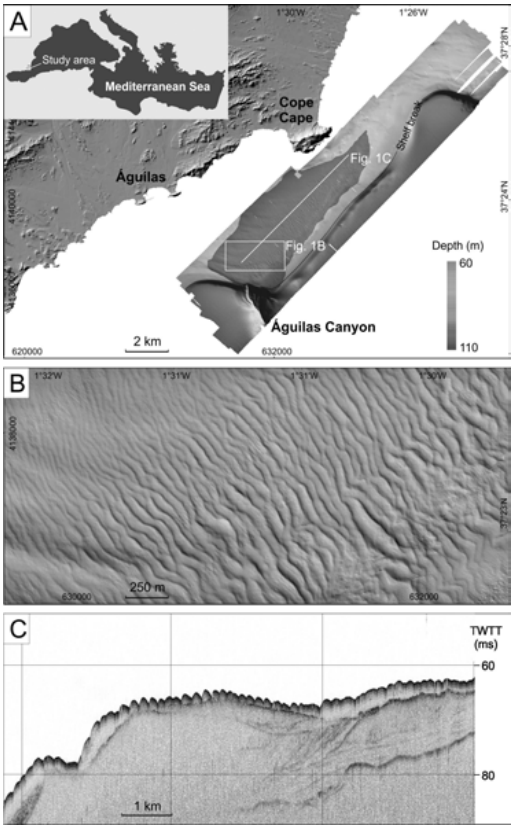

Fig. 1. (A) Bathymetry of the Murcia continental shelf showing the dunes field (grey shadowing). (B) Shaded relief image and (C) sub-bottom seismic profile of the subaqueous dunes.

Data were compared with those obtained in 2001 on board the R/V Emma Bardán using a Simrad EM-3000D system. Widely-spaced sub-bottom seismic profiles were acquired using a TOPAS PS 18 system. Additionally, twenty sediment samples were collected from the dune field (on the slope, crest and though of dunes) and the surrounding using a Box Corer.

In this work, we present the very detailed morphologic and sedimentological analysis of these features with the aim to discuss their possible mechanism of formation; and to assess their potential activity by comparing the present bathymetry with a previous survey in 2001. Dunes are widely distributed between 60 and 110 m depth covering an area of 23 km2 (Fig. 1). Dunes range from 20 to 1400 m in wavelength and from 0.2 to 1 m in height. They correspond to medium and large subaqueous dunes [6]. They display asymmetrical and slightly symmetrical (SI between 0.55 and 0.85) morphology with the lee side oriented towards the SW. Sea-bed samples collected from this area indicates that the bottom sediments are medium- to coarse-grained sands. The asymmetry of the dunes indicates unidirectional along-shelf currents that are consistent with the geostrophic flow described on the Murcia margin [7] suggesting that these features may be controlled by the regional circulation pattern. It is still an open question whether these bedforms remain actives at present. To investigate the long-term dynamics of dunes, two datasets of successive bathymetric surveys (2001 and 2013) will be compared together with time-series analysis of near-bottom currents.

Abstract

In the Mediterranean basin, marine storms, often associated with flash floods of coastal rivers, are episodic and intense physical processes that are capable of transferring terrestrial organic matter to the continental shelf and up to the deep sea by strong bottom currents along submarine canyons. In order to study accurately a such event, an oceanographic cruise (CASCADE) was performed in the Gulf of Lion (NW Mediterranean Sea) in winter 2011. Two mooring lines equipped with a near-bottom sediment trap (25 m above bottom) were deployed at 290m and 365m water depth on the southern flank of the Cap de Creus Canyon. In order to characterize and to assess the origin of the particulate matter fluxes, the total mass flux, amino acids, opal, particulate organic carbon (POC) , as well as its stable isotopic ratio ($d^{13}C$) were determined.

Keywords: Canyons, Organic matter, Stable isotopes, Gulf of Lyon, North-Western Mediterranean

In the Mediterranean basin, marine storms are episodic and intense physical processes that are often associated with flash floods of coastal rivers. These events are capable of transferring terrestrial organic matter to the continental shelf and up to the deep sea by strong bottom currents along submarine canyons. With the aim of improving our knowledge on the transfer of material during extreme meteorological conditions, an oceanographic cruise (CASCADE) was performed in the Gulf of Lion (NW Mediterranean Sea) in winter 2011 [1]. This period is favorable for the study of intense meteoclimatic events and the resulting hydrodynamic processes such as dense shelf water cascading or storm events. During the CASCADE cruise, two mooring lines equipped with a near-bottom sediment trap (25 m above bottom) and a current-meter profiler, were deployed at 290m (Trap 1) and 365m (Trap 2) water depth on the southern flank of the Cap de Creus Canyon (Gulf of Lion) from the 4th to the 21st March 2011 (sampling interval of 35h) (**Fig.1**). In order to characterize particulate matter transfers, the total mass flux (TMF), amino acids, opal, particulate organic carbon (POC) , as well as its stable isotopic ratio ($d^{13}C$) were determined from the trapped material.

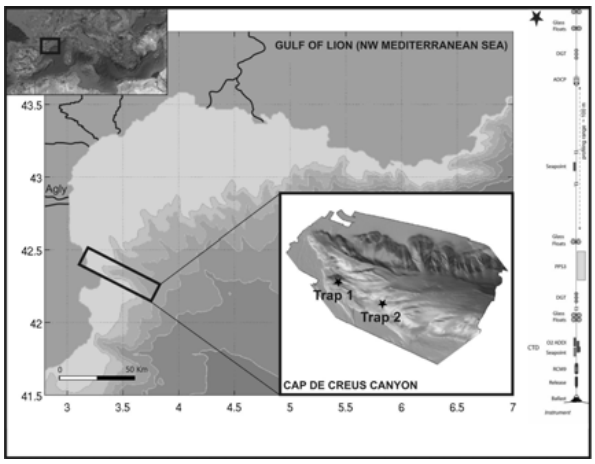

Fig. 1. Location of the Study Area and CASCADE mooring line model

An intense marine storm occurred during the cruise (from the 12th to 16th March 2011) with, simultaneously, flash floods at several nearby coastal rivers (e.g Agly River: flood peak of 1089 $m^3 s^{-1}$ with a return period of 15 years, for information the averaged runoff is 6.5 $m^3 s^{-1}$). At the peak of the storm, sediment traps collected around 150-200 g $m^{-2} d^{-1}$ of POC and opal depleted materials. The grain size distribution of the trapped material showed that settling particles were predominantly (around 75%) composed of silts (4-63 µm), although a slight increase of clays (<4µm) was observed during the storm. Moreover, the $d^{13}C$ values of bulk material varied slightly according to the TMF.

In order to improve our study on the trapped material, samples were fractionated into 3 size fractions: >63mm, 4-63mm and <4mm [2]. In the marine storm samples (cups # 7,8 and 9), the POC-richest grain size fraction was surprisingly the coarse material (POC≈ 4%), followed by clays (POC≈ 2%) and silt (POC≈ 1%) which tend to prove that organic-rich aggregates or biological debris were associated to the coarse lithogenic material. The $d^{13}C$ values of each of the grain size fractions were relatively constant within the silt and coarse fractions (between -25‰ and -24‰). In contrast, an isotopic $d^{13}C$ discrepancy occurred within the clay fraction of trap 1, more exactly in cups # 7, 8 ,9 and 11, which exhibited a more terrestrial isotopic signature (around -27‰). Terrestrial clays deposited into continental shelf sediments and the southern canyon flank were likely resuspended during the hydrodinamical processes of the storm which explain the ^{13}C-depleted values obtained during this period. On the other hand, the ^{13}C-depleted obtained after the peak flood (cup #11) may indicate a more direct transfer of riverine organic matter absorbed on clays.

This study show that the quality (nature and origin) of the trapped organic material during a storm changes according to the size of particles. Further grain size studies should be performed on the trapped material during low mass fluxes in order to get an overall view on the off-shelf export of particulate organic material hrough canyons of the NW Mediterranean Sea.

SEDIMENT TRANSPORT DOWN TO THE BARI CANYON (SOUTHERN ADRIATIC): PROCESSES INVOLVED IN TRANSFERRING PARTICULATE MATTER TO THE DEEP BASIN

L. Langone [1]*, I. Conese [1], S. Miserocchi [1], A. Boldrin [1] and M. Turchetto [1]
[1] CNR-ISMAR, Institute of Marine Sciences - leonardo.langone@ismar.cnr.it

Abstract
Time-series of particle fluxes and hydrological data acquired on moorings deployed between 2004-05 and 2009-2012, document that dense shelf water cascading (shallow or deep) exerts first order control on the particulate fluxes through the Bari canyon system.

Keywords: Sediment transport, Deep sea processes, Bari Canyon

The Bari canyon is an area of dense shelf water (DSW) cascading. Particle fluxes and hydrodynamics were monitored by deploying 3 moorings in both branches of the Bari canyon and on the adjacent open slope from March 2004 to April 2005. Late March of both years were characterized by colder bottom waters, a notable intensification of bottom currents and increased particle fluxes, which indicated intense episodes of dense shelf water cascading. (Turchetto et al., 2007). The Bari canyon was thus showed to be an efficient conduit in delivering suspended sediment from shelf to deep basin. The origin of particles was a mix of marine material by biological production and sediment resuspended from the canyon head and upper slope (Tesi et al., 2008).

Nevertheless, further questions remain, such as: Cascading process occurs every year? Cascading is the only process driving the particle transfer across the South Adriatic margin? On a long time scale, the frequency of cascading events is decreasing due to global warming? To answer these issues, further observations were necessary. In March 2009, a new instrumented mooring (mooring DD) at 860 m water depth was deployed in a field of sediment waves situated down current to the Bari canyon. In March 2010, a second mooring was installed in the northern channel of the canyon mooring BB), in the same position of mooring B deployed in 2004.

Winters 2009-2011 were mild and wet. The Po river discharge remained relatively high throughout the whole winter. In winter 2012, the North Adriatic experienced a severe cold spell with Bora winds and reduced fresh water input from the Po river. The impact of these extreme weather conditions was the formation of extremely dense shelf water. During 2009-2011, trap fluxes showed much lower values with regards to the 2004-2005 experiment. Nevertheless, they varied both seasonally (spring peaks) and interannually. Very low near-bottom currents, never exceeding 20 cm s^{-1}, were recorded at both mooring sites. In addition, the water turbidity showed small amplitude peaks and the water temperature showed only minor decreases. In the canyon, fluxes were higher than those measured on the sediment wave field. In 2012, dense shelf water cascading enhanced mass fluxes up to 11 g m^{-2} d^{-1}. Total mass increased specially in the offshore station, where they were up to 5 times higher than peaks of previous years. In the canyon station, currents exceeded 70 cm s^{-1} and temperature dropped to 12.2°C at the near bottom. Surprisingly, the total mass peak occurred between 16 Feb-1 March, 3-4 weeks ahead of arrival of the North Adriatic Dense Water, suggesting the delivery of dense shelf water from another source area, maybe the Middle Adriatic Sea.

While is apparent that deep cascading of dense shelf water is the main process driving the particle transfer thought the Bari canyon in 2004-2005 and 2012, other processes, such as open ocean convection, storm-driven shelf-to-canyon particle transport, or shallow dense water cascading, were examined as forcing of the enhanced particle transfer during 2009-2011 springs.

No evidence was found to support the open ocean convection since peak fluxes were characterized by particles with low organic carbon contents, while high biological productivity would be expected from enhanced nutrient availability by the convective mixing. In addition, periods of high Chlorophyl-a by satellite images were not linked neither to periods of high TMF, nor to periods with higher OC contents.

The maximum significant wave height recorded at the Monopoli buoy was 4.78 m, but peaks of TMF and wave heights were only sometimes in phase. Hence, resuspension on the shelf by storm events and sediment transport down the canyon can be only a concause of increasing particles fluxes during springs.

In springs 2009-2011, the absence of signal of colder water at the near-bottom of the Bari canyon and in the sediment wave field, accompanied by weak currents, suggest the occurrence of shallow DSW cascading, which caused small-amplitude TMF peaks. In this condition, the poorly dense shelf water detaches from the sea bottom at its neutral buoyancy level and particles vertically sink from the intermediate nepheloid layer.

Abstract
Outcrops of rocks, directly exposed along the upper steep slopes (roughly between the shelf break and down to 800m) of several canyons and on deep rocky banks along southern France and western Corsica continental margins, have been observed during ROV explorations performed by Comex, from late 2008 to mid 2010, under the sponsorship of the French Marine Protected Areas Agency (AAMP). Video observations of these outcrops (unhappily not sampled) show several types of rocks ranging from thinly laminated white marls, massive conglomerates and sandstones, to probably aerially eroded metamorphic, magmatic and granitic rocks. In addition numerous fossil oysters banks have been observed on the Maures, Esterel and Corsica upper slopes by depth ranging between 240 and 750 m water depths.

Keywords: North-Western Mediterranean, Canyons, Continental slope, Rhone Fan

Between late 2008 and mid 2010 the French Marine Protected Area Agency (AAMP) has conducted, with the technical support of Comex SA, systematic explorations of 43 sites located within 13 areas of the French Mediterranean upper continental margins from the Spanish to the Italian borders (30 sites) and west of Corsica (13 sites). The aims of this program were chiefly to obtain states of reference concerning the local/regional environment variability, the protected, and potentially commercial, biological species, and to evaluate the potential various human impacts along the upper continental slope (from the shelf break to locally 800m), particularly within canyons heads and on several deep rocky banks. An unexpected, but not surprising, result from these explorations has been the observation of numerous rock outcrops, which in turn reflect the variability of the geological strata in which these canyons have been cut since the creation of the Western Mediterranean basin in Oligocene times. Off the Gulf of Lions coasts and with the exception of the "*rech Lacaze-Duthiers"*, all canyons appear entailed within Pliocene to Quaternary soft marls [1]. Off Provence, from the *Planier* to the *Blauquieres* banks, the upper continental slope is dissecting hard rocks, which show evidence of aerial erosion, and are presumed to be massive limestone similar to the nearby onshore *Calanques* karstic massifs. Aerial erosion is similarly believed to have shaped most of the likely metamorphic rock outcrops seen in a wide area from Toulon to Levant Island. Blocs of geometrically shaped formations, likely made of sandstone, or siltstone, probably of upper Oligocene/Miocene age, have been observed on the *Magaud* bank along the southern side of the *Stoechades* canyon, where such formations had previously been discovered and sampled [2]. Off Nice, in the *Paillon* canyon, massive conglomerates, of probable Pliocene age, and various marls, also already observed during several previous surveys [3] are locally outcropping by water depth between 400 and 660m. Finally the several ROV surveys, made in various canyons off western Corsica, have mainly shown massive hard rocks, whose nature is difficult to asses without sampling, but which seem to be made of aerially-eroded granite (St Florent to Calvi), rhyolites (of Galeria) and maybe volcanics. Off Propriano, along the *Valinco* and *des Moines* canyons slopes, white indurated marls are observed between 300 and 500m; they may tentatively be attributed to early Pliocene marine deposits. As for the southern french coasts, unfortunately no sampling was performed and therefore our geological attributions remain speculative. In many of the "rocky" canyons, off Provence, Maures, Esterel and Corsica, linear narrow banks of dead, or fossil, big oysters, already locally described in some areas of the Western Mediterranean, and dated around 3500 BC [4], have been observed by water depths ranging between 240m (Galeria canyon) and 700m (off Levant island).

PROCESSES ON THE PRECIPICE: SEAFLOOR DYNAMICS ACROSS THE UPPER MALTA-SICILY ESCARPMENT.

Abstract
The Malta-Sicily Escarpment (MSE) is a steep, sediment-undersupplied, carbonate escarpment incised by a series of submarine canyons. In this study we present data acquired from the upper MSE during the Eurofleets-funded CUMECS cruise to document a complex seafloor morphology comprising gullies, canyon heads, mass movement scars, channels, contourites and escarpments. The evolution of the upper MSE has been driven by the interaction of fault activity, sedimentary activity related to hemipelagic, pelagic and contouritic sedimentation, and seafloor incision by bottom current activity. Submarine mass movements play a key role in canyon development – they control the extent of lateral and headward extension, facilitate tributary development, remove material from the continental shelf and slope, and feed sediment into the canyons.

Keywords: Canyons, Geomorphology, Sediment transport, South-Central Mediterranean

The Malta-Sicily Escarpment (MSE) is a dominant morphological feature of the central Mediterranean, comprising a steep, 3 km high, NNW-SSE trending carbonate escarpment that extends 250 km southwards from the east coast of Sicily [1-2]. The MSE may be classified as a sediment-undersupplied margin because of the low estimated post-Messinian sedimentation rates in the region (~6 cm ka^{-1} [3-4]), as well as its isolation from terrestrial and coastal sedimentary inputs after the Messinian Salinity Crisis [5]. Studies carried out in the 1980s demonstrated that the MSE is also incised by a series of submarine canyons [2]. In June 2012, the Eurofleets-funded CUMECS cruise acquired multibeam echosounder data, high resolution seismic profiles and gravity cores from across 500 km^2 of seafloor across the upper MSE. These data reveal a complex and diverse seafloor morphology, which comprises: (i) A dense network of gullies and distinct larger and wider channels that extend all the way from the heads of the canyons to the shelf break. (ii) Four channels in the deepest part of the outer Malta Plateau. The longest channel (12 km long) dominates the northern part of the study area and its steeper northern wall is covered by a contourite. (iii) 67 mass movements, ranging from translational slides to debris flows, which affect the outer Malta Plateau and upper MSE. (iv) Elongated escarpments, some of which are colonised by *Antipatharia*, encrusting sponges and hydroids. These observations indicate that the upper MSE has been an active area of seafloor, and that its evolution has been determined by the interaction of: (i) fault activity, (ii) sedimentary activity, driven by hemipelagic, pelagic and contouritic sedimentation, (iii) seafloor incision, related to bottom current activity, and (iv) slope instability. The MSE presents an excellent study area to understand how mass movements and canyon processes may be interrelated. The mass movements are likely triggered by loss of support associated to channel and gully incision, canyon head retreat or retrogressive landslide development. The mass movements control the extent of lateral and headward extension of the canyons across the continental slope and shelf, as well as facilitate tributary development. They also remove material from the continental shelf and slope, feeding sediment and driving its transport down-canyon.

Abstract
Four tsunami layers (S7, S8B, S10 and S11) have been defined on the coastal deposits of the Saros Bay, North-eastern Aegean Sea. The sample S7 corresponds to 330 BC tsunamigenic earthquake. S8B and S10 may correspond to the events 394, 476 or 484, while S11 to 1437, 1456 or 1471.

Keywords: Saros Bay, Geohazards

Introduction:

The study area is located on the western extension of the northern branch of North Anatolian Fault Zone (KAFZ). More than 40 earthquakes of M≥6.0 magnitudes, 10 of which in or near the Saros Bay, occurred in the northern Aegean region from 479 BC to present. Even their historical data is extremely scarce, some of these earthquakes have resulted in tsunamis (Figure 1).

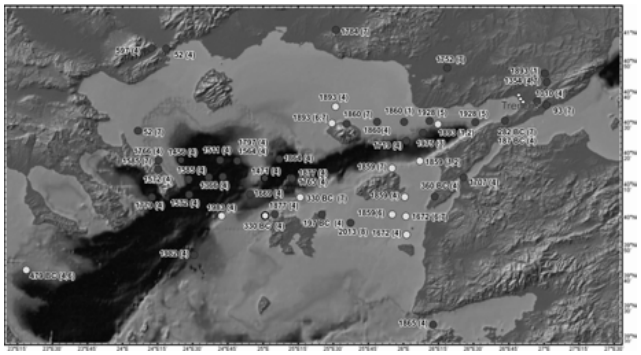

Fig. 1. Earthquakes of M≥6.0 magnitudes which affected the Saros Bay.

Experimental details:

We opened 15 trenches (S1 to S15) in the eastern part of the Saros Bay within the scope of EU project "Tsunami Risk And Strategies For the European Region" (TRANSFER). On the basis of stratigraphic setting, some candidate tsunami deposit samples have been collected for elementary analyses and also for age determination using Optically Stimulated Luminescence (OSL) method.

Results:

Many traces of liquefaction have been detected in the trenches of S12 (levels A and B), S13, S14, S15 (level B) and S15 (level C). Depending on their OSL ages, the sample S13 (1755±54) may be related to the one of the earthquakes occurred in 1659, 1719, 1730, 1752 or 1756, while the sample S14 (1458±37) may correspond to 1402 or 1456 events. None of these liquefaction events correspond to available tsunami records.

The sample S7 dates back to 327±150 BC, corresponding to 330 BC earthquake. The samples of S8 (level B) and S10 date back to 436±98 and 525±132, respectively. The dates of these two samples cover the time span of the earthquakes 394, 476 and 484. The sample S11, on the other hand, dates back to 1454±48, which may correspond to one of the earthquakes occurred in 1437, 1456 and 1471. The only earthquake whose tsunami data has been accurately documented is 330 BC. The study area deserves further paleotsunami studies and numerical tsunami modelling.

WIDE SPREAD GAS EMISSIONS IN THE SEA OF MARMARA, RESULTS FROM SYSTEMATIC SHIP-BORNE MULTIBEAM ECHOSOUNDER WATER COLUMN IMAGERIES

S. Dupré [1]*, C. Scalabrin [1], L. Géli [1], J. Augustin [1], P. Henry [2], C. Grall [2], N. Çagatay [3], N. Görür [3] and C. Imren [3]

Abstract
The Sea of Marmara located on the transform plate boundary between the Eurasian and Anatolian plates is characterized by an intense seismic activity causing catastrophic earthquakes (Ambraseys and Jackson, 2000). The understanding of the evolution of the fluid-fault coupling processes during the earthquake cycle is a challenge and the acoustic detection of gas emissions through the seabed may provide new insights on these processes. Fluid escapes are known to occur at the seabed in the Sea of Marmara (Zitter et al , 2008). The primary goals of the conducted study were to 1) establish an accurate spatial distribution of the seeps at the scale of the entire sea and 2) investigate the relationship with the fault network and the sedimentary environment.

Keywords: Acoustics, Geohazards, Tectonics, Marmara Sea

The submerged section of the North Anatolian Fault system within the Sea of Marmara is characterized by an intense seismic activity, but also by an intense fluid activity at the seabed. The understanding of the evolution of the fluid-fault coupling processes during the earthquake cycle is a challenge and the acoustic detection of gas emissions through the seabed may provide new insights on these processes.

The water column above the submerged section of the North Anatolian Fault within the Marmara Sea was investigated in 2000 and 2007 using side-scan and single beam sonars, acoustic techniques along a few, unevenly distributed profiles (Géli et al, 2008). Most gas emissions in the water column were found near the surface expression of known active faults. However, the effect of a possible bias related to profile implementation could not be entirely discarded. A systematic survey of the deepest areas of the Sea of Marmara (> 300 m), was thus conducted in 2009, using a ship-borne, multibeam echosounder, in order to establish an accurate spatial distribution of the seeps at the scale of the entire sea and to investigate the relationship with the fault network and the sedimentary environment.

Gas emissions clearly appear to be controlled by a combination of factors, including the tectonic activity, but also the presence or not of deep gas reservoirs and the nature of sediment cover. The multibeam, acoustic dataset provides an unique, unprecedented picture of the gas distribution within the deepest parts of the Sea of Marmara, that may usefully contribute to help understand some of the complexities of the tectonic history of the present-day North-Anatolian Fault. The distribution of gas emissions suggests that the Thrace Basin gas province is bounded by the Main Marmara Fault to the south and by the Thrace-Eskisehir Fault to the east and supports the idea that the area that gave birth to the present-day Sea of Marmara, is a broad shear zone, which has been characterized by a succession of episodes of strain localization and of strain partitioning.

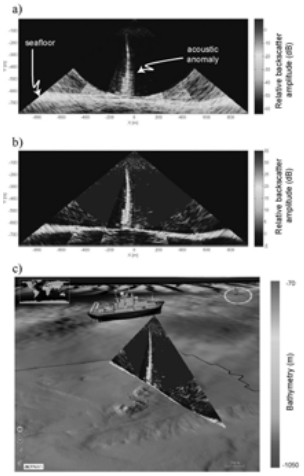

Fig. 1. A) b) Raw and processed polar echograms from EM302 multibeam echosounder water column data (Sonarscope © Ifremer). The acoustic anomaly recorded at 660 m waterdepth is located in the Western High above an active mud volcano located close to the North Anatolian fault (650 m). The acoustic imprint of the plume reaches almost the surface with an height of 600 m above the seabed. c) 3D view (Sonarscope 3DViewer © Ifremer) of the seabed with georeferenced processed polar echogram displayed in Fig. b. Note the R/V L'Atalante (courtesy of Altran) is not to scale. The background bathymetry was acquired in 2000 (Marmara expedition) with a Simrad EM300 multibeam echosounder while high-resolution bathymetry was recorded in 2009 (Marmesonet expedition) with a EM2000 echosounder mounted on the Aster^X AUV (Ifremer).

SHORT TERM MORPHOLOGY EVOLUTION OF NICE CONTINENTAL SLOPE (LIGURIAN SEA)

Maëlle Kelner [1]*, Sebastien Migeon [1] and Emmanuel Tric [1]
[1] Géoazur - kelner@geoazur.unice.fr

Abstract
Time series bathymetric data acquired between 1991 and 2011 have been used to evaluate the morphological evolution of Nice continental slope (South East of France, Ligurian Sea). This quantitative analysis highlights alternation between low morphological variations and erosional events with consequent volumes lost at shallow water depth (0-200m). On the basis of local seismic data, hydrogeological analysis and previous sedimentological analysis, we try to define the triggering erosive mechanism on a few years period.

Keywords: Ligurian Sea, Geohazards, Bathymetry, Continental slope, Geomorphology

Due to the urbanisation growth in the coastline, a greater assessment and predictive risk ability is becoming paramount regarding natural hazard generated in marine environment. Erosion and evolution of continental slopes through time are mainly due to sedimentary process such as submarine failures. This fast morphological evolution is featured by large landslides scars and deposits (volumes can exceed several hundreds of km3). Those large-scale failures have a strong impact but their return period is about several thousand years or more [1]. At smaller time scales, small failures with a volume of several hundreds of m3 are much more common. These failures lead to: (a) regressive motion of continental slope towards the coastline and (b) the deposition of high-frequency turbidites in the deep basins. This small-scale phenomenon acting on short time scale is significant, but is still difficult to detect.

The continental slope offshore the city of Nice (South East of France, Ligurian Sea) has been studied to address the problems of small-scale failures morphology, recent landslides triggering and volumes that could be remobilised during a failure event. Nice is located between the Southern Alps flank and the Northern continental slope of Ligurian sea (western Mediterranean). Cohesionless sediments on oversteepening slopes are affected by moderate seismicity and anthropogenic constructions extended offshore. Moreover, the few but violent Mediterranean rainfalls have an impact on sediments stability because of groundwater outflow. Such as a natural laboratory, this Ligurian margin is characterized by numerous submarine landslides [1]. The most recent and mediatized was initiated in October 16th 1979. This event partially destroyed the new international airport complex of Nice and triggered a 2m tsunami. Thus we focused our study on this high vulnerability area affected by recent instability to define and understand actual erosion process.

Identification of potential areas where slope movements could be triggered requires data with high spatial resolution. For this purpose we have used all the very high resolution multibeam bathymetry dataset acquired between 1991 and 2011. HD Bathymetric data was collected in the frame of different projects: EM1000 Ifremer (spatial resolution 10m, 1991), Creocean (1m, 1999), AUVGEO (2m, 2006), Haligure (1m, 2009) and MRIS (1m, 2011). The covered zone varies according to each of these cruise but data are common on an area from the coastline to 300m seaward and comprise the 1979 scars in front of Nice-côte-d'Azur Airport. Maps comparisons have been done for each time step, using two different techniques: (a) ArcGIS 3D analysis tools "Cut fill" which calculates the volume change between two surfaces pixel by pixel, and (b) an isobaths location comparison each 10m deep to highlight the regressive erosion.

Those methods have revealed the current evolution in space and time of the submarine morphology at shallow water depth (0-200m). Moreover it has provided the specific background to quantify erosion processes of the last 20yrs. Regarding to space evolution, areas of major sedimentation are principally located on gentle slopes (<7°). Moreover, our analysis shows some exceptions of sedimentation on bigger slopes for example the infilling of former thin channels and slide scars. They are rapidly filled and failure morphology could disappear from the sea floor in less than 5years. Biscara et al. (2012) [2] had the same filling results for Gabon slope in about 15-20years. Areas of major erosion failures have been determined mostly on slopes bigger than 10°. They define a scarp and its associated evacuation channel. The airport contours and the 1979 scarp show slow erosion processes. Nevertheless the main repartition of sedimentation/erosion leads us to say that the 1979 scar is still slowly moving. However, it appears that it is not currently the most active zone on the top slope. With these investigations we have established a high-precision quantification of sedimentation and erosion rates along different time intervals. Between 1991 and 2011, alternation between periods of low morphological variations and periods of failure events with consequent volume losses is clearly visible: erosion volumes are multiplied by a factor of 10 during fast periods. Similar small failure event with a return periods of around 5years were highlighted by Smith et al. (2007) [3] in upper Monterey Canyon (California).

Interpretations in term of triggering processes are still in progress using hydrogeological data, regional catalogue of seismic activity and previous sedimentological analysis. Actually such short time variation may be explained: (a) by specific local characteristics such as the presence of sensitive sediment layers reacting to freshwater phreatic inflow due to intense storms on the watershed [4]. For this purpose we are looking at hydrogeological data: rainfall, volumetric flow rates, groundwater outflow. (b) It is also possible that ground motion generated by moderate size earthquakes during the analysed period had a key role in the failure acceleration. In order to analyse this we are using seismological location and PGA values. Finally, (c) sedimentation rates, overload and critical slope can play a fundamental role. It will be initially studied with previous geological and geotechnical research.

These observations and quantifications reveal failure processes that are still quite active and significant over very short periods of time. This whole study is a next step in term of current stability evaluation of the Nice submarine slope which requires the precise identification of slope instabilities, evaluation of their recent and past activity and discrimination of triggering factors.

ACTIVE SEABED PROCESSES AND POTENTIAL GEOHAZARDS IN THE CENTRAL NILE DEEP-SEA FAN FROM INTEGRATED SWATH BATHYMETRY AND 3D SEISMIC DATA

F. Mary [1]*, S. Migeon [1], E. Cauquil [2], J. Mascle [3] and P. Imbert [4]
[1] Géoazur, Valbonne, France - flmary@geoazur.unice.fr

[4] Total, Pau, France

Abstract
Geohazards are consequences of geological processes. If not identified, they may put at risk industrial activity such as subsea installation or drilling, with potential impact on safety and environment. Previous studies showed that the Central Nile Deep-Sea Fan (NDSF) is characterized by a rough and chaotic seabed surface and affected by numerous gravitational instabilities such as landslides as well as by fluid seepages [1]. Mapping this area from swath bathymetric and seismic investigation of the seafloor allowed identify several features directly on the seabed such as active fault scarp, fluid seepages, mass-wasting and mass-flow, or detected in subsurface sedimentary layers such as shallow fault, buried channels, mass transport deposits (MTDs), and shallow gas-charged sediments, which may induce potential and considerable geohazards.

Keywords: South-Eastern Mediterranean, Nile Delta, Bathymetry, Geohazards

Different types of geological geohazards are known to affect continental margin environments. Following a nomenclature defined by Stauffer et al (1999) [2], they can be divided into seabed geohazards (fault scarp, fluid venting, landslides, debris flows) and subsurface geohazards (shallow faults, buried channels and landslides, shallow gas-charged sediments). Among these processes, submarine landslides are among the most abundant and are the main causes for remobilization and transfer of large volumes of sediments on continental margins. Slope destabilizations may cause destruction of infrastructures like drilling platforms, posed or anchored at the seafloor, and may also induce tsunamis in coastal areas. In marine environments, geohazard and risk assessments are thus requiring valuable identification of the different geohazard-related structures and of their signatures, as well as a tentative evaluation of their recent and past activity. This study focuses on the Central NSDF where numerous shallow submarine landslides and abundant fluid seepages have already been identified [3; 4]. Based on a dataset including multibeam bathymetry and backscatter, Chirp and seismic-reflection profiles (Géoazur laboratory) together with 3D seismic data (Total Company), a detailed mapping of the main geohazard-related structures has been established for the study area. On the seabed, failure-related structures are the most abundant and cover up to 25% of the surface of the studied area. Three types of mass-wasting and mass-flow events were observed on the continental slope: (a) Debris flows, characterized by 25-50 km long and 3-5 km wide bodies elongated in the main slope-angle direction; these features were triggered along the upper part of the continental slope where they left spoon-shaped scarps 25 m high. Some debris flows exhibit hundreds of scattered blocks (up to 3 m high and 40-100 m wide) rafted on top of the flows and arranged into linear segments. (b) Slumps are mainly located on the upper slope between 300-435 m water depths; they show as scarps (5 m high) followed downstream by lobate remobilized deposits (3-6 km long, 0.3-1.5 km wide). (c) Finally seabed sedimentary undulations are observed in the northwestern part of the study area, by water depths greater than 1200 m, and cover about 15% of the studied area. These features are 0.05-3 km long and oriented W/E to N-NW/S-SE. On seismic data, they are seen as overlying MTDs. We interpret them either as creeping/extensional features associated with shallow rotational faults or as sediment waves as described elsewhere [5]. Dendritic network of curved grooves lies on the upper continental slope around 900-1100 m water depths; they represent about 5% of the studied area. They are also seen on top of buried MTDs and are interpreted as extensional seabed fractures. Fluid seepage areas, which include large fields of pockmarks and seven mud volcanoes (MV) represent about 5% of the surface of the studied area. Some MVs exhibit recent activity markers such as mud flows. Finally, normal fault scarps, up to 70 m high and few kilometers long, were observed. They are oriented N/S to W/E. On seismic profiles, they can be recognized up to more than 1 s penetration below seafloor and clearly affect deep sedimentary layers; they are believed to be part of the deep Rosetta Fault system. Most of these structures exhibit a well-developed expression at the seafloor, suggesting they have been triggered/deposited (failure-related structures), active (fluid seepages) and/or rejuvenated (fault scarps) during recent times. From 3D seismic, shallow fault, buried channels, MTDs, and shallow gas-charged sediments, were identified within the first 300 ms below the seafloor. The different types of processes affecting the present-day seafloor should thus have had a recurrent activity for a long time period of time. Because of their number and of their distribution, mass-wasting and mass-flow events represent the strongest geohazard within the studied area. Together with fluid ventings, they could have a high hazard potential. Since only few historical earthquakes are known on the Egyptian margin, faulting should represent by opposition a relatively low hazard potential. Our interpretations should however be confirmed by attempts of dating of these processes.

GEOACOUSTIC CHARACTERIZATION OF THE MARMARA ISLANDS SHELF MARGIN, TURKEY

Kurultay Öztürk [1]*, Denizhan Vardar [1] and Bedri Alpar [1]
[1] I.Ü. Institute of Marine Sciences and Management - kurultay@istanbul.edu.tr

Abstract
Acoustic properties of the sea bottom and its dominating structural features have been detected in the vicinity of the Marmara islands, SW part of the Sea of Marmara. Based on new high-resolution chirp seismic reflection data collected in 2010, a series of W-E trending faults bounding the Marmara Island to the south caused characteristic deformative structures on the sea floor. The fault lineation outlined in this study by the aid of distribution of earthquake epicenters were interpreted as antithetic faults, whose sense of displacement is opposite to its associated major fault; namely the northern branch of the North Anatolian fault. Parallel to the global sea level rise, they must be active during the recent evolution of this archipelago within the regional framework of extensional tectonic regime.

Keywords: Marmara Sea, Seismics

Introduction The study area covers the shelf area of the Marmara Islands which are an archipelago in the Sea of Marmara, located in its mid-west portion, off the Kapidag Peninsula on the Asian coast. Among other smaller islands Ekinlik, Koyun, Hayirsiz, Fener, Yer, Tavan and Mamali, the Marmara Island is the highest (710 m) and biggest with a surface area of 117 km^2 [1]. The region has been affected by two moderate-scale earthquakes occurred in the years 1265 and 1935, both representing similar characteristics. Both of them were shallow and affected the western side of the Marmara Island mostly [2]. The main scope of this study is to identify shallow active tectonic features on the sea floor and define seismotectonic characteristic of the region.

Material and Method Chirp seismic experiments are effective and feasible ways for the characterization of the sea bottom structures. We have collected 350-km-line chirp data using Bathy 2010P™ Chirp sub-bottom profiler with 4 transducers, each producing 2-8 kHz simultaneous chirp signals, in array configurations to provide full power capability. Peak signal detection allowed the system to provide high performance sub-bottom survey capability. The depths were obtained using a typical interval velocity of 1500 m/s, which has been found to be appropriate for both the water column and near-surface siliciclastic sediments. We obtained a depth resolution of 0.2 meters with 50-60 meters of bottom penetration, depending on the bottom type and selected pulse length. Kogeo Seismic Toolkit 2.7 was used for elementary data processing.

Results and Discussion Knowledge of the acoustic properties of the sea bottom is necessary in every aspect of marine sciences. The seismic data we gathered represents a series of faults mostly extend east to west and parallel to the southern coast of the Marmara Island, in addition to rapidly changing deformative structures on the sea floor and slump-like features behind these faults (Fig. 1). Stratigraphically the structural elements are evidently small-scale secondary faults with normal-to-oblique character, at the western extension of the boundary fault along the northern shores of the Kapidag Peninsula.

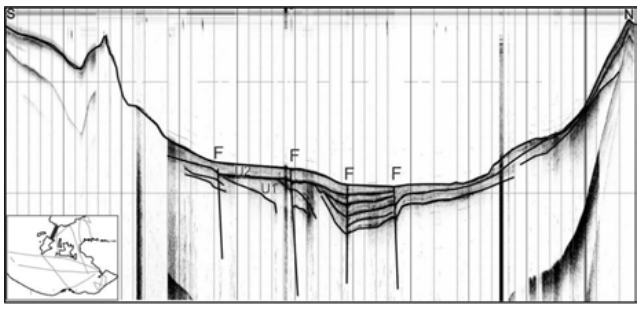

Fig. 1. Succession of normal faults between the Marmara islands

The sediments within the basin are lengthened by these antithetic normal faults possibly dying in a major synthetic curve fault limiting the hanging wall in downdip direction. These are believed to be active faults, which may have been triggered or re-activated by bigger earthquakes (M>7.0) occurring on the main fault cutting through the deep basins of the Sea of Marmara. The distribution of the instrumental earthquakes (Ms≥3) occurred between the years of 1930 and 2012 [3] also reveals this secondary fault activity within the study area (Fig. 2). In conclusion, the structural elements outlined in the study area are directly related with the antithetic faults of the northern branch of the North Anatolian fault, and controlled the development of the shelf area between the Marmara islands.

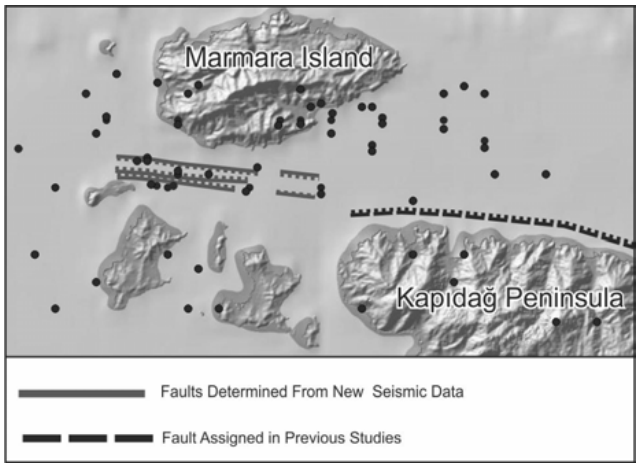

Fig. 2. The comparison of the faults defined in this study with the epicentral locations of the earthquakes (Ms≥3)

LATE QUATERNARY ACTIVE TECTONICS AROUND THE SOUTEASTERN AEGEAN SEA

Atilla Ulug [1]* and Nilhan Kizildag [1]
[1] Dokuz Eylul University Institute of Marine Sciences and Technology - atilla.ulug@deu.edu.tr

Abstract
The high resolution seismic data has been obtained in order to reveal the tectonic activity around the southeastern Aegean Sea. The region is very important in terms of its location in the major plate boundary near the intersection between the Hellenic and Cyprus arcs. A number of active faults have been detected on the seismic profiles that related to this active tectonism.

Keywords: Tectonics, Seismics, Aegean Sea

Introduction
The southern Aegean Sea is a very important region in terms of its seismicity and morphotectonic features. The region has important tectonic significance due to its location in the major plate boundary within the eastern Mediterranean collision zone, near the intersection between the Hellenic and Cyprus arcs. The collision between the Arabian and African plates with Eurasia and the westward motion of Anatolian plate relative to Eurasian plate give rise to N-S extension of the southern section ([1]). This tectonic structure comprises E-W oriented grabens since the Miocene times ([2]). Epicentral distribution of the earthquakes shows a high seismic activity in this region.

Study area
The study area is located in the southeastern Aegean Sea, including Gökova and Hisarönü Gulfs which are bordered by the Bodrum Peninsula to the north and the Bozburun Peninsula to the south (Fig.1). The Gökova Gulf is characterized by wide eastern shelves, narrow southern and northern shelves. Datça Peninsula is bounded by E-W directed fault system located in its both northern and southern border. In the eastern Hisarönü shelf, seafloor gradients are lower than 0.4º ([3]).

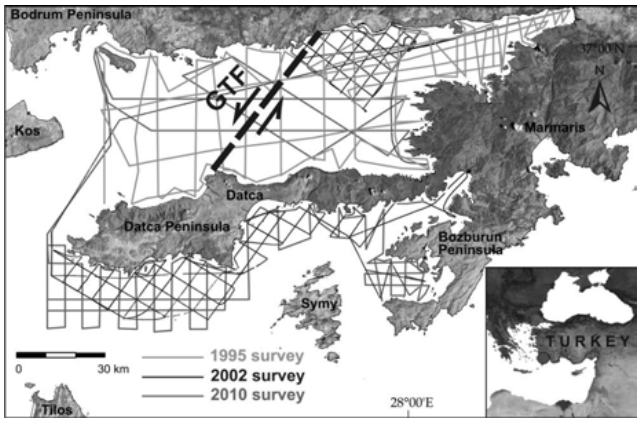

Fig. 1. The location map of study area and seismic lines. GTF: Gökova Transfer Fault.

Materials and Methods
This high-resolution seismic survey was carried out by using 40 in3 Airgun source and 3.5 kHz Subbottom Profiler and Chirp systems in 1995, 2002 and 2010 during a cruise of R/V K. Piri Reis of Institute of Marine Science and Technology (Fig. 1).

Results
The high resolution seismic data have been collected at the southeast Aegean Sea in order to investigate the late Quaternary tectonic activity. A large number of active faults have been detected on the seismic profiles. Overall fault pattern of Gulf of Gökova shows a significant distinction between the western and eastern sectors which separated by Gökova Transfer Fault (GTF, [4]) (Fig. 1). A number of earthquakes were occurred on GTF zone in 2004, in contrast to known E-W direction fault system. This active basin which is associated with strong earthquakes may continue to produce destruction and coastal subsidence. A numerous faults were detected in the western Datça Peninsula ([3]) and Gökova Gulf (Fig. 2). The traces of destructive seismic activity can be seen in the ancient Knidos city. The ongoing tectonic movement of the southeastern Aegean Sea and its surrounding area was always important and should be considered as a region which has the potential to produce earthquakes.

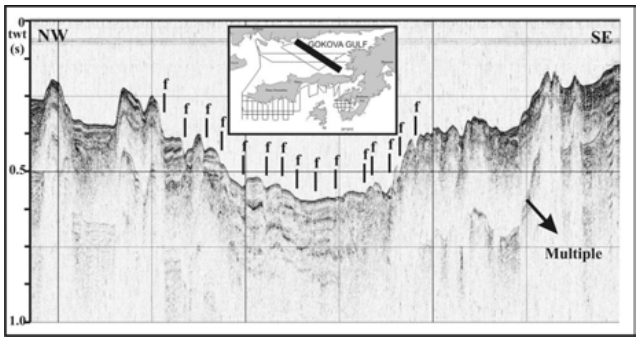

Fig. 2. Airgun seismic reflection profile from Gökova Gulf. f: Fault. Bold line shows the location.

POLYCYCLIC AROMATIC HYDROCARBONS IN SEDIMENTS FROM CYPRUS

E. Darilmaz [1]*, A. Kontas [1], E. Uluturhan [1], I. Akçali [1] and O. Altay [1]
[1] DEU, Institute of Marine Sciences and Technology Baku bulvari No:100 Inciralti-Balcova - enis.darilmaz@deu.edu.tr

Abstract
This study presents 16 US EPA polycyclic aromatic hydrocarbons (PAHs) in 23 surface sediments from Cyprus, Mediterranean. The concentrations of total PAHs were ranged between 4.9-76 ng/g and could be generally considered to be low. The results showed that Naphthalene was the predominant species among the analyzed compounds. PAHs with two and three rings were generally the most abundant, both contributing 50–90% to the sum.

Keywords: Pah, Sediments, North-Eastern Mediterranean

Introduction
Polycyclic aromatic hydrocarbons (PAHs) are well known as environmental pollutants. They are dangerous even at low concentrations and included in the priority pollutant list of the European Union and US Environmental Protection Agency (EPA) due to their mutagenic and carcinogenic properties [1], [2]. The island of Cyprus is located in the Mediterranean Sea and maritime transportation, tourism, treated or untreated domestic and industrial wastewater discharges, oil spills, agricultural wastes reaching the sea by rivers and also mining activities are the main reasons of pollution along the coast of Cyprus.

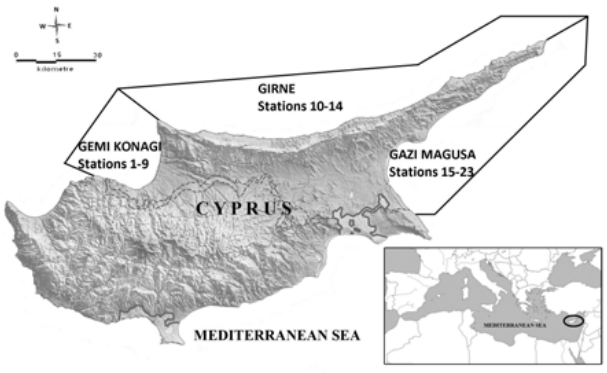

Fig. 1. Sampling areas of Cyprus

Materials and Methods
Surface sediment samples were collected from 23 stations using box core during a cruise of the R/V K. Piri Reis in 2010. This study founded by the Turkish Scientific and Technological Research Council TUBITAK/111Y160. All sampling procedures followed according to internationally well established guideline [3]. Sediment samples were freeze-dryed, sieved (250 μm) and extracted using the microwave system. Extracts were analyzed using an Agilent GC-MS.

Results
Sixteen parent PAHs (naphthalene: Nap; acenaphthylene: Acy; acenaphthene: Ace; fluorine: Flu; phenanthrene: Phe; anthracene: Ant; fluoranthene: Flt; pyrene: Pyr; benz[a]anthracene: BaA; chrysene: Chr; benzo [b]fluoranthene: BbF; benzo[k]fluoranthene: BkF; benzo[a]pyrene: BaP; indeno [1,2,3-cd]pyrene: InP; dibenz[a,h]anthracene: DA; benzo[g,h,i]perylene: BPer) were analysed in sediments. Individual PAH concentrations (ng/g) in sediments ranged between 3-42 for Nap; 0,41-3.55 for Acy; 0.01—0.53 for Ace; 0.02-3.61 for Flu; 0.51-15.3 for Phe; 0.52-12.2 for Ant; 0.25-11.1 for Flt; 0.14-8.39 for Pyr; nd-3.56 for BaA; nd-6.24 for Chr. BbF and BkF were detected only two stations and BaP, InP, DA, and BPer were not detected. Among the all analyzed compounds, Naphthalene was the predominant species. PAHs with two and three rings were generally the most abundant, both contributing 50–90% to the sum. The minimum concentrations of Nap, Acy, Flu, Phe, Ant, Flt, Pyr, BaA and Chr were detected at Gemi Konagi area (Station 7). The maximum concentrations of Ace and Phe were obtained at Girne area besides the highest Nap, Flu, Ant, Flt and Pyr were found at Gazi Magusa area. It is explained that the relatively high individual PAHs and total PAH concentrations at Girne and Gazi Magusa areas depend on shipping, port and maritime activities. Total PAH concentrations ranged from 4.9 to 76 ng/g in sediment from Cyprus. The minimum total PAH level was found at station 7. According to Baumard et al. [4], levels of PAHs can be generally considered to be low.

MARINE ORGANIC POLLUTANTS IN SURFACE SEDIMENTS FROM THE EASTERN AEGEAN COAST

Tolga Gonul [1], Filiz Kucuksezgin [1] and Idil Pazi [1]*
[1] Institute of Marine Sciences and Technology - idil.erden@deu.edu.tr

Abstract
Aliphatic and polycyclic aromatic hydrocarbons, organochlorinated compounds were determined in surficial sediments from the Aegean Sea in 2008. Total aliphatic hydrocarbons ranged from 330 to 2,660 ngg^{-1} dwt, while aromatics varied between 73.5 and 2,170 ngg^{-1} dwt. Total concentrations of OCPs and PCBs in sediments ranged from bdl to 17.8, bdl to 26.1ng g^{-1} dwt, respectively. Based on the sediment quality guidelines, PAH levels at all sites were below the effects range-low (ERL) and effects range-median (ERM) values except fluorene.

Keywords: Aegean Sea, Sediments, Pollution, Pesticides, Petroleum

Introduction
Organochlorines (OCs), such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs), represent an important group of POPs that have caused worldwide concern as toxic environmental contaminants. Among organic pollutants, polycyclic aromatic hydrocarbons (PAHs) are the most ubiquitous and constitute a major group of marine environmental contaminants. The Aegean Sea is part of the Eastern Mediterranean. There are a number of rivers along the Eastern and Western coast of the Aegean Sea through which a large amount of contaminants is being transported into the marine ecosystem thereby causing a great concern for marine pollution. The main objectives of this study are to investigate the occurrence and distribution patterns of OCPs, PCBs, aliphatics and aromatic hydrocarbons in sediments, which gave the information about status of contamination, provide a better understanding of recent distribution, possible sources as well as potential biological risk of DDTs, PCBs and PAHs in the study area.

Material and Methods
14 surface sediment samples with 3 replicates were collected from the Eastern Aegean coasts in July 2008. Meric River Estuary, Dardanelles Strait entrance, Edremit, Dikili, Candarli and Izmir Bays were sampled along the Northern Aegean coast, while Datca, Menderes Region, Kusadasi, Akbuk, Gokova and Marmaris Bays were located in the southern coast. Marine sediment samples were analysed according to [1] for petroleum hydrocarbons, [2] for OCPs and PCBs, respectively.

Results and Discussion
Aliphatic hydrocarbons consisted mainly of C10-C34 *n*-alkanes with total concentrations ranging from 0.25 to 2.37 μgg^{-1} dwt. The total concentrations of 19 PAH ranged from 73.5 ngg^{-1} to 2,170 ngg^{-1}. The highest level was observed at Izmir Inner Bay, which is close to the Metropolitan of Izmir. In the present study perylene, indicating a diagenetic origin was found in all sediment samples and its concentration varied from 9.8 to 85 ngg^{-1}. The entire investigated samples exhibited pyrolytic input except Dardanelles and Izmir Inner Bay. Concentrations of ΣDDT ranged from bdl to 17.3 ngg^{-1} dwt. The concentrations of ΣCyclodienes (including heptachlor, aldrin, dieldrin, endrin) in the sediments were bdl-0.82 ngg^{-1} dwt. The results showed that sediments were mainly under oxic conditions. Also, findings of this study indicated that early DDT influxes and, by implication, non-existing DDT use throughout the region. PCBs concentrations did not exceed the ERM or PEL values, with the exception of sites Candarli Bay and Izmir Inner Bay, which showed concentrations above the ERL and TEL values.

Conclusions
PAHs in the study area tend to be derived predominantly from pyrolytic sources. The sediments from the entire sampling sites except Izmir Inner Bay should have no potential biological impact. The results indicated that the DDTs were the predominant contaminant in the sediments. PCBs were only measured at Candarli Bay and Izmir Inner Bay. The OCP contamination was mainly from the aged and weathered agricultural soils in all sampling stations in the western part of the Turkish coastal zone. Based on the sediment quality guidelines, DDTs and heptachlor would be more concerned for the ecotoxicological risk in the study area. The sediments from Candarli and Izmir Inner Bay could potentially cause acute biological impairment.

A SPATIAL ASSESSMENT ON CHEMICAL CONTAMINATION IN THE MARMARA SEA (TURKEY) SEDIMENTS

Leyla Tolun [1]*, Fatma T. Karakoc [1], Hakan Atabay [1] and Bilge Tutak [1]
[1] TUBITAK Marmara Research Center - Leyla.Tolun@tubitak.gov.tr

Abstract
The study presents a spatial assessment on pollutants such as organic carbon, poly -aromatic hydrocarbons(t-PAHs), Polychlorinated Biphenyls(PCB's) and heavy metals in sediment and biota from the Marmara Sea marine and coastal environment based on the MIM project results (MIM 2011). The contents of 6 elements in 67 samples establish that surface sediments in Istanbul and southern shelf and Izmit Bay display significant enrichments in heavy metals associated with high concentrations of total organic carbon, t-PAH and t-PCBs. The highest contamination of the organic pollutants were found in Izmit Bay.

Keywords: Sediments, Marmara Sea

Introduction
One of the main pressures affecting the marine environment results from chemical pollution. Contamination of the marine environment by chemical substances gives rise to considerable concern as it may result in serious adverse effects on ecosystem functions. WFD(2000/60/EC) and MSFD(2008/56/EC) considering the sustainability of waters, combine the efforts in achieving near background values of the Priority hazardous substances. Monitoring the environmental status of marine/coastal waters is essential since it allows an assessment of weather measures is effective. Chemical monitoring of the Marmara Sea marine environment has done in sediment and biota under the national monitoring program (2011 MIM proje). In this study the results of a limited number of contaminants in sediments such as t- PAH, PCBs and heavy metals were assessed. Enrichment factors were used for the assessment of heavy metal accumulation in sediments. This assessment results will be an initial step in determination of the environmental status of the Marmara Sea.

Material and Methods
67 surfaces sediments were collected from 46 different locations of Marmara Sea using a van Veen - type grab samplerin August 2011. Samples were analysed for their heavy metals(Al, As, Cu, Cd, Cr, Pb and Zn), total PAHs and PCBs contents by means of ICPMS + AAS, HPLC and HRGC respectively. Organic carbon (Corg) contents were measured by means of high temperature combustion method using Elemental Analyzer.

Results and Discussion
The mean organic carbon (Corg %) content for sediment is around 2.03% while the range changes between %0.57 - %5.67 (Figure 1). The Corg values are generally higher in enclosed bays compared to the mean of Marmara Sea. The highest Corg% mean values are recorded at the Izmit Bay. Following Izmit Bay, Kocasu River, South shelf, Bandirma Bay and Gemlik Bay have the highest Corg% mean values respectively. T-PAH concentrations ranged between 2-2547 mg/kg dry weight while the highest values were recorded at the mid and inner stations of Izmit Bay with 2547 and 847 mg/kg dry weight. It is well known that petrochemistry industries and refineries are located in the region. Regional means also support the previous finding with highest mean values recorded at Izmit Bay. Following Izmit Bay, Istanbul, Bandirma Bay and south shelf have the highest mean concentration of PAHs, respectively. According to the sediment quality evaluation approach (Long et al. 1995). All the bays in Marmara Sea are high risk regions in terms of PAH pollution. The highest value of total PBC (28, 31, 138, 153,and 180) was observed in Izmit Bay at IZ-22 station (0.167 µg/kg).Following Izmit Bay, Bandirma Bay and the mouth of Susurluk River showed high concentrations of PCBs. In general, the northern shelf sediments contain slightly lower metal values compared to those of the southern shelf. Total Zinc (Zn) content values in all the samples are above the shale average of 90 mg/kg. Highest Zn content values are observed in Izmit Bay. For all the samples the Arsenic (As) content was found to be above the shale mean of 10 mg/kg. The enrichment factors indicate the anthropogenic effects dominated in Istanbul and southern shelves and Izmit, Bandirma and Erdek Bays .

Abstract
Certaines espèces de microorganismes présentes dans les sédiments peuvent contribuer à la biodégradation des différentes fractions hydrocarbures qui font partie du pétrole. Des sédiments ont été prélevés dans deux sites de la baie de Sfax. C'est principalement la fraction des composés saturés qui est biodégradée, la fraction des aromatiques est uniquement affectée dans le cas des sédiments présentant le pouvoir autoépurateur plus élevé et cultivés dans de l'eau de mer enrichie, le milieu de culture qui enregistre les taux de biodégradation les plus importants.

Keywords: Gulf of Tunis, Geochemistry

Introduction: La biodégradation est le principal processus auto-épurateur du milieu marin. Dans les eaux et les sédiments on peut trouver plus de 30 genres et 100 espèces de microorganismes capables de dégrader les hydrocarbures (Louati, 2003). La biodégradation étant un processus ayant une finalité énergétique, les microorganismes utilisent les hydrocarbures comme source de carbone et d'energie pour leur métabolisme, même si cela implique une dépense initiale d'énergie considérable (Chaillan, 2005).

Materiels et méthodes: Les sédiments avec lesquels on a travaillé ont été prélevés à marée basse pendant le mois d'avril 2006 dans deux sites du littoral tunisien. Une radiale avait été décrite depuis la baie de la ville de Sfax jusqu'aux îles de Kerkennah, situées à une distance de 23 km de Sfax. Ainsi, on a obtenu des sédiments d'une extrémité de la radiale, où se trouve le cap Sidi Mansour, et de l'autre extrémité, correspondant aux îles de Kerkennah. L'objectif de nos expériences est d'estimer le pouvoir auto épurateur des sédiments côtiers susceptibles de recevoir les flux de polluants pétroliers résultant des activités économiques et industrielles dans les alentours. Le but est de vérifier s'il y a dans les sédiments prélevés des microorganismes capables de dégrader les hydrocarbures. Afin d'atteindre cet objectif, on détermine un protocole de traitement de ces sédiments. On prépare deux types de milieux de culture où on laissera incuber les sédiments ; un premier Milieu Minéral et un deuxième milieu correspondant à de l'Eau de Mer Synthétique Enrichie.

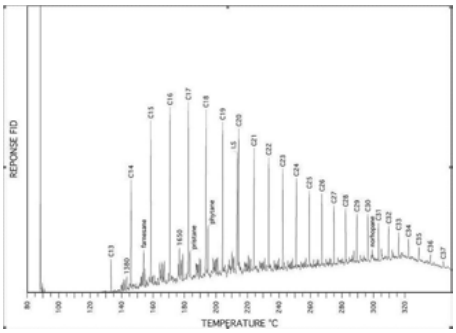

Fig. 1. Chromatogramme du pétrole brut (BAL 150) GC-FID.

Résultats et discussions: Le but de nos travaux au laboratoire était d'estimer la réaction de ces sédiments à une contamination éventuelle par le pétrole, donc leur capacité d'autoépuration. Si on compare le chromatogramme du pétrole BAL-150 (Figure 1) à ceux du pétrole de nos fioles témoins on peut observer une disparition des composés les plus légers, correspondants aux n-alcanes de la gamme C7 à C17. Ainsi, après une période de 26 jours, la plus forte biodégradation a été remarquée dans les échantillons A, correspondant au milieu Eau de Mer Enrichie et au sédiment Sidi Mansour, suivie par le taux observé dans les fioles B, qui se composaient de Milieu Minéral et du même sédiment Sidi Mansour. On peut ainsi déduire que ces sédiments ont une capacité d'autoépuration importante. On pourrait aussi affirmer que le milieu de culture en A, l'Eau de Mer Enrichie, permet une biodégradation plus prononcée car on a aussi observé que, à la différence des autres cas, la fraction aromatique était également dégradée. Ainsi, d'après nos résultats et nos observations, on peut établir que le milieu de culture eau de mer enrichie permet un développement plus intensif des microorganismes présents dans le sédiment que le milieu minéral ; d'autre part, ce sont les sédiments de la zone de Sidi Mansour qui présentent le plus fort pouvoir autoépurateur (Figure 2).

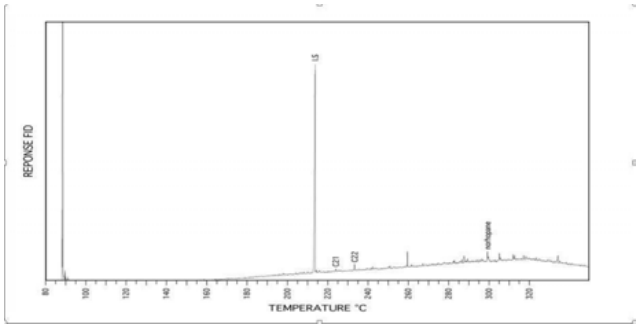

Fig. 2. Chromatogramme de l'échantillon A après 26j d'incubation.

Conclusions: La biodisponibilité des hydrocarbures n'a pas été limitée dans ces essais puisque les composés connus pour être biodégradables ont été totalement assimilés par les microorganismes. Un autre point à souligner est que la population microbienne des sédiments contaminés ramassés sur les plages du littoral de Sfax (Sidi mansour) et sur les îles de Kerkennah contient des souches indigènes aptes à la biodégradation des Hydrocarbures. Cette expérience a démontré que les sédiments du Golfe de Gabès, même non pollués actuellement ou antérieurement par des produits pétroliers, présentent un pouvoir autoépurateur élevé vis-à-vis des hydrocarbures qui leur permettrait une décontamination efficace en cas de pollution pétrolière de la zone.

MESSINIAN CRISIS: SEISMIC STRATIGRAPHIC VIEW FROM THE EGYPTIAN CLASTIC COASTAL PLAIN

John D. Pigott [1] and Mohamed I. Abdel-Fattah [2]*

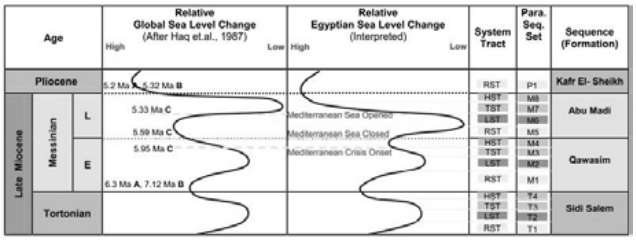
Abstract
A new interpretation of 1100 km of 2D seismic with 18 boreholes constrains the sequence stratigraphy of the Messinian Coastal Plain of the Nile Delta. Detailed seismic facies analysis coupled with depositional log motifs allows the identification of downstepping fluvial terraces within incised valleys. These fluvial terraces represent the preservation of Regressive Systems Tracts (RST) of [1] which record the fall of relative fluvial base level (sea level). Construction of a relative sea level curve (Tab. 1) from these observations shows that prior to closure, the global and Mediterranean relative sea level curves were coincident, but with Messinian isolation, the relative sea level curves are antithetic.

Keywords: Messinian, Sea level, Seismics, Stratigraphy, Nile Delta

The Egyptian Late Miocene stratigraphy directly record the fluvial channel cut and fill stages which bracket the Messinian crisis. Figure 1 illustrates in one reflection seismic line three channels with a downcut valley which record these stages. During the early Messinian, owing to a global sea level fall, the Qawasim sequence records the Nile delta progradation and channel downcutting on the coastal plain with deposition of fluvial RST M1 terraces. At its lowest level, Lowstand Systems Tract (LST) M2 channel lags occur. With a subsequent global sea level rise, as the Mediterranean is still connected, the Nile delta retrogrades with subsequent channel flooding with transgressive systems tract (TST) M3 shales culminating with a Highstand Systems Tract (HST) M4 shale. At around 5.95 Ma, the global and Egyptian sea level curves begin to diverge and at 5.59 the Egyptian Sea Level begins to fall which is recorded by the Late Messinian Abu Madi Sequence (Tab. 1).

Tab. 1. Global sea level change [2] and interpreted Nile Delta sea level change of the Messinian age in Egypt. The ages of the onset, opening and closing of the Mediterranean Sea are from [3]. Stratigraphic ages are from A: [1], B: [4], and C: [3]



As the Mediterranean Sea continues to lower Nile fluvial base levels, channels downcut with Abu Madi M5 terraces ending with M6 channel lags. Suddenly at about 5.33 Ma, the Egyptian sea level curve begins a rapid rise with the Nile Delta rapidly retrograding and the deposition of M7 transgressive prodelta shales which culminate with M8 widespread marine shale deposition accompanying the reconnection of the Mediterranean with the global ocean. These TST events ending with widespread HST shales provide excellent seals for hydrocarbon entrapment in the preserved fluvial terraces as evidenced by commercial gas production within. The construction of an Egyptian Messinian sea level curve which brackets the Messinian Crisis provides potential utility for correlation to other Mediterranean depositional systems if similar high resolution sequence defined relative sea level curves are constructed (e.g. correlations by [5]). However, much work remains to be done in specifying the absolute ages of relative sea level excursions for better temporal constraint upon future correlations documenting this extraordinary event in the Earth's history.

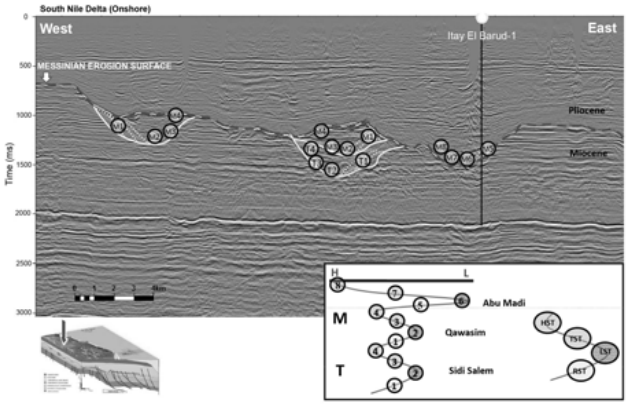


Fig. 1. Interpreted seismic line showing 1. RST deposits of Tortonian (T) Sidi Salem and early Messinian (M) Qawasim channels, 2. The Miocene/Pliocene boundary defined by Messinian sub-aerial surface in the southern part of the onshore Nile Delta area. Approximate depth range corresponding to the two way time scale is from the surface to 3200m.

Abstract

The DREAM workshop has been held in May 2013 in the framework of the MagellanPlus Workshop Series Program. The objective was to identify drill sites in the Mediterranean Sea that would test enduring hypotheses concerning the cause, nature, timing and consequences of a recent, rapid, extreme environmental event, the Messinian Salinity Crisis (MSC).

Keywords: Messinian, Seismics, Evaporites, Levantine Basin, North-Western Mediterranean

The discovery of the Messinian evaporites in the Mediterranean is probably one of the major achievements of the DSDP program. During the 40 years that have passed since the formulation of Messinian salinity crisis (MSC) scenario, many works have been dedicated to this event. Analysis of the onshore outcrops, of offshore seismic records and scattered samples from DSDP and ODP drillings, as well as the substantial effort of climate, chemical and geophysical modelling, have however not been able to provide a unified conclusive interpretation of the Messinian event, so that causes and chronology of the MSC are not yet fully understood. Certainly, the ongoing discussion is mainly linked to the fact that so far, due to technical limitations and safety issues (non-riser drilling vessel), only the few upper meters of the deep buried basin sequence has been recovered. The greater part of the Messinian succession that could provide a unique entire record of the MSC still lacks lithological and stratigraphical calibrations. In 2007, a deep revision of the knowledge of the Messinian event was performed in Almeria (Spain). A number of open question were identified and the need for ultra-deep drilling was stressed as: "… effort must be made to identify drill sites that intersect the most complete evaporite sequences and those that retain their sedimentological characteristics, i.e. avoiding successions that have been strongly modified by salt flow". In addition, many researchers suggested that, the full understanding of the Messinian event, will come from the drilling of different depositional settings, with specific emphasis on the Western versus Eastern basins. In this context, the DREAM proposal has been submitted to the ECORD MagellanPlus Workshop Series Program. The purpose of DREAM was to organise in May 2013 a workshop gathering three generations of scientists (those who participated in the discovery, those who are presently actively involved in research, and the next generation) in order to identify locations for multiple-site drilling (including riser-drilling) in the Mediterranean Sea that would allow to solve the several open questions still existing about the causes, processes, timing and consequence at local and planetary scale of a outstanding case of natural environmental change in the recent Earth history: the Messinian salinity crisis (MSC). The product of the workshop has been the identification of the embryonic structure of an experimental design of site characterization, riser-less an riser drilling, sampling, measurements, and down-hole experiments that will be the core for at least one compelling and feasible scientific proposal. Particular focus has been given to reviewing seismic site survey data available from different research groups at pan-Mediterranean basin scale, and on the need for additional site survey activity including 3D seismics.

Abstract
The DSDP Leg 23 was the only oceanographic cruise dedicated to the Red Sea that permitted to discover the presence of evaporites below the hemipelagic sediments of the Plio-Pleistocene. In the last 40 years the advanced researches in biostratigraphy have permitted to improve the geological dataset for the paleoceanographic reconstructions. In order to understand if the evaporites found in the Red Sea were comparable with those of MSC, new analysis have been carried out on 30 samples collected from cores (26-10) of Site 225A. The new multidisciplinary study has permitted to assume that during the late Messinian the Red Sea was connected to the Mediterranean Sea. Finally, during the Piacenzian the progressive phase of rifting of the Red Sea favoured the seafloor spreading, permitting the connection between the Red sea to the Indian Ocean.

Keywords: Evaporites, Red Sea, Foraminifera, Coccolithophores, Stable isotopes

DSDP Leg 23 was the only drilling cruise in the Red Sea which found evaporites below 170 metre-deep of hemipelagic sediments from the Plio-Pleistocene. Two years later the discovery of Messinian Evaporites in the Mediterranean Basin was made (Ryan et al., 1973). Six sites were drilled in the Red Sea. One of these (Site 225) was cored to a depth of 230 m (Whitmarsh et al., 1974) ending with several meters of anhydrite overlying halite. A strong seismic reflecting horizon (Horizon S) separates the Late Miocene evaporites from the early Pliocene ooze. In the original report, no mention was made of a correlation with the Messinian Mediterranean Salinity Crisis (MSC), which later became the subject of considerable discussion in the scientific community. Over the last 40 years, more advanced research into biostratigraphy and biochronology have allowed the original geological dataset to be improved thereby making if more useful for paleoceanographic and paleoecological reconstructions. Thus, in order to establish whetheher if the evaporites found in the Red Sea are comparable with those of the MSC, a new analysis of the 30 samples collected from cores (26-10) of Site 225A has been carried out here. Results from this multidisciplinary study using micropaleontology, mineralogy and geochemistry indicate that the cores studied span the interval from late Messinian to upper Pliocene. Samples from the late Messinian (cores 26-23) were characterized by strong variations in both on $d^{13}C$ and $d^{18}O$. In particular, samples from core 23 yielded the lowest values of $d^{18}O$ (-5.25‰; -4.95‰) and the presence of specimens of *Ammonia tepida* and *A. beccarii*. The tests of these two species were frequently deformed, indicating stress conditions at the bottom of the Red Sea. Similar assemblages, with low $d^{18}O$ values, typical of "Lago-Mare" conditions have been reported in several Mediterranean outcrops from the late Messinian as well as in the reference section of Eraclea Minoa (GSSP Messinian-Zanclean). Furthermore, specimens of planktonic foraminifera were not found demonstrating that the Indian Ocean was not connected to the Red Sea during that period. In the lowermost part of the Pliocene (cores 22-20), planktonic foraminifera were not yet present, while benthic foraminiferal assemblages were typical of hyposoxic conditions. Calcareous nannofossil assemblages contained *Reticulofenestra cisnerosii*, *Ceratolithus acutus*, and *Sphenolithus abies*. Pyrite and Fe-dolomite were abundant in this interval. The improvement in the environmental conditions started in samples of core 19, demonstrated by the occurrence of several species of planktonic foraminifera (*Candeina nitida*) and coccolithophorids (discoasterids, *Pseudoemiliania lacunosa*, *Helicosphaera sellii*, and small *Geophyrocaspa*. This drastic change in calcareous plankton and in their relative abundance coincides with more stable marine conditions with $d^{18}O$ values between -1.1 and 0.5‰. In the Pliocene, Mediterranean marine fossil records demonstrate that the species *C. nitida* have never been present there, while it is a species typical of the Indian Ocean. The newly obtained data indicates that during the late Messinian the Red Sea was connected to the Mediterranean Sea, with environments characterized by strong variations in salinity similar to those described in the "Lago-Mare" facies. Furthermore, the co-occurrence of *C. nitida*, the drastic increase in other species of calcareous plankton (coccolitophorids and foraminifera) and more stable values of $d^{18}O$, suggest an inflow of water from the Indian Ocean into the Red Sea. Finally, during the lowermost part of the Piacenzian, the progressive phase of rifting of the Red Sea favoured seafloor spreading, opening a connection between the Red sea and the Indian Ocean.

PRIMARY MESSINIAN SALINITY CRISIS SHALLOW GYPSUM VS. DEEP DOLOMITE FORMATION: A UNIFYING BIOGEOCHEMICAL MECHANISM

Wout Krijgsman [1] and Gert J. de Lange [2*]
[1] Paleomagn.Lab., Geosciences Utrecht; NL
[2] Marine Geochemistry; Geosciences Utrecht, NL. - gdelange@geo.uu.nl

Abstract
The Messinian Salinity Crisis (MSC) is a dramatic event that took place ~ 5.9 Ma ago, and resulted in the deposition of 0.3-3 km thick evaporites at the Mediterranean seafloor (1-2). A considerable and long-lasting controversy existed on the modes of their formation. However, during the CIESM Almeria Workshop, a concensus has been reached on several aspects (3). In addition, remaining issues to be solved were identified, such as for the observed shallow gypsum versus deep dolostone deposits for the early phase of the MSC (4). We present here a unifying mechanism in which gypsum formation occurs at all shallow water depths but its preservation is mostly limited to shallow sedimentary settings. In contrast, ongoing anoxic organic matter degradation processes in the deep basin result in the formation of dolomite.

Keywords: Evaporites, Geochemistry, Paleoceanography, Messinian, North-Central Mediterranean

A recently proposed scenario for the Lower Gypsum units of the Mediterranean Messinian salinity crisis infers that primary gypsum only formed in silled marginal basins while dolostones are found at deeper settings. We agree with these observations but reject the suggested coincidental presence of similar sills for all marginal basins as being too fortuitous. The onset of the Messinian Salinity Crisis is marked by the deposition of gypsum-sapropel alternations (Lower Gypsum unit). Increasing evidence has recently been put forward to show that this gypsum precipitation only occurred at marginal settings, while non-evaporitic rocks have been reported from deeper settings (4-7). The difference in sedimentary environment between marginal and deep Mediterranean settings is only tentatively explained by physical properties like tectonic restriction and/or sea level lowering, for which there is no solid evidence. The biogeochemical processes of gypsum formation during the Messinian salinity crisis, however, are poorly understood and commonly neglected. These may, however, explain that different MSC deposits formed in shallow versus deep environments without the necessity of exceptional physical boundary conditions for each. The following important processes have to be considered: a. Water column stratification due to continuing (but episodic?) inflow of oceanic water and enhanced evaporation thus enhanced salinity of Mediterranean water b. Organic Matter (OM) debris fluxes settling into the deep waters and being decomposed through oxygen and sulphate in particular c. Gypsum precipitation is controlled by the product of Ca2+ and SO42- concentrations d. The evaporation stage and related deep-water ventilation rate Gypsum precipitation in evaporating seawater takes place at 3-7 times concentrated seawater (8); seawater is always largely oversaturated relative to dolomite but its formation is thought to be inhibited by the presence of dissolved sulphate (9). Thus the conditions for formation of gypsum exclude those for the formation of dolomite and vice versa. Another process that links the saturation states of gypsum and dolomite is that of OM degradation by sulphate reduction. In stagnant deep water oxygen is rapidly depleted through OM degradation, then sulphate becomes the main oxidant for OM mineralization, thus reducing the deep-water sulphate content. In the latter process also considerable amounts of dissolved carbonate are formed. Implicitly this means that low-sulphate conditions (as anticipated for the MSC deep waters), i.e. unfavorable conditions for gypsum formation, always coincide with anoxic, i.e. oxygen-free conditions, although there is no direct relationship between the two. the Messinian Mediterranean would have been characterized by a reasonably well-mixed upper water mass ('shallow waters'), and a strongly stratified lower 'deep-water mass'. The MSC stratification with deep concentrated brines, is very stable, and can only be replaced by an even higher salinity water mass. As a result, continued evaporation and water replacement leads to (episodically) enhanced Ca and SO4 concentrations in the shallow waters, thus potentially to gypsum precipitation. Decreasing sulphate and concomitantly increasing dissolved carbonate in the deep waters limit gypsum preservation and permit dolomite formation to occur. Ultimately, it is the balance between OM-fluxes (primary productivity) and sulphate supply to the deep-water (ventilation, settling gypsum fluxes) that determine the environmental deep-water conditions, thus formation rate of dolomite. On the basis of this unifying mechanism, we have shown that gypsum precipitation in shallow water depths and dolomite formation in deep water settings during the early phase of the MSC in the Mediterranean is not incompatible (10). As a consequence one would expect a bath tub rim of gypsum at all shallow depths but gypsum appears mainly at silled marginal basins. However, a thick package of heavy gypsum on top of more liquid mud in a marginal/slope setting is highly unstable, thus any physical disturbance such as tectonic activity or sea-level change, would easily lead to downslope transport of such marginal gypsum deposits. The absence of gypsum and the presence of erosional unconformities at the sill-less Mediterranean passive margins concord to such removal mechanism (e.g. 5). In addition, large-scale resedimentation of gypsum has also been found for deep Messinian settings in the Northern Apennines and Sicily. Only at those marginal settings that were silled, the marginal gypsum deposits have been preserved (4).

Abstract

Le projet SIMBAD est dédié à l'acquisition de sismique réflexion haute-résolution ainsi que des données de terrain dans les îles Baléares dans le but d'étudier les dépôts associés à la crise de Salinité Messinienne (CSM) pour contraindre leur variabilité spatiale et quantifier la réactivation post-Messinienne des Baléares. Les marqueurs Messiniens sont ubiquistes dans la région: à terre où des évaporites sont forées vers Palma et en mer dans le bassin Algérien où on trouve du sel. Entre ces deux extrêmes, on trouve des dépôts fins reliés à la CSM qui enregistrent des déformations verticales récentes. Cette déformation est caractérisée par des plis et failles remobilisant aussi des blocs basculés ou chevauchements, de la flexure grande-échelle et une bascule régionale vers le bassin Algérien.

Keywords: Messinian, Balearic Islands, Tectonics

Le promontoire Baléares est un haut continental orienté NE-SO formant la terminaison orientale de la cordillère Bétiques dans le bassin occidental de la Méditerranée. Il est limité par deux bassins extensifs : le Bassin de Valence au Nord qui est un rift avorté Oligo-Miocène et le Bassin Algérien au Sud qui est de nature océanique. Cette configuration tectonique complexe est le résultat de phases extensive et compressive de même direction qui ont commencé à l'Oligo-Miocène et qui continuent aujourd'hui. La campagne SIMBAD (sur le N.O Téthys en janvier 2013) a permis l'acquisition de 1700km de données sismiques haute-résolution pour réaliser une étude comparative des dépôts sédimentaires reliés à la CSM sur promontoire et dans les bassins adjacents. Le but est de comprendre les relations spatio-temporelles entre les dépôts peu profonds sur le Promontoire et les évaporites des bassins profonds. Ces relations sont intimement dépendantes de la réactivation tectonique post-Messinienne du promontoire [2].

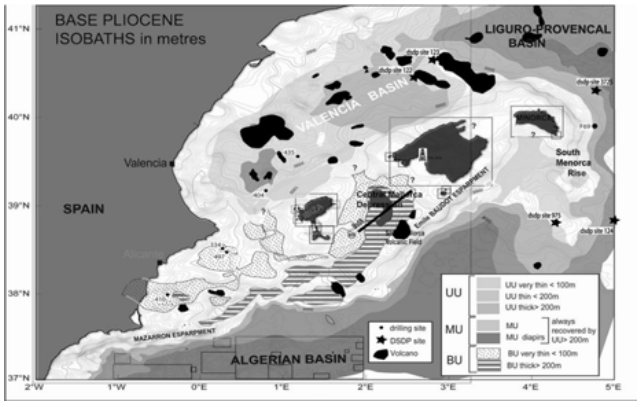

Fig. 1. Carte de répartition des dépôts Messiniens du Promontoire Baléares et localisation de la figure 2

Les résultats préliminaires de la campagne SIMBAD montrent que les marqueurs Messiniens sont ubiquistes dans la région (Fig.1). On les retrouve à des profondeurs variables : à Terre où ils ont été forés dans le cadre d'une étude hydrogéologique dans la zone de Palma de Majorque et se présentent sous forme de couches de gypse, en Mer, des dépôts épais et salifère (UU et MU) sont connus dans tout le bassin Algérien. Entre ces deux types de dépôts, les données de sismique réflexion montrent que des dépôts Messiniens existent partout (BU) sauf sur la plateforme continentale. Ils sont répartis en petits bassins dont on questionne la continuité. En effet ces dépôts Messiniens enregistrent des déformations verticales depuis la CSM jusqu'à aujourd'hui. D'une part, des évidences de compression récente s'expriment par des petits plis et failles locales qui remodèlent la bathymétrie ou les surfaces topographiques comme sur l'île d'Ibiza. Il s'agit parfois de rejeux des structures héritées [1] (anciens blocs basculés liés au rifting de Valence ou de l'extension Algérienne ou des anciens chevauchements bétiques). D'autre part, on observe de nombreuses failles normales mettant en évidence une activité extensive récente. A plus grande échelle, on peut observer une flexure relativement importante des bassins sédimentaires du promontoire Baléares (Fig.2). Enfin, on peut observer une bascule à l'échelle régionale des unités sédimentaires dans l'ensemble du bassin Algérien. Le décalage observé de l'unité Messinienne est de l'ordre du kilomètre entre le Promontoire et le bassin Algérien.

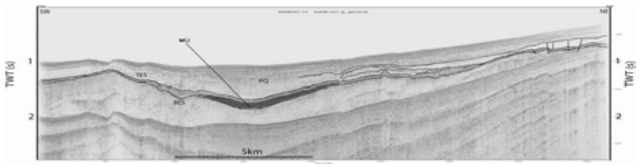

Fig. 2. Profil BA08 montrant la structure de la depression centrale de Majorque avec son bassin salifère flexuré

Nos observations montrent que la répartition des marqueurs Messiniens entre le promontoire Baléares et les bassins adjacents pourrait être continue, ce qui questionne la notion de bassins périphériques et profonds. Les données montrent aussi une forte activité tectonique : d'une part, l'inversion du promontoire Baléares marqué par une déformation compressive et un soulèvement et d'autre part, une extension dont l'origine n'est pas encore identifiée. D'où une question majeure : comment se fait le transfert de contraintes entre la marge Algérienne inversée et le promontoire Baléares à travers la croûte océanique du bassin Algérien?

Abstract
The Seismic atlas of the "Messinian Salinity Crisis" markers in the Mediterranean and Black seas – Volume 2 is a publication project in the framework of the study of the Messinian Salinity Crisis. It follows the publication of a first volume in 2011 (see Editors' websites: http://ccgm.free.fr & http://sgfr.free.fr) and aims to illustrate the seismic characteristics of the MSC markers over news study areas. This publication project is open to anybody from industry and academia willing to contribute.

Keywords: Messinian, Seismics, Mapping, South-Eastern Mediterranean, South-Western Mediterranean

The Messinian Salinity Crisis is a huge outstanding succession of events that deeply modified the Mediterranean area within a short time span at the geological scale.

In 2011, a seismic atlas of the Messinian markers in the Mediterranean and Black seas has been published [1]. This collective work summarizes, in one publication with a common format, the most relevant seismic features related to this exceptional event in the offshore domain. It also proposes a new global and consistent terminology for the MSC markers in the entire offshore Mediterranean area in order to avoid nomenclatural problems. Throughout 13 study areas, the seismic facies, geometry and extend of the Messinian markers (bounding surfaces and depositional units) are described. The Atlas however does not provide a complete description of all what that is known about the MSC and about the geology of each study area. Accordingly, illustrations in the Atlas should be used for a global description of the offshore imprints of the MSC at a broad scale, or for local information or site-specific general interpretations. Interpreted seismic data were carefully selected according to their quality, position and significance. Raw and interpreted seismic profiles are available on CD-Rom.

Volume 2 is currently under preparation with the objectives : (1) to image the Messinian seismic marker from margins and basins that have not been illustrated in the first volume and (2) to complete the extension map of the MSC markers in the offshore and onshore domains at the Mediterranean scale. As the first volume, volume 2 will also aim to share the geological interpretation of seismic reflection data imaging Messinian markers, to make this information accessible to the non geophysician community and to be a reference work that can be used by teachers and future researchers working on the Messinian event. This publication project is open to anybody from industry and academia willing to contribute. At the present time, 16 new sites have been identified [FIG. 1]. Publication of the Seismic atlas of the "Messinian Salinity Crisis" markers in the Mediterranean and Black seas – Volume 2 is planned for Fall 2014. For more details, contact presenting author J. Lofi (atlas coordinator).

This contribution has been funded by the Actions Marges French research program.

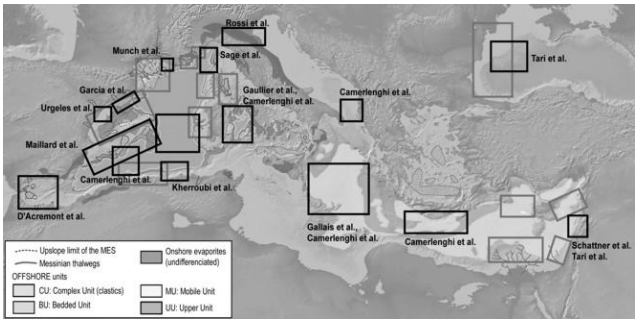

Fig. 1. Distribution map of the Messinian seismic markers in the Mediterranean and Black Seas (work in progress). Grey boxes illustrates areas illustrated in the volume 1 of the atlas. Black boxes highlight areas planned in volume 2.

Abstract
Rifting along the East-Sardinian margin (Tyrrhenian basin) started during Tortonian times in response to the migration of the subducting zone towards its present day position (Calabrian arc, SE Tyrrhenian basin) [1]. The structuring of the margin is partly coeval with the MSC. The margin present-day morphology comprises a succession of eastward-deepening basins bounded by N-S-trending structural highs. The "METYSS" (Messinian Event in the Tyrrhenian from Seismic Study) project is part of a broader, multi-site, integrated scientific study of the MSC seismic markers [2] and aims at better delineating the crustal tectonics, salt tectonics, and sedimentation along the East-Sardinian margin since the MSC.

Keywords: Messinian, Crust structure, Diapirs, Seismics, Tyrrhenian Sea

Since 2009, we acquired 2400 km of seismic-reflection data during the METYSS cruises, off the East-Sardinian margin [FIG. 1 and 2], as part of an integrated multi-site comparative study of the MSC seismic markers at the Mediterranean scale [2]. Interpretation of these data allowed us to identify the following Messinian markers, typical of the Western Mediterranean [FIG. 1] [3] : the Margin Erosion Surface (MES), a polyphased surface commonly found along the margins, the Mobile Unit (MU) made of halite, and the overlying unit (Upper Unit, UU), which comprises alternating dolomitic marls and evaporites [FIG. 1]. Our interpretation has confirmed that MSC units (MU and UU) deposited in the East-Sardinia Basin and on the Cornaglia Terrace, forming topographic lows, whereas the continental slope and the structural highs between these basins were affected by erosion (MES) [FIG. 1 et 2]. In addition, the MSC deposits in the East-Sardinia Basin are thinner than those on the Cornaglia Terrace, that are locally as thick as 800 m for UU and 1000 m for MU, and affected by a vigorous salt tectonics.The salt tectonics and the distribution and thicknesses of the Messinian units provide information about the timing of the opening of the basins. Thus, in the proximal areas (continental slope, East-Sardinia Basin and North Cornaglia Terrace [FIG. 2]), the UU are isopachous, suggesting that the rifting ended prior to the MSC. Conversely, in the South Cornaglia Terrace [FIG. 2], thick MSC deposits and vigorous salt diapirism show that this area was still subject to rifting during the Messinian. The thinning of UU and the absence of MU in the easternmost Cornaglia Terrace [FIG. 2] indicate that this area was only partly opened. Our observations thus confirm that rifting of the East-Sardinian margin has controlled the distribution of the MSC markers. They can also provide some information about the paleo-morphology of the area during the MSC, and some constraints about the timing of rifting between what were, at that time, the margin's proximal and distal regions.

RADIONUCLIDE POLLUTION IN SEDIMENTS OF BODRUM (AEGEAN SEA)

Serpil Aközcan [1]*
[1] Kirklareli University - sakozcan35@yahoo.com

Abstract
The great interest expressed worldwide for the study of radionuclide and environmental radioactivity has led to the performance of extensive surveys in many countries of the world. Radionuclides pollution of the marine environment have been recognized as a serious environmental concern. The natural and artificial radionuclides ^{238}U, ^{232}Th, ^{40}K, ^{226}Ra and ^{137}Cs are found in varying concentration in sand, sediment, sea water and naturally occurring water. In this study, determination of anthropogenic and natural radionuclides in marine sediment taken from Bodrum Aegean Sea has been performed by gamma spectrometry. In general, the distribution of activity concentrations in the study area were in the same order as international levels.

Keywords: Radionuclides, Aegean Sea, Sediments, Monitoring

Sampling and sample preparation
Surface sediment samples were collected from Bodrum in the June 2009- June 2010 the sampling stations are given in Fig. 1. Samples were collected for seasonal. Sediment samples were oven dried at a temperature of 105 ^{o}C for 12 h and sieved through a 250 mesh. The dried samples were transferred to polyethylene Marinelli beakers of 1000 ml capacity. Each sediment sample was left for at least 5 weeks to reach secular equilibrium between radium and thorium, and their progenies. Gamma spectrometry measurements were determined by gamma spectrometer, using HPGe detector. A mixed gamma referance calibration source containing the radionuclides (^{241}Am, ^{109}Cd, ^{57}Co, ^{123m}Te, ^{51}Cr, ^{113}Sn, ^{85}Sr, ^{137}Cs, ^{88}Y, ^{60}Co) in 1 L Marinelli is used for the full-energy peak (FEP) efficiency calibration, produced at the Isotope product Laboratories. The counting time of 150000 s was set for activity of each sediment samples and background.

Fig. 1. Sampling Location

Results and discussion
The activity concentration of ^{226}Ra, ^{238}U, ^{232}Th, ^{40}K and ^{137}Cs in sediments collected from two different locations in Aegean Sea coast has been determined. The highest activity concentrations of ^{238}U and ^{40}K were observed in sediments from Bodrum. The results of this study can be used as a baseline for future research and the data obtained in study may be useful for radiological map of the study area.

INVESTIGATION OF METAL ACCUMULATION IN SURFACE SEDIMENT IN SÜRMENE BAY OF THE EASTERN BLACK SEA

Nigar Alkan [1]* and Volkan Örnek [1]
[1] Karadeniz Technical University - anigar@gmail.com

Abstract
The objective of this surface sediment study was to determine the concentration levels of metals (Cr, Mn, Al, Co, Ni, Cu, Zn, As, Mo and Pb) in spatial extent and relationship with other potential causative factors (sediment grain size, other physical and chemical characteristics of the sediment). These current metal levels were compared with the ground values to determine the status of the metal enrichment in Sürmene Bay surface sediments (located between 40º57'27" N - 40º17'15" E and 40º56'05" N - 40º 04'56" E is in the Trabzon city of the Eastern Black Sea Region).

Keywords: Black Sea, Metals, Sediments, Pollution

Introduction
Sediment is a natural contaminant accumulation area in marine environment. Contaminants from various sources are transported to the coastal area and finally accumulate on sediment layer [1]. Pollutants have some catastrophic effects on aquatic life and living organisms as they can cause to transition and accumulation of metal contents in oceanic environment. This situation can lead to elevated metal concentration in surface sediments and known as metal enrichment mechanism. This elevated concentrations are generally well correlated with particle grain size distribution [2].

Material and Methods
Sediment samples were collected from 17 stations located on Sürmene Bay in December, 2011 and composed of samples after subsampled from the top 2 cm from each stations (Figure 1). All sediment samples were preserved at -18 °C. Grain size were classified according to Folk [3], pH and Oxidation Reduction Potantial (ORP) were measured using a Hach Lange HQ40D multi meter. Total Organic Carbon (TOC) was determined by using modified Walkley-Black titration method [4], Carbonate levels were measured by Piper method [5], Enrichment Factor (EF) was computed by applying Cukrov method [2]. Metal analysis (Cr, Mn, Al, Co, Ni, Cu, Zn, As, Mo and Pb) was performed using sediment passed through a sieve with 63-micron in this study. Analysis after digestion in the closed microwave digestion system were determined using ICP-MS (inductively coupled plasma mass spectrometry) The Collosion Reaction Interface (CRI) was used during the determination of As. Both Sc and In (50 ppb) were added to all standards, blanks and samples and acted as internal standards. All data were given mg/kg dry weight (dw). In this study spearman correlation was performed to evaluate variables.

Results and Discussion
The silt fractions were generally dominant (50%) according to distribution of grain size in sediment samples. Minimum and maximum values were determined for carbonate as 8.54-18.05%, for total organic carbon as 0.26-2.43%, for pH as 6.91-8.24 and for ORP as 159-269 mV. Sediment metal levels (mg/kg dry weight) were determined for Cr as 13.4-82.3, for Mn as 200-447, for Al; 19965-48723; for Co as 8.0-32.8, for Ni as 9.8-26, for Cu as 24.9-3107, for Zn as 102-4259, for As as 5.4-58, for Mo as 0.21-20, for Pb as 15.5-208. Results were compared with earth's crust and the average shale values. Concentrations of Al, Cr, Mn and Ni were found to be higher than the earth's crust and the average shale values while concentrations of Co, Cu, Zn, Mo and Pb were characterized with relatively lower figures. Based on calculated EF values deficiency low enrichment values were found for Cr, Mn, Co and Ni, moderate enrichment value was found for Pb, significant enrichment values were found for Zn, As and Mo, and very high enrichment value was found for Cu in the study area.

MISE EN ÉVIDENCE DU DIACHRONISME DES SÉDIMENTS SUPERFICIELS ET DES MÉTAUX LOURDS EN BAIE D'ALGER (ALGÉRIE).

Farid Atroune [1]*
[1] Faculté des Sciences de la terre/USTHB Bab Ezzouar - faridatroune@gmail.com

Abstract
L'objectif est la quantification de la pollution engendrée par l'Oued El Harrach qui débouche en baie d'Alger et de voir l'évolution des sédiments superficiels en baie d'Alger. La pollution par les métaux lourds dans les sédiments superficiels de la baie d'Alger montre un degré de contamination important et inquiétant. Les fortes teneurs en métaux présents dans les sédiments superficiels se localisent dans le secteur ouest de la baie d'Alger et à proximité de l'embouchure de l'Oued El Harrach. Les analyses sédimentologiques ont évolués, en ce sens que la carte des facies établis par Maouche en 1987 s'est envasée du côté oriental de la baie. La carte établie, montre que durant une vingtaine d'années, l'oued El Harrach n'a pas cessé ses apports en sédiments fins.

Keywords: Sediments, Algerian Basin

Introduction
La pollution par les métaux lourds des sédiments superficiels, charriés par l'oued El Harrach se répartissent sur la baie d'Alger d'une manière diversifiée. En effet Ces sédiments ont généralement une grande affinité pour les sédiments à granulométrie fine. [4] a montré que la fraction inférieure à 40µm occupe plus de 75% des sédiments superficiels de la baie d'Alger ; les métaux lourds sont habituellement associés à la fraction fine. Le bassin versant de l'Oued El Harrach appartient au grand bassin versant côtier Algérois. Il couvre une superficie de 1270 km^2. Il s'étend du Nord au Sud sur 51 Km et de l'Est à l'Ouest sur 31 km.

Matériels et méthodes
Dans la baie d'Alger L'échantillonnage des sédiments de surface a été réalisé en décembre 2008 dans l'Oued El Harrach (Tab 1). Pour la baie d'Alger, les prélèvements ont été pris, à l'aide d'une benne van Veen (mission septembre 2009) à bord d'une embarcation nautique, le plan de positionnement a été calquer sur la mission effectué en 1985. Les métaux (Cu, Zn, Ni, Fe, Pb et Hg) ont été dosés à l'aide d'un spectromètre d'absorption atomique).

Résultats et discussion

Tab 1: Evolution des métaux lourds (en µg/g) en Baie d'Alger

	Cr	Mn	Fe	Cu	Zn	Pb
Maouche, 1987		250-316	3.8-4.8	24-51	123-231	20-161
Chouikhi et al., 1991	11-84	109-350			72-222	18-117

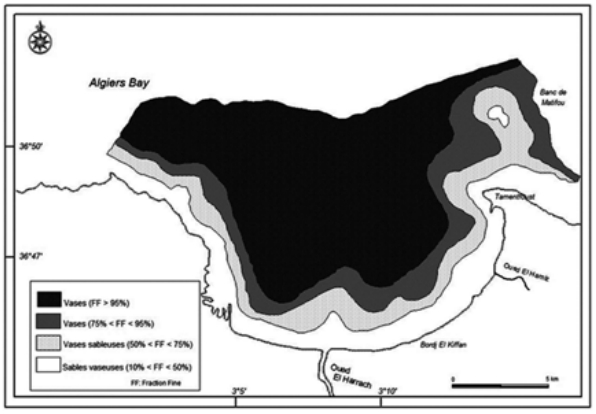

Fig. 1. Carte des facies de la baie d'Alger

A partir de la répartition spatiale (fig1) de ces éléments métalliques on peut déjà constater que, les fortes teneurs en métaux lourds présents dans les sédiments superficiels de la baie d'Alger se localisent dans le secteur ouest de la baie entre le port (rejets d'hydrocarbures, produits chimiques) et à proximité immédiate de l'embouchure (rejets des affluents domestiques et industriels). Les fortes concentrations des métaux lourds s'associent généralement avec des sédiments fins de nature vaseuse et riche en matière organique. Les concentrations faibles se trouvent localisées dans le secteur de la baie, où prédominent des sédiments relativement grossiers par rapport au secteur Est de la baie. Les analyses sédimentologiques ont particulièrement évolués, en ce sens que la carte des facies s'est considérablement envasée du côté orientale de la baie. La carte que nous avons établie, montre que durant une vingtaine d'années, l'oued El Harrach n'a pas cessé de cracher des sédiments fins. De plus la carte des argiles a aussi également sensiblement changé. Nous admettons, à partir de l'analyse des paramètres physico-chimiques que la pollution de l'Oued El Harrach est le résultat de l'absence de traitement des déchets industriels et domestiques.

ORIGINE ET DISTRIBUTION DES MINÉRAUX LOURDS MARINS DU LITTORAL DE BOUMERDES (ALGÉRIE)

Mohamed Bouhmadouche [1]*
[1] labo Géoenvironnement USTHB/FSTGAT BP 32 EL-ALIA Bab-Ezzouar - mbouhamadouche@gmail.com

Abstract
L'étude des minéraux lourds et leurs répartitions dans les sédiments superficiels du plateau continental de Boumerdes a été opérée sur trois fractions granulométriques de sables (80-160µm), (160-400µm) et (400-800µm). Les résultats obtenus montrent la présence d'une fraction lourde comprenant tourmaline, hématite, biotite, sphène et zircon et une fraction légère englobant quartz, muscovite, orthose, calcite et une phase biogène. La distribution de ces minéraux lourds au débouché de l'oued Boumerdes et de l'oued Boudouaou indique que ces minéraux proviendraient du complexe éruptif de Thénia drainés par l'oued Boumerdes. <\/div>

Keywords: Sediment transport, Mineralogy, Algerian Sea

Introduction
Nous nous sommes attachés à caractériser les cortèges minéralogiques (minéraux lourds et légers) transitant par les différents oueds et aboutissant en dépôts marins-littoraux. Les fluctuations des concentrations des minéraux lourds dans les sédiments superficiels terrigènes de la plate forme continentale peuvent être dues à plusieurs facteurs tels que, la source d'apport, les processus sédimentaires d'altération et de transport [1],[2].

1. **Nature et répartition des minéraux lourds** : De manière générale, le cortège minéralogique lourd-léger des sables de Boumerdes présente une certaine monotonie que cela soit du côté qualitatif ou quantitatif. En effet, l'uniformité observée ne nous permet pas d'élaborer des cartes d'iso teneurs de tel ou tel minéral. Toutefois, dans le cas des 2 auréoles de Boumerdes et de Boudouaou, nous donnerons les cortèges minéralogiques particuliers à ces deux zones. Tourmaline, biotite, hématite, Sphène et zircon sont les composants majeurs du spectre des minéraux lourds. L'olivine, épidote, orthopyroxène et clinopyroxène sont très rares. La Tourmaline est le minéral le plus caractéristique du cortège minéralogique lourd représente à lui seul 20 à 60 % des 3 fractions étudiées. Elle est de couleur verte essentiellement mais apparait parfois brune. L'Hématite représente 20 à 40 %, la Biotite représente 10 à 30 % de la fraction lourde. Les minéraux accessoires sont représentés par le Sphène (1 à 8 %) et le Zircon (1 à 5 %) (Tab.1). Les minéraux légers sont représentés par un cortège varié de minéraux où le quartz occupe prés de 60 % de la fraction détritique, ces minéraux se retrouvent tres fréquents dans les falaises côtières du Corso. Les Feldspaths sont représentés par l'Orthose et les micas par de la Muscovite très abondante (20 à 30 %) et présente dans tous les échantillons prélevés à Boumerdes. La phase biogène caractérise l'essentiel de la fraction carbonatée de la région d'étude.

Tab. 1: Distribution de la fraction minérale "lourde et légère" devant oued Boudouaou, oued Boumerdes et de la zone centrale (pourcentage en poids).

Minéraux lourds	Oued Boudouaou	zone centrale	Oued Boumerdes
Tourmaline	15	3	20
Hématite	12	2	10
Biotite	5	4	7
Sphène	1	0	1
Zircon	0-1	0	0-1
Minéraux légers			
Quartz	40	60	30
Muscovite	10	10	1
Orthose	1	1	2
Calcite	8	10	5
Phase biogène	8	10	10

2**. Distribution de la fraction minérale lourde totale** La répartition des minéraux lourds (fig.1) montre des teneurs variant en moyenne entre 1 et 20 % avec 2 maxima de 28 % . Ces teneurs importantes sont en fait localisées exclusivement aux alentours immédiats des embouchures des oueds Boumerdes et Boudouaou traduisant ainsi une origine des apports et un transit côtier résultant depuis la source jusqu'au milieu de dépôt.

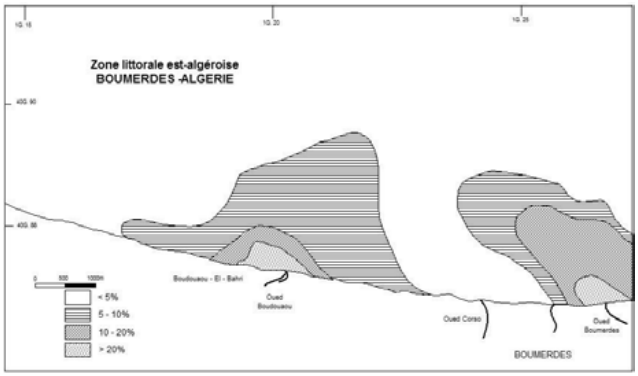

Fig. 1. Répartition de la fraction totale des minéraux lourds

La fraction granulométrique 160-80 µm est caractérisée par des teneurs nettement supérieures aux 2 fractions précédentes; c'est la plus riche en minéraux lourds du sédiment détritique grossier.

Conclusion
En résumé de l'observation de ces 3 fractions nous pourrons déduire que plus la taille des grains diminue, plus la teneur en minéraux lourds augmente contrairement à d'autres régions où l'inverse a été constaté [3]. Cette importance en minéraux lourds dans la fraction la plus fine s'explique logiquement avec les résultats de l'étude en lames minces, qui a montré des minéraux dont la taille est réduite dans la roche mère (Granit de Thénia, micaschistes du « Rocher Noir »).

A CASE STUDY ON TRACE METALS IN SURFACE SEDIMENTS OF CYPRUS

A. Kontas [1], E. Uluturhan süzer [1], I. Akçali [1], E. Darilmaz [1]* and O. Altay [1]
[1] DEU, Institute of Marine Sciences and Technology Baku bulvari No:100 Inciralti-Balcova - enis.darilmaz@deu.edu.tr

Abstract
The heavy metal (Hg, Cd, Pb, Cr, Cu, Mn, Zn, Ni, Fe, and Al) concentrations in sediment were investigated in Cyprus from Mediterranean. The surface sediments were collected from 23 stations in April-May 2010. The results showed that Gemi Konagi area was polluted with Cu and Zn besides Girne and Gazi Magusa areas were polluted with Pb and Cr. All of the Hg, Cd and Pb levels were lower than the Mediterranean backgrounds. The Cu and Zn concentrations at Gemi Konagi area and all of the Cr values were higher than the Mediterranean backgrounds.

Keywords: Metals, Sediments, Pollution, North-Eastern Mediterranean

Introduction
Heavy metals are entering the coastal environment as contaminants, although metals are present naturally in the environment, from anthropogenic sources such as industrial processes, including untreated waste water, municipal sewage effluent, and surface run-off [1]. There is little information about heavy metal contaminations at sediment from Cyprus. The aim of this study is to describe the spatial distribution of heavy metals in sediments from Cyprus.

Materials and Methods
Surface sediment samples (23 stations) were collected using box-core from Cyprus as part of a cruise of the R/V K. Piri Reis (April-May 2010). This study founded by the Turkish Scientific and Technological Research Council (TUBITAK/111Y160). Sediments were placed in acid-cleaned polyethylene bottles and frozen (-20oC). Samples were dried in an oven at 50ºC, and then sieved to pass 63 ?m. All sediments were digested in microwave digestion system (Milestone 1200) with a HNO3-HF-HClO4-HCl acid mixture solutions [2,3]. The levels of mercury and cadmium were obtained by using cold vapour and graphite furnace with AAS, respectively. The concentrations of Pb, Cr, Cu, Mn, Fe, Ni, Al and Zn in sediment were measured by flame atomization (air-acetylene) AAS, using the manufacturer's conditions and with background correction.

Results
The results of heavy metals in sediments were compared with the mean crustal values, Mediterranean background and TEL-PEL values. Comparison of the metal concentrations with mean crustal values revealed that Gemi Konagi area was polluted with Cu and Zn besides Girne and Gazi Magusa areas were polluted with Pb and Cr. The maximum pollution for Cd was found at Girne area. All of the Hg, Cd and Pb levels were lower than Mediterranean backgrounds. The Cu and Zn concentrations at Gemi Konagi area and all of the Cr values were higher than Mediterranean backgrounds.
Metal concentrations ranged between 0.02-0.07 for Hg, 0.03-0.32 for Cd, 1.12-23.8 for Pb, 54.7-144 for Cr, 9.29-127 for Cu, 29.3-128 for Zn, 112-990 for Mn, 43.8-245 for Ni, 10634-50972 for Fe, 6670-56051 µg/g for Al. The maximum concentrations of Hg, Cd and Ni were detected at Girne area besides the highest Pb, Cr and Mn levels were found at Gazi Magusa area. The minimum values of Hg, Cd, Pb, Cr, Mn, and Ni were obtained at Gemi Konagi area. Adversely, the maximum Cu, Zn, Fe and Al values were measured at the same area. Cr levels at all sampling areas and Cu concentrations at Gemi Konagi area were exceeded the numerical TEL values. All of the Ni values were above the TEL and PEL values. The results have been shown that the pollution in sediments from Cyprus was mainly sourced from mining activities, wheathering and erosion of ophiolithic rocks and other sources (agriculture and untreated sewage discharges, maritime activities).

HEAVY METAL CONCENTRATIONS IN SURFICIAL AND CORE SEDIMENTS FROM IZMIR BAY: IMPLICATIONS FOR ANTHROPOGENIC AND LITHOGENIC IMPACT

Müge Atalar [1], Muhammet Duman [1]*, Filiz Küçüksezgin [1] and Lutfi T. Gönül [1]
[1] Dokuz Eylul University Institute of Marine Science and Technology - muhammet.duman@deu.edu.tr

Abstract
The levels of heavy metals were determined in surface and core sediments from the Izmir Bay in 2009. Marine pollution in Izmir Bay is investigated using inorganic and organic geochemical data from surface sediments. The concentrations of 32 elements in 18 samples and three core samples established that surface sediments in Inner Izmir Bay display significant enrichments in As,Al, Cr, Cu, Cd, Fe, Mn, Ni, Pb and Zn associated with notably high concentrations of total organic carbon and sulphur.The zone of moderate enrichment of Cr, Mn, Pb, Zn, Cu and As in the bay seems to be driven by anthropogenic sources.

Keywords: Metals, Sediments, Pollution, Izmir Bay

Introduction
Izmir Bay is one of the great natural bays of the Mediterranean Sea, whose shoreline is dominated by Izmir Metropolitan Municipality (Fig.1). It is divided into four parts: Gülbahçe Bay, Outer, Central and Inner Izmir Bays. It has a total surface area of over 500 km2, a total length of 64 km and opens in the Aegean Sea. Major indicators of pollution in aquatic environments are contaminated sediments that can be defined as soils, sand, organic matter, or minerals accumulated at the bottom of a water body (USEPA, 1998) [1]. Inputs creating pollution in the Izmir Bay consist of the following components; i) domestic waste waters produced by a population of nearly three million people; ii) industrial waste waters; iii) pollutant loads of Gediz river and other streams flowing into the bay; iv) agricultural drainage; v) port activities and sea traffic; vi) atmosferic inputs; vii) upflux from bottom sediments into the water column; viii) material transfer between the bay and the open sea [2].

Material and Methods
The surface sediment samples were collected using a Van Veen type grab sampler and the sediment core samples were obtained using a gravity corer from Izmir Bay during the cruise of R/V K. Piri Reis. Concentrations of metals were determined in the digested phase by inductively coupled plasma–mass spectrometer (ICP-ES/ICP–MS) analysis (ACME Analytical Labs, Vancouver, BC, Canada). Levels of heavy metal pollution in Izmir Bay. The amount of organic carbon (%) was determined by spectrophotometrically in dried sediment samples following the sulfochromic oxidation method.

Conclusion
In general particle size is fining in the sampling area except stations 1 and 4. Bottom sediments in these stations were relatively coarse with 84-96 % sand along the northwest coast of the outer bay while other stations were generally consists of clayey silt in the sampling area. Comparison of the metal concentrations with average crustal values revealed that most of the samples from the outermiddle, inner parts of the bay were polluted with As, Ni, Pb and As, Cr, Cu, Ni, Pb, Zn, respectively. The contamination factors (Cf) were between low and moderate for Mn (0.46-1.53), Cu (0.30-1.60), Co (0.40-1.20), Cr (0.38-1.43), and As (0.38-1.48) and between moderate and considerable for Pb (0.62-6.31) according to the Hakanson (1980) [3] classification in the bay. An EF value of 1.5 indicates that the given element has principally originated from lithogenic source. These results indicated that Cr, Mn, Pb, Zn, Cu and As (EFs > 1.5) came from human impacts. Gediz River discharge, and atmospheric inputs.

ASSESSMENT OF HEAVY METAL DISTRIBUTION IN THE MONTENEGRIN COAST

Danijela Joksimovic [1]* and Zoran Kljajic [1]
[1] Institute of Marine biology, Montenegro - djoksimovic@ibmk.org

Abstract
The aim of the study was to determine the levels and distribution of heavy metals in the sediments in the Montenegrin coast, and also to assess the extent of anthropogenic impact using geo-accumulation index (I*geo*) and metal pollution index (MPI). Surface samples were taken from 10 locations. Grain size and trace element (Fe, Mn, Zn, Cu, Co, Ni, Pb, Cd, As and Hg) variations were analyzed, and MPI as well as Igeo calculated to understand the contamination level of the study area.

Keywords: Metals, Sediments, South Adriatic Sea

Introduction

Pollution of the natural environment by trace metals is a world-wide problem. Trace elements from natural and anthropogenic sources continuously enter the aquatic ecosystem where they pose a serious threat because of their toxicity, long time persistence and bioaccumulation ([1]). Also as other areas on Montenegrin coast is also under a great impact of anthropogenic factors and the activities on the shore. Sediments show a high capacity to accumulate and eventually integrate the low concentrations of trace elements usually found in water. In order to better interpret the results of any contaminant analysis some concepts have been suggested, such as the study of spatial and temporal variance in the objective area using multiple repeated sampling over an extended period of time [2].

Material and Methods

Samples of bottom sediments were taken from a depth of 15-20 cm using an internal diameter plastic gravity corer. The sampling was done in autumn of 2005 and 2006 at 10 stations in the Montenegrin coast, Fig.1. Dry sample (about 0.5 g) were digested with 2 ml of HNO3 (65%), 6 ml HC1 (37%) in a microwave digestion system (CEM. Corporation, MDS-2100) for 30 min and diluted to 25 ml with deionized water and stored in polyethylene bottles until analysis. A blank digest was performed in the same way.All the samples were examined in laboratory using atomic absorption spectrometer equipped with a deuterium-are background corrector and Perkin Elmer MHS-10 hydride generator were used. Standard hollow cathode lamps were used for all elements except arsenic, for which a Electrodes Discharge (EDLs) lamp was used. Each sample was analyzed in triplicate.

Fig. 1. Map of investigation area

Result and Discussion

The Montenegrin coast, as a direct recipient of pollutants of anthropogenic origin from the area, showed the higher contents of heavy metals in bottom sediments in 2005 compared to 2006 when values for those heavy metals on every examined locations was much lower ([3], [4]). The contents of investigated metals in both years are: Fe>Mn>Ni>Zn>Cu>Co>As>Pb>Cd>Hg. The values of microelements in sediments of Boka Kotorska Bay are much higher than on the locations which are under the influence of open sea, except on locations Rt Djeran and Ada Bojana in both seasons. The increase of lead, cadmium, arsenic and mercury on one station in Boka Kotorska Bay can be explained by the fact that this area is under great impact of industry and huge medical complex. Based on the values of MPI, on each location pollution is detected. Comparing seasons 2005 and 2006, MPI is higher in 2005 (1.39-3.04) than in 2006 (1.46-2.63). Locations with higher values of MPI in both seasons are Ada Bojana and Rt Djeran (open sea) and Kukuljina (Boka Kotorska Bay), because this locations has higher content of microelements in sediment. The locations with higher values Igeo are Bar (1.85) and Kukuljina (3.79) for Cd, and Bar (3.2) for Hg. The main reasons of higher contamination are anthropogenic factor, harbor activates and anti-corrosion treatment for vessels.

THE COMPARISION OF THE HEAVY METAL LEVELS IN TWO DIFFERENT BARNACLE SPECIES FROM THE LEVENT MARINA, IZMIR

Sinem Aydin-onen [1], Ferah Kocak [1] and Filiz Kucuksezgin [1]*
[1] Dokuz Eylul University Institute of Marine Sciences and Technology - filiz.ksezgin@deu.edu.tr

Abstract
The biomonitoring study presents the comparison of distribution of heavy metals in seawater and the soft tissues of two major fouling species *Amphibalanus amphitrite* (Darwin, 1854) and *Amphibalanus eburneus* (Gould, 1841) collected from Levent Marina (Izmir) in Autumn 2008 and in Spring 2009. The results showed that two studied species of barnacles are excellent biomonitors and have the ability to accumulate Cu, Fe and Zn in a higher degree than seawater.

Keywords: Metals, Bio-accumulation, Bio-indicators, Izmir Bay

Introduction
The relative contamination of coastal environments can be measured by using suitable biomonitors. Especially mussels and barnacles, key components of the local sublittoral benthos, are used to address the question of metal bioavailabilities [1]. To the best of our knowledge following a literature survey, no previous monitoring of metal contaminants has been carried out in barnacle species from the Aegean coast. The main aim of the present study is to compare the heavy metals using seawater samples and the soft tissue of barnacles, *A. amphitrite* and *A. eburneus*. Materials and Methods Seawater, *A. amphitrite* and *A. eburneus* were collected from the intertidal zone at Levent Marina in Autumn 2008 and Spring 2009 (Fig. 1). For water samples analyses were performed by flame AAS (Varian Spectraa-300 plus) for Cd, Pb, Cr, Cu, Mn, Zn and Fe and by anodic stripping voltammeter (ASV) at the rotating gold electrode for Hg and for barnacle analyses were performed by flame (Cu, Fe, Mn and Zn), cold vapour (Hg) and graphite furnace technique (Cd, Cr and Pb) in AAS by using the manufacturer's conditions and with background correction according to UNEP [2,3].

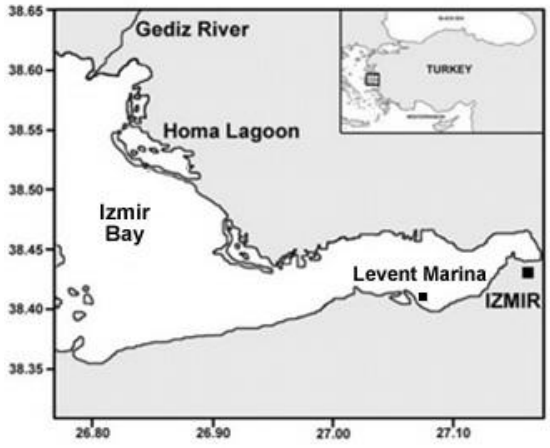

Fig. 1. Location of sampling station in Izmir Bay

Results and Discussion
Among the heavy metals, Cu, Mn, Zn and Fe levels were found higher in the tissue of *A. amphitrite* and *A. eburneus* as compared to seawater samples during autumn (2.41, 1.81, 7.06, 14.10 µg/l) and spring (0.94, 2.31, 0.81, 4.60 µg/l) periods, respectively. Availability of high autumn and spring metal concentrations in the soft tissues of *A. amphitrite* was foundas following ranking Fe>Cu>Zn>Mn. Furthermore, measured high autumn and spring metal levels in *A. eburneus* decreased in the following order Fe, Cu, Zn, Mn and Zn, Fe, Cu, Mn, respectively. Comparing the concentrations of heavy metals in the tissue for each species, *A. amphitrite* was accumulated Cu (208.33 µg/g) in a higher degree in autumn. In contrast, *A. eburneus* was accumulated Fe (389 µg/g), Zn (321.48 µg/g). Concerning the detected metal levels in spring period, higher Cu (378.76 µg/g) and Fe (317.47 µg/g) were recorded in the tissue's of *A. amphitrite* whilehigher Zn level (494.11 µg/g) was measured *in A. eburneus*.

The results of this study showed that *A. amphitrite* and *A. eburneus* has high accumulation capacity for Cu, Zn and Fe. These high accumulated values could be explained due to the high concentration of these metals in the water body and the role of these metals as essential element for the physiological and biological activities of the studied animals [4]. Based on contamination factor [CF is the ratio of metal concentration in the barnacle (ìg g^{-1} dry wt) to the concentration of metal in seawater (mg l^{-1})], barnacles have the ability to accumulate Cu, Zn and Fe in their tissues several times more than sea water (Tab. 1). Comparatively, the levels found in barnacle tissue are generally lower than those reported from contaminated regions in the world [5].

Tab. 1. Concentration factors for heavy metals in *Amphibalanus amphrite* and *Amphibalanus eburneus* in the Levent Marina

	Seasons	Hg	Cd	Pb	Cr	Cu	Mn	Zn	Fe
A. amphitrite	Autumn	1.8×10^{3}	3.5×10^{4}	3.3×10^{3}	8.3×10^{3}	8.7×10^{4}	9.0×10^{3}	2.8×10^{4}	2.2×10^{4}
	Spring	3.2×10^{3}	4.7×10^{4}	2.7×10^{3}	4.4×10^{4}	4.0×10^{5}	8.1×10^{3}	2.5×10^{5}	6.9×10^{4}
A. eburneus	Autumn	1.7×10^{4}	3.4×10^{4}	2.3×10^{3}	2.7×10^{4}	7.7×10^{4}	1.5×10^{4}	4.6×10^{4}	2.8×10^{4}
	Spring	1.5×10^{4}	7.6×10^{4}	6.5×10^{3}	5.9×10^{4}	1.4×10^{5}	1.5×10^{4}	6.1×10^{5}	3.2×10^{5}

Conclusions
In conclusion, Zn, Cu and Fe were the most abundant elements in the soft tissues of *A. amphitrite* and *A. eburneus*. The high levels of heavy metals recorded in the water samples of Levent Marina confirmed the presence of high concentrations of heavy metals in barnacle tissue. These accumulations may relate to their very efficient storage detoxification systems and/or due to the biological needs of animals. The present study concluded that both barnacle species are suitable candidates to be used in biomonitoring surveys for Cu, Zn and Fe particularly at the Aegean coast.

Abstract
Numerous indices have been developed to assess environmental risk of heavy metals in surface sediments, including the total content based geo-accumulation index (Igeo), exchangeable fraction based risk assessment code (RAC), and biological toxicity test based sediment quality guidelines (SQGs). In this study, the three indices were applied to surface sediments from 20 stations along the Egyptian Mediterranean Sea, to assess the environmental risks of heavy metals (Cd, Cr, Cu, Co, Pb, Ni, Mn, Fe, and Zn) and to understand discrepancies of the risk assessment indices.

Keywords: Sediments, South-Eastern Mediterranean, Metals

Introduction
Heavy metals are of considerable environmental concern due to their toxicity, wide sources, non-biodegradable properties and accumulative behaviors [1]. The evaluation of metal distribution in surface sediments is useful to assess pollution in the marine environment. Therefore, the assessment of sediment environmental quality is an essential component of environmental quality assessment of aquatic ecosystems. Several risk assessment indices of sediment environmental quality for heavy metals have been developed on different bases, such as geo-accumulation index (Igeo) on the basis of total content [2,3], risk assessment code (RAC) on the basis of availability [4,5], sediment quality guidelines (SQGs) on the basis of biological toxicity [6], and multiple variant approach [7]. In this study, the heavy metal contamination, chemical speciation and the associated ecological risk in the Egyptian Mediterranean Sea sediments were assessed using different indices i.e. enrichment level (total content, Igeo), availability level (weakly bounded fraction, RAC), and biological toxicity level (Threshold Effect Level (TEL), Probable effects Levels (PEL). The three indices were widely used and accepted for characterizing heavy metal contamination in literature and mandatory regulations.

Materials & Methods
Analysis of total heavy metal concentrations:
A concentrated acid digestion protocol according to Oregioni and Aston [8] was followed and the digested solution was diluted accordingly and measured for Cd, Cr, Co, Cu, Mn, Fe, Pb, Cd, and Zn using an atomic absorption spectrophotometer (AA6650, SHIMADZU, Kyoto,Japan). Reagent blanks, parallel replicates, and a standard reference material (IAEA-405: estuarine sediment, International Atomic Energy Agency, Vienna, Austria) were incorporated in each digestion batch for quality control and quality assurance. Recovery rates of the selected metals ranged from 90.3% to 104%.
Sequential extraction of selected metals:
In the present study, heavy metals (Fe, Mn, Zn, Ni, Cr and Pb) were sequentially extracted following the five step method proposed by Tessier et al. [9] into operationally defined as exchangeable (F1), Carbonate (F2), Fe-Mn hydroxide (Reducible) (F3), organic (F4) and residual (F5). These fractions may be considered to decrease in lability from exchangeable to residual. After each successive extraction, samples were centrifuged at 4000 rpm for 20 min to separate the extracted from the sediments. The concentrations of Fe, Mn, Zn, Ni, Cr and Pb in each of the leachates were determined by AAS (SHIMADZU 6650, Kyoto, Japan) in flame mode.

Results & Discussion
Results showed that based on the average Igeo of target elements, the Egyptian Mediterranean Sea has to be considered not polluted with Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb and Zn (Igeo$\leq$ 0%). On the other hand, over than 95% of the samples are lower than the threshold effect level (TEL) of SQGs for Cd, Zn, Pb and Cu. Risk assessment code analysis showed that Fe has no risk to local environment; Cr, Mn, Ni and Zn have posed low risk while Pb was at medium risk level. The study point out that although there were slight variations in the results of the three indices, the combination of the three indices gave us a comprehensive understanding of heavy metal risks in the surface sediments of the Egyptian Mediterranean coast.

Abstract

Measurements of sulfur and oxygen isotope composition of aqueous sulfate consumed through anaerobic methane oxidation (AOM) coupled to bacterial sulfate reduction (BSR) were used to enhance our understanding of this critical process. We sampled sediment cores at two highly stratified estuaries in the coastal area of the eastern Mediterranean (Yarkon and Qishon) in which sulfate is rapidly consumed and methane concentrations subsequently increase suggesting a coupling between the two. Although the pore fluid geochemistry are similar at the studied sites, the isotope geochemistry is fundamentally different indicating that the mechanism of BSR differs among the studied sites.

Keywords: Redox, South-Eastern Mediterranean, Sediments, Estuaries

Natural global methane production is driven by the microbially mediated process of methanogenesis, during which organic carbon is reduced to methane (e.g. [1]). Organic carbon in marine and marginal marine sediments can be oxidized both aerobically (through oxygen) and anaerobically, through the respiration of various electron acceptors. These other electron acceptors are used in order of decreasing chemical potential, beginning with nitrate, and proceeding through manganese and iron oxides, sulfate [2]. Organic matter that is not oxidized aerobically or anaerobically can undergo further reduction, leading to the formation of methane. Upwardly diffusing methane is oxidized microbially (methanotrophy), both aerobically and anaerobically (anaerobic oxidation of methane – AOM). AOM has been identified in marine and marginal marine sediments mainly coupled to sulfate reduction:

$$SO_4^{2-} + CH_4 \rightarrow HCO_3^- + HS^- + H_2O \quad (1)$$

Methane in marine sediments is almost entirely consumed by anaerobic methane oxidation (AOM) coupled largely to bacterial sulfate reduction [3]. The fact that virtually all methane in marine sediments is oxidized through AOM means that the earth's vast oceans are prevented from becoming a major source of this potent greenhouse gas.

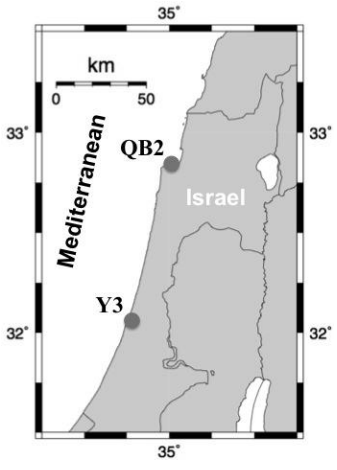

Fig. 1. Map of the study areas in a map of the Eastern Mediterranean region. The dots and the corresponding labels indicate the site locations and names, respectively.

To explore the coupling of bacterial sulfate reduction to AOM, this study focuses on highly stratified estuaries in the coastal area of Israel (The Yarkon and the Qishon-- Figure 1). The estuaries contain high organic carbon load from up-stream and a lower water mass impacted by seawater penetration. At both sites, the geochemisty of the pore fluids indicates rapid depletion of sulfate and intensive production of methane beneath, making these sites ideal locations for studying sulfate driven AOM in the upper sedimentary column. We use coupled carbon isotopes in dissolved inorganic carbon, sulfur and oxygen isotopes in pore fluid sulfate, sulfur isotopes in sedimentary sulfide and carbon isotopes in pore fluid methane to explore these processes in this marginal marine environment. The data is used to elucidate new pathways in the cycling of these environmentally important species, and the findings are applicable the broader marine environment.

Our geochemical measurements in the Yarqon in the Qishon estuarine sediments indicate that although there is similarity in the pore fluid sulfate and dissolved inorganic carbon concentration profiles, the isotopes ($\delta^{18}O_{SO4}$ vs. $\delta^{34}S_{SO4}$-- Figure 2) in the pore fluids are fundamentally different between these two sites. We suggest that this difference exists because the two estuarine sediments consist of different depth distribution of the microbial activity. This is elusive from the concentrations profiles, but easily identified by the isotopes profiles.

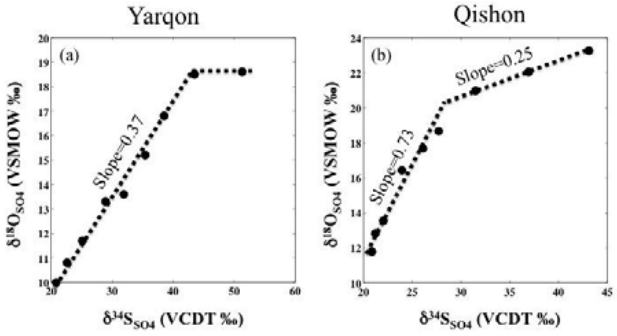

Fig. 2. $\delta^{18}O_{SO4}$ vs. $\delta^{34}S_{SO4}$ data in pore fluid sulfate from the Yarqon (a) and the Qishon (b).

DISTRIBUTION OF PARTICULATE ORGANIC MATTER IN SEDIMENTS AND IN WATER COLUMN IN THE NORTHEAST MEDITERRANEAN (MERSIN BAY)

Emine Erdogan [1]*, Süleyman Tugrul [2] and Özden Bastürk [1]
[1] Mersin University, Faculty of Fisheries - emineerdogan@mersin.edu.tr
[2] Middle East Technical University, Institue of Marine Sciences, Erdemli 33731, Mersin, Turkey

Abstract
In the present study, 4 field studies were performed to collect surface sediments and water samples in the Mersin Bay between February 2009-October 2009. Spatial and seasonal variations of particulate organic carbon (POC), nitrogen (PON) concentrations were measured in the sediments and bulk POM filtered from water samples. In the nearshore waters (< 20 m), POC and PON values of bulk particulates in the bay waters ranged between 20-63 µM and 2.6-7.7 µM, respectively. The POC and PON concentrations of surface sediments at the inshore stations varied between 0.34-0.66 mmol-C/g (dry weight) and 0.05-0.06 mmol-N/g, decreasing to levels of 0.23- 0.61 mmol-C/g and 0.03-0.04 mmol-N/g in the offshore sediments (N/P ratio:7- 10).

Keywords: Sediments, Organic matter, Eutrophication, Mersin Bay

The coastal ecosystem of the NE oligotrophic eastern Mediterranean is impacted by the land-based inputs, mainly by riverine and domestic wastewater discharge [1]. Primary production is potentially limited by phosphorus in the coastal waters due to large N/P ratios in the regional rivers, rain waters and its deep waters [2]. Particulate organic carbon and nitrogen (POC and PON) in the surface sediments reflects the composition of POM sinking from the productive surface layer [3]. POC/PON ratios in the bulk POM ranged seasonally from 6-9 in the inner to 7-10 in the offshore waters. In the eutrophic nearshore waters (SDD ranged between 2-4 m), chlorophyll-a (CHL) concentrations were relatively high (0.92-3.5 µg/L). The POC-CHL ratio estimated from the regression analysis of bulk POM data ranged between 97 in winter-spring and 350 in the less productive summer-autumn period. POC and PON concentrations of the surface sediment varied between 0.34-0.66 mmol-C/g (dry weight) and 0.05-0.06 mmol-N/g (dry weight) in the nearshore zone, with the higher values in the winter-spring period due the increased nutrient inputs by the rivers. In surface sediments of the nearshore zone, POC and PON values varied seasonally between 0.42-0.64 mmol-/g (dry weight) and 0.05-0.06 mmol-/g (dry weight), whereas the offshore surface sediments contained less organic matter 0.23-0.61 mmol-C/g (dry weight) and 0.03-0.04 mmol-N/g (dry weight). The C/N ratios of the nearshore sediments were relatively lower(6.03-7.2) in spring, consistent with the ratios of bulk POM in the water column. However, the sediment N/P ratios increased to levels of 10-12.7 in the summer-autumn samples from the same locations, showing the selective decay of nitrogenous organic matter in the POM in the surface sediments when the POM supply from the surface layer decreased.

COMPOSITION AND ORIGIN OF THE NOVIGRAD SEA SEDIMENTS, EASTERN ADRIATIC COAST

Željka Fiket [1]*, Nevenka Mikac [1] and Goran Kniewald [1]
[1] Ruder Boškovic Institute - zeljka.fiket@irb.hr

Abstract
Composition of the sediments, their origin and deposition conditions in the Novigrad Sea, a small bay in the central part of the eastern Adriatic coast, was studied.

Keywords: Estuaries, Geochemistry, Sedimentation, Central Adriatic Sea

Introduction
The Novigrad Sea is a small, semi-closed bay located in the central part of the eastern Adriatic coast. The main characteristics of sediments of the wider area of the Novigrad Sea, including Zrmanja River and bay of the Karin Sea, were investigated. The Zrmanja River is a small karstic river which discharges in eastern part of the Novigrad Sea forming highly stratified estuary [1]. Geochemical, sedimentological and mineralogical analyses of sediments were carried out in order to gain insight into the composition of the sediments, the origin of materials and the deposition conditions in the Novigrad Sea.

Sampling and methods
For purposes of this study, sediment cores were taken at several locations including Zrmanja River, Novigrad Sea, Karin Sea and Velebit channel. Each core was cut into 2 cm subsamples prior to further analysis. Identification of the mineral composition of sediments was performed by X-ray powder diffraction (XRD). Sediment samples were granulometrically characterized by wet sieving.
The content of carbonates was determined volumetrically. Multielemental characterization of sediments after total digestion was performed by high resolution inductively coupled plasma mass spectrometry (HR ICP-MS). Analysis included determination of major, trace and rare earth elements.

Results and Discussion
Results indicate that the bulk samples are predominantly made up of carbonates, quartz and halite, while clay minerals occur as minor phases. Granulometric characteristics of the sediments indicate an increase in silty component (from 24% to 87%) downstream of Zrmanja River toward the deeper part of the Novigrad Sea. Share of carbonates also decreases from the river (64%) to the estuarine sediments (19%). Sediments with highest clay content and consequently highest metal content were collected from the deepest parts of the Novigrad Sea. Based on the results of statistical analysis three main components of the sediments can be distinguished: 1) lithogenic component - elements bound to clay minerals, 2) authigenic component – elements bound to Fe-Mn hydroxides, 3) biogenic component - elements bound to carbonates.
The vertical distribution of elements in sediment cores reflects source rock geochemistry, hydrogeological conditions, early diagenetic transformations and possible anthropogenic influence. Enrichment of sediments with metals downstream of the Zrmanja River and within the Novigrad Sea is related to salt-induced coagulation of colloidal materials and precipitation of Fe-Mn oxyhydroxides and clay particles. The sedimentation processes in the Novigrad Sea are therefore predominantly influenced by Zrmanja River. Smaller streams, as well as water inflow from the Karin Sea have less pronounced but still important influence on sedimentation in this basin.

[3] Faculty of Mining, Geology and Petroleum Engineering, Zagreb, Croatia

Abstract
Mineralogical, surface physico-chemical, morphological and structural characteristics of micron and submicron-sized mineral particles separated from different sedimentological environments of the eastern Adriatic coast were determined. The physico-chemical characterization revealed a significant increase in cation exchange capacity (CEC) and specific surface area (SSA) with decreasing particle size. Mineralogical, morphological and structural analysis showed that the fractions with higher amount of aluminosilicate, oxide and oxyhydroxide particles exhibit significantly higher values of SSA and CEC, and consequently, increased reactivity of sediments in biogeochemical processes in the marine environment.

Keywords: Sediments, Mineralogy, North Adriatic Sea, Central Adriatic Sea, South Adriatic Sea

Introduction
Coastal sediments are considered as the main sink for contaminants. The most reactive sediment phases are micron and submicron mineral particles due to their exceptionally high surface area and sorption properties. They govern biogeochemical processes and are responsible for transfer of contaminants from water to sediment. This research aims to determine the composition of micron and submicron-sized mineral particles and elucidate their role in biogeochemical processes with respect to their surface physico-chemical, morphological and structural properties.

Study area
Four distinct marine environments were chosen for studying considering their different sedimentological characteristics. The Po receiving basin (1, Fig. 1) is an area under influence of the Po river and receives a fine-grained part of the river load; the open sea location (2, Fig. 1) is an area of deep sea that is not influenced by coastal sedimentation processes; the Malo jezero on the island of Mljet (3, Fig. 1) is a karstic marine lake characterized by precipitation and sedimentation of aragonite [1], and the Risan bay (4, Fig.1) is a very indented marine environment characterized by sedimentation of clayey particles.

Fig. 1. Map showing locations of sampling.

Materials and Methods
Surface sediments were retrieved using Uwitec gravity corer or Van Veen grab sampler. Organic matter was removed by sodium hypochlorite treatment, modified after Kaiser [2]. Different size fractions were separated by gravitational settling, confirmed by laser diffraction, and freeze-dried. Physico-chemical characterization of mineral surfaces (SSA, CEC) was performed, and mineralogical composition (XRD) and morphology determined (FE-SEM).

Results and Discussion
The removal of organic matter significantly increased the share of the clay fraction and values of CEC and SSA in all investigated sediments. Accordingly, the loss of the organic coatings and disintegration of mineral aggregates enlarges the surface area of mineral particles available for interaction with the environment. In addition, this study exemplifies that the SSA and CEC values in different sediment fractions rise significantly with decreasing size (Fig. 2). The fractions with the highest values of SSA and CEC were mainly composed of aluminosilicate, oxide and oxyhydroxide particles.
The highest values for SSA and CEC were determined in sediment samples from locations 2 and 4 (Fig. 2), which also had the highest amount of aluminosilicate, oxide and oxyhydroxide particles. In samples from location 1, SSA and CEC values determined for micron and submicron fractions were still high, while for the original sediment sample they were slightly lower compared to other locations. This could be attributed to the prevalence of quartz, feldspars, and carbonates in the coarser sediment fraction. The lowest values were determined in the sediments with predominately carbonate sedimentation (location 3), revealing lower surface reactivity of carbonate minerals.
The submicron-sized aluminosilicates, oxides and oxyhydroxides represent the most reactive particles that are responsible for removal and transport of contaminants in aquatic environments. Even when they are not the primary constituent of sediments, they still have a significant impact on their surface reactivity.

MANGANESE AND BIOGENIC SILICA ASSOCIATION IN IZMIR BAY SEDIMENT (TURKEY, EASTERN AEGEAN SEA)

Ebru Y. Ozkan [1]*, Hasan B. Buyukisik [1] and Ugur Sunlu [1]
[1] Ege University, Fisheries Faculty, Department of Hydrobiology - ebru.yesim.koksal@ege.edu.tr

Abstract
Biogenic silica (BSi), pore water silica and other biogeochemical paramaters in sediment were investigated by using factor analysis in Izmir Bay.

Keywords: Eutrophication, Benthic-pelagic coupling, Aegean Sea

Biogenic silica (BSi) plays an active role in marine biogeochemical cycles. It is an important mineral found in many marine sediments due to primarily produced by planktonic organisms living in the surface ocean. Also, BSi is a chemical determination of the amount of amorphous silica which can be comprised of different component mainly of biological origin such as diatoms, phytoliths, radiolarians, silicoflagellates and sponge spicules (1). Accumulation of biogenic silica continues as the biosiliceous debris through the water column. In this study, two different methods which are Si/Al and Si/time were used. Si/Al method was calculated according to (2), Si/time was calculated according to (3). Biogenic silica (BSi) of samples via timed dissolution method were determined by plotting extracted silica against time and extrapolation of linear partion of the curve back to the zero time. BSi values of samples were determined by plotting extracted silica against Al and extrapolation of regression back to the zero Al value. In Si/time method, the BSi values were highly correlated with clay-silica, indicating that the dissolution of clay but Si/Al method did not. Therefore it was chosen Si/Al method to represent true BSi. The data set has been subjected to factor analysis. The results showed that 5 factors have been extracted. One of these factors includes the strong association of the BSi in sediment, pore water silica and the manganese. It was observed that aggregate from North (Bostanli) which was not cemented and Neogene aged carbonate rocks from South (Inciralti) are moved towards the inner bay through rivers together with Fe and Mn. Carbonate minerals have dilution effect on clay minerals here. Therefore, it is not possible to mention biogenic silicata since there is no diatom bloom in area where there are stations 4, 5, 6, 7, 14, 15 and 16 (Fig. 1).

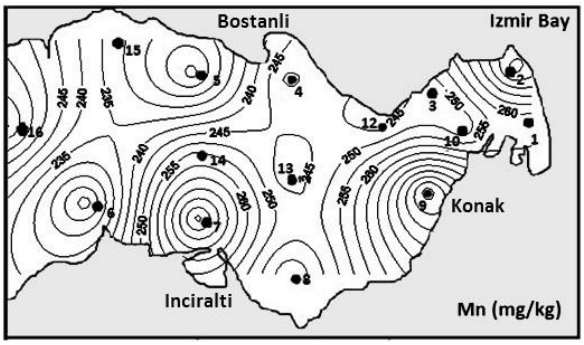

Fig. 1. Distribution of BSi (%) in sediment

On the other hand, when the existence of cold water in Hisar Castle which existed around 1650's in the district of Konak (sta. 8, 9 and 10), it can be thought that this water may enable diatom dominance due to dissolved silicate in deepwater. Infact, it is stated that there source which provide water for the fountain in Agora goes underground till Konak district. Due to bay water which was hypereutrophic before treatment plant (before 2001), in the sediment which contain hydrogen sulfide, Fe^{+3} and Mn^{+4} reduce to as Fe^{+2} and Mn^{+2} dissolved phases. And then these reduced species mobilize to sediment surface and overlying water. As it is seen in Figure 2, there is manganese only at the mouth of river and apart from inner bay. In the retention of manganese in sediment, the importance of the BSi as the carrier phase and the importance of the diatom productivity in the water column might be of paramount. This situation was expressed upon as one of the point that should be investigated in details.

PLANNED STUDIES FOR THE INVESTIGATION OF GEOTHERMAL POTENTIAL IN THE SIGACIK GULF (SEFERIHISAR)

Ozde Bakak [1]* and Erdeniz Ozel [2]
[1] Department of Geothermal Energy, Dokuz Eylul University, Izmir-Turkey - ozde.badur@deu.edu.tr
[2] Institute of Marine Science and Technology, Dokuz Eylul University, Izmir-Turkey

Abstract
The Sigacik Gulf is located in between Teke and Doganbey Bay in the south of Karaburun peninsula in the western Anatolia. This paper give to information about the preliminary results of the single channel seismic survey and consists of the planned studies for the investigation of geothermal potential in the Sigacik Gulf (West Anatolia) within the scope of a PhD Project.

Keywords: Geophysics, Seismics, Aegean Sea, Hydrothermal vents

Introduction
The study area is located in the region between Doganbey and Teke Bay in the south of Izmir Gulf (Fig.1). Sigacik Gulf's surroundings are covered by Mio-Pliocene and younger units. Pre-Miocene basement consists of Silurian, Carboniferous, Triassic, and Cretaceous rocks, and its crops out along high elevated areas such as Karaburun, Seferihisar, and Kusadasi ridges [1]. The geological map of area's surroundings is again worked out using ArcGIS (GIS-based) software from 1/500.000 scale of the geological map of Izmir-Turkey.

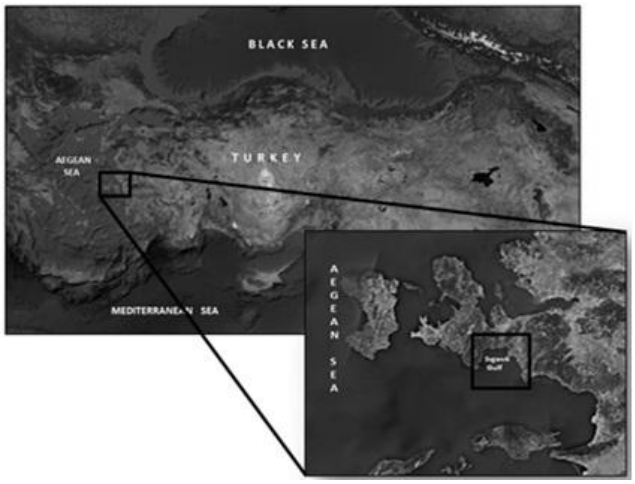

Fig. 1. The location of Sigacik Gulf

Methods
The Single Channel Seismic, Magnetic, Heat Flow, CTD and using ROV for monitoring of seafloor have been planned to investigation of geothermal potential in Gulf of Sigacik. During the single channel survey used to sparker system, which have 1 channel and 12 hydrophone with 17 m long streamer, as a seismic source and seismic data acquisition were carried out on board Dokuz Eylül-1 which is research vessel Dokuz Eylül University (Izmir-Turkey) in 10-12 October 2012. Approximately 250km data were acquired along the total of 27 seismic lines which compose of the 14 DB direction and 13 KG direction seismic lines. The seismic data processing was made using Promax program in the Seismic Laboratuary in the Institute of Marine Science and Technology. Some data processing steps were applied to seismic data such as, data load, geometric load, band pass filter, top mute, trace mixing, and time migration. However, the Sigacik Gulf's map of sea floor depth were obtained from a single channel seismic sections using the Kingdom Suite program (Fig.2).

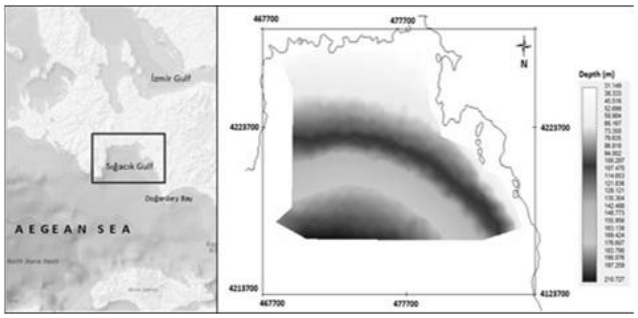

Fig. 2. The Sigacik Gulf's map of sea floor depth

Conclusions
The shallow seismic studies (Sparker) have been applied in Sigacik Gulf in 10-12 October 2012, also Magnetic, Side Scan Sonar, Heat Flow, CTD (Conductivity, Temperature, Depth) and ROV (Remotely Operated Vehicle) have been planned in terms of giving more information about the geothermal potential, in the content of the PhD project.

MODELING HYDRODYNAMICS AND SEDIMENT RESUSPENSION ON ARTIFICIAL REEF SYSTEMS IN THE GULF OF VENICE

M. Sclavo [1], A. Benetazzo [1], A. Bergamasco [1], D. Bonaldo [1]*, S. Carniel [1], F. M. Falcieri [1], M. Aurighi [2] and F. Fiorani [2]

[2] Geology and Geo-Resources Dept., Water Protection Unit, Regione Veneto, Venice, Italy

Abstract
Natural outcropping rock systems (*Tegnùe* in local language) along the northern Adriatic littoral zone represent important sites for biodiversity, protected from the mechanical effects of trawl fishing by artificial reef structures deployed in the surroundings. We describe the modelling approach to characterize the hydrodynamic and sediment transport in the proximity of such artificial reefs The numerical tool was used for investigating the impacts of different monolith systems in terms of increase in local suspended sediments concentration, providing a support for ecological design of such interventions.

Keywords: Coastal management, Gulf of Venice

The coastal zone of the Gulf of Venice (Italy) is characterized by the presence on its sandy-silty seabed of a number of outcropping rocky systems, named *Tegnùe* by local fishermen. These formations represent important biodiversity spots for the northern Adriatic sea; in order to enhance sealife settlement and protect the sites from the mechanical effects of trawl fishing, the Regional government has decided the deployment of monolithic artificial reef clusters in their surroundings. Within the MARINA Project, funded by the Veneto Regional government as a part of the Regional policy for coastal zone protection (*Legge Regionale* 15/2007), CNR-ISMAR was committed to the investigation of the effects of artificial reef systems on hydrodynamic and sediment transport. In particular, the main scope of the activity was to determine whether such structures may determine a turbidity increase (and therefore a water quality degradation) close to the deployment zones, and also to suggest an optimal strategy for future deployments.

A multi-step modelling activity at different time and space scales was carried out. Firstly, a statistical characterization of hydrodynamic conditions on the northern Adriatic sea was provided by means of a basin scale high-resolution (500 m) state-of-the-art, fully 3D numerical model run with reference to a typical year. The ocean hydrodynamic conditions were computed by the Coupled Ocean-Atmosphere-Wave-Sediment Transport (COAWST) modelling system, based on the ocean model ROMS, the wave model SWAN, and the CSTMS routines (Carniel et al., 2011). The hydrodynamic quantities thus obtained were then used for implementing a set of super-high resolution (from 0.15 to 4.00 m mesh size) 3-D hydrodynamic and sediment transport simulations, carried out via the numerical model MIKE-3, providing a broad description of velocity and suspended sediment concentration (SSC) fields close to a single submerged monolith covering the whole range of environmental (hydrodynamic, geometric and granulometric) conditions on the *Tegnùe* zones. Numerical output results were made available to the end-users and policy makers via a THREDDS Data Server (TDS, Bergamasco et al., 2012).
Lastly, results of idealized single-structure runs were then assembled in order to describe real systems: these informations were made available by means of a dedicated graphical query tool (MUD-App).

The main findings show that the SSC increase induced by artificial reef systems is generally negligible (<1%) compared to the background concentration. Only during particularly severe storms (return time one year longer) a stronger increase in SSC (eventually of the same order of magnitude as the background concentration) can take place in the very proximity of the monoliths, rapidly decreasing to less than 10% this value at a 10 m distance from the structures.

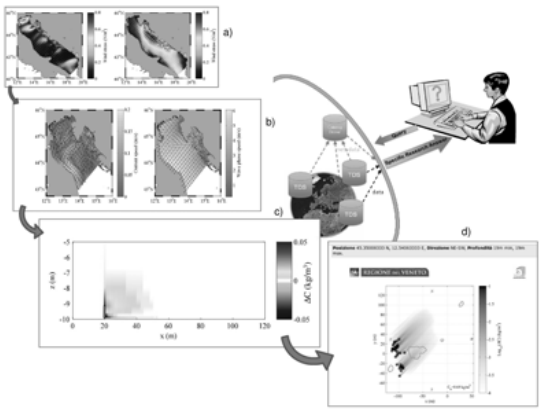

Fig. 1. From atmospheric forcings to sediment transport analysis on artificial reef systems. a) surface stress on the Adriatic sea under different wind conditions; b) current and wave patterns on the northern basin; c) SSC increase close to a single monolith; d) screenshot from the MUD-App representing SSC increase on a real artificial reef system. Results were loaded into a TDS.

CARACTÉRISTIQUES GRANULOMETRIQUES ACTUELLES DE LA LAGUNE MELLAH (ALGÉRIE NORD-EST): EFFETS DE COLMATAGE DU CHENAL DE COMMUNICATION AVEC LA MER

Brahim Draredja [1]*, Khalil Melouah [1] and Hayet Beldi [1]
[1] Université d'Annaba - draredjab@yahoo.fr

Abstract
La granulométrie de la lagune Mellah s'organise de façon concentrique ; allant des sables fins purs près des berges, aux vases pures au centre de la lagune. En effet, la fraction pélitique s'accroît avec la profondeur, où l'extension de celle-ci a augmenté dans la lagune, vingt deux ans après l'opération d'aménagement du chenal de communication avec la mer.

Keywords: Lagoons, Sediments, Sediment transport, South-Western Mediterranean

Introduction

La lagune Mellah est située à l'extrême Est algérien (8°20' E et 36°54' N) et totalise une superficie de 865 hectares, avec une profondeur maximale qui ne dépasse pas 5,2 m. Elle est l'unique lagune en Algérie, de ce fait elle a suscité des études scientifiques ([1], [2], [3], [4]). Ce milieu à vocation aquacole a connu une chute remarquable de sa production halieutique durant les années 80 [5]. C'est ainsi qu'à la fin de 1988, des experts de la FAO ont établi un plan d'aménagement du chenal de communication avec la mer [6], afin d'améliorer les échanges mer - lagune et faciliter la migration des poissons entre les deux milieux. La présente étude est une actualisation des caractéristiques granulométriques de la lagune vingt deux ans après l'opération d'aménagement du chenal.

Matériel et méthodes

La lagune Mellah est une étendue d'eau saumâtre dont la salinité varie entre 23,50 et 35,25 [7], communique avec la mer grâce à un chenal long (900 m) et étroit (2 à 10 m). L'échantillonnage systématique du sédiment a été effectué en mars 2010 à partir de 33 stations. Une analyse granulométrique de la couche superficielle du substrat a été réalisée après une séparation entre les deux fractions fine et grossière à une limite de 63 µm.

Résultats et discussion

Les résultats de l'analyse sédimentaire montrent que, dans la lagune Mellah comme dans la majorité des lagunes méditerranéennes, la granulométrie s'organise d'une façon concentrique ; c'est-à-dire que la taille des grains diminue régulièrement des rives au centre de l'étendue. Ce phénomène serait dû au processus d'accumulation des particules fines dans la cuvette centrale, suite à une forte agitation à la périphérie, puis le courant s'affaiblit vers le centre de la lagune [2]. En effet, les berges du Mellah sont formées de sables fins purs et au fur et à mesure qu'on se dirige vers les grandes profondeurs la fraction pélitique a tendance à augmenter (Fig. 1). Par ailleurs, cette étude nous a permis de mettre en évidence cinq zones lithologiques allant des sables purs près des rives aux vases pures au centre, en passant par les sables légèrement envasés, les vases sableuses et les vases légèrement ensablées (Fig. 1). On signale également la présence d'une forte densité d'herbier à *Ruppia* sp., sur les rives jusqu'à une profondeur de 1,50 m ; ceci participe au maintien de la bande sableuse le long des côtes de la lagune. En comparaison avec les études antérieures ([1], [2], [3]), le taux des pélites a sensiblement augmenté de la périphérie jusqu'au centre de la lagune. Cette situation serait en relation avec le faible hydrodynamisme, suite à l'état du colmatage du chenal, favorisant ainsi la décantation des particules fines surtout au centre de l'étendue, la zone la plus profonde.

CONTEMPORARY AND LATE QUATERNARY EVOLUTION OF IZMIR BAY (WESTERN TURKEY) AND INVESTIGATION OF MORPHOSEDIMENTARY SEABED FEATURES

M. Duman [1]*, B. Akçali [1], G. Dumanoglu [1], C. Eytemiz [1] and T. Ilhan [1]
[1] Dokuz Eylul University Institute of Marine Science and Technology - muhammet.duman@deu.edu.tr

Abstract
This article presents data from high-resolution shallow seismic profiles, side scan sonar, scanning sonar, surficial sediment data and video data for the sedimentary history, characterization and process-description of the Izmir Bay (western Turkey).Rate in sea level rise, seabed morphology, sediment supply, hydrodynamic regime are the main controlling factors of general infill pattern. Inspection by diver video of pockmark like seabed features are showed that some of these features are partly related with the scouring at wreck sites and controlled by the orientation of the wreck structure relative to the prevailing hydrodynamic conditions.

Keywords: Deltas, Sea level, Stratigraphy, Sediments, Izmir Bay

Introduction
Over the last decade, numerous works has been carried out on sedimentary coastal wedges in order to portray their pattern and evolution in relation to the last post-glacial sea level rise, and to estimate their future behavior. High resolution shallow seismic investigation complemented with side scan sonar and gravity coring and radiocarbon dating has been widely performed in many coastal settings around the world. Such detailed studies have been limited around the Turkish coastal areas of eastern Mediterranean and especially inner Gulf of Izmir [1] needs more representative work. In this study, the quaternary growth of Gediz delta in Izmir Bay is described and its relationship to tectonic and sea level change is interpreted. Additionally morphosedimentary seabed features are investigated with sonar and video recordings.
Material and Methods
The seismic, side scan sonar and diver video data that constitute the basis of this work were collected from the research vessel of the Institute of Marine Sciences and Technology in 2010, 2013. Data were recorded and processed using Triton SB Logger-Interpreter. Seismic profiles are divided seismic stratigraphic units, using the technique that described in Allen and Posamentier [2]. Conclusions
The shelf and basin slope area of Izmir Bay is underlain by superimposed deltaic sequences. Following the Holocene post glacial transgression, deltas were re-established deep in ancestral bays and little sedimentation took place on the shelf. The main architecture change occurred at ca. 7000 BP, i.e. when the sea-level rise slowed down comparably. The TST built up during the phase of rapid rise. It is poorly preserved and overlain by the HST that developed during the mid- to late Holocene. Rate of sea-level rise, sediment supply, basement hypsometry and hydrodynamic regime appear therefore as key-factors controlling the general geometry, preservation and nature of the sedimentary infilling. It appears in particular, that wave and current dominated bodies can be preserved in the infill of microtidal bay settings characterized by erosional seabed morphology especially in southern part of the bay. Isopach mapping shows that the thickest sediment sequences on the continental shelf are developed in bay near the limit of delta progradation. According to Aksu et al., [1] the pre-Miocene tectonic framework of the area around Izmir is characterized by north-northeast trending faults. Processed high resolution seismic profiling data show that there is no indication of active faulting and all fault like structures are related with acoustic basement morphology. This pattern is contrary the proposed tectonic models of recent works for Izmir Bay [3], [4]. Individual objects, artefacts or wrecks may act as nuclei to promote scour at local scale. Seismic, sonar and video data showed that scouring at such sites is controlled by the orientation of the wreck structure relative to the prevailing hydrographic regime, bathymetry and geological environment of the site.

MARINE HABITAT MAPPING AND SEA- FLOOR SURFACE STRUCTURES USING SIDE SCAN SONAR AND VISUAL DATA: NORTHERN CYPRUS SHELF SURVEY

T. Ilhan [1]*, B. Akçali [1], M. Atalar [1], R. Kavcioglu [1], Ö. Yegrek [1] and M. Duman [1]
[1] D.E.U Institute of Marine Sciences and Technology - tarik.ilhan@deu.edu.tr

Abstract
The aim of this study, to map seafloor surface structures and benthic areas by using side scan sonar supported with underwater photography and video recordings. In the Northern Cyprus Shelf the outcrop of basement rocks, sedimentary boundaries, habitat areas and the other local targets have been mapped at using SSS records.SSS records have been specify by mosaic maps which are created and possible sediment boundaries of biota have been defined as matching locations with visual data. The resulting morphologic and seabed classification maps were combined to plot the distribution of the predominant habitats in the coastal waters of Northern Cyprus, some of which are of high conservation value.

Keywords: Geophysics, Instruments and techniques, Sampling methods, Sediments, North-Eastern Mediterranean

Introduction
The Mediterranean Sea, especially the eastern Basin, is a unique environment whose structure and function is poorly known. It is considered to be one of the most oligotrophic regions in the world with an overall nutrient deficit that develops towards the east. The Levantine Sea is bordered on the north by Crete, the Dodecanese Islands and Turkey. On the east it is bordered by Syria, Lebanon and Israel and to the south by Egypt and Libya. The island of Cyprus is located in the northeast quadrant of the basin (Fig.1). The margin of the basin includes an island arc from Crete through the Dodecanese Island to Rhodes. The remaining basin margins are of the less complex types consisting of continental shelves, slopes, rises and associated features. The predominant topographic feature of this region is the ‘‘Mediterranean Rise’’ (Carter et al., 1972). The Cilician Basin lies in the northeastern part of the Mediterranean, between Northern Cyprus and the Turkish mainland. The smaller scale bathymetric features of the Levantine Basin are the Lattakia (1000–1500 m) and Cilician (1000 m). The relatively shallow Lattakia and Cilician Basins communicate with each other through a narrow channel of 700 m depth located nearly midway between the sills extending from the northeastern tip of Cyprus to the mouth of the Gulf of Iskenderun. Cyprus is the third largest island in the Mediterranean Sea, located west of Syria and south of Turkey. The island has a maximum length of about 220 km from Cape Andreas in the northeast to the western extremity of the island. Its maximum width, from Cape Gáta in the south to Cape Kormakiti in the north, is about 90 km. The total area of the country is 9.251 km. The surface samples were collected using a Van Veen type grab sampler in November 2011 and 36 surface sediment samples were sampled from three regions (Eastern Cyprus-Kumyali ‘‘K’’, Northern Cyprus; Zeyko ‘‘Z’’ and Arpa Ambari ‘‘AA’’, Western Cyprus; Yedi Dalga ‘‘YD’’) and dried, homogenized and reduced fine powder (Fig.1).

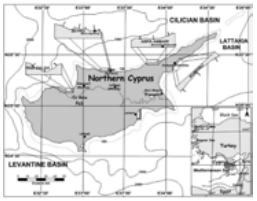

Fig. 1. Location of surface sediment sampling stations from Yedi Dalga, Zeyko, Arpa Ambari and Kumyali regions. Sample locations with three transects (black dots) from each area and labeled water depths.

Materials and Methods
During survey, Side Scan Sonar records had been collected with Imagenex Yellowfin Model 872, at 330 mHz frequency .In every single track, coverage area is 50 m wide at bottom for each side. A set of Hemisphere Crescent A100 D-GPS used for collecting synchronised on-time GPS data. Figure 2 shows mosaic maps after processing of those digital SSS records of tracks by locations. In general, underwater topographic structures of sites that slightly rough near shorline, becomes almost flatten gradually by increased soundings towards offshore. SSS images expose both strong and weak backscattering configurations alog the area. This refletion model is found associated with discrete granular ground at the shallow area and, both acoustic base unit cropped out on the bottom surface and avaliability of spread area of P.oceanica meadows in moderate and deeper sites. Mentioned areas along the sites exhaustively identified with mosaic projection, that prepared by interpreting both Sediment analysis results and applied seismic profiles (Fig.2) Technically it can determined precisely different character and structure metallic non-metallic sunken debris(i.e. shipwrecks, ammo and other navy wreckages, underwater mines , ancient lagans, their pieces, anchors, metal sticks etc) throughout the deepest Subbottom level where waves reach. However, in all of three sites, there is no deterrent material could be detected in bottom or sub-bottom.

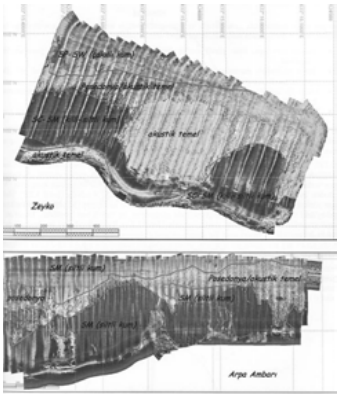

Fig. 2. Zeyko and Arpa Ambari areas Side Scan Sonar Mosaic Map and some structures of seafloor basement.

Results
It is aimed that mapping and classification of biota and sedimentary along studied sites; Protected seagrass meadows that should be concern before engineering application in area is determined by location with visual data.

SHORE-LINE DYNAMICS OF ANAPA ACCUMULATIVE COAST

Marina Krylenko [1]* and Viacheslav Krylenko [1]
[1] Southern Branch of Institute of Oceanology RAS - krylenko@mail.ru

Abstract
For the solution of the practical problems arising during economic development of the coast, frequently it is required to receive quickly the information on dynamics of coast, especially of the accumulative one. The use of space pictures allows estimating dynamics of accumulative coastal forms of any scale and giving a complete picture of the area coast changes. The resort Anapa (Russia) has been used as test area.

Keywords: Beach, Coastal processes, Remote sensing, Black Sea

Introduction
The solution of Black Sea coastal zone complex management problems is impossible without the full information of coasts current condition. The development of coastal natural systems is always accompanied by changes of coastal line planimetric position. Processes occurring at the coast essentially influence functioning of economic complexes. Prevention or minimization of coastal dynamics negative consequences for the economy is the important component of the sea coastal zone management. Therefore countries pay the big attention to the monitoring of the coast modern condition and to the forecast of their development under the change of the climate and the anthropogenic impact.

Materials and methods
The most part of data about the Black Sea coastal line variability available to the present time was received by measuring the width of beaches on stationary section lines or, less often, by the comparative analysis of separate topographical and aerial mappings. However, field tool observation data acquisition demands long expeditionary works and time for the subsequent office processing of results. Traditional methods of topographical survey can't operatively reflect the coastal line change [1]. Use of space pictures allows receiving the periodic information for all studied territory, estimating dynamics of coastal forms of any scale and giving the complete picture of the area coast changes.
Authors of the paper have made the analysis of space series for made at different time pictures of Anapa beaches (Russia) for the long period. While studying dynamics of Anapa bay-bar coastal line for binding the remote sensing contemporary records, the coastal line GPS-tracks and GeoEye high resolution survey of the chosen area were used. It was possible to reference to GeoEye picture the II World War times Luftwaffe (Germany) air photographs of program CORONA (USA) 1966 [2].

Results
Anapa bay-bar is an accumulative sandy body having the length of 47 km, located in a northwest part of the Black Sea Russian coast. Width of the bay-bar makes from 100 m in the northern part up to 1.5 km in the southern. The continuous strip of sandy beaches having the width of 50-200 m has huge recreational value.
In the last some decades the recession of Anapa bay-bar coastal line has been noted repeatedly in the literature [3]. Several hypotheses, about the reasons of reduction of beaches were put forward: hydraulic engineering constructions of port Anapa, groin and seawall at quay, withdrawal of sand from beaches. Meanwhile, comparison of the available photographs covering the period from about 1900th till our time also has shown that the beach on the considered site of coast remains stable while the scope of within- and inter-annual fluctuations water line position reaches 15-20 m.
The interesting information has been received at comparison of the aerial photographs made by the German secret service during II-WW, and satellite pictures for the period from 1966 till present time. It has been found, that at the length of 3 km of the bay-bar most southern part the coastal line has kept former position. The recession of coast is noticeable to the north; the size of this recession quickly increases to the north, reaching 70-80 m that coordinates with the data received by direct measurements. Comparison with CORONA pictures for 1966 has shown that from 1944 till 1966 the Anapa bay-bar coastal line was in rather stable condition; the recession of the coast has begun later. We shall note that fluctuation of the water line noted after severe storms reaches 10-15 m. It is connected with fluctuations of the sea level and complex structure of the underwater slope.

Conclusion
Chronological series of the high resolution satellite pictures is a reliable basis for monitoring fast changes of the coastal line and other elements of the coastal zone, especially on very dynamical accumulative coast. Their analysis has allowed to receive the detailed information about changes of Anapa bay-bar coastal zone for last decades and to connect them with natural and anthropogenic impact on the coastal zone. The conducted work has shown that space pictures application for studying the Black Sea coast of Russia is very perspective. The further researches will promote perfection of monitoring observations methods in the Russia coastal zone.

Abstract
The review of geochronological and historical data documents that the four major northern Mediterranean and Black Sea deltas (Ebro, Rhone, Po and Danube) formed during two short and synchronous intervals when human activities and change of land-use, impacted on their catchments overshooting the effects of climate forcing. These major growth phases occurred under contrasting climatic regimes, respectively during the Roman Empire and the Little Ice Age, and were both followed by generalized delta retreat, driven by two markedly different factors: after the Romans, the fall of the population and new afforestation let soil erosion in river catchments return to natural background levels; since the industrial revolution, instead, flow regulation through river dams overkilled the still increasing sediment production in catchment basins.

Keywords: Deltas, Shoreline evolution, Sediment transport, North-Central Mediterranean, Black Sea

Understanding the life cycle of modern delta systems since the maximum marine ingression is crucial for disentangling the role of natural vs. anthropic forcing, an open issue that bears substantial implications on our full awareness on the management of the coastal zone [1]. By underpinning the timing of the main phases of delta growth with respect to the natural environmental forcing, it is possible to define how pervasively have human populations modified landscapes and to predict delta stability during forthcoming environmental changes [2]. During the last decades, dozens of scientific publications provided new insights on the evolution of modern Mediterranean delta systems by integrating geophysical, sedimentological, paleoenvironmental and geochronological data with key information from historical records, in the form of ancient maps and chronicles (Figure 1).

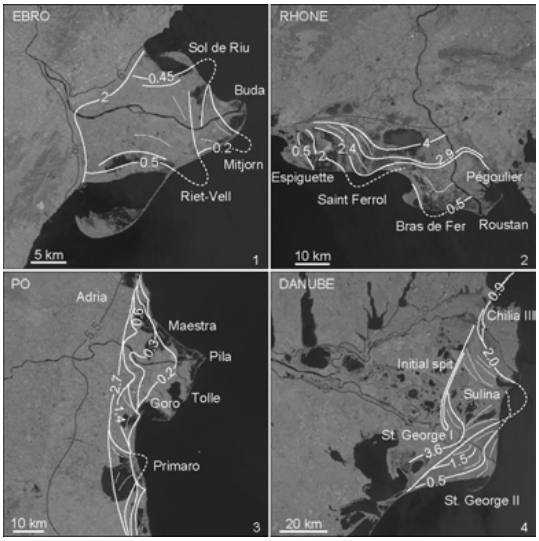

Fig. 1. Satellite views of modern deltas (from the Landsat Archive and the Global Land Survey), with red lines representing their embryonic stages, during the last phases of post-glacial sea level rise (between 9 and 5.5 kyr BP), and the white lines representing the main dated progradational events of delta growth.

The review of geochronological and historical data documents that the bulk of the four largest northern Mediterranean and Black Sea deltas (Ebro, Rhone, Po and Danube) formed during two short and synchronous intervals during which population growth and enhanced human activity overwhelmed the effects of climate forcing. Since the late Iron Age, the rise of classical civilizations and the spread of agricultural activities led to an increase in population and to significant deforestation in central and western Europe [3], reaching the maximum diffusion at the apex of the Roman Empire (around 250 yr AD). This important anthropic control on the environment at European scale resulted in a substantial increase in soil erosion and in the first major burst in the outbuilding of river-dominated deltas. Since the Barbarian invasions, the collapse of the Roman Empire led to a new phase of afforestation and reduced soil erosion that was reflected in a generalized delta retreat at Mediterranean scale, that lasted until the second half of the Little Ice Age. Since the 1650 yr AD, human population begun to growth exponentially, favoured by urbanization and industrialization, leading to important land-use changes. The resulting regional modifications in hydrology and climate, through changes in vegetation cover and runoff, determined a dramatic increase in sediment production, sustaining a major and synchronous progradational phase of all southern European deltas. Following the industrial revolution, flow regulation through river dams, channel diversions and construction of artificial levees, overkilled the still increasing sediment production in catchment basins, and leading to a dramatic decrease in the supply of coarse-grained material to the coasts (Figure 2).

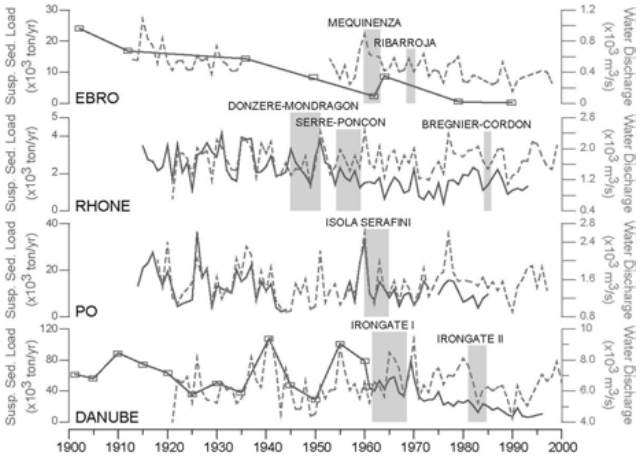

Fig. 2. Coupled diagram of suspend sediment load (continuous) and fresh water (dashed line) demonstrating the impact of anthropic reservoirs on river discharge in all four Mediterranean deltas; gray stripes highlight the timing of construction of major dams.

Delta systems become, therefore, more vulnerable to the action of marine processes, as reflected by a generalized phase of delta erosion and retreat. The chronological constraints available for Mediterranean and black sea deltas indicate how natural systems respond "instantaneously" to human perturbations, and this should be taken into account in any management attempt of the coastal zones.

Abstract

The present study investigates a marine aggregate deposit offshore the Bay of Afandou (Rhodos Island, Greece) in order to be used for beach nourishment. The dimensions, internal structure and sediment properties of the deposit have been designated by the use of a multibeam echo sounder, a sub-bottom profiler and a Smith-McIntyre grab. Preliminary results show that the detected sandy deposit comprises a thick (up to 3 m) surficial formation on the seabed located at water depths between 13 and 35 m with a volume of approximately 1.3-2.0x10^6 m^3.

Keywords: Sediments, Swath mapping, Coastal engineering, Aegean Sea

Afandou Bay is located on the N.E. Rhodos Island coast. The beach morphology is characterized as relatively smooth [1] [2]. The broader area has been subjected to major uplifting tectonic movements (2.9 to 3.7 m) during the Holocene [3] [4]. A Reson Dual-Head Seabat-7125 multibeam system and a Geoacoustics GeoPulse subbottom profiler were used for the detailed mapping and profiling of the seabed, respectively.12 surficial sediment samples were taken along three vertical to the shoreline transects at water depths of 12 to 47 m, for granulometric, geochemical, mineralogic and benthic analyses (fig. 1).

Fig. 1. Bathymetry, seismic tracks and sampling positions in the Afandou Bay

Two main morphological features are present in the Afandou Bay: A submarine canyon at the northeastern part of the bay and a rocky shoal at the southern part. In the central part of the bay, the bottom deepens gradually having the shelf-break at depths of 75 – 90 m. The broader area of the bay consists of medium to fine sand at water depths of 15-35 m, with mud increasing its percentage, but remaining always lower than sand, in greater water depths. No *Posidonia oceanica* meadows were detected, but sparse appearances of the invasive green alga *Caulerpa racemosa* var. *cylindracea* were found. At the central part of the Afandou Bay, acoustic tomography has depicted a sub-surficial sedimentary formation with sigmoid clinoforms at depths of up to 40 m below mean sea level, which evolves to an oblique parallel layer formation in greater depths. (fig.2).

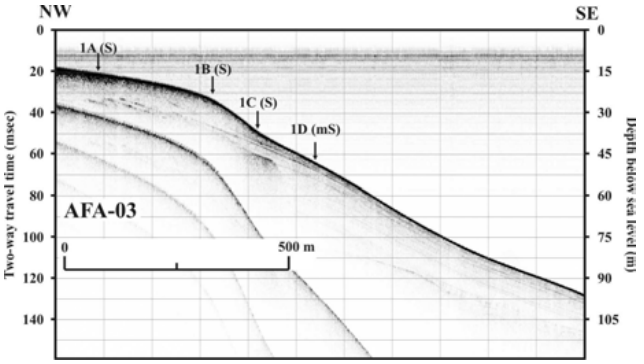

Fig. 2. High resolution seismic profile, showing the extention of the sandy deposit in the Afandou Bay. Arrows indicate the sampling positions of sediments. S: sand; mS: muddy sand.

Based on the above internal structure and sediment configuration, it is estimated that the thickness of the sand deposit is sufficient (1-7 m) in water depths from 13 to 35 m, with the thickest deposits being at depths of 17 to 25 m. The surface of the area under investigation is about 0.65x106 m2, thus, in case that the average thickness of the sand that can be extracted is 2-3 m., the volume of the aggregate can reach up to 1.3-2.0x10^6 m^3.

Abstract
The scope of the present contribution is to investigate the formation and evolution of the Kyparissiakos coastal dune field, during the last transgression (Holocene), on the basis of geophysical techniques (ERT, VES), detailed morphological mapping and existing geoenvironmental information.

Keywords: Geophysics, Coastal processes, Shoreline evolution, Lagoons, Ionian Sea

Introduction
The Kyparissiakos Gulf is part of the western coast of Peloponnesus (Greece), facing the Ionian Sea and has a total coastline length of approximately 70 km. The coastal zone is composed of sandy or gravelly sandy sediments, backed by coastal dunes and alluvial plains that have formed on a post-Alpine (i.e. Neogene and Quaternary) siliciclastic sequence, which locally exceeds 400 m in thickness [1]. The upper part of this sequence (Upper Pliocene) is composed of alluvial and lacustrine sediments that have accumulated mainly in the central part of the Kyparissiakos Gulf. The transition from Pliocene to Pleistocene occurred without any interruption of sedimentation and, therefore, it is very difficult (in some cases, impossible) to differentiate between the relevant deposits [1].

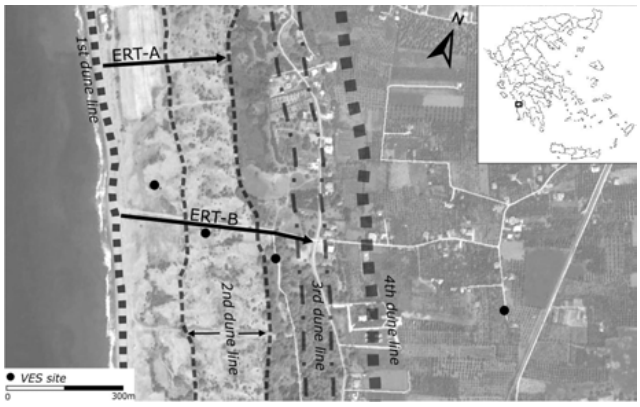

Fig. 1. Satellite image of the study area with annotation showing the dune lines, the geophysical sections and soundings.

The dune field of Kyparissiakos Gulf includes four dune lines (Fig.1) that lie at distances of 650m (4th), 450-470 (3rd), 140-180m (2nd) and 30-40m (1st) from the shoreline. Elevations in the dune field vary between 2 m and 13 m, with the highest corresponding to the 3rd dune line. With the exception of the most recently formed 1st dune line which is a typical foredune, the rest of the dune lines present characteristics similar to those of parabolic dunes, aligned to the prevailing onshore W and SW winds [2], [3].

Methodology
For the needs of the present investigation, a geophysical survey was carried out with the application of geoelectrical methods. Two (2) resistivity sections (ERT) were carried out, perpendicular to the general direction of the dune lines, to provide detailed information of the subsurface resistivity distribution up to 40-50m depth. In addition, four (4) geoelectrical soundings (VES) were carried out, for a deeper investigation of the subsurface lithological structure [4] (for locations see Figure 1).

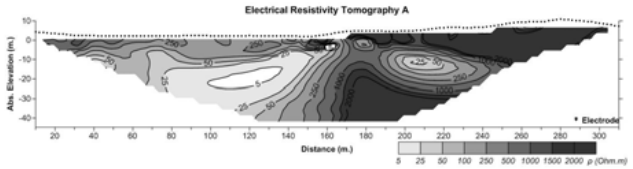

Fig. 2. Electrical Resistivity Tomography A (inversion model)

A detailed morphological map of the dune field was also produced using the technique of high-accuracy real-time kinematic differential GPS.

Discussion
The dune field consists of medium sand, well sorted due to its Aeolian origin [2]. The dune field has developed on the top of an extensive complex of beach barriers incorporating shallow lagoons. These upper Holocene formations, that are regarded as the base on top of which the dune field has been developed, overly an Upper Pleistocene formation of shallow marine/lagoonal deposits; which incorporates layers rich in beach material (i.e. sand, pebbles, gravels) and sandy clay. The geophysical survey indicates that this formation, having an average thickness of 35 m, should have been exposed to subaerial erosion during the last regression of sea level (prior to 21.000 years BP). In addition, this formation, which overlies non-permeable marly Pleistocene deposits, hosts fresh water aquifers that vary in volume seasonally.
The analysis and evaluation of the results of the geophysical survey in the dune field area, has provided information capable of adumbrating these aquifers (5-100 Ohm.m) under the 1st and 2nd dune lines (Fig. 2). As a result, it is concluded that the depicted geophysical structures are equivalent to the previously mentioned lagoonal deposits.
Finally, on the basis of morphological measurements and comparison with previously collected data, it seems that the 1st dune line is under erosion, mainly due to storm wave activity.

DANUBE DELTA'S COASTAL MORPHOLOGY AS A COMPONENT IN SPATIAL PLANNING FOR SPATIAL AND TIME BALANCING ACTIONS

Cristian Trifanov [1]*, Marian Mierla [1] and Iulian Nichersu [1]
[1] Danube Delta National Institute - kris@indd.tim.ro

Abstract
This study presents the geomorphologic evolution of the Sulina's coastline by analyzing reliable map databases and comparative examination considering the spatial planning future actions through ICZM framework. In this low sector, the actual modeling processes are obvious through progression and regression that have direct consequences on the coast. The evolution of the shoreline, analyzed through its actual dynamic perspective is the outcome of the conjugate action of natural factors complex with the active and diversified human intervention.

Keywords: Coastal systems, Black Sea

Introduction
The relative stability of the coastline in the studied area reveals processes of erosion and/or deposition of sediments from Danube River corresponding to their historical periods. These processes were accelerated by the human pressure/activities. Phenomena related with constant or repeated energy fluctuations are inducing modifications to the natural environment in the area. The main repercussions can be observed in the ratio between the marine and the deltaic surfaces and also on vegetation [1]. The main actors shaping this area are: the Danube River system that discharges an average 60 millions of tons of river deposits and 200 milliards of m^3 of water per year, the Black Sea's NE-SW currents, the position at 45^o latitude in northern hemisphere that generates the alternation of temperatures, the climate change, sea level variation (Fig. 1) and the omnipresence of the human pressures impact. Therefore coastal area of Danube Delta suffered major modifications in the past decades which lead to a morphodynamic imbalance. Due to major coastal morphological changes induced by hydrotechnical works on the upper Danube but mainly the ones inside the water complex of the Danube Delta, triggered numerous field activities in monitoring and investigation that developed into a heterogeneous database.

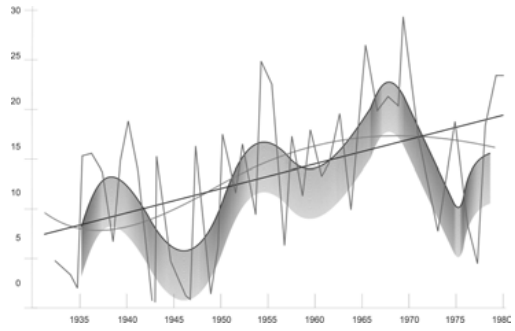

Fig. 1. Level variation of the Black Sea in Constanta harbour during 1933-1980 by Eng. P. leabu IGFCOT 1981 according to the only maregraph available.

Anthropogenic impact - prone to high risk
River regulation by cutting meanders of Danube's main branches has increased the water flow and the discharges (naturally distributed) have been modified. Thus the accelerated alluvial processes have repercussion on the previously formed Sacalin Island, expanding south of the St. Gheorghe branch. Hydrotechnical development of the "Litoral Belt" also known as Tataru channel parallel to the coastline that connects Sulina in the north and St. Gheorghe in the south lead to disconnection of the Rosu-Puiu water complex from the purging system towards Black Sea affecting the water circulation inside the complex and also defragmenting the coastal landscape. During 1862 and 1902 the Sulina branch suffered heavy river regulation favoring transportation and other economic activities. Thus, from 93 Km was reduced to 64 Km plus the embankment works at the shedding led to heavy impoundment of the coast towards the south. The anthropic pressure via investment projects, tourism and the necessity for expanding despite the lack of strict regulation concerning ethics and conduit have led to disruption of this sensitive area, destabilization of the existing habitats, a defective land cover and land use management and chaotic development of economic activities inside a Biosphere Reserve. The increasing environmental risks are based on climate instability, changes in seawater temperature and salinity, particular or unpredictable occurrence of storms, sea level variations, and coastal waters eutrophication [1].

Coastal processes analysis
The most important energetic drivers in evolution of the coastal shore are the currents and the waves. Mostly acting together, the mechanical imprint of these drivers share the same genetic element - the wind, an extremely important factor in development of the abrasive process. The hydrological component that has the most important effects in the dynamics of the shoreline is the combination of variation of the sea level and the waves[2]. The long term evolution of the shoreline is hard to predict however if the genesis hypothesis of the Danube Delta is taken into account along with the fact that sea level of the Black Sea is rising results the statement that the whole accumulation front is under a process of regression. The analysis of the shoreline evolution can be done on a 100 years period based on existing cartographic documents and debates. In this sense there were used documents like "Major State of the Army" dating from 1880 compared with two editions of Gauss projections printed in 1952 and 1972, European Commission of the Danube printed the Danube Map in 1870 under Ch. Hartley and published at Leipzig in 1887, the hydrographic map of D.D. in 1910 and topographic map of D.D. by Geography Institute in 1983 [2]. By comparing all the historical documents using modern GIS techniques can be established shoreline sectors under impoundment or marine abrasion processes therefore a progression or a regression of the coast's shoreline.

Interdisciplinary approach
Sustainability is the quality of human activities to develop without exhausting available resources and without destroying the environment, therefore without compromising the ability to meet the needs of future generations. World Conference on the Environment in Rio de Janeiro in 1992 paid special attention to this concept, which involves establishing a balance between economic growth and environmental protection and finding alternative resources. When referring to the overall economic development of a country or region the synonym usually preferred is durable development [3]. The importance of coastal morphology as a component to spatial planning studies is reflected in the sustainability indicators. As long as the coastal morphodynamic processes are taken into account for future development projects the loss of environmental and economic assets will decrease to a point of sustainable balance between landforms, economic growth and environmental conservation.

Rapports des modérateurs

Basin wide multi-ship surveys

Toste Tanhua, GEOMAR, Kiel, Germany

Résumé

An introduction to multi-ship surveys on a global basis was given by the moderator, Toste Tanhua, with emphasis on the World Ocean Circulation Experiment (WOCE), GEOTRACES and GO-SHIP, as well as its Mediterranean version - MED-SHIP. This was put into context of multi-ship surveys carried out in the Mediterranean Sea, such as POEM (Physical Oceanography in the Eastern Mediterranean). The introduction summarized the benefit of multi-ship surveys, but also some of the requirements for successful multi-ship surveys such as common methodologies and data reporting formats for consistency and interoperability, and a focused data collection and synthesizing routine. During the session several presentations were given that presented results from multi-ship surveys, including results from argo floats that can in some sense be regarded a fleet of ships (platforms), see the individual abstracts for this session.

The discussion after the presentations highlighted some issues with data availability from multi-ship surveys. Particular attention was given to data availability. The audience debated on whether or not some data portals were public or not, and which data sets were publically available, or not. Even the perception of publically available data sets is different; some investigators commented that the data are publically available on a ?just send me an email and I send you the data? basis. Other scientists were of the view that a publically available data set should be available by mouse-click from a data portal. One particular issue with the Mediterranean Sea data is that there is a multitude of data centers available, very often these are formed by projects with a time-horizon; after the end of the project the data might not be available to a data repository. There was also some discussion on which data repositories should be used for Mediterranean data, at least seven different data centers were mentioned during the discussion. There was a consensus that a more structured data archival structure would be desirable for the Mediterranean Sea science.

Coastal / open waters exchange - 1

Miroslav Gacic, OGS, Trieste, Italy

Résumé

The presentations mainly focused on the functioning of semi-enclosed bays and lagoons. Lagoons and their water and sediment exchange with the adjacent sea are mainly controlled by tidal variability. This issue was addressed by both experimental and modelling techniques which enabled rather good estimation of the water and sediment balance (Mancero et al., Lerrede et al.). On the other hand, semi-enclosed relatively deep bays exchange and communicate with the adjacent sea under wind and coastal circulation forcing. Here both experimental and numerical approach were discussed (Napolitano et al., Zambianchi et al.). An interesting Lagrangian experiment was also presented in an semienclosed bay.

Sediment transport is often determined by the strong longshore current (Bourrin et al.) and possible accident and its consequences on the hydrosedimentary conditions in a semienclosed environment was also addressed (Duffa et al.). Mediterranean coastal areas are rich in submarine freshwater sources and an interesting study (Rodellas) was presented estimating the importance of these sources in the overall freshwater balance in the Mediterranean, showing that their contribution is comparable to the annual riverine discharge. Estuaries are very sensible coastal environments subject to wave and current impact and some works were presented in this session as well (Abdallah and Cerralbo). Finally thermal conditions and possible flooding events in coastal areas and channels were addressed (Pasaric et al., Altiok et al.)

Coastal / open waters exchange - 2

Xavier Durrieu de Madron, France

Résumé

Full room. This popular session (full room) comprised nine presentations dealing with a wide range of topics covering different regions of the Mediterranean and the Black Sea. The session focused on processes at play for the exchanges between the coastal zone and the open ocean as well as between different sub-basins (straits). Several presentations concerned the influence of wind-induced and mesoscale processes on the shelf-slope exchanges, and the characterization of tidal flows. The discussion highlighted the importance of using both observations and modelling to better understand the processes and define the main features at play, and also the need of sharing the available observations within the community.

Mesoscale variability

Sana Ben Ismail, INSTM, Tunisie

Résumé

The session on mesoscale variability comprised ten presentations covering a wide range of circulation features with horizontal ranging from few km to few tens/hundred of km, with vertical scales ranging from tens to thousand meters and temporal scale from few days to several week/months. Difficulty in studying and modeling ocean dynamics is due to the complexity of mesoscale processes and their continuous interplay with the general circulation. The study of eddies, filaments, fronts and upwelling requires a combination of measurements, satellite observation, altimetry and models.

Most of the presentations concerned main mesoscale processes (Alboran Gyre, Irapetra eddy, Sicily Channel fronts, Ligurian dispersion) and combined analysis based on high resolution model, altimetry, satellite data, glider, in situ measurements. Discussions focused on the importance of a very high resolution model to give a new insight on the dynamics of the Mediterranean and Black Sea. The importance of temporal scales of variability and the large panel of geographic regions studied such as Gibraltar Strait, Algerian basin, Sicily Channel, Ionian Sea, Cretan Sea, Levantine Basin and Black Sea show the relevance to study mesoscale processes in the Mediterranean and Black Sea.

Operational oceanography

Joaquin Tintore, Spain

Résumé

The room was completely full with more than 10-15 persons standing up.

The session was introduced by the moderator, Joaquín Tintoré who presented some initial ideas on the state of the art of operational oceanography, the appropriate time now for enhancing operational oceanography given the significant scientific, technological and computing power advances and the challenge of integration of observing and forecasting systems in a semi-enclosed sea such as the Mediterranean.

Nine well structured and clear presentations where made, addressing some of the key scientific questions that are at the heart of operational oceanography: water masses formation and dynamic effects, atmosphere-ocean interactions, downscaling modelling initiatives addressing consistency between regional and local simulations biogeochemical fluxes and physical-biological coupling, physical and biogeochemical data assimilation, results from new observing technologies such as HF radar, gliders, as well as tools for decision support. An interesting and lively discussion followed addressing both specific questions on the above mentioned topics as well as on more general issues such as reliability of models, integration between the different observing platforms (in particular between gliders and HF radar), data availability, etc.

Physical and biogeochemical modelling

Javier Ruiz, Spain

Résumé

The coupling of physics and biology is the backbone of marine ecosystem functioning. It is, therefore, at the core of the knowledge-based management of the marine environment. The session evidenced this key role of physical-biological coupling in providing advice for management in the case of a coastal lagoon and a marine protected area. It also contained presentations that analyzed the coupling at different scales and trophic levels, including primary production in the Gulf of Lion and fisheries in the Alborán Sea. Unfortunately we missed a speaker to talk on quality control for models, a subject that had raised expectation owing to previous debates at CIESM plenary sessions on the dangers involved in the present obsession of the scientific community to accumulate publications rather than knowledge. It is the moderator's opinion that the attendants enjoyed the session both for the interesting presentations and for the subsequent live debate. This subject (physical-biological coupling) might be more neatly identified in future congresses to draw the attention of a larger number of speakers.

Sub-mesoscale variability

Nadia Mkhinini, ENSTA, Paris, France

Résumé

Most of the sub-mesoscale studies are located on the upper ocean where sub-mesoscale processes are in particular dominant due to the presence of lateral density gradients, vertical shear, weak stratification and also the presence of a surface boundary. The

sub-mesoscale mechanisms were described in this session, using observational, modelling and analytical studies.

The presentations included studies of coastal dynamics (Forget et al., Fusco et al.), the use of various datasets acquired by radar or Doppler profiler, and eddies' formation (Bosse et al., Mkhinini et al.). Resolving sub-mesoscale dynamics, where the relative vertical vorticity - contrary to mesoscale dynamics - equals or exceeds the planetary vorticity, by using the mesoscale field is a challenge for models and observations.

Thermohaline cells and biochemical status - 1

Samuel Somot, Météo-France / CNRM, Centre National de Recherches Météorologiques, Toulouse, France

Résumé

Most of the talks were oriented towards physical ocean science targeting the monitoring, modelling, and finally understanding of the Mediterranean ThermoHaline Cell (MTHC) focusing on the three main water mass formation areas (NW Mediterranean Sea, Adriatic Sea, Aegean Sea).

Three main topics were discussed following the poster short presentations :

1. The decadal variability of the Eastern Mediterranean basin involving the Adriatic Sea, the North Ionian Sea, the Levantine Basin and the Aegean Sea. The main signature is the fluctuation of the salinity in those seas but impact can reach activation of different deep-water formation areas, change in thermohaline intensity and impact on biogeochemistry and upper-traphic level status. Recently named BIOS (bimodal oscillation), this decadal variability is still not fully known and understood. In particular, the relative role of the internal variability versus the externally forced variability by air-sea fluxes is not clear yet. In addition, the modelling of this variability is far from being achieved. This raises the need for improving the modelling of the interannual to decadal variability of the MTHC. Velaoras, Gacic, Civitarese, Malanotte-Rizzoli, Josey and Somot were the main participants to the discussion.

2. The modelling of the exceptionnal Winter 2011-2012 in the Adriatic Sea was then discussed. This very cold winter sees the formation of very dense water (up to 29.5 kg/m3) formed in the Northern part of the Adriatic and was well monitored. Up to now, only one model was used to try to simulate this event. He is only able to qualitatively reproduce this phenomena but the quantitative reproduction is not reached yet. The understanding of the relative role of the key factors leading to such phenomena is only possible if models are able to reproduce them first. This underlines the need for modelling exercise of golden (interesting and well-observed) case study in a multi-model coordinated framework. The discussion was mainly leaded by Chiaggato and Somot.

3. The last discussion topic was not fully debated (time limit) and started from a question by Querin : « What is the best resolution in the ocean and in the atmosphere to ideally simulate the Mediterranean Sea ? » This question can be enlarged in a wider question : 'What are the open key challenges and current limits of the Mediterranean Sea physical modelling community ? '

Thermohaline cells and biochemical status - 2

Chiara Santinelli, Italy

Résumé

The Mediterranean Sea can be considered an ideal basin to study the main physical and biogeochemical processes occurring in the oceans. The main goal of this session was to assess how physical processes can explain the peculiar biogeochemical features of the Basin.

Presentations focused on the impact of deep water formation on the oxygen, nutrient distribution and N/P ratio at the Dyfamed station (L. Coppola and O. de Fommervault), in the MEDOC area (T. Severin) and in the Otranto Strait (E. Souvermezoglu) and on the effect of mesoscale activity on surface DOC distribution in the Tyrrhenian Sea (C. Santinelli). The importance of atmospheric input was shown for the Eastern Mediterranean Sea (P. Pitta), while the impact of terrestrial input on biogeochemical processes was discussed for the northern Adriatic Sea (R. Precali) and the Mersin Bay (E. Erdogan). Finally the importance of modelling effort (Arsouze T.) combined with in situ data (DOC, C. Santinelli) was highlighted.

The discussion focused on: (i) the processes that could explain the high DOC concentrations observed in the anticyclonic gyres, (ii) the role of deep water formation in C export to depth, in the oxygen distribution and in N/P ratio and (iii) the impact of atmospheric input on biogeochemical processes in the Eastern and Western Mediterranean Sea. The importance of temporal series of biogeochemical properties at fixed stations was stressed. Finally, it was highlighted that a huge amount of data are now available for the Mediterranean Sea, so a multidisciplinary and interdisciplinary effort appears crucial in order to assess the link between the main physical and biogeochemical processes occurring in the Basin. Modeling efforts, in situ-data and the information coming from the satellite should be combined in order to address the main unresolved questions for the basin.

Variability on climatic scales - 1

Sergiu Dov Rosen, Israel Oceanographic & Limnological Research, Israel

Résumé

Climate variability takes place on various time scales: paleoclimatic, interdecadal to centennial, seasonal to interannual, and intra-seasonal. Climate variations happen as well on all spatial scales, from the regional to the global. Seven presentations covering both observational and model assessment of variability in regional and whole Mediterranean, on seasonal to decadal and centennial scales were presented, aiming to improve our understanding of natural and human-induced climate patterns, as well as the linkages between large-scale and regional climate variability. An element which appeared significant in regard to the IPCC 5th Assessment report of Group 1 is the fact that the model results presented did not account for the flow through Suez Canal, increased since the beginning of 1990s following its deepening and widening, fact which seems to contribute significantly to the trend of increasing salinity in the Eastern Mediterranean (demonstrated by a faster measured sea level rise there) and through it to the whole water circulation in the Mediterranean and in the Atlantic.

Variability on climatic scales - 2

Katrin Schroeder, Italy

Résumé

During the second session on Variability on Climatic Scales the conveners discussed a variety of topics, ranging from impacts of extreme winter atmospheric conditions on decadal oceanic oscillations, to assessments of sea level and sea surface temperatures rises in different parts of the Mediterranean and related mass mortalities, up to the suggestion of the building of a control barrage at the Strait of Gibraltar.

Thus, variability on climatic scales has been interpreted and discussed from the point of view of a number of interrelated disciplines: physics (oceanographic and atmospheric), biology and even engineering. Further, the temporal scales and frequencies of ?variability on climatic scales? have been described in many different ways: as oscillations, seasonality, trends, interannual variability. This leads of course to consider the variability also on a wide range of spatial scales, that interact with each other.

Modern oceanographic disciplines are no longer dedicated to the definition on ?how the ocean is?, but more and more ?how the ocean varies?. But ?variability? is a very wide topic, and the range of themes that were touched during the session demonstrates how complex the problem of detecting and describing it is, even restricting the field only on the climatic scales.

Ventilation transients

Manuel Bensi, OGS, Trieste, Italy

Résumé

Six presentations were given in this scientific session, all focusing on a single general theme: the thermohaline variability of the water masses formed by processes of ventilation.

Two presentations focused on the long-term variability of the Levantine Intermediate Water in the easternmost part of the Med Sea, others on the variability observed in the deep layers of the Gulf of Lion, Adriatic and Aegean Seas. Additionally, important issues such as the combination of numerical models and in-situ data, and the study of changes in ventilation in a view of transient tracers were discussed here. The final debate focused on several arguments: firstly, the reliability of numerical models in the Med. Sea and their capacity to reproduce the observed variability of the water masses, taking into account also contributions from the Nile and Suez Channel runoff; secondly, the importance of a more complete approach in studying the dense water formation, considering the effects of the geostrophy in the spreading of the newly formed dense water (the example of a stream-tube model applied to the Aegean Sea was presented and briefly discussed). Finally, the discussion focused on the importance of the preconditioning factors for the dense water formation, such as the thermohaline properties (i.e. salt content) which can favor or reduce the possibility that a large winter heat loss could produce the ventilation of a basin.

THE CO2 SYSTEM IN THE MEDITERRANEAN SEA: A BASIN-WIDE PRESPECTIVE

M. Álvarez [1]*, A. Luchetta [2], H. Sanleón [1], L. Mintrop [3], T. Tanhua [4] and G. Civitarese [5]
[1] Instituto Español de Oceanografía - marta.alvarez@co.ieo.es
[2] ISMAR, Trieste
[3] MARIANDA, Kiel
[4] Geomar, Kiel
[5] OGS, Trieste

Abstract
During April-May 2011 two cruises (M84/3, RV Meteor, Istambul-Vigo, and EF11, RV Urania, Bari –La Spezia) overdetermined the CO_2 system in the MedSea for the first time. The internal consistency analysis for pH, alkalinity and total inorganic carbon confirmed the use of CO2 constants from Mehrbach et al. (1973) [1] and others [2] and [3]. This analysis reveals some insights about the peculiar physico-chemical characteristics of MedSea waters. Vertical distributions of these properties will be presented and discussed along with property-property plots to characterize the different water masses in the MedSea subbasins. The sensitivity of MedSea waters to CO2 increase will be discussed using the vertical distribution of buffer factors and the saturation state for calcite and aragonite

Keywords: Chemical speciation, South-Western Mediterranean, South-Eastern Mediterranean, Tyrrhenian Sea, Ionian Sea

Introduction

The studies about CO_2 variables in the MedSea are relatively scarce [4] despite its relevance as a small laboratory for ocean processes [5] and its significant contribution to the storage of anthropogenic carbon [6]. In this study will present the first internal consistency analysis for CO_2 measurements in the MedSea although partial, using pH, alkalinity (TA) and dissolved inorganic carbon (DIC) data collected during the M84/3 and EF11 cruise, some interesting results related with the peculiarity of the MedSea waters are obtained. Additionally, basin-wide and subbasin vertical distributions of CO_2 species will be presented. The sensitivity to the CO_2 increase in the atmosphere will be studied using several buffer factors [7] and the saturation state for calcite and aragonite.

Methods

During the M84/3 (on board) and EF11 (at lab) cruises (Figure 1) pH was measured spectrophotometrically following [8], TA with potentiometric methods [9] and [10] and DIC was also measured with a S

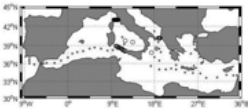

Fig. 1. Figure 1. Mediterranean Sea map with the stations sampled during the Meteor M84/3 (dots) and Urania EF11 (circles) cruises.

OMMA coulometric method. Certified reference materials were used to control the quality of our measurements.

Results and discussion

Using data from M84/3 the preferred combination of constants is the following: for CO_2 those from Merhbach et al. (1973) refitted [1], for sulphate [2] and for total borate the equation by [3]. This is also the preferred option for global synthesis studies as GLODAP or CARINA. In studying the relationship between the residuals (measured minus calculated values) for pH and TA a clear distinct relation is detected for high salinity waters in the MedSea.

Deep waters under 500 dbar in the eastern MedSea present a quite homogeneous pH25T, TA and DIC distribution, 7.966±0.004, 2614±4 umol/kg and 2310±5 umol/kg, respectively, while in the western basin are more variable 7.907±0.045, 2525±9, 2264±8, respectively. In the pressure range between 150 and 500 dbar, Levantine Intermediate water evolves in the eastern basin for pH25T, TA and DIC values from 7.982±0.02, 2626±7, 2308±13 to 7.891±0.02, 2576±13, 2319±14 in the western basin, respectively.

We studied different buffer factors [7], which quantify the sensitivity of MedSea waters CO_2, pH and carbonate saturation state to changes in DIC (at constant TA, e.g., air-sea CO_2 exchange) and TA (at constant DIC, addition of strong acid or base). We found that MedSea waters are more resistant to changes in DIC and/or TA than Atlantic waters to the west of the Strait of Gibraltar, because any buffer factor is lower in the Atlantic. The CO_2 system in the western basin is in general more sensitive to changes in DIC and/or TA than the eastern part, buffer factors are lower in the western MedSea.

The CO_2 sensitivity to changes in DIC at constant TA (air-sea CO_2 exchange) is the highest, then the change in the saturation state due to additions of a strong acid or base, then the change in the saturation state due to air-sea CO_2 exchange, then the change in pH due to the air-sea CO_2 exchange (equivalent to the change in CO_2 due to a strong acid /base addition). Finally, MedSea waters are able to buffer changes in pH due to strong acid/base additions.

VARIABILITY OF OCEANOGRAPHIC PROPERTIES IN THE EASTERN MEDITERRANEAN DURING THE LAST THREE DECADES

V. Cardin [1]*, G. Civitarese [1], D. Hainbucher [2], M. Bensi [1] and A. Rubino [3]

Abstract
We present temperature, salinity and oxygen data on an east-west transect through the eastern Mediterranean Sea collected during METEOR cruise M84/3 in April 2011. These data together with data gained on previous cruises during the period 1985-2011 are analysed in terms of regional aspects of the evolution of water mass properties and heat and salt content variations. Special attention is given to the variability of thermohaline properties of the LIW and AdDW. Results are evaluated considering pre and post-EMT situation in the eastern Mediterranean to elucidate which is the present state of the hydrography the Eastern Mediterranean.

Keywords: Hydrography, Circulation, Intermediate waters, Salinity, Levantine Basin

Several changes in the circulation, temperature (T) and salinity (S) patterns have occurred in the last three decades in the Eastern Mediterranean. A number of cruises (such as METEOR cruises as M4-1987, M31-1995, M44-1999, M51-2001, M71-2007, and the latest M84/3-2011, POSEIDON 298, MERIAN MSM13/2, MERIAN15/4) have been accomplished to help understanding the processes involved. Hydrographic observations conducted in April 2011 assess the present status of circulation in the eastern Mediterranean. These observations highlight the importance of intense spreading of the intermediate waters. The highly saline Levantine surface(LSW)/Intermediate Waters (LIW) dominate the upper water column of the easternmost area of the Levantine, spreading towards west and occupying the upper 500m (figure 1). The permanent Rhodes Gyre breaks the main salinity tongue with the outcrops of the isohalines. This pattern seems to be a further evolution from the situation already present in 2008 when a maximum value of 39.34 was measured in the formation area being now extended more westward. The westernmost part of the transect is always occupied by the AW (Atlantic Water) being very reduced spatially. However, its intrusion into the Levantine is very variable and may depend on the circulation present in the Ionian (Gacic et al. 2010) .

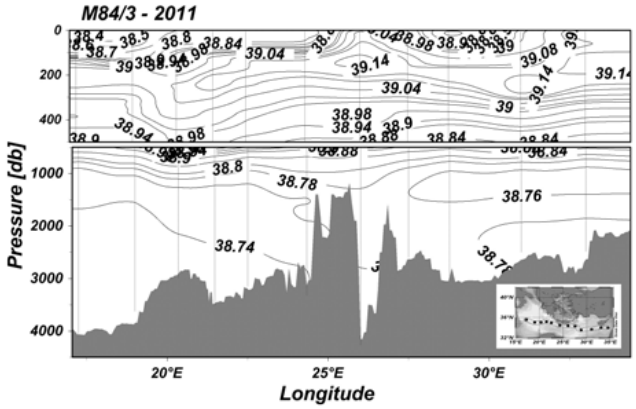

Fig. 1. Salinity distribution during April 2011 (METEOR Cruise M84/3)

Data from the 1987 Meteor cruise M5/6 permitted to study the hydrographic conditions prior to the EMT (Eastern Mediterranean Transient) in the Ionian and Levantine basins when the AdDW (Adriatic Deep Water) was clearly the main contributor to the EMDW (Eastern Mediterranean Deep Water). At that time, the deep layer was characterised by salinities lower that 38.68 along the whole transect. Observations conducted in 1995 and 1999 (figure 2) during the EMT phase clearly show Aegean high salinity waters outside the Cretan Passage. Enhanced salinity (values higher than 38.84) relative to 1987 was ubiquitous already in early 1995 (Roether et al. 2007), except than in the western Ionian deep layer that was still occupied by low salinity waters (<38.68). These high salinity waters were still present in the easternmost part of the Levantine basin in 2001, blocked by the bathymetry constraint of the Herodotus Trough.

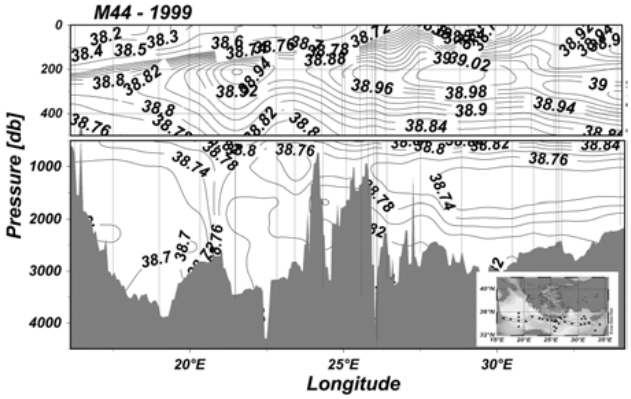

Fig. 2. Salinity distribution during April-May 1999 (METEOR Cruise M44/4)

A further major change occurred between 1999 and 2003 in the abyssal part of the Ionian basin, where AdDW return to be the principal contributor to the EMDW. However, its properties profoundly differred from the pre EMT situation being warmer and saltier than ever (Rubino and Hainbucher, 2007). Our data collected In 2011 confirm the persistence of the above oceanographic characteristics and the expected changes, hypothesized by Bensi et al. (2012) are still to happen.

Abstract
Le système d'information MISTRALS vise à faciliter la communication des observations et des produits scientifiques entre les différentes équipes et disciplines du chantier, et à diffuser ces informations à l'ensemble de la communauté scientifique. Son portail offre un catalogue et des interfaces simples de sélection et de téléchargement de données fortement hétérogènes (observations de terrain, produits satellite, résultats de simulations numériques...) et gérées dans plusieurs centres de données. Tout chercheur intéressé par le bassin méditerranéen est invité à le visiter : http://mistrals.sedoo.fr .

Keywords: Time series, Vertical profile, Remote sensing, North-Western Mediterranean, Circulation models

MISTRALS (Mediterranean Integrated STudies at Regional And Local Scales) est un chantier décennal de recherche et d'observations systématiques, dédié à la compréhension du fonctionnement environnemental du bassin méditerranéen et de son évolution sous la pression des changements globaux de la planète. Il est fondé sur sept programmes interdisciplinaires de recherche, parmi lesquels HyMeX (Hydrological cycle in the Mediterranean eXperiment), ChArMEx (Chemistry-Aerosol Mediterranean eXperiment) et MERMeX (Marine Mediterranean eXperiment) s'intéressent particulièrement aux phénomènes marins physiques, chimiques et biogéochimiques, et à leurs interactions avec les autres compartiments du système terre (atmosphère, fleuves, littoral, surfaces continentales...). Etudiant d'autres échelles de temps le projet PaleoMeX (Paleo Mediterranean eXperiment) comprend aussi des prélèvements en milieu marin. Les différents projets bénéficient des mesures d'observatoires de l'environnement sur le long terme, dont notamment le programme MOOSE (Mediterranean Ocean Observing System on Environment), l'observatoire atmosphérique CORSICA (Centre d'Observation Régional pour la Surveillance du Climat et de l'environnement Atmosphérique et océanographique en Méditerranée occidentale ») ou la composante Sciences de l'Environnement du projet MEUST (Mediterranean Eurocentre for Underwater Sciences and Technologies).

Les données générées ou utilisées par les programmes de MISTRALS sont non seulement issues de différentes disciplines, mais également de natures (format, volume, nombre de dimensions spatiales, représentativité...) très hétérogènes : mesures issues de campagnes intensives, suivi sur le long terme des paramètres environnementaux, observations opérationnelles *in situ* et satellite, résultats de simulations numériques, enquêtes de terrain qualitatives... Dans ce contexte, le système d'information MISTRALS constitue un outil transverse aux différents programmes et vise à faciliter les échanges entre les communautés de recherche.

Un portail d'accès à l'ensemble des données scientifiques utiles ou produites par ces programmes a été mis en place : http://mistrals.sedoo.fr/ . Les informations sur les différents jeux de données (métadonnées) sont homogènes et conformes aux normes en vigueur (ISO19115, directive INSPIRE, indexation basée sur le *thesaurus* Global Change Master Directory). Le portail offre des outils de recherche dans ce catalogue par mots clés ou par sélection d'un ou plusieurs critères (période, zone géographique, type d'instrument...). Il permet d'accéder directement à des jeux de données de toute nature, gérés par différents centres de données (CORIOLIS, ESPRI, ICARE, SEDOO), grâce à la mise en place de protocoles d'interopérabilité (voir figure 1).

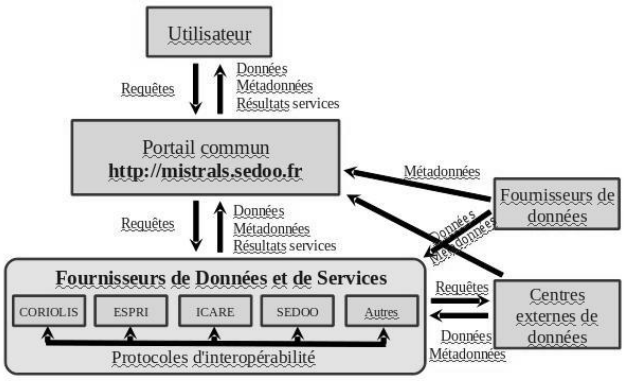

Fig. 1. Structure du portail MISTRALS

Le portail MISTRALS donne déjà accès à plusieurs centaines de jeux et s'enrichit quotidiennement de nouvelles données, issues notamment des campagnes intensives 2012 et 2013 des programmes HyMeX, ChArMEx et MERMeX. Chaque jeu de données est disponible dans son format natif, et les plus recherchés sont retraités et homogénéisés (format, unités, flags de qualité...) afin de faciliter leur utilisation par tous. Le système d'information MISTRALS est en constante évolution et se dotera prochainement de fonctionnalités avancées, de type SIG, visant à servir les besoins recherche, mais également à diffuser des produits à l'ensemble de la société civile.

Le portail MISTRALS est un outil à la disposition de tous les scientifiques intéressés par le bassin Méditerranéen. N'hésitez pas à consulter le catalogue en libre accès et à remplir le formulaire d'enregistrement pour accéder aux données. Le portail MISTRALS est également susceptible d'accueillir les données de nouveaux projets ou de remplir des missions de sauvetage de données anciennes. Merci de contacter mistrals-contact@sedoo.fr si vous avez ce type de besoin.

Abstract

Toxic monomethylmercury (MMHg) accumulates to harmful levels along the marine food chain and presents a health risk at a global scale. The origin of MMHg in the marine water column is under debate. Bacterial methylation of inorganic Hg in sediments and in the oceanic water column may be in play. We investigated MMHg distributions in the contrasted basins of the Mediterranean Sea as part of the GOSHIP cruise M84/3 on RV Meteor. The 8 full depth vertical profiles cover a West-East transect from oligotrophic to ultra-oligotrophic waters. MeHg concentrations were generally higher in the more productive Western Basin. Our findings suggest that quantity and the quality of phytoplankton may influence the production of MeHg in the oceanic water column.

Keywords: Mercury, Open sea, South-Central Mediterranean, South-Western Mediterranean, South-Eastern Mediterranean

Monomethylmercury (MMHg) accumulates to harmful levels along the marine food chain and presents a health risk at a global scale. The origin of MMHg in the open ocean marine water column is under debate. Bacterial methylation of inorganic Hg in shelf sediments and subsequent advection to open ocean waters has been suggested to be the major pathway. Repeated evidences hint that in situ production in the oceanic water column may be equally if not more important. Determinations of MMHg in sea-water are still scarce mainly due to analytical limitations that did not allow detecting ultra-trace concentration levels, in the femtomolar range. Three techniques are used today to measure MMHg in sea-water and of which all imply a derivatization step: cryofocussing hydrate generation (Stoichev et al., 2002), ethylation (Bloom, 1989) and propylation (Monperrus et al., 2005). Determination of MMHg in sea-water by species-specific isotope dilution, derivatization by propylation, and detection via gas chromatography–inductively coupled plasma mass spectrometry (ID-GC-ICP-MS) was shown to be most promising (Monperrus et al., 2005). At the GET laboratory we improved the performance of this method by optimizing the coupling between a gas chromatograph and a high resolution sector field inductively coupled plasma mass spectrometry (Element XR). We applied this method to samples from the GOSHIP cruise M84/3 on RV Meteor to the Mediterranean Sea (04/2011). A total of 83 samples were taken in pre-cleaned 250mL Savillex PFA Teflon bottles. Pre-cleaning in a class 100 clean lab involved soaking the bottles for 24h in concentrated (10N) and diluted (1N) bidistilled HCl at 120°C. Bottles were double bagged and all handling was done in an ultra-trace clean manner. On board, each bottle was rinsed 3 times with the sample from the GoFlo bottle, filled to the top, acidified with bidistilled HCl to 0.4% (v:v) and tightly capped. Acidification converts dimethylmercury (DMHg) to MMHg. The measured MMHg is therefore the sum of both species. Sub-samples were double bagged and stored in the dark at 4°C until analysis in the home laboratories. Samples were taken at 8 stations along the East-West transect. The set of samples was split in a way that the samples were analyzed in the 3 partner laboratories: 1) GET laboratory in Toulouse, France, IFREMER, 2) IFREMER Nantes, France and 3) University of Athens, Greece. Triplicates were taken at several stations to provide an intercomparison.

1) MeHg (MMHg+DMHg) was analyzed at the GET laboratory *via* isotopic dilution gas chromatography sector field inductively coupled plasma mass spectrometry (GC-SF-ICP-MS) after derivatization with propylborate and extraction into hexane. The 8 full depth vertical profiles consist of 83 samples (stations 292, 297, 306, 313, 319, 324, 331, 340). MeHg distributions show typical vertical profiles (Heimbürger et al., 2010) with very low surface concentration and highest concentration in the oxygen minimum zone and generally higher in the more productive Western Basin (mean=252±130fmol/L, range=11(LOD)-723fmol/L, n=83).

2) MeHg (MMHg+DMHg) was analyzed at the IFREMER Nantes laboratory *via* cryofocussing hydrate generation followed by cold vapour atomic fluorescence spectrometry (CVAFS (Cossa et al., 2003; Stoichev et al., 2002). The 4 full depth vertical profiles consist of 47 samples (stations 297, 313, 319, 340; mean=143±116fmol/L, range=40(LOD) to 467fmol/L, n=47). Those are the same samples that were measured at the GET laboratory and both measurements compare well.

3) Another 4 profiles were analyzed at the University of Greece *via* ethylation followed by CVAFS using a MERX automated analyzer (Brooks Rand).

We will present and compare the results of the different applied MeHg determination methods and put our results in context with previous work. Our findings suggest that quantity and the quality of phytoplankton may influence the in situ production of MeHg in the oceanic water column. This is important as global change may alter the trophic regime of the future Mediterranean Sea and therefore marine Hg dynamics. Changes anthropogenic Hg emissions may also alter the marine biogeochemical Hg cycling. Repeated basin wide ship surveys are required to monitor both Hg and its most toxic form, MeHg, in mediterranean waters at appropriate spatio-temporal scales.

CENTRAL MEDITERRANEAN IN 2010-2013 AS SEEN FROM THE ARGO FLOATS

V. Kovacevic [1]*, L. Ursella [1], G. Notarstefano [1], M. Menna [1], M. Bensi [1] and P. Poulain [1]
[1] Ist. Nazionale di Oceanog. e di Geof. Sperim. OGS - vkovacevic@ogs.trieste.it

Abstract
The set of Argo floats navigating inside the Central Mediterranean Sea (Ionian Sea, and adjacent southern Adriatic Sea) in the period 2010-2013 is analysed. Description of differences and similarities during the observed period is limited to the intermediate and deep layers.

Keywords: Temperature, Salinity, Deep waters, Intermediate waters, Ionian Sea

The deep Argo float profiles provide measurements of temperature and salinity down to 2000 m. Moreover, the float parking depth at 350 m allows tracking the major pathways of the intermediate waters (mainly the Levantine Intermediate Water, LIW), together with associated thermohaline properties. The float trajectories show that some of them either follow the perimeter of the Ionian or cross the basin, and some of them enter/exit from the Adriatic Sea. In addition to the intermediate layer, the deep horizon (1000 - 1300 m) has been chosen as indicative of the sources of the dense waters formed in the surrounding basins (i.e. the Adriatic Sea) and their possible spreading paths. Our approach does not take into account the exact time-space collocation of the data, but rather gives a comprehensive view of the properties, as smoothed in time and space. Generally, the meso-scale and sub-basin scale variability are characterized by a number of permanent, semi-permanent and transient eddies. The most persisting one is a central Ionian anti-cyclone, whose footprint is observed throughout the period from the absolute dynamic topography of the sea surface, and whose influence protrudes down to the deep. Its position (18-20 °E, 35-37 °N) is in the vicinity of the deepest Ionian trough (> 4000 m). Other anti-cyclonic mesoscale eddies are observed along the outer edge of the Ionian, as for example the Pelops anti-cyclone on the eastern side. A relatively steady circulation characterizes the north-western periphery of the Ionian, where the intermediate paths follow the isobaths prevalently in the southward direction. The destiny of these floats is to cross the Ionian toward its southern end (like in 2011) or toward the centre (2013), or to escape toward the Sicily Channel (like in 2010). The northern Ionian, adjacent to the Strait of Otranto, is characterized by a variable mesoscale activity: the anti-cyclonic veering may turn into cyclonic, preventing the escape of the floats into the Adriatic like in 2011. On the contrary, as seen at the end of 2012, a very intense intermediate flow in a narrow band along the eastern flank brings back into the Southern Adriatic the float that exited from there. All such features are observed when following each float individually.

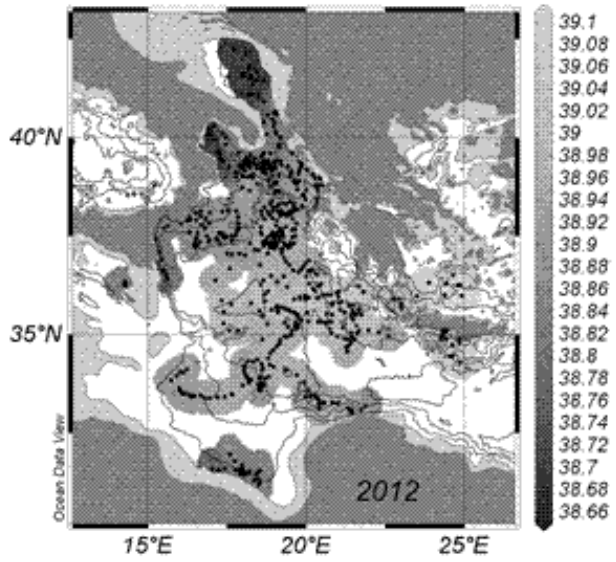

Fig. 1. Salinity distribution at 350 m horizon in 2012

As far as the thermohaline properties are concerned, the 350 m horizon is characterized by lower salinity along the north-western perimeter of the Ionian (Fig. 1), associated with the southward flow, while on the eastern side, higher salinity is associated with the northward flow. The most remarkable feature of the year-to-year variability concerns the Adriatic Dense Water (AdDW). Due to the particularly severe winter conditions in 2012 ([1]) AdDW attained large density and by the end of 2012 showed up as a cold tongue overflowing the sill in the Strait of Otranto, and filling the deep layers of the northern Ionian (Fig. 2). Almost simultaneously, a salty LIW protrudes along the eastern flank into the Southern Adriatic (Fig. 1).

Abstract
During spring of 2011, three oceanographic cruises were conducted in a coordinated fashion in order to produce base-line data of important physical and biogeochemical parameters that can be compared to historic data and be used as reference for future observational campaigns. Here we will present an overview of important results from these three cruises, and will put this in context of "repeat hydrography" and how that can be applied to the Mediterranean Sea system in the future. We will show a set of sections showing the large-scale distributions of physical and chemical properties along the full length of the Mediterranean Sea.

Keywords: Carbon, Nutrients, Salinity, Levantine Basin

The Mediterranean is a semi-enclosed Sea characterized by high salinities, temperatures and densities. The net evaporation exceeds the precipitation, driving an anti-estuarine circulation through the Strait of Gibraltar, contributing to very low nutrient concentrations. The Mediterranean Sea has an active overturning circulation, one shallow cell that communicates directly with the Atlantic Ocean, and two deep overturning cells, one in each of the two main basins. It is surrounded by populated areas and is thus sensitive to anthropogenic forcing. Several dramatic changes in the oceanographic and biogeochemical conditions have been observed during the past several decades, emphasizing the need to better monitor and understand the changing conditions and their drivers. In order to document the current change of the Mediterranean Sea, and to quantify changes in physical and biogeochemical properties across the whole Mediterranean Sea System, the cruise on the German RV Meteor was carried out in 2011. This cruise covered all major basins and most sub-basins of the Mediterranean Sea, and measurements of several key physical, chemical and biological parameters were carried out. The cruise was planned to repeat stations that have been sampled in the past, and to fit into the concept of repeat hydrography, as defined by the GO-SHIP panel. Later, an initiative called by the CIESM, a suggestion for a GO-SHIP like program in the Mediterranean Sea was presented, i.e. MED-SHIP. The M84/3 cruise was coordinated with two other, shorter, cruises that were carried out almost synoptically in the Mediterranean Sea. Several stations were selected to be inter-comparison stations to facilitate the use of the full data set from all three cruises. The other two cruises were: 1) the cruise on the German Poseidon, cruise 414, that focused the investigations on identifying and quantifying the routes and entrainment rates of the Adriatic Deep Water into the Ionian Sea and to investigate the spatial and temporal variability of the spreading and mixing of the Ionian Deep Water, and 2) the cruise on the Italian ship Urania that focused on development of a dynamic calibration procedure for oceanographic sensors, the continuation of the long-term monitoring of straits, as well as an update of the knowledge on the oceanographic conditions in the Ionian/Tyrrhenian Sea area. The quasi-synoptic data set is an example of international cooperation needed to carry out observations fit to document changes and variability of interior ocean properties. Here we will present some results from the cruise, focusing on the large scale distribution of properties across the whole Mediterranean Sea System. This presentation is based on a manuscript submitted to the special issue on "physical, chemical and biological oceanography of the Mediterranean Sea" in the journal Ocean Science (Tanhua et al., 2013).

STUDY OF SEA WAVES AND LONGSHORE CURRENT OFF ROSETTA PROMONTORY

AbdAllah M. AbdAllah [1]*, Ahmed A. Elgindy [1] and Magdy M. Farag [2]
[1] Prof of physical Oceanography - drabd77@yahoo.com
[2] Assistant Prof of Physical Oc.

Abstract

Wave observations in Abu-Quir Bay were used to study wave characteristics in the Bay and to simulate longshore current along Rosetta promontory using BOUSS2D model under different wave conditions that may be encountered in the region. These observations were obtained by using Cassette Acquisition system (CAS) during 1986 at 18m depth contour.
Statistical analysis of wave observation showed that: - Extreme NW waves have a height of 4.4m and peak period of 8sec. Maximum wave height and peak period of N waves are 4m and 8sec respectively. NE waves propagate in extreme conditions with height of 3.9m and peak period of 8sec. This extreme wave values were used to simulate longshore current along Rosetta promontory using the BOUSS2D model. This model results showed a good agreement with field observations

Keywords: Coastal processes, South-Eastern Mediterranean

Introduction

Rosetta promontory is located on the eastern side of Abu-Quir bay (figure 1). The Rosetta promontory is suffering from erosion problems caused mainly by the combined action of waves and longshore current. Understanding of wave characteristics and longshore current regime off Rosetta coast is very important to deal with this problem.

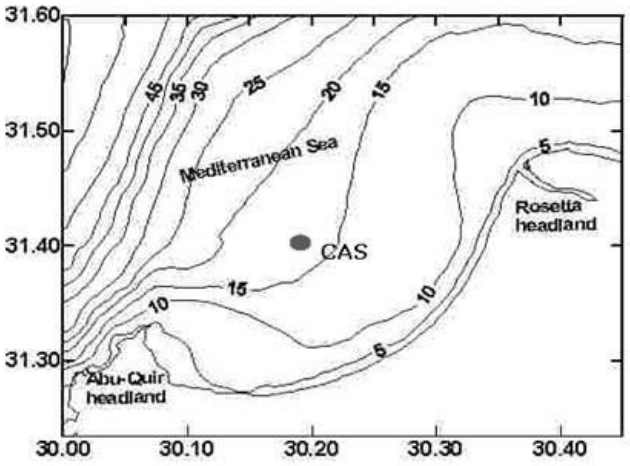

Fig. 1. Location of CAS system in Abu-Quir.

In the present work BOUSS2D model (Okey and Zeki,2001) was used to simulate the nearshore current regime off Rosetta promonotiryin . This model is a comprehensive numerical model for simulating the propagation and transformation of waves in coastal regions and harbors based on a time-domain solution of Boussinesq-type equations.

Tab. 1. seasonal and annual variations of significant wave characteristics measured at 18m depth in Abu Quir Bay during 1986. (D is the standard deviation of the data)

Season	Significant wave height			Significant wave period		
	Mean (m)	D (m)	Max (m)	Mean (sec)	D (sec)	Max (sec)
Winter	0.91	0.59	2.62	7	2.6	10.7
Spring	0.94	0.56	2.63	5.8	1.63	9.1
Summer	0.90	0.38	1.91	6.2	1.3	10.7
Autumn	0.98	0.84	4.19	6.6	1.8	10.7
Annual	0.93	0.56	4.19	6.3	1.60	10.7

Analysis of the observed wave data in Abu-Quir Bay(Table1)at.18m depth contour during 1986 show that:

1- Maximum wave height was 4.19m.
2- There are seasonal variations in available wave data characteristics associated with seasonal variation in wind regime.
3- Predominant wave direction is NW. This is due to the prevailing wind direction from this sector.
4- The peak wave period is 8sec. The maximum of the significant wave period at 18m depth during 1986, 10.7 sec, was found in NW, N and NE wave sectors.

Using BOUSS2D model, the longshore current regime off Rosetta promontory was studied for 5 different wave events at deep water to discuss the wave induced current in the study area at the extreme wave condition. These events include 5 wave conditions with wave approach directions (300º, 330º, 360º, 30º and 60º), wave period (Tp=8 sec) with incident wave height 4m. For the western side, the predominant direction of the predicted longshore current is from north to south. This is due to the effect of NW, N and NE wave action. For the eastern side, the predominant direction of this current move from west to east due to the effect of N and NW wave action. This current reverses its direction to west due to the effect of NE wave action. The maximum value of longshore current was 1.2 m/sec. Generally the model simulations agree with the observations.

DAILY VARIATIONS IN SEA SURFACE TEMPERATURE AND EFFECT OF ATMOSPHERIC CONDITIONS ON WATER STRATIFICATION

Husne Altiok [1]*, Sabri Mutlu [1] and Lalehan Can [2]
[1] Istanbul University Institute and Marine Science and Management - altiokh@istanbul.edu.tr
[2] Isik University

Abstract
The diurnal change of the atmosphere-sea interaction will be investigated by using in situ and synchronized measurements of the atmospheric and oceanographic parameters in the Marmara Sea, having a two layered stratification. Surface currents, temperature, salinity and pressure in the water column will be measured for 10 minutes intervals during one year period by using a buoy system. Air temperature and pressure, wind speed and direction, solar radiation and humidity will also be measured. The diurnal cycle of the physical processes on the sea surface which is essential for the marine ecosystem by investigating the sea-atmosphere interaction for a two-layered system with an integrated approach.

Keywords: Air-sea interactions, Stratification, Heat budget, Marmara Sea

Sea surface temperature (SST) shows fluctuations during daytime due to solar radiation and reaches its maximum value in the afternoon. In addition to the solar radiation, wind also effects the temperature changes of the surface water in two mechanisms. Firstly, as the wind stress increases the heat exchange between the seawater and the atmosphere increases. The other mechanism is the vertical and the horizontal movements in the seawater that develop as a result of the impulse driven by the wind stres (1). In the stratified seas, like the boundary of the atmosphere-surface water interface, the transition interface between the upper and lower layers also forms a boundary. By investigating the diurnal sea surface temperature changes, it is possible to reach more detailed information about the atmosphere-sea interaction and to calculate the heat exchange in the most accurate way. Such studies were performed primarily in the tropical regions where the heat transfer between the atmosphere and the sea and the sea surface temperature variations are highest. Afterwards in the subtropical regions, especially for determining the biologic and chemical processes and calculating the acoustic propagation, researches are needed to calculate the diurnal sea surface temperature changes. Recently, in a study about global variations of diurnal warming by using 10 years of global infrared satellite data, it is showed that the diurnal warming each year were observed in large regions in the tropics and midlatitudes (2). In this study, diurnal SSTvariations and atmosphere-sea interaction will be investigate by using buoy system located in Izmit Bay in the Marmara Sea (3). Temperature and salinity profiles indicate two layer structure in the Bay (Figure 1) throughout the year. The salinity of the upper layer has a small change

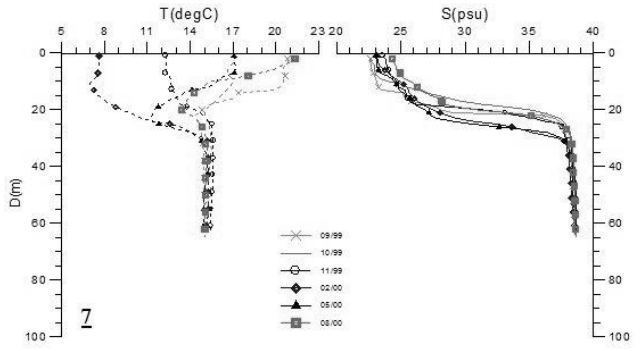

Fig. 1. Temperature and salinity profiles in the buoy location.

whereas its temperature reflects seasonal variation accordance with atmosphere. The data obtained from sensors arrays from buoy system will be transferred to the data process center located on land in real time. Appropriate filtrations will be applied to the obtained data for quality control. The quality checked time series data obtained from these filtrations will be analyzed using spectral analysis methods and variation frequencies of each parameter will be determined. Therefore, the hourly, daily and monthly changes of the parameters measured in the water column in short time intervals will be averaged and the atmospheric influence to the stratification in the water column will be clarified. Besides the determination of the diurnal cycle, the most important result that will be obtained from this study will be the collection of the precise, frequent, in situ and synchronized data set of atmospheric and oceanographic parameters representing the Marmara Sea which can be used in modeling of the aquatic ecosystem and acoustic propagation.

STATISTICAL ANALYSIS OF INTERACTION BETWEEN THE BLACK SEA AND THE MARMARA SEA BY TEMPERATURE AND SALINITY TIME SERIES

Melih Kayisoglu [1] and Husne Altiok [1]*
[1] Istanbul University Institute and Marine Science and Management - altiokh@istanbul.edu.tr

Abstract
The purpose of this study is to investigate the interactions of the water masses between the Black Sea and the Marmara Sea by using CTD measurements in the both ends and the vicinity of the Strait of Istanbul. The statistical analyses of the monthly variations of the temperature and salinity data collected in the period of 1997-2010 are evaluated. The results showed that not only annual changes but also short term changes play a significant role on the modification of the water masses.

Keywords: Time series, Temperature, Salinity, Black Sea, Marmara Sea

The Strait of Istanbul is a narrow (0.7-3.5km), long (~31km) and shallow (30-100m) channel that connects the Black Sea and the Marmara Sea. It has a two-layered flow system, and this is fundamentally important for the water exchange between both of the seas. The upper layer flows from the Black Sea with a salinity of about 18psu, and the lower layer flows from the Marmara Sea with a salinity of about 38psu (Ünlüata et al., 1990; Yüce 1996). The layers have short term changes in physical, chemical and biological parameters due to hydrodynamic characteristics of the strait system. Monitoring of physical characteristics of these water masses assists in understanding the interaction between these two seas.

The statistically analyzed CTD data, which is used in this study, were collected in the Strait of Istanbul (Figure 1) by R/V ARAR of the Istanbul University, Institute of Marine Science and Management (IMSM-IU). The qualities of the temperature and salinity data at each station were controlled, and missing data were interpolated to obtain whole time series. After examining the time series of the temperature and salinity profiles, representative depth for the layers was chosen. 5 meters depth was chosen at all stations for the upper layer. For the lower layer, 40meters depth was chosen at Marmara Sea stations, it is 3 meters above the bottom depth at the stations Strait of Istanbul and the Black Sea.

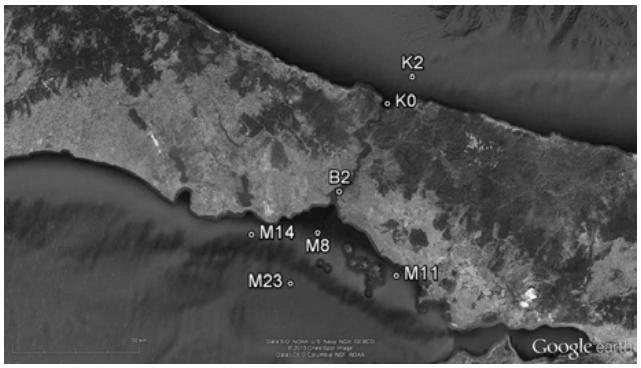

Fig. 1. Station locations

The temperature of the upper layer between the Black Sea and the Marmara Sea were significantly correlated and the minimum coefficient is 0.96, whereas the upper layer salinity between these seas were not strongly correlated, it is about 0.24. On the other hand, the lower layer temperature correlation coefficient was weak and they decreased from South to North. The correlations of the lower layer salinity between the Marmara Sea and strait stations indicated important result. The correlation between the Marmara Sea and the northern exit of the strait was higher than the correlation between the Marmara Sea and the southern exit of the strait. This can be explained by irregularities in the strait such as upper and lower layer blockages.

The annual average of the upper layer temperature at all stations indicates seasonal variations but their salinity change in seasonally only at the stations in the Marmara Sea (Figure 2a). The salinity rates of the upper layer increased by the distance from the strait in the Marmara Sea. The annual average of the lower layer temperature and salinity indicates the seasonal changes at the stations in the strait and its Black Sea exit (Figure 2b).

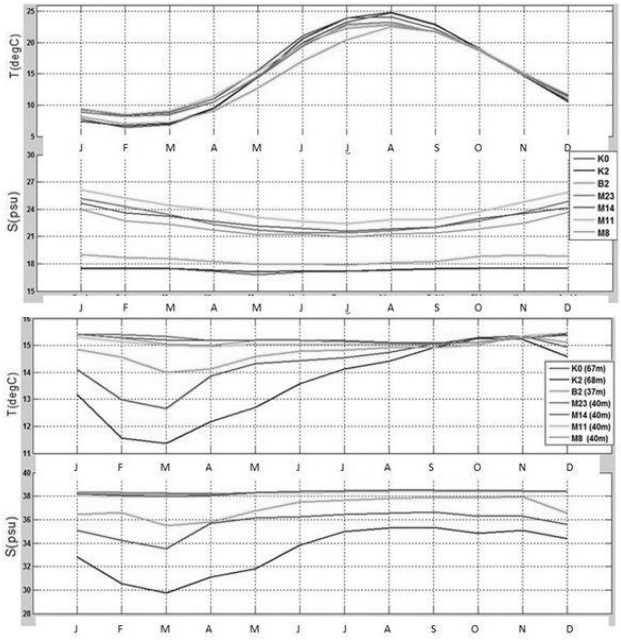

Fig. 2. The annual temperature and salinity for upper (a), and lower (b) layers

SUSPENDED SEDIMENT CHARACTERISTICS IN COASTAL WATERS OF THE GULF OF LIONS OBSERVED FROM FIXED AND MOVING PLATFORMS

François Bourrin [1]*, Xavier Durrieu De Madron [1], Laurent Beguery [2] and Stéphane Kunesch [1]
[1] CEFREM UPVD - fbourrin@univ-perp.fr
[2] DT INSU

Abstract
Suspended sediment characteristics such as concentration, size, shape and nature were obtained from both optical and acoustical sensors installed on buoys, mooring lines, gliders and ship-based measurements during various meteorological conditions in 2011 and 2013 on the continental shelf of the Gulf of Lions. Such measurements permitted to characterize suspended particles properties at different time and space-scales in the western Mediterranean Sea. Autonomous platforms such as gliders would be useful to complement coastal observatories between fixed platforms.

Keywords: Coastal waters, Gulf of Lyon, North-Western Mediterranean, Sediments, Particulates

Suspended particles characteristics measurements are essential for estimate suspended sediment fluxes from source (rivers) to sink (open sea) in the coastal zone. Most of suspended sediment transport occurs during extreme meteorological events. Since few measurements are available during floods and storms, there is a need to collect new data across the whole shelf to better understand the sediment dynamics and suspended particles transport during energetic conditions.

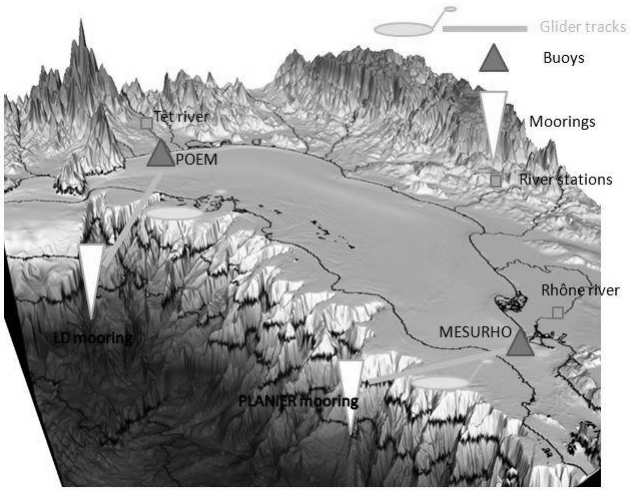

Fig. 1. Glider deployment strategy at the scale of the continental shelf of the Gulf of Lions between existing fixed platforms.

Suspended sediment characteristics such as concentration, size, shape and nature were obtained from both optical and acoustical sensors installed on buoys, mooring lines at fixed location under various weather conditions and from ship-based measurement during fair-weather conditions in 2011 and 2013 on the continental shelf of the Gulf of Lions. Moreover, we successfully deployed gliders equipped with optical sensors (cdom, fluorescence and backscattering sensors at various wavelength) in the coastal area between 30 and 200m. Such autonomous platforms regularly cruised closed to these fixed platforms allowing comparison/calibration between measurements (Fig. 1).

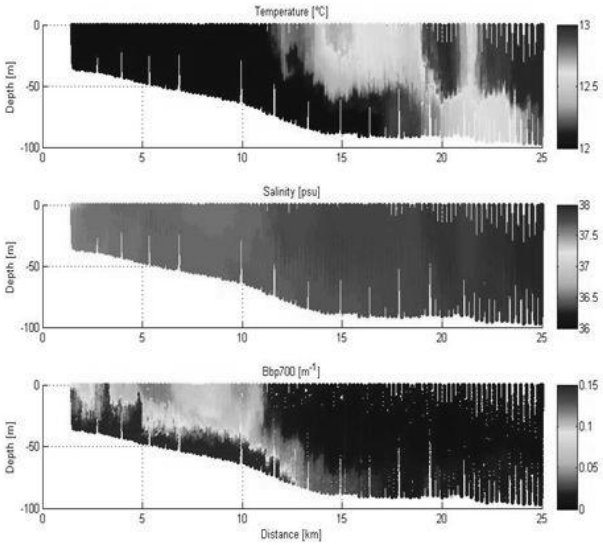

Fig. 2. Glider transect during a typical Mediterranean storm in March 2011between POEm buoy and LACAZE-DUTHIERS mooring.

Observations permitted to measure optical properties of suspended particles during various events such as floods, storms, winter dense water formation and spring bloom. Glider measurements showed that sediment resuspension can occur down to depth of 80m during strong storms and resuspension is predominant along the mid-shelf bud belt (Fig. 2). Optical measurements also permitted to distinguish suspended river-born particles and sea bottom resuspended sediments [1]. These observations will provide useful quantitative data to improve sediment transport models

TIDAL PROPAGATION IN A MEDITERRANEAN MICROTIDAL ESTUARY

Pablo Cerralbo [1]*, Manel Grifoll [1], Arnoldo Valle-Levinson [2] and Manuel Espino [1]
[1] Universitat Politecnica de Catalunya (UPC) - pablo.cerralbo@upc.edu
[2] Department of Civil and Coastal Engineering, Florida (USA)

Abstract
A set of numerical experiments has been designed to study the tidal propagation in Alfacs Bay (Delta de l'Ebre), a microtidal Spanish estuary in the Mediterranean. Results showed amplification of tidal amplitudes around 8% toward the head of the bay. Numerical simulations investigated whether the tidal behaviour was caused by coastal morphology or by bathymetry. Results suggested that geometrical effects are more influential than those from bottom friction. The tidal propagation was consistent with that derived from a linear analytical model. Although the tidal amplitude is a few tens of centimeters, its effect on the circulation seems relevant.

Keywords: Tides, Ebro Delta, Coastal models

Introduction
The Ebro Delta is characterized by the presence of two semi-enclosed bays, (Alfacs and Fangar bay, Fig. 1). Both bays receive direct freshwater input from drain channels of rice fields in the surrounding area during 9 to 10 months in the year. Alfacs Bay is about 11km long by 4km wide with an average depth of about 3.1 m (maximum of 6.5 m in the middle). The mouth is about 2.5 km wide.

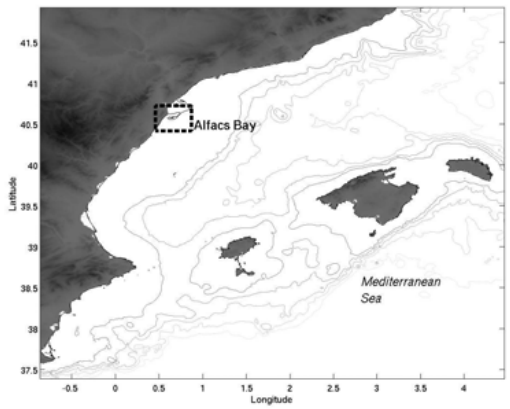

Fig. 1. Alfacs bay delimited by dotted box.

The non-tidal flow in the area has been studied in the past [1], showing a persistent structure during most of the year: a salty layer in the bottom and freshwater layer on top due to freshwater input. The bay is microtidal, with a mixed tidal regime (Form ratio=1.1), being K1, M2, O1, P1, S2 and N2 the main harmonics (ordered by importance).

Methods and Results
A set of numerical experiments has been designed to study the tidal propagation for different scenarios. The numerical model is the Regional Ocean Modeling System [ROMS, 2]. Three different approximations were implemented. The first one is a geometrical simplification of the bay (constant depth of 6m with a rectangular schematization of the coastline). The second configuration included the effects of the coastline (coastal effects). The third and realistic configuration used real bathymetry and coastal line (Fig.2 left images). The free surface elevation has been imposed as an astronomic wave made of the main harmonics described before. A total of 210 days of simulation were performed in order to analyze the amplitudes and phases using T_TIDE software [3]. Moreover, some tests with wave frequencies close to natural resonance of the bay has been done.

Initial results show how the amplitude of each harmonic increases toward the head of the bay in a range of 2-8% of its amplitude at the mouth (Fig 2. right images). These results are in agreement with similar studies using analytical models [4]. Comparison of the different approximations shows the effects of bathymetry and coastline constraints, being the latter the main contributor to these amplifications. A field campaign during summer 2013 has been designed in order to confirm the results revealed by the numerical experiments and the analytical model.

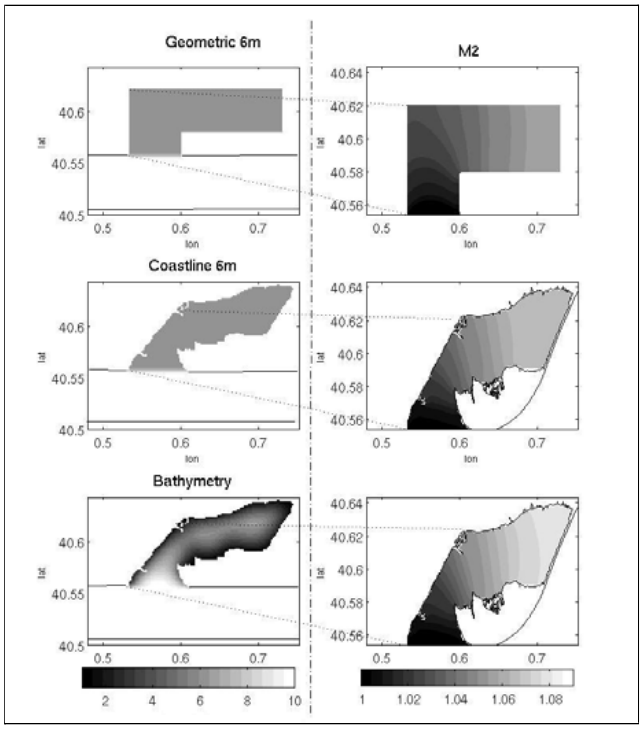

Fig. 2. On the left, the domains used in each test case. Right images shows the relative amplification of the M2 amplitude to the amplitude on the open sea for each case.

HYDROSEDIMENTARY MODELING AS PART OF MARINE RADIOLOGICAL POST-ACCIDENTAL MANAGEMENT TOOLS: THE BAY OF TOULON CASE STUDY

Christiane Dufresne [1] and Céline Duffa [1]*
[1] Institut de Radioprotectioon et de Sureté Nucléaire (IRSN) - celine.duffa@irsn.fr

Abstract
As part of its research programs, IRSN carries out research on the consequences of a possible accidental release of radionuclides into the marine environment. Hydrodynamic and sediment modeling are necessary tools to provide radionuclide dispersion and sediment trapping simulations. An integrated hydrosedimentary model is developed on Toulon area since it is the home port of many French nuclear vessels.

Keywords: Instruments and techniques, North-Western Mediterranean, Models

Introduction
IRSN develops tools to support experts and decision makers in post-accidental situation. The Fukushima nuclear accident in 2011 has shown that significant marine environment contamination must be taken into account. Dedicated tools are necessary to be able to provide radionuclide dispersion forecast.
Hydrodynamic modeling enables to calculate advection and diffusion of tracers. Coupling it with sedimentary behavior modeling provides an adapted tool to simulate radionuclides future, dealing both with dissolve and particulate phases.
Toulon harbour, which presents a complex hydrodynamic situation, is situated in the Little Bay of Toulon. This area is half-closed by a 1km long seawall, which divides the Little Bay from the Large Bay, open to the Mediterranean Sea. Therefore, a dedicated model has been implemented from Cap Sicié in the west to the Presqu'île de Giens in the east (Longitude: 05.832° to 06.132°; Latitude: 43.04° to 43.13°) [1].

Method
We need to reproduce hydrodynamic and sedimentation phenomena in this specific area as accurately as possible. Circulation modeling was performed using the operational MARS-3D code (3D hydrodynamical Model for Applications at Regional Scale), a three-dimensional model with reduced vertical coordinates based on the resolution of the Navier-Stokes equations [2]. This is a finite difference model for free surface based on solving Navier-Stockes equations. For our application, two domains are nested off-line. Lateral incoming fluxes (salt, momentum and temperature) and elevations at the open boundaries of the finner domain is provided by a coarser model (NORMED) simulating the Northern Mediterranean Basin (its southern open boundary is located at 39.5°N) and validated with both temperatures from AVHRR imagery and in-situ data [3].
The effect of waves and currents on the sea bottom and, in particular, sediment resuspension phenomena, is taken into account. The sea bottom affects waves due to variations in depth at scales greater than wavelength scale. Therefore, WW3 wave's model [4] is implemented on this area. The sediment inputs due to river discharges have to be taken into account. They are estimated by dedicated in-situ devices moored in the two main rivers (water height, turbidity, suspension matter grain size).

Results
Calculated currents have been compared with ADCP (Acoustic Doppler Current Profiler) in situ measurements for the period 2009-2012, showing a good agreement [5]. An exemple of modelled currents is presented on Figure 1.
Radionuclides are introduced into the model as tracers. Based on the sedimentation model developed here, two high assumptions can be made: the radionuclides are only carried by clays and the balance between liquid and solid phase concentrations is always consistent (conditional upon the Kd). Next, the radionuclides adsorbed by clay particles will follow the same course as these clay particles: sedimentation, resuspension and advective transfer.

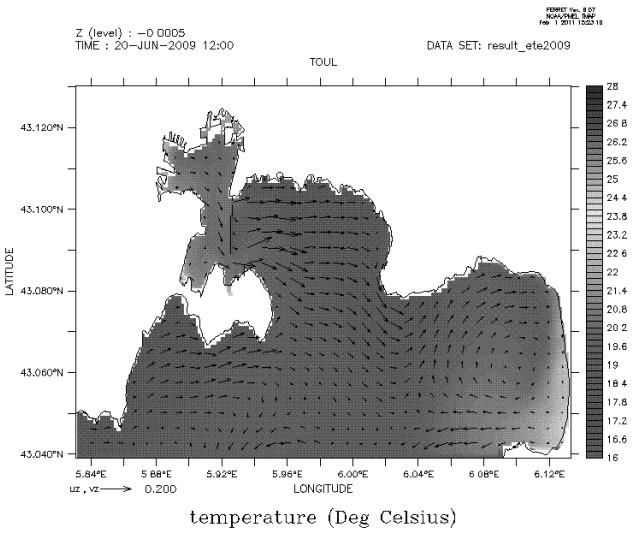

Fig. 1. Simulated surface current and temperature on July 20th 2009

Conclusion
In the event of a nuclear incident or accident involving a vessel either at sea or in dock, the use of a dedicated dispersion model is essential. In particular, such an assessment will form the basis of decisions regarding different sampling strategies, aimed at targeting any measures to be implemented.

Abstract

Water exchanges between the Thau lagoon and the Mediterranean Sea are studied by numerical modeling and in-situ measurements. ADCP currentmeters and multi-parameter probes at sea, in the lagoon, in the channels and on the catchment, allow monitoring the system at high frequency. A first experiment, in 2012, permits to highlight some storm events. A numerical model of the hydrodynamics of the lagoon and its shoreface is also used to show that level differences between the sea and the lagoon have a high impact on the exchanges through the channels. The elevation of the sea during storms causes episodes of filling/emptying likely to modify the hydrological characteristics of the lagoon.

Keywords: Lagoons, Coastal waters, North-Western Mediterranean

Coastal environments, including coastal lagoons, are areas of high biological productivity supporting many economic activities. Coastal marine ecosystems are at the interface between the continent and the offshore sea. This position leads to significant variability of physicochemical (e.g. temperature, salinity, nutrient concentration) and biological (freshwater vs. marine species) variables affecting the functioning of these ecosystems. The increased use of coastal marine environments (e.g. fishing, aquaculture) and the anthropization of catchments (e.g. urbanization of the coastline and the hinterland) concomitant to global changes can amplify this variability. This leads to significant changes on hydrology, nutrient fluxes from superficial and ground waters, currents, productivity, and littoral exploitation, which ultimately affect all the ecosystemic services provided by this environment and its habitability.

In this communication, we focus on the case of the Thau lagoon and its shoreface. The Thau lagoon is one of the largest French Mediterranean lagoon. With an average depth of 4 m, this lagoon is connected to the Mediterranean Sea through two narrow channels. Its hydrodynamics has been widely studied [1] and many biological aspects have been explored [2]. The effect of floods was also particularly investigated [3].

We focus here on the exchanges between the sea and the lagoon and on their hydrological implications (temperature, salinity). The implications for biogeochemistry and ecology will not be discussed. The installation of monitoring stations at long-term and high-frequency, part of the "Marine Observatory of Sète" of the OSU OREME, comes up to these objectives. We point out some episodes of observed sea-storms (ADCP and multi-parameters probe) and their effects on the circulations in the channels (3 ADCP) and in the lagoon (multi-parameters probes). Hydrological data on the Vène river are also available. These measurements highlight the link and the time lag between each of these stations, the lagoon acting as a buffer with respect to the open sea. These data are also used to validate a numerical model implemented on the Thau lagoon and its shoreface (see Figure 1). The numerical model is a direct application of the latest works of Michaud et al [4] including the effect of forcing waves in the Symphony model, which works by nesting domains from the offshore to the coastal scales [5]. The computation of the sea level takes into account both classical forcings (tide, dynamic height, wind, atmospheric pressure) and significant setup induced by waves. Indeed this sea level and its difference with the level in the lagoon regulate exchanges between the lagoon and its shoreface. Normally, the exchanges through the channels are driven by the semi-diurnal tide. During storms, the exchanges are re-enforced leading to a filling/emptying system. This extreme situation completely changes the hydrological characteristics within the lagoon but also in the shoreface submitted to the plume of discharged waters from the lagoon. Different episodes of measurements confirm this scenario. The numerical model also shows a massive input of water into the lagoon at the rising of the storms and then its output to the open sea at the falling of the storms. In order to illustrate the emptying phase, we show here a result of modeling for a passive tracer initially in the lagoon and exported outside and for the trajectory of a particle initially in the lagoon and also exported to the open sea (Figure 1).

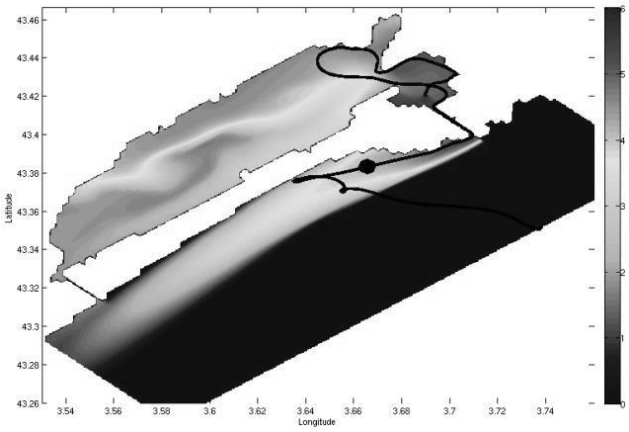

Fig. 1. Concentration (logarithmic scale) of a passive tracer regularly produced at the entrance of the lagoon simulated on 2008, 01/05, 0. am. Lagrangian trajectory of a simulated surface buoy from 2008, 01/01, 0. am to 2008, 01/08, 0. am., with its position (black dot) on 2008, 01/05, 0. am.

ANALYSIS OF THE INLET CURRENTS OF GRADO-MARANO LAGOON SYSTEM AND COMPARISON WITH THE VENETIAN LAGOON (NORTHERN ADRIATIC SEA)

I. Mancero Mosquera [1]*, V. Kovacevic [1], M. Lipizer [2], A. Triches [2], F. Arena [1], R. Villalta [2], G. Fontolan [3] and M. Gacic [1]

Abstract

The flow through the Grado-Marano lagoon inlets is tidally driven: more than 90% of the energy is due to the astronomical forcing [1]. The second source of variability is due to the Adriatic seiches accounting for 7% of the total kinetic energy. Local winds are responsible of the variability in the ,residual currents (tides and seiches removed). NE Bora wind increases the residual inflow into the lagoon through the easternmost inlet and favouring the outflow through the westernmost inlet. Such a behaviour is similar to what has been reported for another Northern Adriatic lagoon, namely the Venetian lagoon.

Keywords: Lagoons, North Adriatic Sea, Coastal systems, Currents, Wind

Introduction

In order to assess the main characteristics of the water exchange between the lagoon and the open sea, and hence, the possible consequences on the transport of the suspended solid matter, bottom-mounted Acoustic Doppler Current Profilers were employed to take measurements of water velocities in the two inlets of the Grado-Marano lagoon, Grado (390 m wide) and Lignano (310 m wide), both with about 11 m depth. The measurements were performed in the framework of the monitoring programme under the auspices of the "Regione Friuli Venezia Giulia, Direzione Centrale ambiente, energia e politiche per la montagna" and lasted from July 2010 through September 2011. The relative narrowness and shallowness of the inlets make the flow almost rectilinear and mainly vertically homogeneous.

Methods

Principal Component Analysis (PCA) was applied in order to quantify the along channel flow variability. Harmonic Analysis was used to study the tidal oscillations present in the flow. The Fourier-based methods were employed to find out the seiche signal. Wavelet methods allowed to study the nature of the remaining (no tides and no seiches) variability. Finally, PCA of the local wind velocity time series is utilised to assess the current flow regime under different wind conditions.

Results and discussion

PCA shows that more than 99% of energy is contained in the principal component aligned with the along channel axis. Further analyses were thus carried out with the principal component of the vertically-averaged current series. Tidal forcing accounts for about 90% of the energy in the flow, with the semidiurnal group (S2, M2, N2, K2) prevailing over the diurnal one (K1, P1, O1). M2 and S2 alone contribute over the 75% of the variability while the strongest diurnal K1 contribution is about 7.5%. These results resemble the results from previous research conducted in the nearby Venetian lagoon [2] where the contribution of M2 and S2 was estimated to be between 70 and 78% of the total energy. The semi-diurnal group shows an in-phase behaviour with time lag of about 20 seconds, while the diurnal group shows a time lag of 10 minutes.

Fourier spectra of the de-tided series show significant energy remaining at the frequencies corresponding to the Adriatic seiches. In addition to the two main modes of 21.1 h and 10.9 h, spectral methods revealed high coherence peaks at the frequencies of higher harmonics: 7.04, 5.24, 4.29 and 3.59 hours. This study thus confirms four of the several high-order Seiche harmonics reported in [3]. Further analysis carried out with the Wavelet transform yields an estimation of energy contribution by seiche signal of about 84% in Grado and 77% in Lignano; hence, about 8% of the total energy.

Removal of the seiche oscillations is achieved by the least squares fit of the Wavelet scales enclosing Adriatic Seiche periodicities and subtracting them from the non-tidal time series. The residual time series thus obtained is classified according to a simultaneous record of wind velocities in a nearby meteorological station. Wind data is decomposed into Principal components: the wind variance is mainly due to the winds from the North-East, *i.e.*, the Bora wind (PC1), and from the South-East, scirocco wind (PC2). Each wind principal component is partitioned in classes 5 m/s large starting form -15 m/s to 20 m/s. Moreover, a "Calm" state was defined when the wind speed was less than 3 m/s. The effect of the wind PC1 on the currents is studied while the PC2 is in a calm state, and vice versa [1]. The response of Grado and Lignano residual currents ("Y") to the strongest wind component (PC1) is of exponential nature, following the model $Y = Ae^{(b*PC1)}$ strongly resembling the results achieved for the Venetian lagoon. The exponential rate "b" is estimated to be about -0.15 and -0.13, and the coefficient "A" is -0.0049 and 0.0107 in the inlets of Grado and Lignano, respectively. The wind PC1 thus exerts similar effect but with opposite sign in the two inlets, Grado and Lignano. The exponential rates in Venice were0.12 and 0.1 in Lido and Chioggia (Venice lagoon) [4] whilr "A" was estimated to be -0.0207 and 0.0332 in Lido and Chioggia, respectively.

Conclusions

Major similarities have been found between the two biggest Adriatic lagoons, i.e. the Venetian lagoon and the Grado-Marano lagoon system. Both have similar inlet flow regimes. Astronomical tide is the main driving force in the inlets. The semi-diurnal group is prevalent. While the main seiches modes exist in both lagoon systems, there is a strong evidence of the presence of higher harmonic seiches in Grado and Lignano inlets. The residual currents are affected by winds, mainly the PC1, in an exponential manner. Hence, an event of Bora (observable in PC1) of 10 m/s speed would increase the average out-flowing in Lignano by about 360%, and the inflowing in Grado by almost 450% with respect to the Calm conditions. Therefore, the effect of the wind PC1 is significant in the Grado-Marano lagoon as well as in the Venetian lagoon [4].

HIGH-RESOLUTION MODEL STUDIES OF THE CIRCULATION IN COASTAL AREAS OF THE TYRRHENIAN SEA (INCLUDING THE GULF OF NAPLES)

P. De Ruggiero [1], E. Napolitano [2]*, R. Iacono [2], S. Pierini [1] and G. Spezie [1]
[1] Università Parthenope
[2] ENEA - ernesto.napolitano@enea.it

Abstract
A very high-resolution, sigma-coordinate, primitive equation model of the circulation in the coastal area of Campania has been developed. The model is nested with a regional model of the whole Tyrrhenian Sea circulation. Here we describe the main features of the coastal model, and the first test simulations performed, including that of a Kelvin wave propagation episode whose signature had been observed near Capri in June 2003.

Keywords: Coastal models, Tyrrhenian Sea

1.The model The coastal area of Campania, including the Gulf of Naples, is an interesting region, not only from a physical oceanographic viewpoint, but also in a more general environmental perspective, because of the strong impact of human activities on the marine ecosystem. We have implemented a very high-resolution, three-dimensional primitive equation numerical model (1/144° of horizontal resolution and 40 sigma-levels) of the circulation in this area (see Figure 1), based on the Princeton Ocean Model (POM). Our coastal model (COSM hereafter) is one-way nested with a model of the Tyrrhenian Sea circulation (TYREM, see [1]), having a horizontal resolution of 1/48°, which is in turn nested with a coarser resolution model of the whole Mediterranean Sea circulation [2].

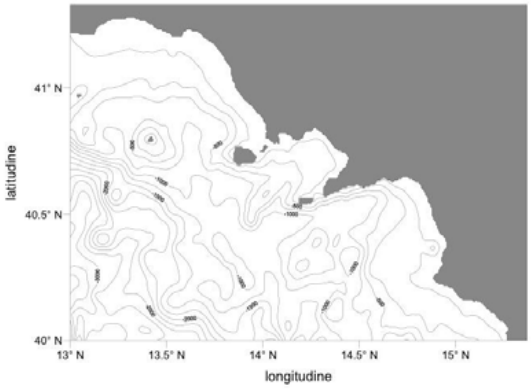

Fig. 1. Model domain and bathymetry

The model bathymetry is interpolated from the 30" GEBCO dataset (General Bathymetric Chart of the Oceans). Thanks to the small grid spacing, a very weak smoothing is needed to keep the pressure gradient error under control. This gives the very realistic topography shown in Figure 1. The surface forcing is provided by ECMWF wind data. Test cases in different seasonal scenarios have been performed, showing that the nesting is working correctly, and is crucial for a correct representation of the interaction between the coastal dynamics and the large-scale circulation of the Tyrrhenian Sea (details will be given in [3]).

2. A Kelvin wave propagation case study In June 2003, the current data measured by a current-meter moored in the Bocca Piccola of Capri suggested a possible coastal wave episode, that could be related to a strong wind event occurred a few days before. A process-oriented study by Pierini et al. (2005) [4], using a simplified three-layer model, provided evidence that the observations were consistent with the propagation of an energetic internal Kelvin wave resulting from the relaxation of a strong upwelling produced by the wind event. We have therefore sought to reproduce this episode with COSM, performing a series of simulations of increasing degree of realism, with the purpose of identifying the key elements of the dynamics.

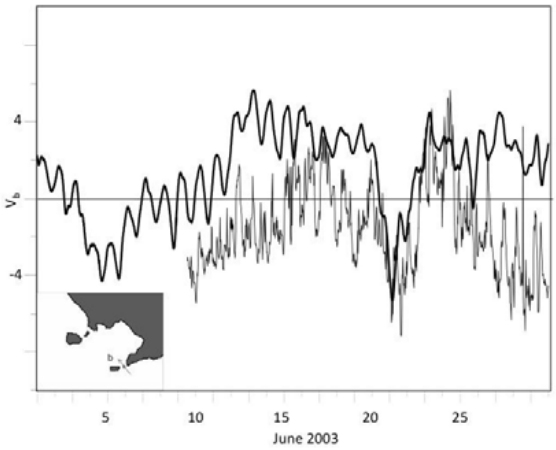

Fig. 2. Time series of the current at 25 m of depth at the mooring location (b). Thick (fine) line denotes values from the numerical simulation (observations).

Experiments have shown that a realistic stratification in the initial conditions is needed to capture the Kelvin wave phase speed and cross-shore structure. The best result, obtained with the June 2003 stratification, is shown in Figure 2, where the lower curve shows the current measurements, and the thicker line shows the current simulated by the model at the same location. The difference between observations and model simulation before t=20 June and after t=25 June is to be accounted for by the poor spatial resolution of the surface winds used to force the model.

WHY HAS NORTHERN ADRIATIC RECENTLY BEEN EXPOSED TO INCREASED FLOODING?

Miroslava Pasaric [1]*
[1] Andrija Mohorovicic Geophysical Institute Faculty of Science, University of Zagreb - mpasaric@gfz.hr

Abstract
Hourly sea-level data at Bakar are used to examine the flooding of the Northern Adriatic coast in the period [1951-2012]. An increase in the frequency of moderate and especially of extreme floods, as well as in their duration, is evident from 2008 onwards. The trend in relative sea level can explain the increase of moderate events; for extreme events the increase is partly attributed to the trend, but also to recent changes in the frequency and/or intensity of storm surges.

Keywords: Sea level, Geohazards, Air-sea interactions, North Adriatic Sea

In recent years Northern Adriatic has repeatedly been exposed to exceptional storm surges and coastal flooding. At Bakar, which is the second longest operating tide gauge on the eastern Adriatic coast and has been uninterruptedly recording since 1949, during the last four years the absolutely highest sea level was surpassed on two occasions - on 1 December 2008 and again on 1 November 2012.

Hourly sea-level data recorded at Bakar in the period [1951-2012] are used to examine the occurrence of extreme sea levels in the Northern Adriatic in the last sixty or so years. We define an event as every occurrence of hourly sea level exceeding a selected percentile value - 99.90th for moderate and 99.99th percentile for extreme events. Flood is defined as an uninterrupted series of consecutive events.

The data reveal that the eleven highest events took place in the period from 1 December 2008 onwards. There is an interdecadal variability in the occurrence of extreme events, but from 2008 onwards an increase in frequency of moderate and especially of extreme events, is evident. Furthermore, the extreme floods have increased not only in their number, but also in their duration. One may examine values of the selected percentiles when calculated over shorter (8.9 years) time intervals (Figure 1, full line): the values for the last interval are markedly higher than those for the entire period.

The recent increase in the frequency and intensity of flooding may be related to relative sea-level rise but also to long-term changes in atmospheric forcing. To distinguish between the two processes, linear trend in sea level is calculated. In this, a well-established relationship of 2 cm/hPa between monthly anomalies of sea level in the Northern Adriatic and those of air pressure [1] is used to eliminate the effects of air pressure and wind [2] on the sea-level trend. The atmospherically-corrected sea level at Bakar displays, over the [1951-2012] interval, a linear trend of 1.2 mm/yr.

In order to investigate the effects of sea-level rise on the occurrence of extreme sea levels, we subtract the obtained trend from the original hourly sea-level data. The percentile values for the detrended data (Figure 1, dashed line) indicate that the increased flooding due to moderate (> 99.90th percentile) events in recent years may be explained by the trend in relative sea level. However, even upon removal of the linear trend, the 99.99th percentile value for the most recent interval is 8 cm higher than the long-term one. This suggests that the increase of the extreme events cannot be attributed only to the sea-level rise, but also to recent changes in the frequency and/or intensity of storm surges.

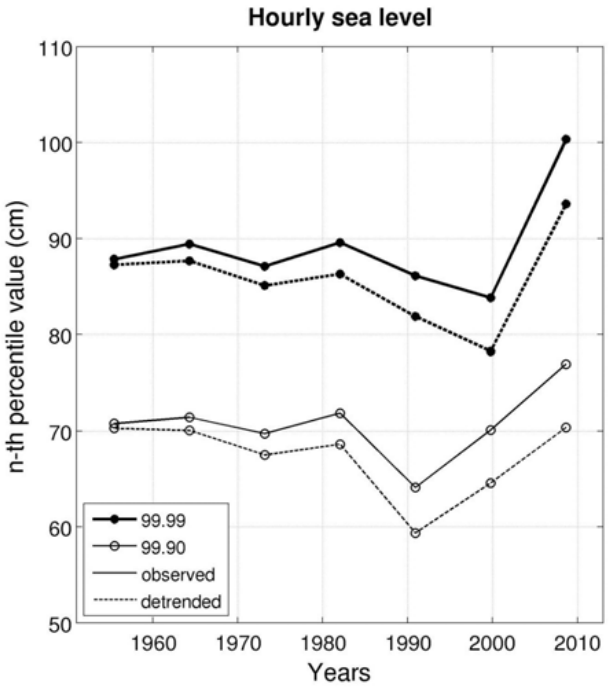

Fig. 1. Hourly sea level data at Bakar (Northern Adriatic) in the [1951 - 2012] period: 99.90th (thin line) and 99.99th (thick line) percentile values, calculated over seven consecutive windows of 8.9-years length. Full line denotes percentiles for original data, and dashed line for sea level data, from which linear trend has been subtracted.

SUBMARINE GROUNDWATER DISCHARGE INTO THE ENTIRE MEDITERRANEAN SEA

V. Rodellas [1]*, J. Garcia-Orellana [1], M. Feldman [2], P. Masqué [1] and Y. Weinstein [2]
[1] Inst. Ciència i Tecnologia Ambientals - Dept. Física. Universitat Autònoma de Barcelona. Spain - valenti.rodellas@uab.cat
[2] Dept. Geography & Environment. Bar-Ilan University. Israel

Abstract
In this work we aim to estimate the magnitude of Submarine Groundwater Discharge (SGD), encompassing both fresh groundwater and recirculated seawater, into the entire Mediterranean Sea through a mass balance based on the inventory of ^{228}Ra in surface water. Our preliminary results suggest a SGD flow on the order of ~ 10^{11} $m^3 \cdot yr^{-1}$, which is comparable to the freshwater inflow from rivers. Thus, SGD may represent a major pathway for the delivery of terrestrial compounds (i.e. nutrients, metals, carbon), which may significantly impact biogeochemical coastal cycles of the Mediterranean Sea.

Keywords: Coastal waters, Radionuclides, Hydrology, Water transport, North-Central Mediterranean

Introduction & Methods

Submarine Groundwater Discharge (SGD), encompassing fresh groundwater and recirculated seawater, has been recognized as an important component of the hydrological cycle and a dominant vector of its associated chemical constituents to the coastal sea. The biogeochemical reactions occurring in the subterranean estuary result in enhanced concentrations of dissolved land-derived compounds (i.e. nutrients, metals, carbon, pollutants) in SGD, being typically much higher than in receiving coastal waters. Thus, SGD inputs may have a significant impact on coastal biogeochemical cycles.

In this study, we aim to estimate the SGD flow into the entire Mediterranean Sea based on the distribution of ^{228}Ra in surface water. ^{228}Ra is an appropriate tracer of SGD to the whole Mediterranean mainly because (i) its primary sink is its radioactive decay and (ii) its removal must be balanced by an input term that is due almost entirely to inputs from continental margins [1]. Assuming other sources are constrained, SGD ^{228}Ra fluxes can be determined and converted to SGD water flows using the ^{228}Ra content in brackish coastal groundwater.

During the M84/3 (April 2011) and MedSeA (May 2013) cruises onboard of the R/V Meteor and the B/O Ángeles Alvariño, respectively, more than 50 surface water samples distributed throughout the Mediterranean Sea were collected (Fig. 1). ^{228}Ra concentrations were determined through RaDeCC measurements (via ^{224}Ra ingrowth from ^{228}Ra) [2] and gamma spectrometry [3].

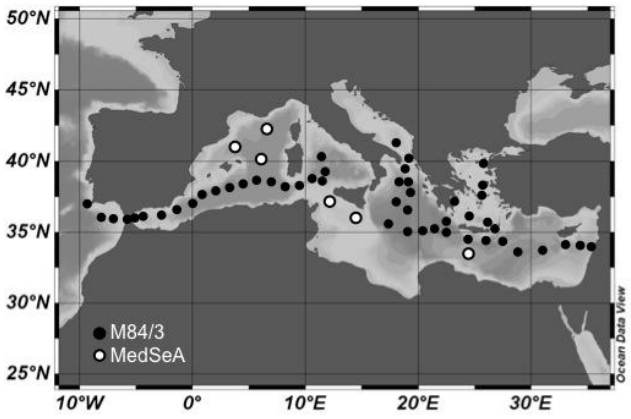

Fig. 1. Map of the surface samples collected during the M84/3 (April 2011; solid circles) and MedSeA (May 2013; empty circles) cruises onboard of the R/V Meteor and the B/O Ángeles Alvariño, respectively.

Results & Discussion

Preliminary results obtained via RaDeCC measurements showed typical ^{228}Ra concentrations, ranging from 6 to 35 $dpm.m^{-3}$ in surface waters of the Mediterranean Sea. Here we develop a preliminary approach to estimate the SGD to the Mediterranean Sea. Assuming a relatively homogeneous concentration of 15 $dpm \cdot m^{-3}$ throughout the surface Mediterranean waters (~150 m depth; winter mixed surface layer in Levantine Mediterranean [4]), the total inventory of ^{228}Ra equals ~ $6 \cdot 10^{15}$ dpm. Considering steady state and that radioactive decay is the main removal mechanism, the loss by ^{228}Ra decay (λ=0.12 yr^{-1}) should be balanced by ^{228}Ra inputs. Potential major sources of ^{228}Ra to the upper Mediterranean Sea are riverine inputs, atmospheric dust, release from continental shelf and slope sediments, seawater inflowing through the straits of Gibraltar and Bosphorous, and SGD. All these terms must be thoroughly constrained in order to determine the inputs that can be attributed to SGD. While this is not yet available, we are following a previous study conducted at the Atlantic Ocean that revealed that more than half of the ^{228}Ra inputs were derived from SGD [1]. Assuming that in the Mediterranean Sea, SGD supplies also half of the ^{228}Ra input, it results in a rough ^{228}Ra-derived SGD flux of ~ $3 \cdot 10^{14}$ $dpm \cdot yr^{-1}$. Considering an average SGD ^{228}Ra concentration of 1400 $dpm \cdot m^{-3}$ (as determined for the Atlantic; [1]), our preliminary interpretation suggests a total SGD flow on the order of 100 $Gm^3 \cdot yr\text{-}1$ (~ 10^{11} $m^3 \cdot yr^{-1}$). Although it is a preliminary attempt and it is subject to large uncertainties, our results show that the magnitude of SGD is comparable to the riverine inputs (2 - $4 \cdot 10^{11}$ $m^3 \cdot yr^{-1}$; [5]). Since the concentrations of dissolved chemicals (e.g. nutrients, metals, carbon) in SGD usually exceed those in rivers, SGD is probably a major conveyor of terrestrial compounds and contaminants to the sea, which could result in significant impacts on coastal Mediterranean biogeochemical cycles.

Abstract
We present selected results of an experiment carried out in the Gulf of Naples (GoN) in the summer of 2012. Different aspects of the surface circulation in the Gulf, a coastal area of the South-Eastern Tyrrhenian Sea were targeted during the experiment. An assessment of the importance of the local wind forcing in the case of summer breeze regime is illustrated, as well as results regarding relative dispersion and the detection of surface transport barriers (Lagrangian Coherent Structures) developing in the area.

Keywords: Currents, Coastal processes, Water transport, Gulf of Napoli, Tyrrhenian Sea

Introduction
In the framework of the MED TOSCA (Tracking Oil Spill and Coastal Awareness network) project, a field experiment was conducted in the summer of 2012 in the Gulf of Naples, organized by DiSAm and ISMAR, with the cooperation of OGS, UAegean, TEI, IASA and RSMAS (see above, authors' list). The goals of the GELaTo (Gulfofnaples Eulerian/LAgrangian TOsca) 2012 experiment carried out between July 27th and August 6th, were: i. The study of the surface circulation in the area, ii. The validation of HF radar data, iii. The assessment of relative dispersion regimes in the area (at submesoscale), iv. The test of novel drifter designs and the intercalibration of different near-surface lagrangian instruments, v. The identification of connectivity paths within the area, in terms of Lagrangian Coherent Structures.

Materials and methods
The GoN is a very intensively monitored coastal area. In particular, since 2004 a 3-antenna HF radar system has been providing hourly surface current data at 1 km spatial resolution over the entire Gulf area.
Moreover, in the framework of the TOSCA project a circulation model of the GoN was set up, namely a local implementation of the Regional Ocean Modeling System (ROMS) with 300 m horizontal resolution, forced by the SKIRON atmospheric model (0.05°, 1h resolution) and by the Mediterranean ocean Forecasting System (1/16° deg with SLA,SST, T/S profiles assimilation) ocean model at the open boundary conditions.
The GELaTo experiment implied a very intensive drifter deployment, recovery and redeployment activity in the Gulf, as well as continuous HF radar measurement of surface currents. During GELaTo 46 drifters of different designs were deployed in the GoN (divisible into two broad categories, current-following and oil spill-following units), their trajectories resulting in the spaghetti diagram shown in fig. 1.
Radar data were acquired continuously and shared, together with the drifter trajectories, in near-real time among the participants as well as with the MPO Division of the RSMAS - University of Miami, that handled the data processing for Lagrangian Coherent Structure identification on the basis of Finite Time Lyapunov Exponents.
Moreover, during GELaTo the ROMS circulation model was utilized in forecast mode, utilizing the SKIRON forecast data.

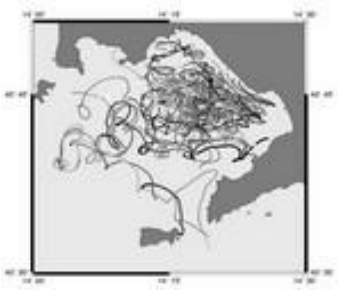

Fig. 1. Trajectories of drifters deployed during the GELaTo 2012 experiment

Results
In this communication we focus on points (i), (iii) and (v) of the main goals of the GELaTo 2012 experiment. Drifter trajectories, HF radar data as well as numerical simulations showed that the typical surface circulation in the GoN is dominated by the oceanic response to the forcing breeze regime. As a consequence, the overall current patterns rotates the entire 360° over the 24 hours, clockwise. Separation of drifter triplets is seen to kick in after a time of the order of 2-3 days. Lagrangian Coherent Structures have proved tricky to sample, mainly for logistical reasons (transmission of HF radar data time delay and ship relocation time necessities); however, a targeted experiment in a specific subarea of the Gulf allowed to point out their presence, which may have important consequences on pollutant retention and water renewal in the GoN.

INTERNAL TIDES DISTRIBUTION IN THE CENTRAL MEDITERRANEAN SEA

Jihene Abdennadher [1]* and Moncef Boukthir [1]
[1] UR11ES88,Institut Préparatoire aux Etudes d'Ingénieur de Tunis, University of Tunis - jihene.abdennadher@ipeit.rnu.tn

Abstract
We have investigated the spatial distribution of the internal tides in the central mediterranean sea using a very high-resolution of the Regional Ocean Modelling System (ROMS). The main potential sites of internal tides generation were identified. Enhanced energy conversion occurs close to the generation sites which may lead to strong mixing in these area.

Keywords: Tides, Continental slope, Sicily Channel, Adventure Bank, Messina Strait

1. Introduction

The Sicilian Channel has been extensively studied during the last years[1-2]. However, very few is known about the generation of the internal tide in this channel. Indeed, except sparse observations [3-4], the vertical structure has not been sufficiently addressed. In this study we try to clarify the distribution of the K_1 and M_2 internal tides in Sicilian Channel as well as their energetics. The horizontal resolution is about 1.4 km in both longitudinal and latitudinal directions.

2. Results

Assuming that the advection of baroclinic energy is negligible, the integration of the energy equation over a given domain and taking the average over one tidal period (denoted by an overbar) yields to:

$$\iiint g\,\overline{\rho' w_{bt}} dV = \iint \overline{p_i \vec{u}_i} \vec{dS} + \iiint \bar{D} dV$$

where ρ' is the water density perturbation, wbt is the vertical velocity induced by the barotropic tide flow, ui is the baroclinic velocity, p_i is the internal pressure perturbation, D denotes the dissipation. In this equation, $p_i \vec{u}_i$ is the energy flux that is associated with the propagation of internal tide, and $g\rho' w_{bt}$ represents the conversion rate from surface to internal tide energy.

The dissipation of the internal tides is numerically estimated from the previous equation by subtracting energy flux divergence from the energy conversion.

The maximums of the depth-integrated conversion rate from the surface to internal tidal energy depicts different generation sites for M_2 and K_1 internal tides (Fig 1 and 2). For M_2, Three main generation sites were identified, namely, the Messina strait, the narrowest passage through the western sill of the Adventure Bank, the northwest of Sicily and the northwest of the Pantelleria isle. In the Sicilian Channel the baroclinic energy flux depicts a propagation of the M_2 internal tide toward the north and southwest from the most efficient generation site. On the other hand, the K_1 internal tide enrgy is totally dissipated close the main generation regions namely, the Adventure Bank's edge, the surrounding of Pantelleria isle, the south east of the Malta plateau and the Messina strait. This result is coherent with the fact that K_1 frequency is subinertial at these latitudes and so K_1 cannot propagate. Finally, it is important to note that K_1 internal tide is globally less energetic than M_2 in the whole model domain and particularly in the Sicilian Channel.

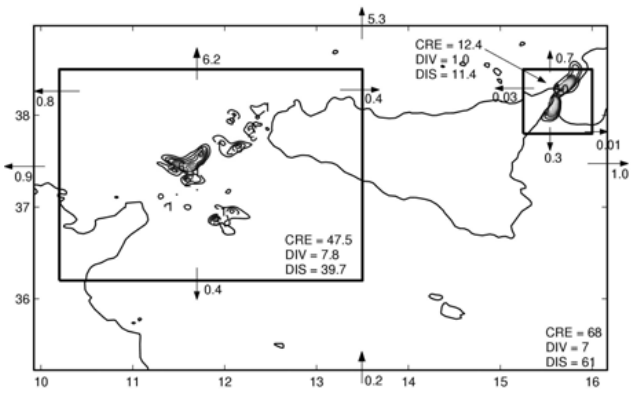

Fig. 1. Model predicted distribution of the depth integrated conversion rate from the M_2 surface to internal tide. Integrated baroclinic energy flux across the bounding transects is given in MW. Conversion(CRE),dissipation(DIS) and flux divregence(DIV) are in MW

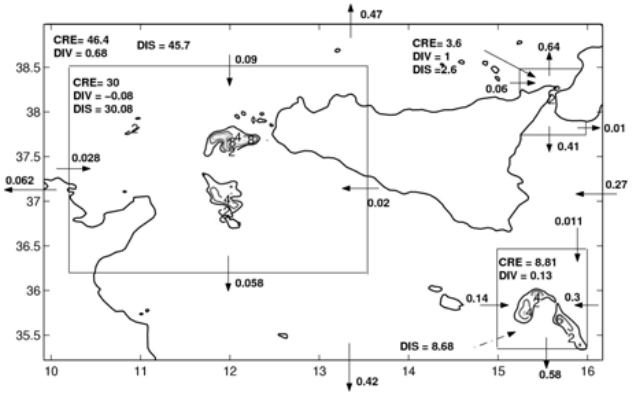

Fig. 2. Model predicted distribution of the depth integrated conversion rate from the K_1 surface to internal tide. Integrated baroclinic energy flux across the bounding transects is given in MW. Conversion (CRE),dissipation(DIS) and flux divregence are in MW

A sensitivity study to the initial stratification were established. The K_1 (M_2) internal energy with summer stratification is 30% (18%) greater than that obtained with winter stratification. Moreover, the M_2 energy ray slope depends strongly on stratification. Indeed, in the Sicilian Channel, the energy ray bends slightly toward the east with winter stratification compared to that obtained with summer one.

SEASONAL VARIABILITY OF THE ATLANTIC TUNISIAN CURRENT DERIVED FROM A HIGH RESOLUTION MODEL

Imene Ben Jaber [1]*, Jihene Abdennadher [1] and Moncef Boukthir [1]
[1] UR11ES88,Institut Préparatoire aux Etudes d'Ingénieur de Tunis, University of Tunis - imen.ben_jaber@yahoo.fr

Abstract
A high resolution eddy-resolving primitive equation numerical model (ROMS), is used to study the variability of the Atlantic current along the Tunisian coast. The seasonal variability of the two MAW flows crossing the Sicily Channel is significantly different. The main flow along the Tunisian coast, which gives rise to the Atlantic Tunisian Current (ATC) is stronger than the Atlantic Ionian Stream (AIS) from fall to winter. The ATC, which seems to be present during the year, is characterised by high spatial and temporal variability as suggested from model results and also from the analysis of eleven years of combined maps of TOPEX/Poseidon and ERS-1/2 altimeter data.

Keywords: Circulation, Mesoscale phenomena, Sicily Channel

1. Introduction

The Seasonal circulation of the central Mediterranean Sea was investigated by many authors [1-3]. It is important to note that very few data have been collected along the African coasts which imply a substantial under sampling of Tunisian and Libyan waters on the shelf slope and on the continental shelf. The current off Cap Bon [4] may be truncated by the sampling [5]. Although these efforts allowed understanding a lot about this circulation, some interrogations remain without convincing answers. One of the main objectives of this work is to examine the time and spatial variability of the Atlantic Tunisian Current (ATC), which is not well documented. Moreover, its long-term variability in space and time is only inferred from surface drifters [6] and SST satellite images [7]. To this end, we have investigated the seasonal variations of the surface circulation in the central Mediterranean Sea from a high resolution eddy-resolving primitive equation numerical model (ROMS) and from eleven years of combined maps of TOPEX/Poseidon and ERS-1/2 altimeter data.

2. Model set up

The model used in this study is based on the Regional Oceanic Modelling System (ROMS), a three-dimensional primitive equation, finite difference hydrodynamic model. The horizontal grid resolution is chosen to be about 2.8 km and the model was initialized with realistic temperature and salinity fields. At the four open boundaries, temperature, salinity and velocity fields are fully specified by a bilinear interpolation of the coarse resolution model fields (MED12) onto the high resolution model grid (ROMS).

3. Results

The model is able to simulate the major water masses and the circulation patterns in the central Mediterranean Sea. The AW and LIW paths as well as the cyclonic and anticyclonic features deduced from models [2,5] and from observations [1, 7-8] are quite reproduced. The path of the Atlantic Tunisian Current and its variability are clarified, particularly south of Lampedusa. The ATC flows eastward mainly along the 200 m isobath. South of Lampedusa, it splits into two branches. The first branch directly flows toward the southern part of the Levantine basin, while the second flowing over the Tunisian shelf. The latter divides into two branches, the first one invades the Tunisian shelf in the Gulf of Gabes and recirculates anticyclonally on the shelf, while the second continues flowing southeastward as an important coastal current and comes close to the Libyan coast, giving rise to a strong coastal jet near the Libyan current. This scheme is different from an earlier ones estimated from models of coarse resolution and it is in agreement with the recent one [9]. A small cyclonic vortex develops downstream Cape Bon and it seems that it constrains the AW towards the Tunisian slope increasing its velocity [9]. However, the existence of this mesoscale feature should be confirmed by oceanographic surveys. The ATC is stronger than the AIS from fall to winter. In January, the AIS is close to the Sicilian coast, and the ATC to the Tunisian coast. The AW is colder in the AIS than in the ATC due to mixing with upwelled waters [5]. In July, the AIS meandered, whereas the ATC appears weak or not present at all, in agreement with previous studies [2-3]. Nevertheless, our results show that the ATC is clearly present in July for year 2006, suggesting a possible interannual variability of this current. We believe that the ATC is present during the year, although it is difficult to be identified in July, because of the recirculation in the Sicily Channel. Surface geostrophic current anomalies computed from eleven years of combined maps of TOPEX/Poseidon and ERS-1/2 surface altimetric slope anomalies, particularly confirmed the observed high spatial and temporal variability of the sea surface circulation. This result is very encouraging for reconstructing the total current which is the sum of the geostrophic current anomalies, the mean current, and the Ekman current. The available long time series of satellites data in addition to their high spatial coverage make now possible a monitoring of the main eddies in the eastern Mediterranean Sea, which was not possible from *in situ* measurements.

Abstract

The winter of 2012 experienced peculiar atmospheric conditions that triggered a massive formation of dense water on the continental shelf and in the deep basin of the Gulf of Lions. New observations highlight the interaction of these processes and their role to the progressive modification of the NW Mediterranean deep waters.

Keywords: Deep waters, Water convection, Time series, Gulf of Lyon

In the Gulf of Lions, dense water formation shows a high interannual variability. Although open-sea convection is the main mechanism for the renewal of the Western Mediterranean Deep Water, the influence of dense shelf water cascading has been suggested by several studies. Analysis of historical temperature-salinity profiles from the late 1960s suggested mixing of deep cascading and convection dense waters, with a subdecadal recurrence [1], the winters 2005 and 2006 being the last major events [2].

A comprehensive set of hydrological and hydrodynamical observations- including an array of moorings, a glider repeat section and an hydrological survey - was collected during the winter and summer 2012 that provide new insights on the propagation and mixing of both type of the dense shelf waters, and their influence on the modification of the Western Mediterranean Deep Water [3].

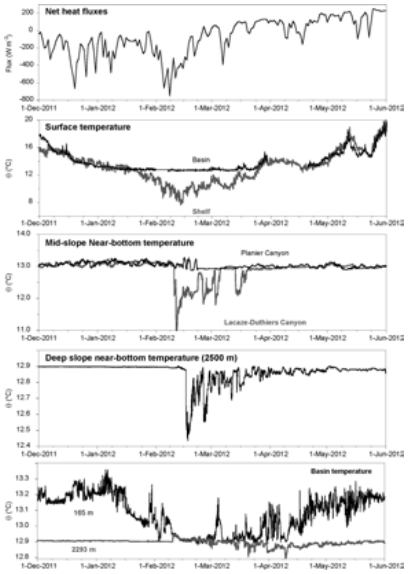

Fig. 1. Time series of net heat flux and surface temperature on the shelf and in the basin, potential temperature on the slope and in the basin during the winter and spring 2012 in the Gulf of Lions

Strong northern wind during winter 2012 induced strong heat losses both on the shelf and in the basin. From an atmospheric point of view, winter 2012 can be considered as exceptional over the North-Atlantic and Europe region with the predominance of the Atlantic Ridge (AR) atmospheric regime [4]. This regime, characterised by an anticyclonic anomaly in the North Atlantic and a cyclonic anomaly over the Baltic Sea, is particularly favourable to strong, cold and dry northerly winds over the Gulf of Lions enhancing air-sea heat fluxes. Most of the winters with large positive anomalies of the number of AR days generally correspond to years when thermo-haline anomalies indicative of intense shelf and open-sea convections were observed in the basin .

The production rate of dense water formed by open-sea convection during the winter 2012, estimated to ~1.1×10^6 m^3 s^{-1}, was about one order of magnitude larger than the mean flux of dense shelf water exported beyond 1000 m depth (~0.07×10^6 m^3 s^{-1}). In summer, the dense water of coastal origin created a distinct bottom layer up to a few hundreds of meters thick over the central part of the NW Mediterranean basin, which was overlaid by a layer of newly formed deep water produced by open-sea convection. The large increase of the volume of bottom water in the basin, with respect to that of the dense water exported from the shelf, implied a large entrainment of ambient waters during its propagation down the slope and in the basin, including newly formed deep water. This event significantly altered the thermohaline characteristics of the deep basin, hence contributing to amplify the Western Mediterranean Transition [5].

GEOSTROPHIC CURRENTS AND KINETIC ENERGIES IN THE BLACK SEA

Milena Menna [1]* and Pierre M. Poulain [1]
[1] OGS - mmenna@ogs.trieste.it

Abstract
Drifter measurements and satellite altimetry data are combined to investigate the surface geostrophic circulation of the Black Sea in the period 1999-2009. Seasonal and interannual variability of currents and kinetic energy fields are described with particular attention to the mesoscale and sub-basin coastal eddies.

Keywords: Black Sea, Circulation, Surface waters

The upper-layer circulation of the Black Sea derives from a complex interaction among different and multi-scale processes. The main characteristics of the basin, sub-basin and mesoscale patterns are analysed using drifter data combined with satellite sea level anomalies.

The combination of these two independent datasets allows to remove the biases that arise from the irregular sampling of drifters and to enhance the accuracy of satellite data in the coastal areas. Regression models are used to remove the currents directly induced by the winds from the drifter velocities and to combine drifter and satellite altimetry data, following the methods of [1] and [2].

The combined dataset is used to estimate pseudo-Eulerian velocity statistics for different time periods and to describe the spatio-temporal variability of the surface circulation in different regions of the Black Sea. The pseudo-Eulerian statistics computed with the combined geostrophic currents are defined as 'unbiased' because they are less affected by the non-uniform drifter sampling ([1]; [2]).

The Rim Current is stronger in winter/spring (mean speeds of about 20-25 cm/s; maximum values larger than 40 cm/s along the Anatolia and Crimea coasts; Fig.1), forming a cyclonic loop that surrounds the Western and Eastern Gyres (speeds less than 15 cm/s). In summer/fall the Rim Current is weaker, with mean speeds of about 15-20 cm/s (Fig. 2).

The sub-basin Batumi Eddy is usually anticyclonic with a diameter of ~ 100 km and is located in the south-east corner of the basin (between 41°-42°N and 39.5°-42°E; Fig. 2). Periods of intense activity are observed in 2006 and 2008, when this structure shows higher dimensions (diameter of ~ 200 km) and speeds larger than 30 cm/s; occasional seasonal inversions of the circulation in the Batumi region, from anticyclonic to cyclonic pathway are observed in winter 2001-2002 and fall 2004, 2006 and 2008. The sub-basin Sevastopol Eddy, located off the western side of Crimea peninsula, has a less periodic nature with respect to the Batumi Eddy; it is usually observed in spring and summer with speeds of about 15-20 cm/s.

The interannual variability of mesoscale eddies located along the Anatolia, Caucasus and Crimea coasts is described in terms of kinetic energy of velocity residuals (KE). These eddies are permanent (Crimea, Sinop and Kizilirmak eddies), quasi-permanent (Bosphorus, Bartin, Sukhumi eddies) or intermittent (Caucasus, Sakarya, Kerch eddies) features and can interact and merge with each other showing values of KE between 200 cm^2/s^2 and 600 cm^2/s^2.

Results are compared to those in [3] based only on drifter data.

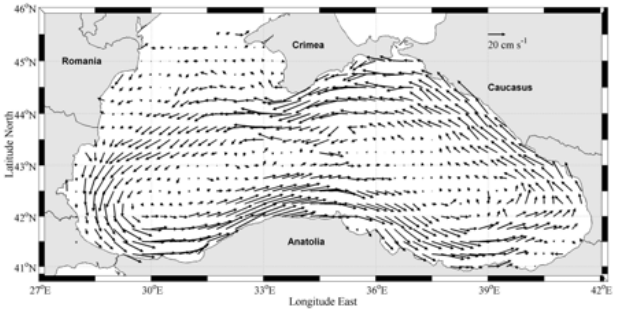

Fig. 1. Unbiased estimates of the surface geostrophic circulation in the Black Sea during winter/spring (December-May).

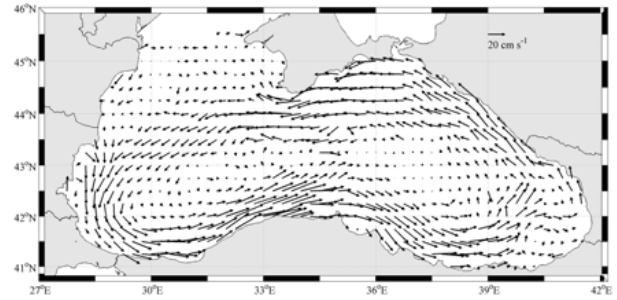

Fig. 2. Unbiased estimates of the surface geostrophic circulation in the Black Sea during summer/fall (June-November).

VORTICITY DISTRIBUTION, VARIABILITY AND SOURCES IN THE BLACKSEA

Milena Menna [1]*, Gian L. Eusebi Borzelli [1], Pierre M. Poulain [1] and Giulio Notarstefano [1]
[1] OGS - mmenna@ogs.trieste.it

Abstract
The vorticity balance in the upper layer of the Black Sea is analyzed using several data sources (drifter data, Argo float CTD profiles, satellite sea level anomalies and ocean surface wind velocities) in order to estimate the respective contribution of each term in the vorticity equation. The tube stretching term induces positive vorticity in all the regions of the Black Sea and seems to play an important role in the vorticity balance of the basin.

Keywords: Black Sea, Wind, Circulation

Vorticity is an important descriptive feature of ocean dynamics, whose variations are related to the balance of external forcing, associated with wind-stress, and internal processes. Internal processes produce vorticity variations through adjustment of internal pressure gradients (i.e. baroclinic adjustment) and/or through variations in the depth of the tube flow (tube stretching).

The Black Sea is a typical marginal, semi-enclosed, dilution basin characterized by a stable stratification, a simple basin geometry and a smooth bottom topography; therefore, it is the ideal location to study the relative contribution of the different terms to the vorticity balance in the ocean and to analyze fundamental hydrodynamic interactions common to different areas of the World Ocean.

The large scale structure of the Black Sea upper-layer dynamic is predominantly cyclonic (i.e. positive vorticity) with some anticyclonic rotations (i.e. negative vorticity) located in the coastal areas of the north-west and south-east sectors. According to the previous studies cyclonic circulation of the basin is maintained by wind-stress curl ([4]), although input due to winds is not able to reproduce the observed vorticity levels ([3]).

This consideration opens the issue of analysing the relative contribution of the individual terms that concur to the vorticity balance of the basin. The Black Sea is divided in four sectors, following the spatial distribution of prevailing winds, and the mean values of the vorticity equation terms over the period 1999-2008 are estimated for each sector.

In Table 1 the main results of this analysis are presented. The vorticity of the geostrophic currents is positive in the North-East, South-West and South-East sectors and slightly negative in the North-West sector. The wind stress works against the current vorticity in all sectors except in the North-East sector, with values of order 10^{-13} s^{-2}. The tube stretching terms induce a positive vorticity in all the sectors of the Black Sea, with larger values in the North-East and South-West areas and magnitudes comparable with the wind stress terms. Also the baroclinic terms prompt the cyclonic vorticity of the upper layer circulation, but their contributions are three/two orders of magnitude smaller than the wind stress and the tube stretching terms.

These considerations suggest that the tube stretching terms plays an important role in the vorticity balance of the Black Sea. The predominant role of the tube stretching term is supported by significant yearly variations in the upper layer thickness of the basin, as estimated from the phase speed of the internal gravity waves, and by the increment of freshwater inflow in the basin during the period considered ([1]; [2]).

Table 1. Mean amplitude of geostrophic currents, relative vorticity field associated with surface circulation, wind vorticity input, tube stretching and baroclinic terms estimated in each sector of the Black Sea.

	NW	NE	SW	SE
Mean geostrophic currents (cm/s)	9.3	15.8	15.8	12.4
Relative vorticity (s^{-1})	-3e-8	1.7e-6	2.3e-6	9.1e-7
Wind vorticity term (s^{-2})	-0.7e-13	0.12e-13	-4.4e-13	-0.6e-13
Tube stretching term (s^{-2})	3e-12	5.2e-12	5.3e-12	4.1e-12
Baroclinic term (s^{-2})	0.88e-15	2.5e-15	2.5e-15	1.6e-15

Abstract
The coastal circulation of the Gulf of Lion has been studied over a ten year period with *in situ*, remote sensing and numerical data. Intrusions, eddies, transient structures and frontal jets can strongly influence water fluxes in and out of the gulf. Transport fluxes as well as horizontal and vertical diffusivities are being assessed with data from varions *in situ* platforms. All these results bring new understanding on the influence of mesoscale processes on cross-shelf and interregional exchanges.

Keywords: Circulation experiments, Circulation models, Coastal processes, Gulf of Lyon, Mesoscale phenomena

The circulation of the Gulf of Lion (GoL), northwestern Mediterranean Sea, is complex and highly variable [1]. It is strongly influenced by the Northern Current, generally considered to constitute a dynamical barrier along the shelf. Exchanges between the GoL and offshore waters are thought to be induced by processes associated with the Northern Current [2,3]. This paper focuses on mesoscale processes at the eastern and western sides of the GoL.

The coastal circulation of the GoL has been studied over a ten year period with *in situ*, remote sensing and numerical data. The present study includes *in situ* data acquired during SARHYGOL (2000-2001), GOLTS (2002-2005) and LATEX (2007-2011). A realistic 3D numerical model Symphonie is run from 2001 to 2010 at high resolution (1 km) [4].

On the eastern side of the gulf, during specific conditions, a vein of the Northern Current (up to 1/3 of its measured flux) can intrude on the shelf. On the western side, wind conditions can affect whether the current enters or exits the gulf [5]. During stratified summer conditions, elliptical, shallow, anticyclonic eddies are observed north of Cape Creus [6,7], following northwestern wind events [8]. Two different generation processes can create them [9,7]. Generally eddies are associated with water retention; but transient structures can also detach from them and rapidly exit the gulf [7].

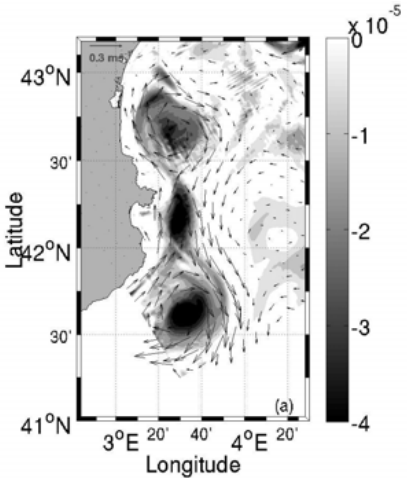

Fig. 1. Modeled relative vorticity [s^{-1}] and current velocity field at 20 m depth on September 3, 2010. From north to south: eddy in the western part of the Gulf of Lion, transient structure, eddy in the Catalan basin.

During the LATEX 2010 cruise, Lagrangian Coherent Structures derived from in situ data exhibit a frontal jet by which coastal waters escape from the GoL [10]. Transport fluxes are assessed, as well as horizontal diffusivities, using two approaches: i) combining stirring rates estimated from Lagrangian drifters with surface temperature gradients; ii) mapping a passive tracer's dispersion.

These mesocale processes (intrusions, eddies, transient structures, fronts) have an influence on interregional exchanges that can have strong impacts on biogeochemical and biological systems.

Abstract

The Rhône River has a major influence on the biogeochemistry of the Gulf of Lions in the Western Mediterranean Sea. The biogeochemical fate of the Rhone River organic particles was investigated over several years within the Mermex programme using two approaches: (i) the tracking of organic particles origin using carbon paired isotopes ($^{13}C/^{14}C$) on density fractionated particles and (ii) the estimation of sediment mineralization using a fixed benthic station and a microprofiler with oxygen micro-electrodes at the Mesurho Buoy near the Rhône River mouth and the adjacent shelf. We combine spatial and temporal variability of organic matter mineralization in the Rhône River delta.

Keywords: Deltas, Sediments, Carbon, Gulf of Lyon

Coastal zones are a major compartment in System Earth and play a crucial role in the biogeochemical carbon cycle. Within coastal seas, deltas are critical interfaces between land and the coastal area, as they receive most of the particulate input from the rivers and act as buffer for organic matter (OM) fluxes. Due to the extreme variability of estuaries and deltas, on both spatial and temporal scales (hydrology, production-respiration balance, coastal circulation...), the balance between deposition, burial and consumption of particulate organic matter by the benthic ecosystem is largely unknown, making this zone the most uncertain in the marine realm with regards to CO_2 uptake or release[1]. Large quantities of terrestrial OM inputs can be buried or mineralized depending on their origin, reactivity and deposition pattern. At the same time, flood inputs with their extreme sedimentation rates or intense resuspension during storms with particulate matter recirculation may play a major role in defining the fate of particulate organic matter. We approached the question of the fate of Rhône River organic inputs in the delta using two distinct methodologies:

- we used a combination of two in situ techniques measuring oxygen microprofiles in the sediments and defining the diffusive oxygen uptake of the sediment, to estimate the biogeochemical transformations of particulate organic carbon in the Rhône delta and its spatial and temporal variability.
- we measured carbon isotopes ($D^{14}C$, $\delta^{13}C$) in the bulk and density-fractionated sediments in order to assess the origin and reactivity (residence time) of particulate organic carbon.

Oxygen micro-profiles and calculations of diffusive oxygen uptake (DOU) were obtained by two *in situ* techniques: i) an oxygen micro-profiler deployed on an array of stations[2] ii) a new benthic station equipped with oxygen micro-electrodes and environmental sensors. This new device performs daily measurements of oxygen microprofiles, with a potential for high frequency measurements (4 per day) during special events. Time series typically encompass periods of 1-3 months. The micro-profiler complemented these time series with a spatial coverage of oxygen demand at selected seasons. We deployed the benthic station at the Mesurho station near the Rhône River mouth together with the oxygen micro-profiler with the ultimate goal of studying the mineralisation of particulate organic matter delivered during floods. The first results obtained during low flow conditions and low turbidity showed that the measurement system is stable over time allowing temporal variation and floods to be recorded. During the turbidity events of spring 2012, oxygen demand rises by a factor of 3-4. We discuss the importance of flood events and resuspension in controlling the variability of DOU in this system.

Radiocarbon and $\delta^{13}C$ in four different fractions[3] of sediments obtained by density fractionation were measured in order to isolate different natures of OM. Previous studies based on bulk ^{14}C analysis of surface sediment of Rhône delta (Fig. 1) have shown an aging of the OM and a decreasing proportion of terrigenous OM with increasing distance off the river. The first results indicate that the signature in $\delta^{13}C_{OM}$ and $D^{14}C_{OM}$ of the density-fractionated material show a similar pattern as the bulk sediment, with a general aging of each density fraction and a progressive loss of the terrestrial signature with the distance offshore. This may be attributable to retention of terrestrial large and light particles (such as vegetal debris) in the prodelta (the nearshore region of the subaqueous delta), large mineralization of the labile fractions associated to aggregates or minerals and recirculation/mixing of continental shelf particles.

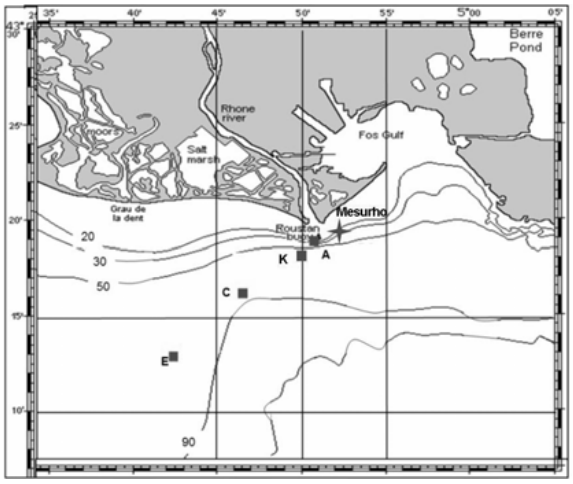

Fig. 1. Position of the station investigated. Squares are regular sampling stations during Mermex-River cruises and star is the the Mesurho station.

Overall, the two techniques used in this study indicate that retention and mineralization of terrestrial particles mostly occur in the prodelta with relative accumulation of refractory organic carbon in continental shelf sediments. Although the deltaic biogeochemical system is stable over time, disturbing events such as large resuspension events or floods[4] have an internal dynamics that can profoundly affect the fate of organic matter in this region.

MODELING THE TURKISH STRAITS SYSTEM: A GRAND CHALLENGE FOR MEDITERRANEAN AND BLACK SEAS CLIMATE STUDIES - BOSPHORUS AND DARDANELLES STRAITS COUPLING

Gianmaria Sannino [1]*, Adil Sözer [2] and Emin Özsoy [2]
[1] ENEA - UTMEA.CLIM - gianmaria.sannino@enea.it
[2] Institute of Marine Sciences, Physical Oceanography, Mersin, Turkey

Abstract
An all-time modeling challenge aims to establish a sound understanding of the high energy environment of the Turkish Straits System, relating to inter-basin water and material transports and their influence on the sensitive ecosystems of the adjacent seas. As a first step in this direction, well resolved, high level, physically representative predictive models of the Bosphorus Strait exchange flow hydrodynamics are developed, adequately representing its complex topography, hydraulic controls, dissipative hydraulic jumps, mixing and turbulence mechanisms, with the application of appropriate basin boundary and initial conditions and judiciously selected numerical and physical model options. Moreover preliminary results from an ambitious multi-scale coastal ocean model representing the entire Turkish Straits System will be discussed.

Keywords: Circulation models, Bosphorus Strait, Dardanelles, Marmara Sea

The scientific questions on the role of the Turkish Straits System (hereinafter TSS) in coupling the adjacent basins of the Mediterranean and Black Seas with highly contrasting properties, in a region of high climatic variability and materials transport depending critically on the cycle of water can only be answered by model predictions of the processes that determine the integral properties of the coupled sub-systems. This can only be achieved if the entire TSS is modeled as a finely resolved integral system that accounts for the high contrasts in seawater properties, steep topography, hydraulic controls, fine and meso-scale turbulence (Özsoy et al. 2001), nonlinear and non-hydrostatic effects (Ilicak et al. 2009), thermodynamic states and an active free-surface in the fullest extent, based on well represented fluid dynamical principles. As a first step to approach coupled modeling of the TSS, a well resolved, physically representative predictive model is developed of the Bosphorus Strait hydrodynamics, including the effects of complex topography, hydraulic controls, turbulent mixing with the application of appropriate basin boundary and initial conditions. The results for idealized and real geometry model configurations provide a deeper understanding of the establishment of the maximum exchange regime of inter-basin transports, and comparisons with a series of detailed observations provides an enlightened view on the climatic and short-term variability of the system. Asymmetrical and nonlinear behavior of the strait dynamics is observed as a result of the various controls and turbulent dissipation. Results obtained independently from ROMS and MITgcm models for almost identical configurations for the Bosphorus Strait indicate similar satisfactory performance in predicting the basic elements of the flows. The possible impacts of these essential features of the TSS system on the mixing and transport processes and coupling of regional seas are discussed.

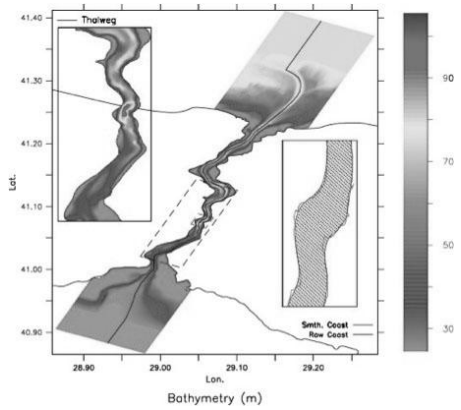

Fig. 1. Bosphorus model grid and bathymetry.

As a second step in modeling the TSS, an ultra high-resolution, physical representative model is developed for the entire system: Dardanelles-Marmara Sea-Bosphorus.
The extreme environment has been represented as a whole and with the full details of its highly contrasting properties. The huge computing resources needed to run such an ambitious model have been provided by the EU initiative PRACE (Partnership for Advanced Computing in Europe). The numerical model used is based on the non-hydrostatic MITgcm. The MITgcm solves the Boussinesq form of the Navier-Stokes equations for an incompressible fluid fully non-hydrostatic with a spatial finite-volume discretization on a curvilinear computational grid. Moreover it has been formulated with an implicit free-surface, and partial step topography. A non-uniform curvilinear orthogonal grid covers the entire model domain. The maximum horizontal resolution (about 50 m) is reached in the Bosporus and Dardanelles Straits. To adequately resolve the complex hydraulic dynamics of TSS, the model grid is made by 72 vertical z-levels, and the formulation adopted is non-hydrostatic (Sanchez-Garrido et al. 2011). It should be noted that such a model configuration represents a novelty respect to any other model implemented in the same region in the past. Preliminary results obtained from a climatological initialized configuration indicate satisfactory performance in reproducing the main features of the flow exchange between the Aegean Sea and Black Sea. Results are discussed in terms of mixing, hydraulic control and transport processes.

ATTENUATION OF UVR AND PAR IN IN SURFACE COASTAL WATERS OF THE NORTHWESTERN MEDITERRANEAN SEA DURING MERMEX PROJECT

RIchard Sempéré [1]*, Julien Para [1], Bruno Charrière [1] and Marc Tedetti [1]
[1] MIO, Marseille - richard.sempere@univ-amu.fr

Abstract

Radiometric and chromophoric dissolved organic matter (CDOM) measurements were performed monthly between November 2007 and December 2008 at the SOFCOM coastal station in the Northwestern Mediterranean Sea during MERMEX project. The values indicated that the waters were highly transparent throughout the year. The relationships between CDOM absorption and Kd in this oligotrophic system suggested that CDOM contributed to UVR attenuation in the UVA domain, but also played a significant role in PAR attenuation.

Keywords: Organic matter, Ocean colours, North-Western Mediterranean

Due to its weak cloud cover, the Mediterranean atmosphere is characterized by higher solar radiation levels than those found at similar latitudes in the Atlantic Ocean (Mermex group, 2011 and references therein. The Mediterranean Sea, which is known as a low chlorophyll low nutrient (LNLC) oligotrophic system, is characterized by a blue color that does not extend as deep as predicted by its Chlorophyll content alone. This discrepancy between ocean color and Chlorophyll concentration was suggested to be attributed to either an "excessive" level of CDOM (Morel and Gentili, 2009) or to the presence of Saharan dust in the upper layer may also cause this discrepancy (Claustre et al; 2002). Solar radiation strongly influences biogeochemical cycles and ecosystem functions in the ocean. Photosynthetically available radiation (PAR: 400-700 nm) provides energy for photosynthesis and induces primary production, which all marine food webs ultimately depend on. In contrast, energetic ultraviolet radiation (UVR: 280-400 nm) has numerous deleterious effects on living organisms that inhibit photosynthetic activity and damage DNA. Here we report that surface irradiance strongly varied with season (particularly for UVR-B) and was from 0.14 to 4.6, 12 to 59 and 30 to 159 $\mu W\ cm^{-2}$ for UVR-B (305 nm), UVR-A (340 nm) and PAR (490 nm), respectively. Examination of the UVR-B/UVR-A, UVR-B/PAR and UVR-A/PAR surface irradiance ratios indicated that UVR-A and PAR were similar and evolved temporally. In contrast, the UVR-B increased 7 to 8 fold more than its UVR-A and PAR counterparts during the summer. The strong temporal variability of UVR-B may be explained by its higher dependence on direct/diffuse irradiance ratios than UVR-A and PAR. The diffuse attenuation coefficients for downward irradiance [$K_d(\lambda)$] of UVR-B, UVR-A and PAR were from 0.21 to 0.48, 0.16 to 0.27 and from 0.04 to 0.09 m^{-1}, respectively. These values indicated that the waters were highly transparent throughout the year. The relationships between CDOM absorption and $K_d(\lambda)$ in this oligotrophic system suggested that CDOM contributed to UVR attenuation in the UVA domain, but also played a significant role in PAR attenuation.

TIDAL VARIABILITY IN THE STRAIT OF OTRANTO

Laura Ursella [1]*, Vedrana Kovacevic [1] and Miroslav Gacic [1]
[1] Ist. Naz. di Oceanografia e di Geofisica Sperim. - lursella@ogs.trieste.it

Abstract
Various current data, collected in the Strait of Otranto during the period 1994-2007, have been analysed with the aim of describing the characteristics of the tidal motions and their contribution to the total flow variance.

Keywords: Currents, Tides, Otranto Strait, Waves

The principal tidal constituents in the area were the semi-diurnal (M2) and the diurnal (K1), with the latter one predominant. The total flow was, in general, more energetic along the flanks than in the middle of the Strait. Specifically, it was most energetic over the western shelf and in the upper layer along the eastern flank. In spite of the generally low velocities (a few cm/s) of the principal tidal constituents, the tidal variance has a pattern similar to that of the total flow variance, that is, it was large over the western shelf and low in the middle. The proportion of non-tidal (comprising the inertial and sub-inertial low-frequency bands) to tidal flow variances was quite variable in both time and space. The contribution of the low-frequency motions predominated over the tidal and inertial ones in the eastern portion of the strait during the major part of the year, particularly in the upper and intermediate layers. In the deep, near-bottom, layer the variance was evenly distributed between the low frequency, diurnal and semi-diurnal bands. A prominent exception was observed near the western shelf break during the summer season when the contribution of the tidal signal alone to the total variance reached 77 %. This high contribution was mainly due to the intensification of the diurnal signal at that location in the proximity of both the surface and bottom layers (velocities of about 10 cm/s) (Fig.1). The largest amplitude of the diurnal constituent appeared in the deepest layer and this is explained in terms of the first baroclinic mode pattern.

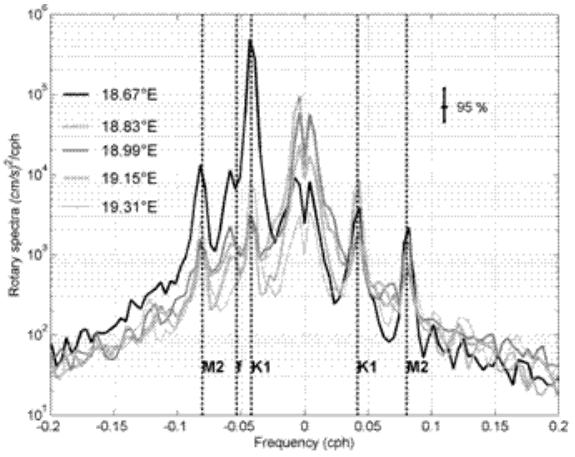

Fig. 1. Rotary spectral analysis in the near bottom layer along the Otranto section (39.85°N) for the summer period from OTRANTO/OGEX project. The 95% confidence level is indicated.

Beckenbach and Terril (2008) [1], studied a similar phenomena and explained this intensification in terms of a baroclinic internal tide generated through the interaction of a barotropic tide with topography. In these circumstances, subinertial internal waves can exist beyond the critical latitude and explain a consistent part of the variance. Orlic et al. (2011) [2] and Mihanovic et al. (2009) [3] found that summertime stratification occasionally generates internal coastal waves that travel daily around an island in the southern Adriatic Sea, creating the conditions for resonant excitation of the diurnal frequency by sea breeze and/or diurnal tides. Local wind obtained from ECMWF (European Centre for Medium-range Weather Forecast) and sea level data from the tide gauge located in Otranto (40.1471°N - Rete Mareografica Nazionale, http://www.mareografico.it/)were thus analysed and compared with the flow to find the possible origin of this diurnal intensification. No evidence of significant diurnal signal in wind and sea level were found (Fig. 2) Having excluded the sea-breeze impact on the intensification of the diurnal tidal signal, the most likely cause remains the generation of the topographically trapped internal waves and the diurnal resonance in the tidal response. These waves were sometimes generated by the barotropic tidal signal in the presence of summer stratification. The presence of the internal diurnal waves was confirmed by the phase shift between the diurnal signal in the coastal sea level and in the currents at the station over the shelf break. However, these waves were not continuously generated (Fig. 2), and did not generate amplification on the on-shore side of the shelf break in the similar stratification conditions. This indicates that the topographic slope as well as the density stratification is the necessary element for the resonance. This phenomenon may stimulate the diapycnal mixing during the stratified season and enhance ventilation of the near-bottom layers.

Abstract
One massive stranding of Euphausiid *Nyctiphanes couchii* was recorded along the north-western Sicilian coast of "S. Vito Lo Capo" between March 17th 2013 night and March 18th morning. Random samples were collected in order to obtain the size structure of the specimens. Considering the knowledge on the species biology and meteo-marine conditions, it has been suggested that the unusual phenomenon is due to intense upwellings in the area.

Keywords: Crustacea, Water transport, Tyrrhenian Sea

Nyctiphanes couchii (Bell, 1853) is a neritic species common in the shelf-seas of the NE Atlantic, W Mediterranean, but also in the Adriatic and Aegean Sea [1]. It provides a large fraction of plankton biomass throughout the year, constituting an important key species in the food webs for several fishes and cetaceans [2,3]. Adults total length (TL) ranging between 12 and 17 mm with an observed length at first maturity of about 12 mm. *N. couchii* breeding at age of one year, during spring and summer, with females that are able to carry about 50 eggs attached to the thoracic legs [4]. The species makes diel migrations to the surface waters at night [3], but the rate, time and amplitude of these migration are essentially unknown in the investigated area. A massive beaching of this euphausiids occurred in "S. Vito Lo Capo", a shallow bay located in the north-western Sicilian coast, between March 17th 2013 night and March 18th morning (Fig. 1).

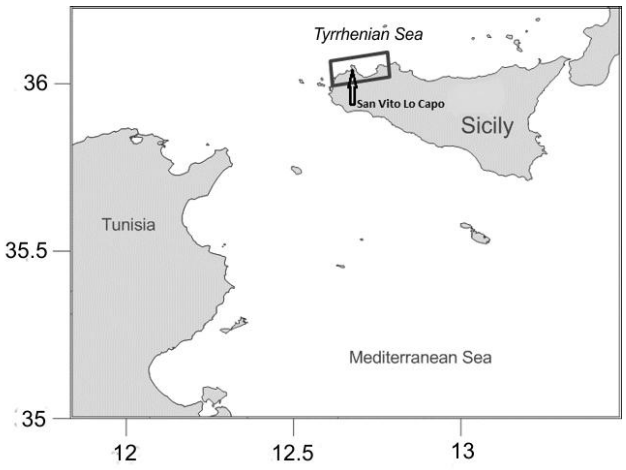

Fig. 1. Position of "S. Vito Lo Capo" bay, located along the north-western Sicilian coast.

The local Office of Coast Guard informed our Institute about the stranding, highlighting a very large patch of pink color (reporting "neonatal crustaceans") along 1 km of beach (Fig. 2). An inspection of our researchers identified the species *N. couchii* along the beach as well as the pools on rocky shores. Random samples of the specimens were collected in order to obtain a length frequency distribution (LFD). Each individual of a random sub-sample was photographed by digital camera connected with a stereomicroscope with a magnification of 8X (Leica DC 200, software Leica IM 50) and measured as carapace length (CL) (software Image Pro Plus Vers. 4.1. Media Cybernetics). Weather conditions and satellite images were verified in the three days before the stranding.

A total of 509 specimens were measured with CLs ranging between 2.2 and 5.4 mm. The shape of the distribution was unimodal with a peak of frequencies at 4 mm CL, although a sign of a component of smaller individuals could be recognized (Fig. 2).

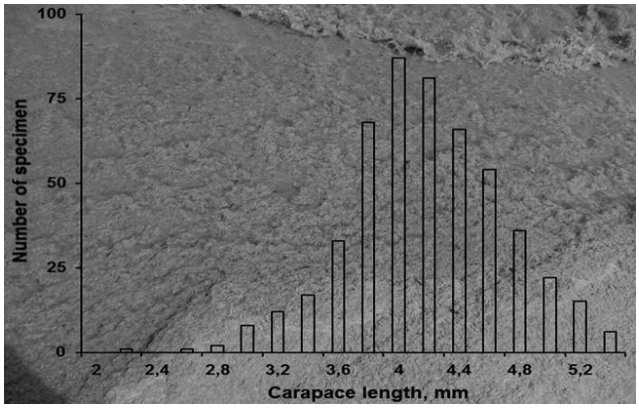

Fig. 2. Length Frequency Distribution of stranded Nyctiphanes couchii, overlapped to the photo of straddling specimens on the shoreline.

Although the cloudy sky did not allow to analyzed the satellite image of sea surface, the strong wind from SE, blowing at about 70 km/h, favorable to upwelling in the area, followed by rough sea from MW, supports the hypothesis that *N. couchii*, with a poor swimming ability, was stranded as consequence of oceanographic adverse condition. The stranding of small shrimps was repeatedly reported along the coasts of the "Maddalena Archipelagos" (Sardinia, central Tyrrhenian sea), being the more recent occurred on March 12th 2013 [5]; however, according to the information collected by fishermen, the massive stranding of this species was recorded for the first time in the S. Vito Lo Capo Bay.

THERMOHALINE STRUCTURE AND COLD INTERMEDIATE LAYER PROPERTIES OF THE BLACK SEA AS INFERRED FROM ARGO FLOATS

Anil Akpinar [1]*, Bettina Fach [1] and Temel Oguz [1]
[1] Institute of Marine Sciences,Middle East Technical University - anil@ims.metu.edu.tr

Abstract
The thermohaline structure of the oxygen-rich cold intermediate layer (CIL) with temperatures below 8ºC in the Black Sea is of great importance due to the oxygen deficiency of the water column below the biologically productive euphotic zone. The long-term data compiled from the Argo float profiles document temporal and spatial variability of its distribution and the likely mechanisms leading to its formation.

Keywords: Hydrography, Black Sea, Water convection, Temperature, Vertical profile

Data from seven ARGO profiling floats operating in the Black Sea between 2002-2009 have been used in this study. Three of these floats were located at the parking depth of 1550m, and the rest at 200m, 500m, 750m and 1000m depths. All of them collected vertical profiles of temperature and salinity from 1550m depth to the surface once a week. Both the CTD data and position data have been used to examine temporal changes in the horizontal current velocity [1] and temperature and salinity at the floats parking depths. Sea surface height anomaly data from AVISO have been used as supplementary data set in order to identify the mesoscale features provided by the float data. In this work the CIL thickness and lower boundaries are considered as an indicator for the intensity of ventilation of subsurface waters in the Black Sea (Table.1-Fig.1). A thick CIL is generally observed in March, but there is no seasonal cycle or a specific parameter affecting CIL thickness. The results suggest that CIL is thicker and deeper in anticyclones whereas it is thinner and is at shallower depths in cyclones. Simultaneous observations in cyclonic and anticyclonic patterns reveal an 80m difference in the lower boundary of CIL and a 60m difference in CIL thickness. Among the average thickness values obtained from the floats, the smallest value is ~29m due to its location in the cyclonic Western Gyre. CIL is observed as an isothermal layer formed when the cold water formation at the surface merges with the already existing old CIL, prefarably in the cyclones during February-March. Its formation in the cyclonic gyres emphasizes importance of the uplift of the pycnocline and the upwelling of the old CIL to the surface rather than generation of cold water as a result of convection only. Cold water formation seems to be affected by mesoscale processes as well.

Tab. 1. Average depth, temperature, salinity, sigma-theta and thickness of CIL for each float

Float no.	Mean Depth (m)	Mean Temperature (°C)	Mean Salinity (psu)	Mean Sigma-theta (kg/m3)	Average Thickness (m)

NEW WATER MASSES AT INTERMEDIATE DEPTHS ON THE TUNISIAN SIDE OF THE SICILY CHANNEL

S. Ben Ismail [1]*, K. Béranger [2], C. Sammari [1], M. Brahim [1] and G. Gasparini [3]
[1] INSTM 28 rue 2 mars 1934 - sana.benismail@instm.rnrt.tn

Abstract
This study used data collected during six hydrographic cruises in the western half of the Cap Bon – Mazara del Vallo section during 2003. The analyses of transects reveals the presence of Western Intermediate Water (WIW) in April and Ionian Water (IW) in March-April on the Tunisian side of the channel in a transitional layer between Atlantic Water (AW) and Levantine Intermediate Water (LIW). The conclusions on seasonal and mesoscale variability are confirmed by a high resolution numerical simulation.

Keywords: Mesoscale phenomena, Circulation models, Sicily Channel, Vertical profile

Introduction

The Sicily Channel (SC) is located at the junction between the eastern and the western Mediterranean. At depth the SC is composed of two narrow passages, the Tunisian passage to the west and the Sicilian passage to the east and are separated by sub-marine mountains. The SC large scale circulation can be schematized as a two-layer system composed of a surface layer of fresher water flowing eastward (mainly composed of AW) and a salty bottom layer (mainly composed of LIW) flowing westward [1]. Our study highlights the presence of transitional waters intermittently observed between AW and LIW, in the Tunisian passage. There are the WIW and the IW. The WIW forms during winter in the northwestern Mediterranean due to the surface cooling of AW and has been recorded in the Algerian Basin by [2], flowing eastwards below the AW in the Algerian Current through the Channel of Sardinia. The WIW is characterized by a relative minimum of temperature. The IW flows above the LIW towards the Tyrrhenian Sea, and is characterized by a relative maximum of temperature close to the Sicilian shelf [3]. The detailed pathways of these water masses is not well documented in the central Mediterranean. Then to assess the mesoscale and seasonal variability of these water masses in this area, we compare high sampling *in situ* data with a high resolution numerical simulation.

Data and model

We used results from several transects made in 2003 with a high sampling (5 km) in the Tunisian passage in 2003. The data highlight transitional waters between AW and LIW with intermittent signatures [4]. The measurements are compared to results from a high resolution ocean simulation MED16 [5] using OPA model in a regional configuration forced by ECMWF atmospheric fields from 1998 to 2008.

Results

According to the in situ data, a transitional layer is observed at the interface of AW and LIW and evidences specific patterns, mainly characterized by temperature anomalies both horizontally and vertically. Along the April transect in the Tunisian passage, at about 170 m depth, a temperature minimum (WIW) is observed near Tunisia while a temperature maximum (IW) is found in the eastern part of the section (Fig. 1a). The WIW is then observed in May 2003 between 100 and 200 m depths (T=13.85 °C, S=38.20, at 175 m) whereas the upper AW is warmer by about 0.5°C. The WIW core is delimited by the isotherm T=14°C, corresponding to an extent of about 14 km from the coast. A strong signature of IW is observed during March and April 2003 (Fig. 1a) between 100 and 200 m depths (T=14.8°C, S=38.5, at 150m depth**)** whereas a lower one is noticed during the second half of the year.

In the model (Fig. 1b), the two water masses are well identified in April 2003. But temperature values in the intermediate layer are higher than in *in situ* data. The IW is also particularly well identified in March and the WIW is located very close to the Tunisian shelf especially in April, May and June. These characteristics and the two-layer schema are sometimes changed due to anticyclonic mesoscale eddies which can occupied the center of the SC [4].

Conclusion

This study highlights the presence of new water masses in the Tunisian passage, the western part of the Sicily Channel. The observations show, for the first time, the presence of WIW in the SC and confirm the path of IW initially recognized by [3]. The comparison with the model outputs has revealed local recirculation occurring in spring and summer on the Tunisian side of the SC, that could explain a weakening in the ATC.

NEW INSIGHTS ON THE IERAPETRA EDDY GENERATION

Abstract

The paper present results of a 23-year high resolution simulation of the Mediterranean simulation obtained by running the OPA rigid-lid model forced by ECMWF fields several times. The detailed study of a particular eddy highlights the main simultaneous roles played by the Cretan outflow through the Kassos Strait and by the Asia Minor Current instabilities.

Keywords: Circulation models, Mesoscale phenomena, Cretan Arc, Levantine Basin

Introduction - The Ierapetra eddy (IE) is a well-known feature of the circulation in the Levantine basin, the most eastern part of the Mediterranean Sea, which was first pointed out by the analysis of POEM observations, as an anticyclonic structure located south-east of Crete. This pattern has then been called by [1] as the Ierapetra anticyclone. Several hypotheses for the IE generation have been proposed concerning the roles of the wind [2], of the Mid Mediterranean Jet variations [1] and of the Cretan outflow [3]. But some questions remain open concerning the main processes triggering the IE. In this paper, we focus on the generation process of IE, using a high resolution ocean simulation MED16 [4] forced by ECMWF atmospheric fields, repeated several times. In particular, the strategy of the simulation allows to investigate two different ocean circulations forced by the same winds.

Results - We compare the model outputs for years corresponding to the ECMWF atmospheric forcing of year 2000. The generation of IE is modeled in August of year 20 whereas no generation of IE is noticed during year 11. The circulation features are then checked before the beginning of the generation for this particular sets of results, according to maps of the circulation at 56 m depth. During year 20, the Asia Minor Current (AMC) meanders regularly and small anticyclonic vortices appear embedded in the current. These anticyclonic eddies of about 50 km diameter and of thin vertical shape have a short life-time and are often mixed again with the AMC several kilometers forwards. In July, the AMC highlights a large meander and a small anticyclonic circulation is captured at the south-east corner of Crete. The anticyclonic circulation is sandwiched between Crete and Kassos islands. In August (Fig. 1a), the previous small anticyclonic circulation is still centered at the south-east corner of Crete and, at the same time, subsurface saline Cretan waters outflow through the Kassos Strait. The flow of Cretan waters is deviated around the northeast rim of the anticyclonic circulation in an anticyclonic pathway. It consequences an enhancement of negative vorticity inside the anticyclonic circulation. The IE is now well defined with a strong vertical shape and a core of saline waters at subsurface.

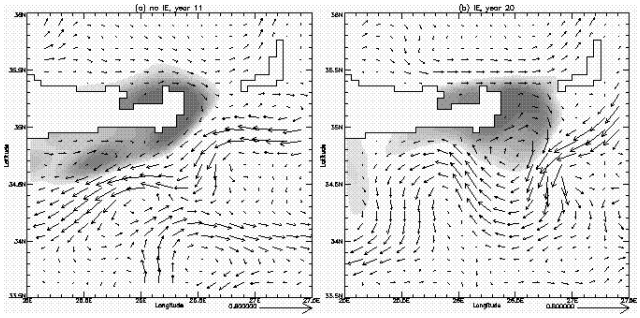

Fig. 1. Currents at 56 m depth in August (a) of year 11 and (b) 20 of the simulation. Salinities higher than 39 are shaded in grey. One vector over two is plotted.

During year 11, the Asia Minor Current follows closely the northern coast and meanders are few and of low amplitude. The Cretan Water outflow remains close to the Cretan shelf. No anticyclonic eddy is noticed close to the Kassos Strait (Fig. 1b).

Conclusion - We argue that the condition to have the generation of an Ierapetra eddy in the model needs two ingredients at the same time: (i) the presence of an anticyclonic vortices generated and bring by the Asia Minor Current between Crete and Kassos islands, and, (ii) the outflow of saline Cretan waters winding round the initial anticyclonic eddy. This result has been confirmed by the analysis of other eddies in the simulation. Thus, the wind role, in the model, is not a sufficient ingredient to generate an Ierapetra eddy.

Acknowledgments - Modeling work was supported by SHOM and Mercator Ocean. Atmospheric forcing was made available by the ECMWF. Computations were made at IDRIS from the CNRS (project i010227).

Abstract
A pilot experiment aiming at investigating the small scale dynamics and variability of the seawater fine thermohaline structure, the processes of vertical exchange of momentum and mass, and mechanisms of the nepheloid layer formation in the Besòs submarine canyon, situated in the continental slope close to Barcelona, was carried out by using the prototype moored profiler "Aqualog".

Keywords: Instruments and techniques, North-Western Mediterranean

Oceanographic conditions in the NW Mediterranean are characterized by high mesoscale variability determined by the dynamics of the alongslope Northern current [1]. A high variability of the baroclinic front associated with this current, the intense lateral exchange between different water masses, the interaction between the current and irregular bottom relief and mesoscale eddies generated by the instability of the current, determine the complicated spatial distribution of water masses [2]. In recent years important anomalies were observed in the thermohaline characteristics and dynamics of the water masses in the Western Mediterranean [3, 4]. A detailed study of the short period variability helps clarifying the formation mechanisms of the observed anomalies and to better understanding the mechanisms of nepheloide layering observed in submarine canyons [5].

A mooring was deployed at the depth of 808 m at the canyon axis on March 23, 2012. The mooring system included two AANDERAA RCM current meters with Seapoint turbidimeters at fixed depths: one below the subsurface floatation at the depth of 42 m and the other one at 4-5 m above the bottom anchor. An "Aqualog" profiler (prototype from P.P. Shirshov Institute) moved down and up at 0.17-0.18 m/s along the mooring line within the depth range of 60-792 m. The profiling cycles were preprogrammed to start every 4 hours from 16:00 on March 23. The profiler carried one Nortek Aquadopp acoustic Doppler current meter, one SBE 52MP CTD probe and one Seapoint turbidimeter. When the carrier was moving, profiles of pressure, conductivity, temperature and turbidity were measured with a vertical resolution of 0.17-0.18 m, while the vertical resolution of the current velocity and the acoustic backscatter was about 1.05 m. The profiler operated until 14:00 of April 3. The total profiled length was about 92 km.

Comparison of the current meter data obtained by the profiler at the topmost profiling depth with those of the upper RCM showed very good correlation both for the current speed and direction. The current speed usually differed by less than 0.02 m/s within the subsurface layer at 40-80 m depth. The current structure of the bottom layer was much more complex. No evidence of the bottom Ekman spiral was observed; at 790-792 m and 803-804 m, the currents were usually directed coherently either northwestward or southeastward. The upper layer dynamics was dominated by inertial oscillations. In the pycnocline at 300-600 m depth, interpycnocline eddies were observed at a time scale of about 2 days. The nepheloid structure became evident in the acoustic backscatter profiles. It should be noted that the vertical distribution of the acoustic backscatter was in agreement with the turbidity profile, being at minimum in the cold intermediate layer. The lower boundary of this layer underwent huge oscillations with amplitude of up to 250 m (Fig.1,2). The amount of the sound backscatterers suspended in the water was usually largest at 400-600 m. In one occasion the eddy carried a large amount of particulate matter from the near-surface layer throughout the deep sea. Several times the amount of the suspended sediments increased for 12 h or so at 600-800 m depth.

The obtained results allow to better understanding the nepheloid layers forming processes in the submarine canyons of the NW Mediterranean.

THE LIGURIAN DISPERSION EXPERIMENT 2010 (LIDEX10): SATELLITE, DRIFTER AND GLIDER PRELIMINARY RESULTS.

Elena Mauri [1]*, Riccardo Gerin [1], Isaac Mancero [1] and Pierre-Marie Poulain [1]
[1] OGS, Borgo Grotta Gigante, 42/c, Sgonico, Trieste, Italy - emauri@inogs.it

Abstract
Surface drifters and a glider with physical and biogeochemical sensors were deployed in the southern Ligurian Sea in July 2010 to study the surface dispersion and explore the mesoscale and submesocale 3D features associated with it. Following the drifters, the glider sampled the southern Ligurian Sea and the Corsica Channel. The drifter and glider data were analysed in concert with MODIS surface temperature and chlorophyll concentration satellite maps. The sampled coastal and open sea areas showed different behaviours. The shallow area near the Italian coast was characterised by an offshore-flowing filament evolving quite fast while the open sea, close to the Corsica coast, was dominated by mesoscale gyres with longer time evolution.

Keywords: Ligurian Sea, Mesoscale phenomena, Ocean colours, Hydrography

Introduction
During the LIgurian Dispersion EXperiment (LIDEX10) performed in the southern Ligurian Sea and the Corsica Channel, between 3 and 21 July 2010 a Slocum glider was deployed in conjunction with low-cost satellite-tracked CODE drifters. The main focus of the experiment was to contribute the understanding of the surface dispersion in a coastal area. In this work the shallow area and the open sea mesoscale features are described using MODIS (Moderate Resolution Imaging Spectroradiometer) satellite images, glider and drifter data.

Materials and Methods
In the framework of the LIDEX10 experiment [1], small clusters of drifters were released in the vicinity of a front associated with the Arno River Plume to study the properties of local submesoscale to mesoscale dynamics. The drifter deployment locations were fine-tuned by using the information derived from in-situ CTD casts, the MODIS satellite images and the outputs of a circulation model. A shallow (200-m) Slocum glider was deployed in the vicinity of the drifters and was piloted for the first 18 days of the experiment. Frequent surfacings and continuous route modifications were performed to steer the glider in order to collect nearly contemporaneous information of the water column below the majority of drifters. The glider sampled temperature, salinity, oxygen, CDOM fluorescence and backscatter at 553 and 880 nm along the water column between the surface and 200 m depth. Diurnal MODIS chlorophyll concentration (Chl) and nocturnal Sea Surface Temperature (SST) data, with 1 km nominal resolution, were downloaded from the NASA dedicated web page. They were mapped and projected to obtain images of Chl and SST. Glider and drifter tracks and daily track segments were overlaid on the respective daily images in order to illustrate the motion of the mesoscale features.

Results
The 18-day drifter tracks show a clockwise current starting in front of the Arno River mouth, following the Italian cost and then heading west, north of Elba Island. Chl images show filaments detaching from the coasts partially followed by the drifters. The glider was steered to sample some of the mesoscale features. Fig.1 displays a MODIS Chl image on 12 July 2010 superimposed with the drifter (white) and glider (blue) tracks for the entire campaign. Temperature, salinity and oxygen distributions show two different environmental characteristics: 1) One more coastal with lower salinity at the surface originating from the Italian rivers Arno and Cecina. Satellite images show the rapid evolution of the filaments marked by high optically active components in the surface water. 2) A more open sea environment characterised by a vein of low salinity probably due to the AW (Atlantic water) intruding in the basin from the south (Fig.2). Several small eddies are evidenced in the satellite Chl and SST images close to the Corsica coast. The signal of the mesoscale structures is also captured in the glider data with higher temperature, lower salinity and oxygen than the surrounding waters. From the analysis of the SST images the entire campaign was characterized by a gradual increase of SST also present in the glider data. An intrusion of relatively cold water north of Corsica is also evident in conjunction with a lower satellite-derived Chl. The CDOM concentration in the entire basin is lower in the upper 50-m layer than in the deeper area, while the backscattering at 880 nm seems higher close to the bottom in the shallow costal area due to the re-suspension and below the filaments detached from the coast.

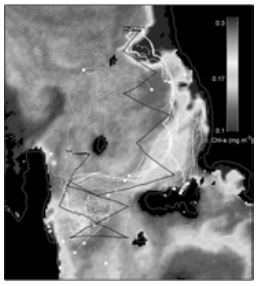

Fig. 1. MODIS Chl image on 12 July 2010 with drifter tracks (white) and glider tracks (black) overlaid for the entire campaign.

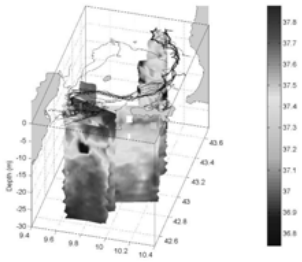

Fig. 2. 3D plot of the salinity sampled by the glider and drifters tracks during the entire campaign zoomed between 0 and 30 m depth.

FIRST CTD MEASUREMENTS WITH TOWED UNDULATING VEHICLE IN CROATIAN COASTAL WATERS

Zoran Pasaric [1]*, Iva Medugorac [1] and Mirko Orlic [1]
[1] Andrija Mohorovicic Geophysical Institute Faculty of Science, University of Zagreb - pasaric@irb.hr

Abstract
Quasi-synoptic 3D measurements of hydrographic properties are performed in the vicinity of the Cetina river mouth (16º41'E, 43º26'N) at the eastern Adriatic coast. The shallow fresh-water plume slightly warmer than the surrounding sea is revealed. The plume is surface-advected rather than bottom-advected, with anticyclonic, cyclostrophic gyre formed in front of the mouth and a narrow coastal current extending downstream.

Keywords: Coastal waters, River input, Salinity, Temperature, Central Adriatic Sea

Detailed hydrographic measurements were performed on 5 September 2012 in the Middle Adriatic coastal area in front of the Cetina river mouth (Figure 1). The river itself is of major importance for various human activities including water supply, agriculture and electric energy production. Its natural hydrological-cycle regime at the lower part of watercourse is significantly changed by numerous hydrotechnical works including several power plants and reservoirs. Because of prolonged stay in reservoirs, the water at the river mouth is warmer in summer than it would be in natural conditions. The average outflow into the sea, strongly controlled by the electricity production, is slightly above 100 m^3/s. From the river mouth the sea bottom sharply slopes to form a wide plateau at a depth of some 50 m.

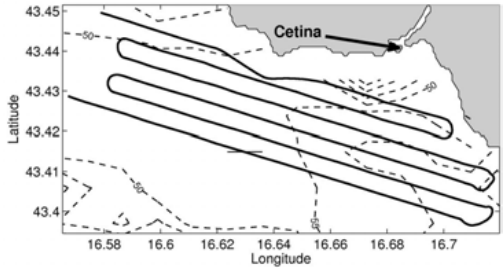

Fig. 1. The ship path (full) and the bottom depth (dashed).

The measurements were preformed by towed, light weight, computer controlled undulating vehicle (manufactured by Sea Sciences Inc.). The towing speed was 5 knots with undulations covering the water column from near surface to some 35 m depth. With 4 to 5 undulations per kilometer, typical horizontal resolution was about 200 m along the ship track. In present application the payload included only the SBE 49 CTD probe. With sampling rate of 16 Hz the vertical resolution was typically better than 0.1 m. Time, GPS position, the vehicle and bottom depths, temperature and conductivity were monitored and continuously recorded by on-board computers in real time. The ship path is shown in Figure 1. The survey covered the area of some 11 by 2.5 km, with approximately 500 m between along-shore passes.

Basic check revealed excellent data quality with only one few-second gap in more than 7 hour long record. As a first step, thanks to the high vertical resolution, all the data are linearly interpolated at regular depths (every 0.1 m) along the vehicle path. Subsequently, the whole water column is divided into 1 m thick layers. Averaging is performed within each layer resulting in a nearly regular 2D grid, depending on where the vehicle path intersects particular layer. The first layer is discarded due to reduced raw data availability close to the surface. Finally, triangle-based linear interpolation is performed in each layer separately, resulting in regular 3D grid of all quantities.

The Cetina plume is shown to be relatively shallow, extending approximately 5 m below the surface (not shown). It is seen as a water mass of reduced salinity and slightly increased temperature in comparison with the surrounding sea water. It is the salinity that has the dominant influence on the density (Figure 2). The plume is obviously surface-advected rather than bottom-advected, the equilibrium depth being much smaller than the coastal-wall depth [1]. The distribution of properties at a depth of about 5 m suggests that there is an anticyclonic, cyclostrophic gyre in front of the Cetina mouth and a narrow coastal current extending in the direction of Kelvin wave propagation, the inertial length scale being larger than the width of river mouth [2].

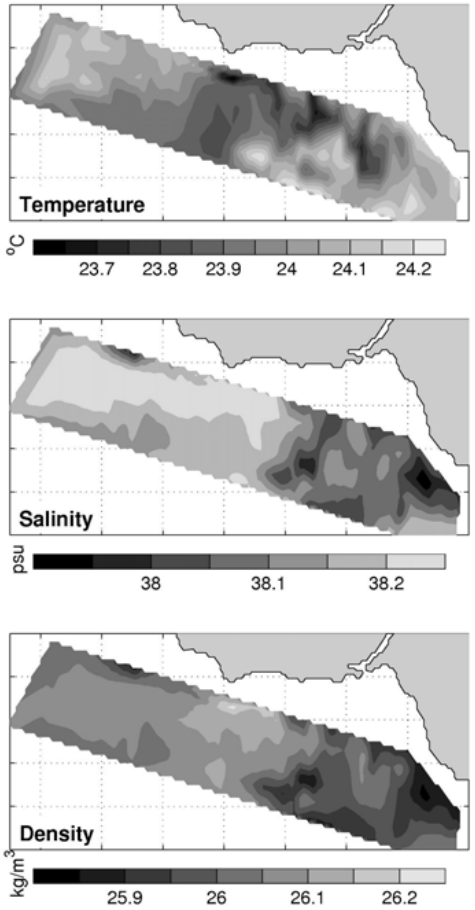

Fig. 2. Temperature (top), salinity (middle) and density (bottom) at 4-5 m depth.

SATELLITE AND FIELD OBSERVATIONS OF A SEA SURFACE COLD FILAMENT OFF CAPE PASSERO (SOUTH OF SICILY, CENTRAL MEDITERRANEAN SEA)

Ettore Salusti [1]* and Francesco Bignami [1]
[1] ISAC-CNR - ettore.salusti@gmail.com

Abstract
We here analyse thermal satellite images, Quik SCAT wind data, CTD and ADCP transects crossing a cold filament off Cape Passero, the southern tip of Sicily, sampled during the SYMPLEX 99 cruise (November 1999). Its width is ≈ 25 km, its length is ≈ 200 Km, the lateral thermal anomaly is $DT \approx 2$ °C and it is seen to be mostly flowing over a 100-120 m deep sea bottom. It is best identified by its temperature low values in the filament core (upper 50 m), with outcropping isothermals, but also its salinity and bottom turbidity data are of interest. It shows weak along-flow widening, indicating low entrainment of surrounding waters. Among other effectes, this supports the idea that filaments has to be seen as a set of streamlines of high potential vorticity.

Keywords: Currents, Sicily Channel, Mesoscale phenomena, Coastal processes

INTRODUCTION

Cold filaments are short-lived dynamical structures which are characterized by properties (salinity, temperature,..) that may significantly differ from the adjacent waters. They have the shape of elongated shelf-rooted tongues and are generally governed by non-linear dynamics. The fillament space scales are about 100-300 km in length, 10-20 km in width, 30-50 m in thickness while the resulting time scales are of one-two weeks and typical geostrophic velocities are 10-50 cm/s. We here analyze one among the cold filaments observed off the southern tip of Sicily (Cape Passero) in the Channel of Sicily (Central Mediterranean Sea), sampled during the SYMPLEX 99 cruise (24 Oct. – 6 Nov. 1999). Satellite thermal images in relation with Quik SCAT wind data, and 84 CTD and a few ADCP transects, crossing this cold filament, allow us to investigate its peculiar dynamics.

IN SITU HYDROLOGIC OBSERVATIONS

Conductivity, temperature, and pressure were recorded at 32 Hz and logged on nine-track tape at sea. Absolute calibration of salinity is based upon in situ bottle sampling while temperature calibration is based upon measurements from reversing thermometers . Significant relative changes for temperature and salinity are conservatively estimated to be 0.01 °C and 0,001 respectively. During post-cruise processing conductivity data are filtered with a low-pass digital filter with an effective analog time constant of 0.1 s. This time constant was found to minimize salinity spiking in most sections of the records, although some residual spikes remain.

Hydrologic transects:

Among more than 212 CTD stations of the SYMPLEX 99 cruise, we focus our attention on 5 east-west transects. The northernmost transect is called A (~ 36° 20' N). The second is B (~ 36° 00' N), then C (~ 35° 40' N), D (~ 35° 40' N) and finally E (~ 35° 00' N). Although some of the A-E transects cross only partially the filament, all are nevertheless analyzed here to teach some insight on the filament evolution. We here discuss just one among these transects the nearest to Sicily.

Transect A The maximum sampling depth of CTD casts is 3490 m. Such casts where made between 14° 44' and 15° 47' E (with an average spacing of 18 Km). The overall salinity field has a complicated structure with local maxima and minima. In addition a rather sharp shelf-trapped salinity front (15° 15 ' and 15°.30' N) confines the Ionian waters to the east of the shelf break. The intersection of the filament and the CTD transect has a salinity absolute minimum S = 37.27 (at z ~ - 32 m and 15° 00' E) in a larger patch characterized by S < 37.76. This salinity core is trapped over a shelf only ~ 100 deep. The surface salinity is as low as 37.79 over the filament core and increases to 37.80 -37.83 in the adjacent stations. The temperature of the filament centre is ~ 18.63°C. The transect A surface temperature is minimal ~ 22.79°C in station 007, ~ 20 Km east the salinity core. Then it increases to 23.43-23.66°C in the surface of adjacent stations. At 40-100 m depth one has a temperature front around 15°.22' E, but near the salinity core one has a rising of the isotherms of ~ 20 m for T = 17.94°C and 50 m for T = 14.60°C at 100-150 depth. Finally the density has a more regular behaviour, that reminds that of T since the water is mainly thermally stratified. The density of the filament core is ~ 28.86 where dissolved oxygen is 5.23 ml/l. Deeper than 100 m, at ~ 15° 20' E there is again a front while in the 0-100 m surface layer density increases slightly towards East. Around 40-50 m depth the density is 27.09 , slight larger than in the adjacent stations. The isopycnals also show a mild uplift of ~ 10 m in the salinity core region, such that the integral of such excess density at station 007 between the sea surface and the salinity core is ~ 5.2 m.

In synthesis from these observation we see a cold surface filament, most flowing over a 100-120 m deep sea bottom, contored by fresher MAW masses, then it flows following the general circulation. Along the region of our observations, it is characterized by a small evolution of its hydrologic characteristics, which supports its identification with a set of high potential vorticity streamlines, a kind of particularly stable and regular flow, which analysis finally is the goal of this study.

ON THE RELEVANCE OF TIDAL FORCING ON THE SIMULATED MEDITERRANEAN TERMOHALINE CIRCULATION

Gianmaria Sannino [1]*, Adriana Carillo [1] and Cristina Naranjo Rosa [2]
[1] ENEA-UTMEA-CLIM ROMA - gianmaria.sannino@enea.it

Abstract
An eddy-permitting tidal model of variable resolution is implemented covering the whole Mediterranean Sea. The good agreement found between the model circulation and most of the available observations confirms both the robustness and effectiveness of the grid refinement technique. The effects produced on the Mediterranean circulation by the tidal forcing are investigated through the comparison of two simulations differing only in the presence of the tidal forcing. Even though the main characteristics of the thermohaline circulation appear similar in the two simulations, some quantitative and qualitative differences are observed: the main differences found in the Strait of Gibraltar propagate into the whole basin, have an impact on the water column stratification, and consequently on the convection events.

Keywords: Tides, Circulation models, Circulation experiments, Water convection, Gibraltar Strait

The Mediterranean Sea is a semi-enclosed basin displaying an active thermohaline circulation (MTHC) that is sustained by the atmospheric forcing and controlled by the narrow and shallow Strait of Gibraltar (hereinafter SoG). Within the SoG the MTHC takes the form of a two-way exchange: an upper layer of fresh and relatively warm Atlantic water spreads in the Mediterranean basin, and a lower layer of colder and saltier Mediterranean water sinks as a tongue in the North Atlantic at intermediate depths. The interaction between the intense tidal forcing (Candela et al. [1990]) and the complex geometry of the SoG influences the two-way exchange via hydraulic control (Bryden and Stommel [1984], Sannino et al. 2009). The exchange is subject to vigorous mixing and entrainment (Wesson and Gregg [1994]) as well as intermittent hydraulic controls over the main sills and in its narrowest sections (Sannino et al. [2007, 2009]). In the last 15 years several numerical models were implemented to reproduce and understand the Mediterranean circulation and its variability. The main features were reproduced by coarse resolution models, characterized by a horizontal grid space of 20–25 km. Further understanding regarding the physical mechanisms driving the mesoscale variability of the Mediterranean circulation has been achieved only recently by means of eddy-permitting/resolving models having a horizontal grid space spanning from 5 to 15 km. However, even in the last aforementioned modelling studies the horizontal resolution cannot be yet considered sufficient to fully reproduce the physical mechanisms of the two-way exchange of the SoG. In most of the previous models the Strait is approximated by a rectangular pipe having a cross-section wider than the real dimension, in general more than double, and a flat bathymetry. Moreover, none of the previous models took into account explicit tidal forcing. In this work, we investigate the effects produced on the simulated MTHC by the explicit application of tidal forcing. To this end, results from two numerical experiments reproducing the actual climate conditions, performed with and without tidal forcing are presented, and their differences discussed. The numerical model used for the present work is based on the MITgcm. The model domain extends over the entire Mediterranean Sea including the Gulf of Cadiz at west in the Atlantic Ocean. It is covered by a nonuniform curvilinear orthogonal grid characterized by a maximum horizontal resolution of about 1/200°reached in the SoG. From the Strait the resolution smoothly degrades toward 1/16° in the rest of the model domain. Such a model configuration represents a novelty respect to any other model implemented in the same region in the past. To adequately resolve the dynamics of the different water masses in the Mediterranean 73 vertical z-levels were used. They are unevenly spaced and have a thickness ranging from 3 m at the surface to 300 m at the ocean bottom. The depth of the first level is 1.5m and that of the deepest is 5300 m. In order to properly represent the hydraulic behavior of the Strait as suggested by Sannino et al. (2007, 2009) the model includes also the tidal forcing, both internal (equilibrium tides) and lateral (coming from the western open boundary). The inclusion of tidal forcing in a fully baroclinic Mediterranean model represents another novelty respect to any other model implemented in the same region in the past. The model is forced at the surface through the specification of wind stress and heat fluxes from the ERA40 reanalysis database provided by the ECMWF. The general surface and the intermediate circulation given by the models reproduced quite well the main features of the basin-scale circulation. The simulated volume transport through the main straits and channels of the Mediterranean were in good agreement with most of the available in situ observations. The hydrographic analysis of the model results revealed that the characteristics and the distribution of salinity and temperature in the basin were in good agreement with observations. However, even though the main characteristics of the MTHC appeared similar in the two simulations, some differences were observed. The tidal simulation represented in a realistic way the two-way exchange in SoG in terms of mixing, fluxes and velocity fields. This influenced the characteristics of the inflowing MAW and outflowing MOW in terms of thickness and depth profiles; in particular the MAW was thinner, shallower and faster in the tidal experiments. These differences propagate into the whole basin, having an impact on the water column stratification, and consequently on the characteristics of the main convection events.

VERTICAL AND HORIZONTAL MIXING ESTIMATES THROUGH A LAGRANGIAN EXPERIMENT IN THE NORTH AEGEAN

Elina Tragou [1] and Vassilis Zervakis [1*]
[1] Department of Marine Sciences University of the Aegean - zervakis@marine.aegean.gr

Abstract
The vertical and horizontal turbulent diffusion coefficients in the mixed layer can be estimated via Lagrangian sampling. Our method is tested on data taken during a Lagrangian experiment aiming to record Black Sea water outflowing in the North Aegean, in April 2008. Hydrographic records from drifters, CTD and thermosalinograph are combined to assess the temporal rate of change of water properties, as well as their spatial gradients on a Lagrangian frame of reference. The method gave vertical eddy diffusivities ranging from 10^{-3} to 10^{-2} m^2 s^{-1}, and horizontal diffusivities ranging from 10^3 to 10^4 m^2 s^{-1}.

Keywords: Circulation experiments, Turbulence, Aegean Sea

Assessment of the horizontal and vertical mixing in the ocean is not trivial. Horizontal mixing requires either the measurement of the relative dispersion from drifter clusters [1], or the evaluation of absolute dispersion via the estimation of Lagrangian decorrelation scales of long drifter tracks [2]. Vertical mixing requires either the direct measurement of vertical shear of horizontal velocity using expensive and demanding microstructure profilers, or the indirect assessment through either budget estimates [3] or density overturn analyses [4]. In this work we present a method to assess both horizontal and vertical mixing simultaneously, through fast sampling of the horizontal and vertical distribution of hydrographic characteristics in the vicinity of a Lagrangian drifter, and the temporal evolution of these properties. A Lagrangian experiment was scheduled aiming to record the evolution of the surface plankton community in the Black Sea waters outflowing in the Aegean Sea [5]. In such an experiment, Lagrangian sampling is preferred to Eulerian, due to the absence of hard to measure advection terms. In the case of a Lagrangian frame of reference, advection is not an issue; the fluxes involved in modifying hydrographic and biogeochemical properties correspond to turbulent lateral and vertical mixing. Thus, a carefully planned Lagrangian experiment would be based on recording (a) the temporal evolution of properties following the same water body and (b) the horizontal and vertical gradients affecting the turbulent fluxes. In the April 2008 experiment a drifting sediment trap and a surface drifter were released in the Black Sea outflow and followed a nearly circular path around an anticyclone in the North Aegean. The R/V Aegaeo followed a meandering path around the drifter tracks, thus recording the horizontal gradients of T/S properties in the surface layer. The horizontal information was gridded to provide estimates of horizontal gradients along the path of the drifters. Vertical gradients were recorded via successive CTD casts during periodic sampling at the drifter positions. Air-sea fluxes were determined using direct measurements from the Poseidon buoy at the Athos site, to the northwest of Lemnos island. Thus, the equations of heat and salt in the surface mixed layer, balancing the rate of change of temperature and salinity to the divergence of air-sea and turbulent fluxes, define a linear system which can be solved for the vertical and horizontal diffusivities, K_v and K_h respectively.

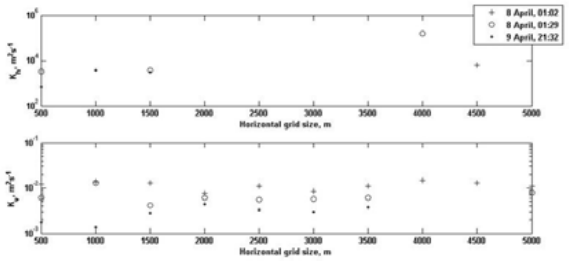

Fig. 1. Sensitivity test results for horizontal (top) and vertical (bottom) eddy diffusivity estimates as a function of spatial grid cell-size in assessing horizontal gradients.

Applying the above method to our observation gave estimates of K_v ranging from 10^{-3} to 10^{-2} m^2 s^{-1}, and K_h from 10^2 to 10^4 m^2 s^{-1}, with one extreme value of 10^5 m^2 s^{-1}. We should note here that the horizontal diffusivity values in particular depend on the scale of the horizontal T and S gradient estimation, as revealed by the sensitivity test's presented in figure 1. Missing horizontal diffusivity estimates on the above figure correspond to negative diffusivity values, i.e. areas of converging flow. This is not surprising for this area, as it is mainly characterized by strong thermohaline frontal features between adjacent water masses of distinctly different temperature and salinity properties.
An experiment was also performed excluding the air-sea fluxes from the heat and salt equations. The results were very similar to the present ones, indicating the minor role of air-sea exchanges in the evolution of the thermohaline properties of the surface layer for this particular stage of Black Sea outflow in the Aegean. However, it should be noted that the experimental period was very mild in terms of weather and fluxes were rather weak due to the transition from winter to summer conditions.

THE FLOW FEATURES OF THE SE LEVANTINE-LONG TERM IN-SITU MONITORING 1995-2012

G. Zodiatis [1]*, D. Hayes [1], I. Gertman [2], P. Poulain [3] and M. Milena Menna [3]
[1] Oceanography Center University of Cyprus - gzodiac@ucy.ac.cy
[2] 2Israel Oceanographic and Limnological Research
[3] 3Istituto di Oceanografia e Geofisica Sperimentale

Abstract
The knowledge of the hydrodynamic features of the Levantine substantially increased during the POEM cruises. The hydrographic survey of the area between 1995-2012, during the CYBO and HaiSec cruises, along with data from CYCLOPS, MSM/14 and from floats, drifters and gliders (NEMED,YPOKINOUMODA,GROOM) have provided insight on the flow features in the SE Levantine. Namely, the two eddies of Cyprus and Shikmona, and the offshore cross basin flow jet (MMJ). It is well-documented that the Cyprus eddy is the most influential feature in the area, while the generation of the Shikmona eddy was observed for the first time and with the Shikmona gyre to re-established during periods when the above eddies co-exist.

Keywords: Hydrography, Circulation, Levantine Basin

Preface The general anticlockwise circulation along the coastline of the Eastern Mediterranean Levantine was first proposed by Nilsen [1], while half a century later Ovchinnikov et. al . [2], during several cruises between 1960s and 1970s, showed a similar schematic of the circulation, enriched with sub-basin flow structures, such as the Rhodos gyre. In 1980s, during the cruises of POEM group [3], it was first defined a more detailed structure of the circulation, consisted by several alternative cyclonic and anticyclonic eddies and gyres and an offshore cross basin jet named as the Mid Mediterranean jet-MMJ. Moreover, the Shikmona gyre was defined as a non-permanent multi-pole gyre, consisted by three eddies, of which the Cyprus warm core one the most well pronounced [4]. With the development of the ocean predictions-hindcasts and the possibility of assimilation of in-situ and satellite data, the Mediterranean Forecasting System-MFS depicted an improved pattern of the circulation in the Eastern Mediterranean Levantine, showing the co-existence of the anticlockwise along shore and the offshore cross basin currents [5]. The same period Millot and Taupier-Letage [6] using SST satellite imagery arguing a simplifier flow pattern similar to that proposed by Nilsen [1]. The present work aims to provide new strong evidence about the circulation in the Eastern Mediterranean Levantine Basin, using high spatial resolution synoptic in-situ data obtained the last 10-15th years from various in-situ observing platforms, such as ship cruises, gliders and floats missions, XBTs, drifters. **Discussion and Results** Renewed in-situ investigations in the South-eastern Levantine Basin, in the framework of CYBO, MFSTEP, CYCLOPS, HaiSec, YPOKINOUMODA, MSM/14, GROOM, NEMED made possible to give new strong evidences about the seasonal and inter-annual fluctuation of the MMJ, the Cyprus warm eddy variability, the Shikmona eddy generation and the periodical re-establishment of the Shikmona gyre [7,8,9]. The long term seasonally collected in-situ data sets reveal that the dominant flow features in the SE Levantine is the Cyprus warm core eddy, that undergoes significant seasonal and inter-annual fluctuations in terms of its shape, size, intensity and location. Moreover, it was found the establishment of a secondary warm eddy in the most SE part of the area, the Shikmona eddy, during periods when the Cyprus eddy became weaker, as was shifted westward or southward from Eratosthenes SM and when the strong northward current, flowing usually along the Israel-Lebanese coast, becomes unstable. The latter is evidently also from the drifters trajectories, gathered by the NEMED project showed that this eddy is detached away from the northward current towards the area of the secondary eddy, as observed by CYBO cruises. During theses long term observing campaigns-missions it was found periodically the re-establishment of the Shikmona gyre, when the co-existence of the Cyprus and Shikmona eddies were observed, particularly, during certain short periods, which are related to the mechanism of the generation and destruction of the warm core eddies circulated within the Shikmona gyre, when is present. The pathway of the AW in the area, especially along the northern periphery of the Cyprus warm core eddy provide an additional evidence about the MMJ been a cross basin current. The in-situ data sets obtained in the SE Levantine from 1995-2012, provide a clear definition of the mesoscale variability of the circulation in the SE Levantine, where: a) the Cyprus and Shikmona eddies, as well the MMJ are the dominant flow features; b) the Cyprus warm eddy undertakes strong spatial and temporal variability; c) the variability of the spatial displacement of the Cyprus warm eddy affects the MMJ and the eastward transfer of the AW; d) The Shikmona eddy found to be established for certain periods when the Cyprus warm eddy shifts to the west, south-west; e) the MMJ flows along the northern periphery of the Cyprus warm eddy and is the major current transferring the AW in the area and f) close offshore to Egypt there is a westward re-current too.

SEA SURFACE CURRENTS BY HF RADAR IN THE MALTA CHANNEL

A. Drago [1], J. Azzopardi [1], A. Gauci [1], R. Tarasova [1], G. Ciraolo [2], F. Capodici [2], S. Cosoli [3]* and M. Gacic [3]

Abstract
An HF radar observing system composed of CODAR SeaSondes is providing real-time surface current pseudo-Eulerian maps every hour in the strip of sea dividing Malta and Sicily. This initiative forms part of the CALYPSO project that aims to support the efficient response against marine oil spills in this busy area of maritime transportation in the Mediterranean. Besides servicing Maltese and Sicilian public entities responsible for civil and environmental protection, surveillance, security and response to hazards, the HF radar data are also shedding distinctive information on the surface circulation variability in the area at meso and seasonal scales.

Keywords: Circulation, Malta Channel

In a joint effort conducted by Maltese and Sicilian partners, the CALYPSO project is funding the setting up of an HF radar network to monitor sea surface currents in the Malta Channel. The two radar units on the Malta side, at Ta' Sopu in Gozo and Ta' Barkat in Malta, are already in operation since Summer 2012, while a third unit at Pozzallo harbour will be added to complete the coverage closer to the Sicilian coast. The CALYPSO radar network engages the latest technology to extend the coverage performance with use of multi-static data processing software at the radar site in Malta. In combination to numerical models, the radar data are intended to primarily support applications to optimise intervention in case of oil spill response as well as to endow tools for search and rescue, security, safer navigation, improved meteo-marine forecasts, monitoring of sea conditions in critical areas such as proximity to ports, and better management of the marine space between Malta and Sicily.

The spatial coverage and high temporal resolution of the HF radar data collected since September 2012 is permitting a unique and detailed characterization of the surface circulation in the Maltese shelf area. The data are organized in time series of hourly averaged velocity vectors at each radar measurement grid point on a regular spatial matrix of 47 x 40 points spanning 13.84356º to 15.37942ºE in longitude and 35.7454º to 36.7988ºN in latitude. Statistical diagnostics include the mean flow, the variance, the mean kinetic energy and the eddy kinetic energy at each grid point calculated over different time scales, and combined in space by means of pseudo-Eulerian 2D plots for each statistical parameter. Fig. 1 shows the mean surface circulation over the period September 2012 to March 2013, confirming the presence of the energetic and meandering Atlantic Ionian Stream (AIS) [1] in the central part of the channel, characterised by currents reaching 30-40 cm/s, and directed towards SE as it exits into the Ionian.

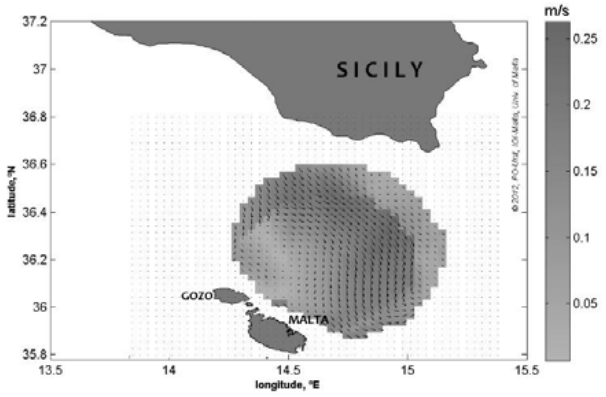

Fig. 1. **Mean surface velocity field (Sept 2012 – Mar 2013)**

The circulation in the Malta Channel and sea around the Maltese Islands is characterized by a strong mesoscale variability that has been studied by numerical models [2]; the eddy field component is significant and is known to depend both on internal dynamical processes as well as on the influence of the synoptic scale atmospheric forcing [3]. The fine grid resolution of the radar data permits a detailed representation of these main mesoscale signals. Substantial eddy field structures are generated along the AIS and over the shallow bathymetry in particular around the Maltese Islands. Besides trapping water and particulates, these eddies have associated vertical motions that influence phytoplankton biomass distributions and thus bear important links to biological processes, in particular to the location of fisheries. When the AIS flow shifts closer to the island (Fig. 2(1)) the SE flow is particularly intense. The currents closer to the coast tend to swerve against the SE tip of Malta as a swift flow; the currents further offshore continue to flow away from Malta. When the AIS vein is displaced away from the coast, a mesoscale anticyclonic eddy formation comes into action and tends to reverse the flow to a NW direction closer to the coast (Fig. 2(2)). These eddy formations can become even more complex when the AIS is weaker.

OIL SPILL RISK ASSESSMENT ON THE MALTESE COASTAL AREAS

A. Gauci [1]*, A. Drago [1], J. Azzopardi [1], A. Deidun [1] and A. Bonnici [1]
[1] University of Malta - adam.gauci@um.edu.mt

Abstract
A significant percentage of the global oil transport goes through the Mediterranean sea. Most of the maritime traffic carrying oil and other dangerous liquid substances travels across the Malta Channel. The risk of marine spillages within the stretch of sea between Malta and Sicily is very high and beaching on the Maltese shores can cause irreversible environmental damage at the detriment of important economic resources. The aim of this work is to determine the probability and volume percentage of oil that would reach the coast in case of an accident in the proximity of the Maltese Islands. Various spill scenarios are considered to get a realistic estimate as much as possible.

Keywords: Models, Malta Channel, Circulation models

In this work the MEDSLIK Oil Spill Model is used to perform an assessment on the vulnerability of the Maltese coast to potential impacts of marine oil spillages. Although similar risk analysis have been performed in other regions, quantitative assessments are still lacking for the Maltese Islands. Moreover, such studies necessarily rely on the availability of data that can well represent meteo-marine conditions in the area. In this study, data derived from marine and atmospheric models run by the Physical Oceanography Unit of the University of Malta over a period of one whole year was used. A regular grid of points representing spill origins around the Maltese Islands was considered (Figure 1). Simulations each of 120 hours duration (5 days) were run for every point for every day for the year 2011 (365 days), and 500 tons of light oil was assumed to instantaneously leak at midnight for each simulation. The oil spill vulnerability index was set on the basis of the spill origin, the location of beaching, and the time taken for the oil to reach the coast.

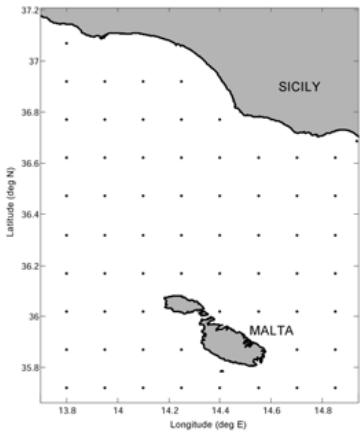

Fig. 1. Points on a regular grid considered for oil spill origin in the simulations.

For each oil spill simulation, the percentage of oil reaching the coast was determined. In order to have a clearer indication of the damage and the effected resources, the coastline regions corresponding to major bays, ports, reverse osmosis and fish farms were initially identified and treated separately. Such areas cover most of the important Northern and Southern regions of the main island (Malta), the smaller island Gozo as well as Comino (Figure 2). The MEDSLIK input files consist of averaged fields updated every 6 hours and describing the marine conditions produced by the ROSARIO96 forecasting system. These fields extend over the Malta Shelf Area, with a spatial resolution of 1/96°, and prepared operationally through the daily re-initialization from the Sicily Channel Regional Model (SCRM) that produces daily averaged forecasts with a resolution of 1/32° [1]. Surface forcing is derived from the hourly high resolution forecast fields by the SKIRON atmospheric model which is run on a daily basis by the University of Athens [2].

Before carrying out the risk assessment analysis, the performance of the MEDSLIK oil spill model was validated. The ROSARIO96 forecast sea surface currents were compared to vectors recorded by the HF radar network that was recently installed in the region as part of the CALYPSO project [3]. The trajectory module of MEDSLIK was also used and the results were compared with the recorded and transmitted positions of six MetOcean iSVP drifters. Such equipment was deployed in the Malta Sicily in December 2012 as a joint effort between CALYPSO, the Argo-Italy programme [4] and the WP3 of the EU FP7 SIDERI project [5].

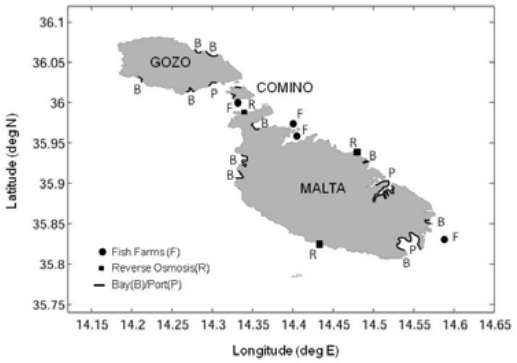

Fig. 2. Location of bays, ports, reverse osmosis and fish farms on the Maltese Islands.

A large number of runs were required and although script files were written to automate the process, the MEDSLIK model still needed a reasonable time to run simulations over the required timelines. The regions that are most prone to oil spill impacts were determined on the basis of the percentage of beached oil. The coastal sea area around the Maltese Islands was divided into regions and the typical timeframe for a spill within each region to reach the coast was determined.

DESCENTE D'ÉCHELLE DES MODÈLES DE CIRCULATION OCÉANIQUE VERS LES MODÈLES CÔTIERS PAR RAPPEL SPECTRAL.

Gaelle Herbert [1]*, Pierre Garreau [1], Franck Dumas [1] and Valérie Garnier [1]
[1] IFREMER/ centre de Brest DYNECO/PHYSED - gaelle.herbert@ifremer.fr

Abstract
L'efficacité du "rappel spectral" est évaluée en utilisant un modèle hydrodynamique (MARS3D) forcé par un modèle de circulation générale (MFS/MOON). Cette technique permet de réduire les dérives entre le modèle global et le modèle régional, aux échelles de la circulation globale. Pour cela, la température et la salinité du modèle régional sont spectralement rappelées vers la solution du modèle global en intégrant un terme de rappel dans les équations des traceurs. Afin d'estimer les paramètres de rappel les mieux adaptés, plusieurs simulations-test sont effectuées en Mediterranée. Les champs de salinité et température sont ensuite confrontés aux observations. Les résultats montrent que le rappel spectral est capable d'atténuer les erreurs de la circulation grande échelle sans réduire de manière significative l'activité méso-échelle.

Keywords: Circulation models, North-Western Mediterranean, Coastal models

Les systèmes d'analyse et de prévision à haute résolution (i.e sub kilométrique) pour l'océanographie côtière comme PREVIMER couvrent des régions limitées de l'océan et sont de ce fait imbriqués dans des systèmes hauturiers globaux à plus basse résolution (typiquement de 3 à 10 km). Dans un contexte opérationnel il est cependant essentiel de maintenir la cohérence entre les solutions hauturières et côtière au cours du temps pour assurer aux utilisateurs des systèmes un continuum côte/large. Par ailleurs, un maintien de cette cohérence à faible coût permettra de se passer, dans les systèmes côtiers, d'assimilation de données contrôlant la circulation à grande échelle, cette circulation étant bien contrôlée dans les systèmes hauturiers. En sciences de l'atmosphère, [6] et [7] décrivent des méthodes pour le downscalling d'une solution globale sur des modèles à aires limitées et démontrent la possibilité de conserver un accord statistique entre solution globale et locale. En Océanographie physique, on ne trouve pas à l'heure actuelle le même genre de démarche. Il existe cependant des approches similaires pour des solutions numériques de cas-test [5] afin d'évaluer finement ce type de méthode ou dans le cadre de modélisations de grande échelle afin d'obtenir des solutions numériques statistiquement en accord avec les observations synthétisées [5] ou non [4] en climatologie.

Dans cette étude nous examinons et évaluons l'usage d'une méthode peu couteuse (i.e sans assimilation de données sophistiquées) : le rappel spectral. La méthode s'appuie sur la méthode semi-prognostique proposée par [1] puis revisitée par [3]. Elle consiste à construire un terme de rappel introduit dans les équations thermodynamiques (rappel sur la température et la salinité) qui influence directement la solution du modèle dans les bandes de fréquence et de nombre d'ondes prescrit, laissant les variations à l'extérieur de ces bandes libres d'évoluer de façon prognostique. Ce terme est construit à partir d'un incrément d'analyse qui, une fois filtré temporellement et spatialement, est réintroduit au cours d'une seconde simulation de la fenêtre temporelle considérée. Le modèle hydrodynamique utilisé est MARS3D (Model for Applications at Regional Scale) développé à l'IFREMER. Le code est décrit en détail par [2]. Le modèle couvre la zone comprise entre 39.5°N – 44.5°N et 0°E-16°E avec une résolution horizontale de 1.2 km. Les conditions aux limites sont issues de la solution globale MFS/MOON qui a une résolution horizontale de 6 km.

Afin d'estimer les paramètres du nudging les mieux adaptés au maintien de la cohérence des systèmes hauturier/côtier, plusieurs simulations-test en mer Méditerranée sont effectuées sur l'année 2010. L'impact du spectral nudging sur le réalisme des solutions numériques est ensuite évalué par comparaisons des champs de T et S simulés aux observations satellites et in situ. La figure 1 montre un exemple de comparaison effectuée entre la SST fournie par le satellite SEVIRI, moyennée sur le mois d'octobre, la SST simulée par l'un des modèles rappelés (pour lequel le spectral nudging a été appliqué) et celle simulée par la simulation équivalente sans rappel (dite "simulation libre"). Les résultats montrent un meilleur accord entre les observations et le modèle une fois le spectral nudging appliqué. En particulier, on observe la disparition du biais chaud dans la région du Golfe du Lion. Par ailleurs, des calculs d'énergie cinétique turbulente ont montré que le spectral nudging n'était pas responsable d'une diminution significative de l'énergie associée aux petites et moyennes échelles.

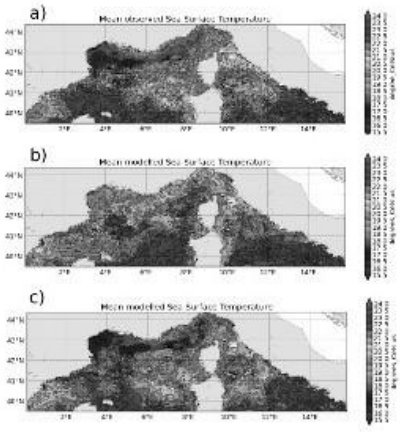

Fig. 1. Moyenne de la Température de surface (°C) sur le mois d'octobre 2010 d'après le satellite SEVIRI (a), le modèle régional MARS3D "libre" (i.e sans rappel spectral) (b) et après application du rappel spectral (fenêtre temporelle choisie: 7 jours) (c).

ESTIMATION OF MEAN DYNAMIC TOPOGRAPHY FROM HF RADAR MEASUREMENTS

Zoi Kokkini [1]* and Vassilis Zervakis [1]
[1] University of the Aegean, Dep. of Marine Sciences - mar01045@mar.aegean.gr

Abstract
Current velocity measurements from a WERA HF radar system are used to estimate Mean Dynamic Topography. The HF radar is installed on the eastern part of Lemnos island, facing the Dardanelles Strait exit in the Aegean, with the aim of monitoring and quantifying the Black Sea outflow into the Mediterranean. A one-year long data set is analyzed in an effort to isolate the barotropic geostrophic component of the flow, as a first step in evaluating the mean dynamic topography.

Keywords: Currents, Aegean Sea, Dardanelles, Surface waters

High Frequency radars have become a major tool in coastal oceanography and monitoring (Paduan and Graber, 1997). The University of the Aegean, in collaboration with the Hellenic Centre for Marine Research, have deployed an HF radar at the eastern coast of the Greek island of Lemnos, facing the Dardanelles exit in the Aegean, in an effort to assess and monitor the Black Sea outflow. The sea-surface circulation in the region east of Lemnos is measured by a four antenna dual site HF WEllen RAdar (WERA) (Gurgel et al., 1999). The radar transmits at a central frequency around 13.45 MHz, and the azimuthal information is retrieved through a direction finding technique. Radial current maps are obtained for 17 minutes and then averaged to produce semi-hourly maps of radial currents .The range of the coverage area is about 70 km, with a resolution of 1.5 km, after interpolation throughout the field. This work is an attempt to retrieve the shape of the mean dynamic topography in the area covered by HF radar. The challenge in our method is to extract the barotropic geostrophic current from the variable surface circulation. The latter contains wind-forced, tidal currents, inertial oscillations and possibly other wave motions. Extracting the mean currents by averaging over large time periods (monthly averaging) would efficiently remove wave and tidal motions. However, the wind-forced component of the currents would remain in the velocity signal, especially if the period of consideration is characterized by a relatively constant wind field. So, we decided to isolate periods with very low wind-speeds (lower than 2m per second), in order to attempt to remove the directly wind-forced velocity from our record. Once data from windy periods are removed, long temporal averages of the velocity fields provide maps of coastal geostrophic currents. It is then possible to obtain an estimate of the mean-dynamic topography of the sea-surface, by integrating horizontally the $u = +\frac{g}{f}\frac{\partial \eta}{\partial y}$ and $v = -\frac{g}{f}\frac{\partial \eta}{\partial x}$, with η the surface slope, *u*,*v* the current components measured by the radar and *f* the Coriolis (Liu et all 2012). The integration can be performed in two ways: starting from about the middle of the measurement domain, at a point (x_0, y_0), we can integrate zonally first along a latitude line, to obtain $\eta(x, y_0)$. Afterwards we integrate meridionally, starting from the latitude defined by (x, y_0).

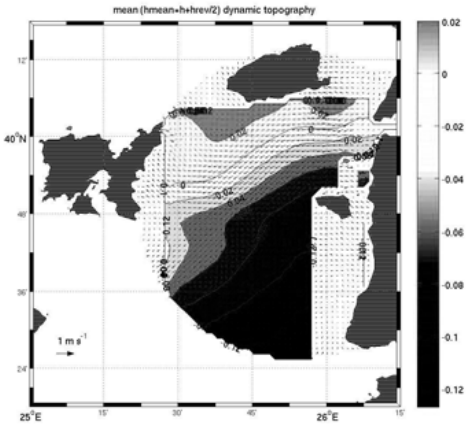

Fig. 1. Mean Dynamic Topography estimate for summer 2010, from the Dardanos HF radar data

The second method of integration is done in a similar way, however the meridional integration of equation precedes the zonal integration. Using the above two integration methods, we obtain two estimates of the MDT. We can consider the mean of the two estimates, $\langle\eta\rangle = 0.5\,(\eta_A+\eta_B)$ as our best estimate for the MDT, while the difference $\delta\eta = \eta_A-\eta_B$ is considered as an assessment of the integration error.

Due to the scarcity of periods without wind, it is only possible to estimate velocity fields from calm days over seasonal periods, in order to obtain enought velocity records to subtract the wave and inertial variability. As an example, the mean dynamic topography from summer 2010 is presented in the following image.

The dynamic topography field obtained with this method is compatible to the general circulation observed in the region, and can be a source of high-resolution dynamic topography information for further use.

Abstract
The Rhone River is the largest source of fresh water discharge to the Mediterranean Sea. As it is also an important source of particles, it constitutes a key forcing for the ecosystems of the Gulf of Lions in the northern part of the western basin. In order to assess the input and fate of suspended material at the Rhone River mouth and the influence of extreme events, a multidisciplinary oceanographic moored observatory has been installed in 2009 for high frequency measurements. Data are collected and sent in near real time to an onshore data centre. Data are available for the scientific community and addition of new sensors is still ongoing in the framework of the MOOSE, MERMEX, AMORAD and PERSEUS programs.

Keywords: Rhone Delta, Instruments and techniques, River input, Gulf of Lyon, Monitoring

The Rhone River accounts for one third of the average total freshwater input to the Mediterranean Sea. Draining an industrialized catchment, it is an important source of nutrients, suspended particle matter (SPM), carbon and other chemicals including contaminants [1]. These inputs strongly influence the ecosystems of the gulf of Lions [2]. A good knowledge of i) the quantity of water, suspended particulate matter, nutrients and contaminants brought from the Rhone River to the sea and ii) the resuspension by extreme meteorological events is thus needed to understand and model physical and biogeochemical processes in this area.

In addition to the SORA station located in Arles 50 km upstream from the sea, the MesuRho instrumented platform was installed at the Rhone River mouth (East Roustan buoy : 43°19.2N, 4°52E, 20 meters of water depth) in order to provide data at sea in the fresh/saline water transition zone. Since June 2009, the MesuRho station (fig.1) provides near real time high frequency measurements.
The system was initially equipped with two multi-parameter probes (one below the subsurface and one close to the sea bottom), a meteorological station, a photosynthetic active radiation sensor (PAR), an Acoustic Doppler Current Profiler (ADCP). Sampling and transmission interval has been set to 0.5 hour for all sensors. In 2012, a nitrates sensor and a fixed benthic station with oxygen micro-electrodes for sediment mineralization studies were added. The 3 year experience of operating the system in various weather conditions has demonstrated the interest of the use of an immersed flotation buoy as a plateform for installing sensors. In the near future, a subsurface and an atmospheric sensors will be added for radioactivity monitoring.

Complementary data acquired during surveys from 2010 to 2013 were used to qualify and when possible to correct the temperature, salinity, fluorescence and turbidity time series. As the plume salinity strongly varies away from the coast, specific surveys were conducted very close to the buoy. Data from the subsurface and bottom multi-parameter probes are compared to data profiles from a CTD sensor including a turbidity sensor and a fluorometer. Water samples also allow for SPM and Chlorophyll-a quantification.

This observation system is part of the coastal operational oceanography in situ network of the North Western Mediterranean Sea. Data are transmitted six times per day (each four hours) to the Coriolis *in situ* data centre (www.coriolis.eu.org), which provides an interface for data visualization and download. This interface can be used to check the instrument fair working.
Temperature and salinity data were made available for the MyOcean community and served for operational model validation purpose [3].

The long time series recorded at the MesuRho buoy show the impact of extreme events. Strong floods caused a salinity decrease down to the subsurface sensor associated with a possible increase of turbidity. At the bottom, turbidity increase were recorded under south-east swells associated with sediment resuspension events [4]. An example is shown for spring 2012 (fig.1). First results from the benthic station dedicated to the study of the fate of particulate organic matter delivered during floods showed that during the turbidity events of spring 2012, oxygen demand rises by a factor of 3-4.

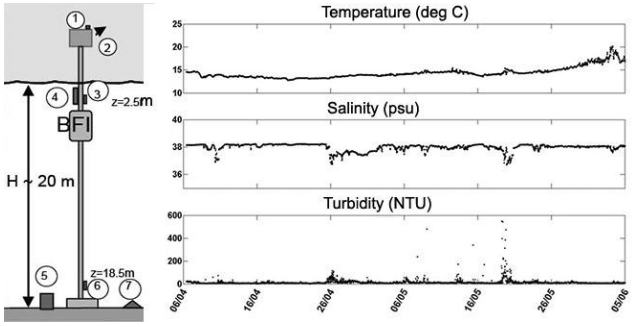

Fig. 1. (left) MesuRho observatory instrumentation : meteorological station + PAR (1), ABIN control and transmission (2), multi-parameter probes (temperature, pressure, conductivity, turbidity, fluorescence, dissolved oxygen) (3, 6), ISUS nitrate sensor (4), benthic station(5)
(right) Time series measured by the bottom multi-parameter probe in april-may 2012 : temperature (top), salinity (middle) and turbidity (bottom). The high turbidity event of 20 May occured under south-east winds.

Abstract
Existing coastal observatories in European waters are composed of platforms such as moored buoys, piles, profiling systems, gliders, 'ferryboxes' and automated systems on of board ships of opportunity. JERICO project strives to integrate existing infrastructures and provides a platform for the identification and dissemination of best practices for the design, implementation, operation and maintenance of observing systems and the dissemination of data. In order to reach these objectives several kinds of actions are undertaken, amongst which the offer of Trans-National Access (TNA) to a number of coastal observatories and calibration facilities for international research and technology development. This presentation will give a short overview of the selected Mediterranean TNA proposals and a focus will be drawn on some of the TNA results.

Keywords: Instruments and techniques, Coastal engineering, Ligurian Sea, South-Western Mediterranean, North-Western Mediterranean

Coastal observatories dotted along Europe's coastlines deliver a wealth of information on the state of its seas. These observatories are composed of moored buoys, piles, profiling systems, gliders, shore-based HF radars, 'ferryboxes' and automated systems on board ships of opportunity (e.g. fishing boats). JERICO strives to integrate these observatories at the European level, and provides a platform for the identification and dissemination of best practices from the design to the operation and maintenance of observing systems and the dissemination of data. It aids in the optimization of the use of existing infrastructures and in the promotion of interoperability. It has also initiated research to advance the state of the art, and has invited the international scientific community to access key infrastructures. In order to reach these objectives several kinds of actions are undertaken, amongst which the offer of Trans-National Access (TNA) to a selection of coastal observatories and calibration facilities operated by the JERICO Consortium for international research and technology development. A primary objective is to mobilize scientists and engineers across Europe, encouraging firstly those who haven't such facilities at their disposal in their countries. The access offered by JERICO includes ferryboxes, fixed platforms, gliders, and associated support calibration laboratories and a dozen of them are located in the Mediterranean Sea. This presentation will give a short overview of four Mediterranean TNA experiments selected after the first TNA call in 2012 and will focus on a selection of scientific results introduced hereafter. Two of them address calibration and the other two explore scientific themes of interest for the Mediterranean community.

Calibrating sensors regularly is the prime requirement for getting reliable data from coastal observatories and ensuring their long-term relevance as viable providers of information on the marine environment. The OGS-Oceanographic Calibration Centre in Trieste and the calibration facilities at the HCMR Thalassocosmos complex in Crete hosted users for calibration experiments. The first one was accessed by a HCMR team that wished to improve their experience in calibrating high-quality oceanographic temperature sensors using primary ITS-90 reference standards. The experiment involved full calibrations of two SBE 35 thermometers from Sea-Bird Electronics, Inc. owned by the HCMR that will be used as reference sensors for temperature measurements in their calibration laboratory in Crete (Greece). The second one was accessed by a team from CNR-ISSIA with the purpose of enhance the accuracy of dissolved oxygen, chlorophyll-a and turbidity probes used for *in-situ* observations on a long term basis in the W1-M3A off-shore observing system in the Ligurian basin. The performed experiment allowed obtaining an extremely accurate laboratory calibration and a test at sea for oxygen and fluorescence sensors.

Gliders make oceanographic measurements traditionally collected by research vessels or moored instruments, but at a fraction of the costs. The CSIC/IMEDEA gliders infrastructure was accessed by a team from CNR/IAMC Oristano to study the central part of the Algero-Provencal sub-basin, representing a buffer area between the northern Provencal sub-basin and the southern Algerian one, characterized by the presence and action of the Balearic front. The experiment is midway, and a first mission was just concluded, with the deployment of a Seaglider which flew from the surface to about 1000 m following a route between the Balearic Islands and Sardinia. A second mission is planned in early Autumn 2013. This transect is also annually monitored by CNR with CTD and LADCP during oceanographic cruises. The data collected during the glider missions and oceanographic cruises will help to assess the inter-annual variability of physical and biochemical properties of water masses and to understand the exchanges of salt and heat through the sub-basins in the western Mediterranean.

Fixed platforms allow long term -sensor testing and -measurements. The presented experiment is led by CNRS/OBS-VLFR and consists in the implementation of automatic Dissolved Oxygen (DO) measurements in the mooring operated by CNR/ISMAR in the Corsica Channel (Ligurian Sea). The deployment began in November 2012 and is planned to last for twelve months under the aegis of JERICO TNA, then it will continue for at least other six months as a collaboration of CNR/ISMAR, CNRS/OBS-VLFR and the Mediterranean Institute of Oceanography. The final purpose of the research is to integrate the DO concentration in the long term time series data in the Ligurian basin to track and evaluate the water mass variability and to estimate the time lag between the eastern and the western part of the Ligurian Sea. Further observations regularly acquired by sensors installed on the mooring and data collected during the periodic maintenance cruises, will be available for completing the study.

The development of high-quality and comprehensive coastal observing systems has only recently moved forward, principally at national and regional level. In this overall context, the JERICO project aims at creating a solid and transparent organization towards an operational service for the continuous and sustainable delivery of high quality environmental data and information products related to the marine environment in European coastal and shelf seas. It promotes joint research initiatives and standardisation as illustrated by TNA experiments.

Abstract
A 3D-variational (3DVAR) scheme is applied to the operational forecast system of the Mediterranean Sea for the assimilation of surface chlorophyll concentration. The core of the 3DVAR scheme is the background error covariance matrix that is decomposed in a series of operators that account for different dynamics of the marine ecosystem. The results show that the assimilation scheme improves the model skill in reproducing observed values and spatial patterns of the chlorophyll and nutrient fields. Moreover, it is shown that the method is modular and capable to be continuously improved, and suitable for implementation in an operational framework.

Keywords: Models, North-Western Mediterranean

Introduction
The use of a three-dimensional variational approach for the operational biogeochemical assimilation may present some advantages compared to other sequential approaches: it is computationally efficient and it does not require the inversion of the background error covariance matrix or of the observational operators [1]. Moreover the background error covariance can be decomposed in a sequence of linear operators that account for different components of the covariance matrix, and the modular structure of the decomposition is particularly suitable for operational applications.

Matherial and methods
In the present study, the assimilation of surface chlorophyll is used to constrain the three-dimensional fields of phytoplankton variables in the biogeochemical forecasting system of the Mediterranean Sea. The numerical model OPATM-BFM is the coupling of properly modified versions of the OPA transport model [2] and the BFM model [3]. The observations consist of satellite surface chlorophyll maps, which are obtained from MODIS optical data by means of an algorithm specifically developed for the Mediterranean Sea [4]. The definition of the background error covariance matrix B is a crucial aspect of the 3DVAR scheme. B is defined in terms of a matrix product $B=VV^T$, where the definition of V can be based on a priori knowledge of the covariance matrix B [1]. And V can be decomposed into a sequential linear multiplication of a number of linear operators Vi. For the assimilation of surface chlorophyll concentration, the decomposition of V is defined as VvVhVb, which is designed to describe the vertical error covariance of the chlorophyll fields (Vb), the horizontal error covariance (Vh) and the state variable error covariance (Vb). In particular Vb provides covariance among the variables which describe the four types of phytoplankton simulated by the model. Moreover, the solution of the assimilation is defined in a reduced order space, where the inversion of B is not required.

Results and discussion
We compared the results of a run that uses the 3DVAR assimilation scheme (AR), with a control run (CR) without assimilation. The results demonstrate that the skill performances of the forecast system are improved by the assimilation of surface chlorophyll. The AR run has better skill in reproducing observed values and spatial patterns of the chlorophyll and nutrient fields than the CR run. For instance, Fig. 1 shows the time series of the mean surface chlorophyll concentration in the CR, AR and satellite for two sub-regions (North Western Mediterranean and Levantine basin, NWM and LEV). For both the sub-regions, the assimilation provides the largest improvement of model performances in reproducing the bloom events from December to March.
However, the results of the NWM indicate that a bloom event, which is not reproduced by the CR in April, is partially corrected by the assimilation. The low efficiency of assimilationhas to be sought in the model formulation and dynamics. More specifically, it has to be ascribed to the low vertical mixing conditions. The absence of the appropriate conditions of vertical mixing implies that nutrients are not transported to the surface layer, and thus the chlorophyll synthesis is strongly limited by the nutrients lack. This result showed the necessity for a further improvement of the error covariance matrix B. A new formulation of the Vb operator that takes into account the missed mixing conditions, has been developed and successfully tested. The present study shows that 3DVAR approach is suitable for the application in the biogeochemical operational forecasting, because the modular structure of the Vi operators allows for continuous improvement of the assimilation scheme.

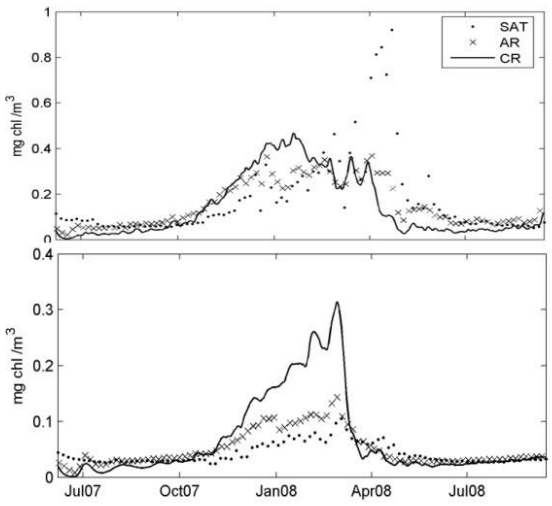

Fig. 1. Time series of surface chlorophyll concentration as observed by satellite (SAT) and modelled in the CR and AR. Spatial mean over the NWM (upper panel) and LEV (bottom panel).

THE IMPACT OF NEW MULTI-PLATFORM OBSERVING SYSTEMS IN SCIENCE, TECHNOLOGY DEVELOPMENT AND RESPONSE TO SOCIETY NEEDS; FROM SMALL TO LARGE SCALES…

Joaquin Tintoré [1]* and SOCIB/IMEDEA science&technology team [2]
[1] SOCIB and IMEDEA (CSIC-UIB) - jtintore@socib.es
[2] SOCIB and IMEDEA (CSIC-UIB)

Abstract
New technologies are key components of recent observing systems that enhance the capabilities to characterise ocean state and variability in quasi real time today. The challenge for the next decade is the integration of theses technologies and multiplatform observing and forecasting systems to (a) monitor the variability at small scales (e.g. mesoscale/weeks) to (b) resolve the sub-basin/seasonal and inter-annual variability and by this (c) establish the decadal variability, understand the associated biases and correct them. Recent studies from SOCIB have shown the importance of this new small to large-scale multi-platform approach in ocean observation. Some examples will be discussed together with initial ideas on the new capabilities to respond to science priorities, technology development and response to strategic society needs.

Keywords: Mesoscale phenomena, Balearic Islands, Coastal systems, Coastal management

New technologies and small scales. New monitoring technologies are progressively implemented in the world oceans leading to major changes in our understanding of their variability. Gliders, soon to become fleets of gliders, are an example of theses new technologies implemented in coastal to open ocean regions allowing repeated high resolution monitoring of specific areas, by this showing the dynamical relevance of new features, such as for example sub-mesoscale eddies characterised by strong horizontal gradients and intense vertical motions. These eddies, that could not be routinely monitored before, interact with the underlying mean flows, and can block the general circulation in key ocean regions; or they can give rise to enhanced upper ocean biogeochemical exchanges modifying the ecosystem response at a scale that was not previously observable on a routine basis. These are just two examples of the contribution of new technologies to address and better understand state of the art oceanic questions of worldwide relevance in a climate change context.

Multi-platform integrated systems. When different types of these new monitoring technologies are implemented and used together with more traditional platforms, we are then confronted with the new multi-platform integrated observing systems –also called ocean observatories- that are being established in the world oceans. Theses new observing systems respond to a twofold **change of paradigm** in ocean observation that, following Delaney and Barga (2009) will be presented and discussed. These observing systems can in turn be integrated with powerful modelling and forecasting systems available today, giving rise to the new multiplatform observing and forecasting systems that can allow us to describe the three-dimensional oceanic structures and understand the underlying processes of multiple interacting spatial and temporal scales that characterise the variability of our oceans. Theses systems are already providing answers to state of the art scientific questions, enhancing technology development and increasing our capability for knowledge-based response to society needs. This is the mainstream activity of SOCIB and IMEDEA (CSIC-UIB) in the frame of ongoing EC funded initiatives such as PERSEUS, JERICO, GROOM, E-AIMS, TOSCA, MEDES4MS, or MyOcean2 among others and is also at the core of the new EC initiatives on Marine Research infrastructures.

SOCIB. The **B**alearic **I**slands **C**oastal Ocean **O**bserving and Forecasting **S**ystem, is one such ocean observatories, a new multiplatform observing and forecasting system, a facility of facilities extending from the nearshore to the open sea. SOCIB provides streams of oceanographic data and modelling services to support operational oceanography in a European and international framework, therefore also contributing to the needs of marine and coastal research in a global change context. SOCIB benefits from the strategic position of the Balearic Islands, an Atlantic/Mediterranean transition area, one of the 'hot spots' of biodiversity in the world's oceans and was the logical step to more than 25 years of work in physical oceanography in the Balearic Islands. SOCIB (Tintoré et al., 2013), is unique among the new observing and forecasting systems in that its mission and objectives are science, technology and society driven. Together with NANOOS it is one of the few examples that run from the coastline to the open ocean. Seven major **Observing Facilitie**s are now operational: a 12 MHz long range HF radar system in the Ibiza channel, coastal and open ocean gliders, coastal moorings and fixed stations, Argo profilers and surface drifters, a nearshore monitoring system of selected beaches and a new coastal catamaran (24 m LOA). The **Modelling Facility** is presently running an operational ROMS model for ocean currents (WMOP, nested to MONGOOS/MFS system), a wave operational system (established together with *Puertos del Estado*), as well as a pre-operational meteo-tsunami system to support Balearic harbours authority. The **Data Centre Facility** is the core of SOCIB and is developing and implementing a data management system following international standards of quality assurance and inter-operability. It is also performing specific developments and tools for the different facilities. Its main functions and capabilities range from data reception to its distribution and visualization (via web services and THREDDS/OPeNDAP protocols), passing through processing, quality control, documentation, standardization and archiving (NetCDF format and CF conventions), and data discovery (based on OGC protocols).

Key challenges. The challenge for the next decade is the integration of new technologies and multiplatform systems selecting key control sections in coastal/open ocean regions, major straits or channels for routine monitoring of these control or choke points (following Heslop et al., 2012) to establish ocean state and variability, evaluating for example the relevance of mesoscale activity, shelf/slope exchanges, water masses formation, etc. The impact of these new systems cannot be overlooked and it is important we face and prepare the forthcoming generations and ourselves. These types of new marine infrastructures are presently establishing new ways of international cooperation that will lead to major science breakthroughs, innovations in oceanographic instrumentation and new ways of science based coastal and ocean management.

DEVELOPMENT OF A NOVEL TOOL TO PREDICT DIFFERENT WATER QUALITY SCENARIOS WITHIN A MARINE PROTECTED AREA (MPA) IN THE MALTESE ISLANDS: THE 2D SHYFEM-BFM MODEL

A. Cucco [1], G. Umgiesser [2], A. Deidun [3]*, R. Tarasova [3], J. Azzopardi [3] and A. Gauci [3]

Abstract
Effective operational marine conservation and management is thwarted by a lack of financial and human resources. A coupled 2D hydrodynamic (SHYFEM) and ecological (BFM) model was developed in the current study as a Decision Support System (DSS) to spearhead good governance of a Marine Protected Area (MPA) in Dwejra (Maltese Islands) in the Central Mediterranean. Two scenarios were considered – one with the current levels of nutrient runoff from land and one in which such levels are increased as a result of a greater human activity within the area. Although the developed numerical modeling platform needs to be refined and to be run for a longer time-frame, its output suggests that it is a promising tool to assist in the operational management of an MPA.

Keywords: Models, Nutrients, Diatoms, Dinoflagellates, South-Central Mediterranean

Introduction
One of the most frequent and impacting vectors of changes in the environmental status of coastal areas is the input of dissolved nutrients, from both point and diffused sources.The simultaneous occurrence of high nutrient loads, high water temperatures and low hydrodynamic flushing of water bodies may lead to dystrophic and anoxic events, with cascade effects on the entire marine ecosystem. Understanding and predicting the mechanisms leading to such events is therefore of fundamental importance for a proper management of the marine environment within marine areas of high conservation value, such as MPAs. The operational monitoring of the relevant water parameters is frequently thwarted by prohibitive demands on costs and manpower.

Materials and Methods
In this context, we developed an integrated numerical platform that is able to provide, operationally, an evaluation of the Current Environmental Status (CES) of the Dwejra MPA on the island of Gozo (Maltese Islands, lon=14° 11'17"; lat=36°03'14"). This system is based on a coupled 2D hydrodynamic and ecosystem model and constitutes a pilot case of a Decision Support System (DSS) formulated to support the governance of an MPA's coastal waters, capable of forecasting different water quality scenarios arising under different nutrient loads. In particular, an ecological model (BFM - Vichi et al. 2007) and a shallow water finite element hydrodynamic model (SHYFEM – Umgiesser et al., 2004) have been coupled to each other (Cucco et al., 2012) and applied to reproduce the main hydrodynamic and biogeochemical processes affecting the water quality features within the Dwejra MPA in Gozo. Both hydrodynamic and biogeochemical flux models run operationally to predict, on a daily basis, the changes in both hydrodynamic and biogeochemical variables. The hydrodynamic and biogeochemical model domain covers the coastal waters of the Malta archipelago in their entirety (up to a distance of 20 km from the coast) by means of an unstructured grid, with a spatial resolution varying between a few km for offshore areas to a few hundred meters for the more coastal areas around the Dwejra site. Boundary conditions for the hydrodynamic module were provided by the ROSARIO sub-regional oceanographic prediction system (ROSARIO, 2006), whereas boundary conditions for the biogeochemical module were downloaded from MyOcean Web data services (MyOcean, 2012). Responses of ammonium, diatoms, dinoflagellates, carnivorous and omnivorous zooplankton to varying input of nitrates to the aquatic system in question were monitored. About 110 boathouses, frequented by approximately 220 persons annually, mainly during the spring and summer periods, are located around the periphery of the same lagoon. The nutrient loads produced by the boathouses were estimated by means of the so-called "*equivalent population*" procedure. This method is based on an estimation of the nutrients concentration of the sewages generated by anthropogenic activities. Considering the boathouse agglomerate as a 'camping' activity, for which 1 EI corresponds to 2 physical persons frequenting the area, an equivalent population of about 110 EI was adopted to represent the current scenario. Adopting the same table of conversion from EI to nutrients loads adopted in Italy, the wastewaters produced daily by each EI is characterized by a BOD_5 at 20° C equal to 60g of oxygen (Art.74 of Law 152/06 of the Italian Ministry of the Environment). A set of 2 simulation scenarios have been carried out for the 1st July-1st September period (when boathouse occupation levels are highest). Such an exercise involved varying the value of EI in the area, to represent a corresponding increase in the number of boathouses in the area, from the current number of 110 boathouses to 160, in order to explore the water quality consequences of a more permissive environmental policy in future.

Results and Discussion
According to the output of the developed numerical platform, a scenario where nutrient (nitrate and phosphate) input to the coastal area is increased (as a result of the increase in boathouses in the area) is also characterized by a corresponding increase in ammonium levels, which increase by approximately 30%, and in dinoflagellate populations, whose annual blooming at this time of year in the Mediterranean (e.g. Daly Yahia-Kefi et al., 2005) is further accentuated. Diatom populations, already depressed at this time of year in the Mediterranean (e.g. Daly Yahia-Kefi et al., 2005), do not exhibit any significant increases in their abundances in the EI160 scenario, as do both omnivorous and carnivorous zooplankton classes. The fact that no cascade effect of the surge in nutrients up different trophic levels within the pelagic food web at Dwejra was observed might be due to the intense hydrodynamic flushing and advection that the Dwejra area is generally subjected to, which in turn results in low nutrient residence times within the lagoon. Such observations are further confirmed through the results of a third simulation (assuming an EI value of 210), run over the 1st June-30th September period.

MIXING VOLUME: A HYDRODYNAMICS INDICATOR FOR ECOLOGICAL STUDIES

Abstract
The cleaning capacity of Mediterranean lagoons depends largely on hydrodynamics. We propose for such semi-enclosed ecosystems a hydrodynamics indicator, i.e., the mixing volume. This indicator allows discriminating between areas where the lagoon water is well-mixed with the inflowing sea water, and confined areas. An application of this indicator is presented for the Bages-Sigean lagoon and its use for biogeochemical budget modelling for studies of eutrophication phenomena will also be discussed.

Keywords: Restoration, Eutrophication, Lagoons, North-Western Mediterranean

Mediterranean coastal lagoons are semi-enclosed ecosystems subject to intensive anthropogenic inputs and its cleaning capacity depends on three main hydrodynamic factors: flushing potential of tide, meteorological forcing and freshwater runoff. The efficiency of physical cleaning processes is commonly approached with residence time. This hydrodynamics indicator is not sufficient for addressing ecological questions that need a spatio-temporal indicator to distinguish between areas where the lagoon water is well-mixed with the inflowing sea water, and confined areas. We propose a hydrodynamics indicator the mixing volume that can be estimated using hydrodynamics modelling and based on the renewal time concept defined for well-mixed tank (Figure 1).

Fig. 1. Cartography of renewal time into the Bages-Sigean lagoon calculated using the numerical hydrodynamics MARS-3D model.

An example of calculation of the mixing volume is shown for the Bages-Sigean lagoon (Western Mediterranean French coast) using the numerical hydrodynamic MARS-3D model [1].
Preliminary results show how this indicator varies during the year responding to the seasonally changing environmental conditions. It appears that the mixing volume, depending on wind and tide induced water body circulation, exhibits a low seasonal variability (Figure 2). In the Bages-Sigean lagoon water body circulation is strongly constrained by the complex lagoon topography (Figure 1).

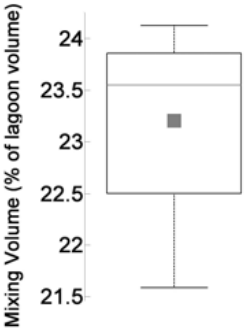

Fig. 2. Variability of the "Mixing Volume" indicator under different environmental conditions expressed as a percentage of the whole lagoon volume (i.e. 65 Mm3).

We will finally present the use of this mixing volume to improve how hydrodynamics processes can be taken into account in spatially not explicit budget models (LOICZ-like model) that are applied on coastal lagoon ecosystem to study eutrophication phenomena.

RESPONSE OF THE PELAGIC ECOSYSTEMS TO THE DEEP CONVECTION IN THE NORTHWESTERN MEDITERRANEAN SEA

Fayçal Kessouri [1]*, Caroline Ulses [1] and Claude Estournel [1]
[1] Laboratoire d'Aérologie, Observatoire Midi Pyrénées - Faycal.Kessouri@aero.obs-mip.fr

Abstract
The north western mediterranean deep convection redistributes organic and inorganic matters all over the water column; the consequent spreading of the deep and intermediate waters induces important modifications of the biogeochemical budgets also far from the NWM region. The large and intense bloom of the NWM that follows winter mixing represents the most important process of the basin itself probably at the origin of large carbon export to the deep layers and high biodiversity of the region. The presentation focuses on the modeling of an annual cycle also documented by observations at different periods.

Keywords: Models, Water convection, Blooms, Nutrients, North-Western Mediterranean

Similarly to most of the temperate regions of the global ocean, but conversely to the rest of the basin, the North Western Mediterranean is characterized by a bloom-like trophic regime.
The general objective is to understand the sensitivity of the North Western Mediterranean biogeochemical behaviors to the alterations/modifications of the environmental forcing [1,2]. The first step is to assess the coupled modeling performances in relation with the CASCADE and the DeWex experiments of the MERMEX-MISTRALS program to represent the most important processes of the basin in terms of primary and secondary productions and export toward the deep layers. A modified version of the high resolution 3D model ECO3M-S [3] was coupled to the hydrodynamic SYMPHONIE model [4]. The model configuration had a 1 km horizontal resolution, and uses 40 vertical sigma levels. . Two data sets of atmospheric and oceanic forcing at different resolution have been used. Different options for the initialization and boundary conditions of the biogeochemical model have also been tested. A simulation running from January 2011 to December 2011 was analysed. Comparisons were performed with the available data set including nutrients, dissolved and particulate organic matter from the CASCADE experiment in March 2011 during mixed to weakly stratified conditions and the MOOSE experiment in May 2011. Sea surface chlorophyll concentrations were also compared with the 4 km resolution Modis satellite images .

The results illustrate :
- the spatial and temporal evolution of convection and how the associated physical structures affect the ecosystem (planktonic groups..),
- the quantification of the N/P ratio, its evolution along the seasonal cycle and its impact on the zooplankton and phytoplankton groups,
- the spatial evolution of the nutriclines and of the bacterial distribution,
- and finally, the history of the planktonic ecosystem during the key periods for the North Western Mediterranean including the winter mixing, the bloom development and the complete establishment of the stratification.

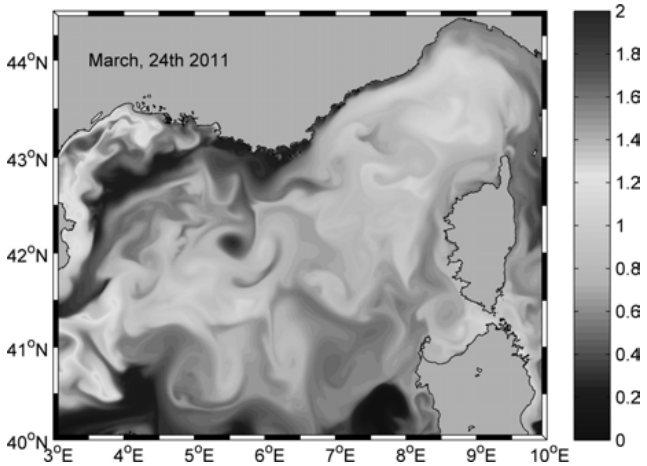

Fig. 1. Chlorophyll a concentration (in µg/l) during the spring bloom in the north western mediterranean sea from the SYMPHONIE/ECO3M high resolution model

RECOMMENDED METHODOLOGY AND CONSIDERATIONS FOR ACCEPTANCE OF THE CALIBRATION AND VALIDATION OF A HYDRODYNAMIC MODEL

Sergiu Dov Rosen [1]*
[1] Israel Oceanographic & Limnological Research - IOLR - rosen@ocean.org.il

Abstract
This paper present a concise set of model calibration and validation criteria, based on a number of extensive numerical coastal hydrodynamics and water quality model studies, for which the author served as specifyier of the modeling conditions, data provider, supervisor and reviewer.

Keywords: Models, Coastal models, South-Eastern Mediterranean

Purpose
Marine and coastal developments are nowadays based on a-priori ecological modeling using numerical models of the hydrodynamic transport integrated with bio-geo-chemical numerical models. The reliability of the model outcomes depend not only on the ability of the numerical tools to simulate the various hydrodynamic and ecological processes, but to a high degree, also on performing a proper calibration and validation of the models. Below we present a concise set of criteria required to obtain reliable outcomes from hydrodynamic models of the coastal zone. They were derived based on extended experience of the author in providing data and specifications suited to the modeling goals, supervision and results review of extensive numerical modelling studies, using leading edge software packages by renown commercial bodies. The outcomes are summarized in the following lines and are suitable to be applied for similar modelling investigations.

System Performance Criteria
Model calibration should be performed generally in accordance with the criteria agreed. The overall model performance for obtaining an acceptable calibration and validation of the model should be based on a number of **system performance criteria** (an assessment of whether or not the results obtained via the calibration and validation process of the model are satisfactory for a reliable assessment). The main purpose is to ensure that controlling factors and processes for the simulations are satisfactorily represented by the model. It is noted that the system performance criteria are considered the most important elements for the acceptance of the calibration and validation of the hydrodynamic modeling.

System Performance Criteria consist of:

1. Checking the calibrated model's ability to represent the general and observed current patterns in the study region – comparison of simulated and measured snapshots of the currents for various flow situations (both directions alongshore currents, on-offshore currents, calm conditions, stormy conditions).
2. When relevant - check the calibrated model's ability to represent the general and observed flow patterns in the study region – comparison of simulated stratification pattern with observed vertical profiles (flow, temperature, salinity) represented in the model.
3. When relevant - check the calibrated model's ability to properly simulate the transport of pollutants – comparison of measured and simulated concentration distribution (nitrogen, phosphorous, TSS).
4. When relevant - check the calibrated model's ability to reproduce observed variability in water quality (Chlorophyll, nutrients, dissolved oxygen) in selected zones of the study region – comparison of simulated and measured ranges in dedicated zones.
5. When relevant - check the calibrated model's ability to obtain expected residence times in selected zones of the study region – comparison against previous studies.

Supporting Performance Criteria
It is understood that specification of criteria for hydrodynamic and water quality calibration, without provision of a detailed data set for the modelling (input data as well as calibration data), may result in unrealistic model performance, hence the outcomes must be evaluated against the system performance criteria as specified above. However, as a supporting instrument, also quantitative performance criteria for certain hydrodynamic and water quality selected parameters should be used in the assessment. The quantitative performance criteria outlined below constitute the required performance for stations/zones where sufficient data for both the measured parameters and the underlying controlling input data (such as wind, solar radiation, fluxes and concentrations at model boundaries, pollution loading etc.) exist.

Hydrodynamic parameters:

a. Sea levels (RMS error between measured and simulated levels, corrected for datum differences) within 15% of the monthly tide range, defined by the values of the monthly averages of the daily measured tide lows and tide highs, provided the trends are similar. Timing of highs and lows accurate to the hourly time.

b. Current speeds (average deviation between measured and simulated speeds) within 20% of the monthly average current speed. Current speeds below 1cm/s will not be included in the computation.

c. The current directions differences between the measured and simulated main monthly currents should be confined within a ± 10 deg range. The main directional sectors to be identified from current roses, and the main directions to be calculated as the mean direction in each directional sector weighted with respect to the speed (both for measured and simulated data). This criterion will apply to locations with pronounced and reasonably easily identifiable main current directions.

d. Current speed and direction vertical profile distribution within the criteria under **b** and **c**, provided also that measured and modeled currents profiles have in general similar trends.

e. Timing of values accurate to the hour, months are defined by Gregorian calendar.

f. The above sea level and current criteria are applied to the model calibration period as well as the model validation period.

The cal/val process must be presented in a detailed report including reasoning and main results, prior to cal/val acceptance of the model. Proper details for Initial Conditions and for Boundary Conditions, including for wind, currents (including wave induced currents where relevant), sea levels, etc.

Abstract
The eastward current at the Strait of Gibraltar (the Atlantic Jet) fertilizes the southwestern Mediterranean and it is the responsible for the comparatively high fish landing of this region. However, we demonstrate in this communication that the high kinetic energy of this current negatively impacts the recruitment of anchovy owing to the advection and dispersion of larvae and post-larvae. The inhibitory effect of kinetic energy on anchovy landings is not a transient but a persistent state. Only an exceptional combination of events can release anchovy recruitment from this inhibition to create landing outbreaks. We disentangle here what are these events and their high sensitivity to climatic fluctuations.

Keywords: Fisheries, Alboran Sea, Mesoscale phenomena, Recruitment

A comparative analysis of historical anchovy (*E. encrasicolus*) fisheries record [1] and data from remote sensors [2] indicates that anchovy recruitment in the Alborán Sea is extremely sensitive to the Atlantic Jet (AJ) flowing eastward from the Strait of Gibraltar. During the 17 years analyzed, anchovy recruitment was largely unconnected to the spawning stock biomass in the area. However, conditions where the AJ had a strongly weakening were able to create years of massive landings.

One of such rare events occurred at the year 2001 when the AJ, and its associated western anticyclone gyre, almost vanished during autumn and winter. This persistent absence created exceptional conditions for recruitment because of diminished advection and dispersion of early stages thus creating an exceptional year for catches. This pattern of enhanced recruitment during weak AJ is coherent with in situ observations on the effect the AJ has on ichthyoplankton distribution in the northwestern Alborán.

AJ incursions to the north are accompanied by a substitution of neritic ichthyoplankton (such as anchovy) by oceanic ones in the shelf [3]. These results show the high sensitivity of Western-Mediterranean fish to the Mediterranean-Atlantic balance of water masses and, therefore, to the climate changes that control them.

Abstract
Repeated observations made by gliders in the Ligurian Sea have revealed the presence of anomalously warm and saline sub-thermocline eddies. They are likely formed along the shelf slope off West-Saridinia during upwelling events generated by northerly winds, have a life time much greater than two months and are expected to participate both in the spreading of the Levantine Intermediate Water in the whole basin and in the preconditioning of deep convection in the Gulf of Lion.

Keywords: Intermediate waters, North-Western Mediterranean, Mesoscale phenomena, Turbulence, Upwelling

Since 2010, sustained observations of the circulation and water properties of North-Western Mediterranean Sea have been carried out in the framework of MOOSE [1]. As an important part of this integrated ocean observing system, gliders [2] are regularly deployed in the Western and Eastern parts of this basin and revealed, in particular, outstanding warm core eddies in the Ligurian Sea.

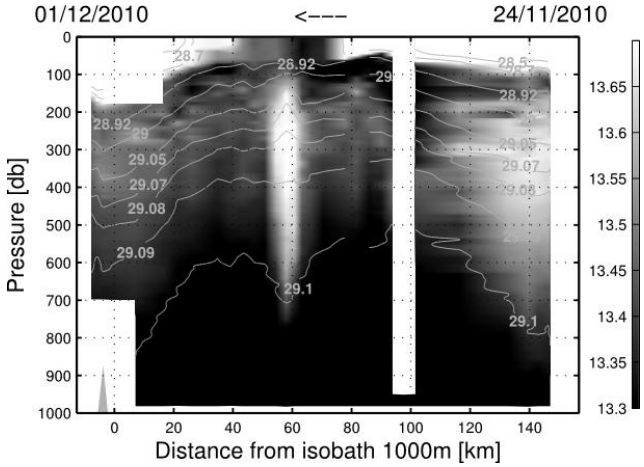

Fig. 1. Temperature section [°C] and density contours [kg/m^3] across the Ligurian Sea revealing the presence of a warm core subsurface eddy.

These eddies are characterized by a low-stratified core located at about 400m depth. Their cores are composed of Levantine Intermediate Water (LIW) and are much warmer (+0,3°C) and more saline (+0,1psu) than the surroundings. They have a radius of about 5km, which is order of the internal deformation radius (~5-15km). The lenticular shape of the isopycnal deformation associated with these eddies below the thermocline is a typical feature of sub-thermocline Submesoscale Coherent Vortices [3]. Geostrophic velocities computed from the glider section with a reference given by the depth-averaged velocity estimates from the gliders navigation lead to velocity maximum within the eddies of about 5-10cm/s, which corresponds to a Rossby numbers of 0,1-0,2. Nevertheless, the small radius of these SCVs regarding the internal deformation radius suggests an importance of the centrifugal force in the cyclostrophic balance and thus higher relative vorticity than estimated.

In order to track back their formation area, we analysed the LIW characteristics over the whole Western Mediterranean by taking all available Argo and CTD profiles performed during the last few years [4]. The data show the LIW Vein flowing northward at intermediate depth along the Sardinian coast and its slow erosion in terms of T/S characteristics while flowing to the North. Due to dynamical barriers, the waters composing their cores should have similar characteristics (or slightly less pronounced) while tracing back to their formation area. So, they are most likely formed along the shelf-slope West of Sardinia at around 41°N. The observations of the LIW SCVs are separated of about 250km from their hypothetical zone of formation. If we therefore assume them to be advected at about 5cm/s (mean currents are not very strong at depth), they should have spent at least two months to travel North to the place where they were observed.

Sea Surface Temperature images of the West coast of Sardinia often exhibits cross-shore positive temperature gradient, sign of an upwelling caused by strong northerly wind events. From a CTD and a glider section realized during two different upwelling events, we were able to observe an uplift of the isopycnals at depth as observed in upper part of the LIW SCVs. The baroclinicity of the flow is enhanced during such upwelling events and the LIW Vein takes the form of an undercurrent isolated from the surface. Dynamical processes likely implicating the interaction of the flow with the topography (change in slope steepness, corner-shaped isobaths at around 41°N [5]) and the wind forcing should then be at play to destabilize the flow and eventually detach the eddies.

These particular kind of SCVs transporting LIW should have strong implications for the physics of the basin. They likely play an active role into the spreading of the LIW (like the Sardinian Eddies formed at the south-west corner of Sardinia [6]) and this is especially important to set the stratification of the Northern basin before the winter. This is critical for the deep convection phenomenon, since their low-stratified core furthermore locally precondition the water column and favour the winter vertical mixing.

Abstract

An HF radar system has been deployed along the Provencal coasts for probing the surface circulation in this region which is characterized by a large scale flow (Northern Current) and by a broad range of other scales of variability induced by meteorological and tidal forcing. The presentation is an overview of the radar network, of the surface current mapping facility offered by the system, of recent observation results and of an application in assimilation of radar data.

Keywords: Coastal processes, North-Western Mediterranean, Circulation, Remote sensing

An HF radar system has been implemented for 3 years in the region of Toulon-Hyeres (France) with the objective of probing the surface current variability with large spatial coverage (50 km), at relevant time and space resolutions (1 hour-5 km) and during a significant period of time (several years).

The mapping of surface current by radar primarily addresses the variability of the Northern Current (NC), flowing in the North Western Mediterranean, and the meso/submesoscale activity in the region. This remote sensing activity is performed in conjunction with high resolution modeling, measurements at sea and the collection of other remote sensing data (SST, altimetry).

An operational perspective is also targeted in the frame of the emerging Mediterranean Ocean Observing System on Environment (MOOSE, INSU-CNRS). A first step was reached recently by radar derived current maps provided in real time on a web interface.

The radar has been single-site during the first 1.5 years and then dual-site up to now. The network uses monostatic and bistatic radar units.

This presentation presents the radar system and emphasizes on its relevance to meet the scientific objectives and also to satisfy a large variety of users.

Recent results are shown concerning the NC variability over 3 years, showing in particular the bathymetric guiding effect (figure); the main periods of variability as revealed by spectral analysis; signatures of remarkable features like meandering and frontal events; an overview of recent results on data assimilation of radar currents to optimize wind and open boundary forcing of a regional NEMO-based model (Glazur64).

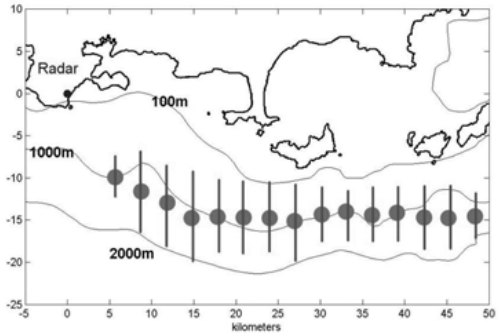

Fig. 1. Radar derived mean position of the Northern Current over 28 months (red points) and corresponding rms bars in the Toulon-Hyeres region.

MESOSCALE AND SUB-MESOSCALE VARIABILITY ALONG THE COASTS OF THE SOUTHEASTERN TYRRHENIAN SEA

Anna Maria Fragliasso [1]*, Giannetta Fusco [1] and Giorgio Budillon [1]
[1] Università degli Studi di Napoli 'Parthenope' - anna.fragliasso@uniparthenope.it

Abstract

The dynamical aspects of the Southeastern Tyrrhenian Sea were studied using data provided by moored Acoustic Doppler Current Profilers (ADCPs) located along the southern coasts of Italy. The observations highlighted the variability of the long-shore currents and showed the presence of a surface jet north of the Strait of Messina due to the atmospheric forcing. In order to study the dynamical variability, we used the wavelet analysis and identified the presence of inertial oscillations and internal waves, linked to the tidal regime of the area.

Keywords: Mesoscale phenomena, Tyrrhenian Sea

The Southeastern Tyrrhenian Sea is characterized by a dynamics strongly connected to the presence of a complex bathymetry and influenced by several narrows, such as, the Strait of Messina that connects the Ionian and the Tyrrhenian Seas. The analysis of ADCPs data acquired from February to September 2008 between Sicily and Campania (fig.1) showed a typically barotropic behavior with changes in direction and intensity mainly due to the basin scale circulation [1].

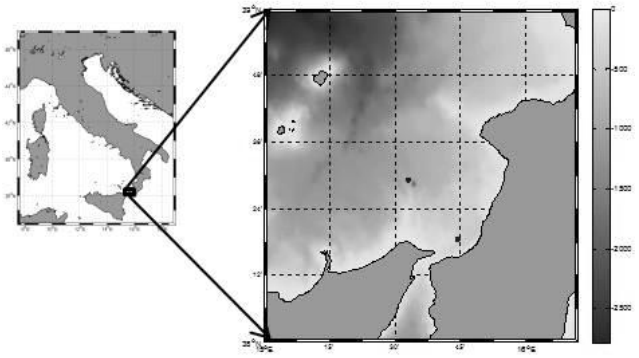

Fig. 1. Moorings Positions.

Moreover, our results showed that under particular atmospheric conditions, the presence of a strong coastal current is established in the surface layer, highlighting the existence in the mixed layer of a strong surface jet flowing towards NE north of the Strait (fig.1) from mid-May to mid-June, characterized by maxima speed values of about 30 cm/s on both zonal and meridional components of the current (fig.2a-2b).
Wind data provided by the European Centre for Medium-Range Weather Forecasts (ECMWF) showed that during the same period the wind was mainly directed towards NW. According with Ekman's theory, we observed a clockwise rotation in direction and a decrease inmagnitude of the currents with the depth (fig. 2a-2b).
This direct relationship between surface currents and the wind stress was assessed by means of the Cross-Wavelet (XWT) and the Wavelet Coherence (WTC) analysis, highlighting a strong in-phase correlation on both zonal and meridional components during the observed jet. It is well known that the Ionian and the Tyrrhenian Seas, at the sill of the Strait of Messina, show an opposite configuration of tidal regimes, that seems to be responsible for the development of internal waves trains propagating from the sill northward and southward of the Strait [2].Our tidal analysis on the U and V components of currents, acquired by two ADCPs north of the strait (fig.1), has confirmed previous results [3], highlighting the prevalence of semi-diurnal component in the whole area. The wavelet analysis of residual currents, showed the presence of several harmonics, such as those related to the inertial motion with an oscillation period of about 17 hours or internal waves with a period shorter than 20 hours. These waves, with a sub-inertial oscillation frequency, are a particular type of waves guessed and observed at straits similar to that of Messina. Here, the tide generates waves trains propagating towards north and south and are typically caused by the sudden depth increase just out of the sill of the strait. These waves oscillate with a frequency lower than the tide that generated them and propagate over long distances. Our observations and analyses show the presence of mesoscale structures and phenomena of particular interest, such as internal waves and inertial motion, highlighting the importance of the Southeastern Tyrrhenian Sea dynamics and the need to broaden the knowledge of this area.

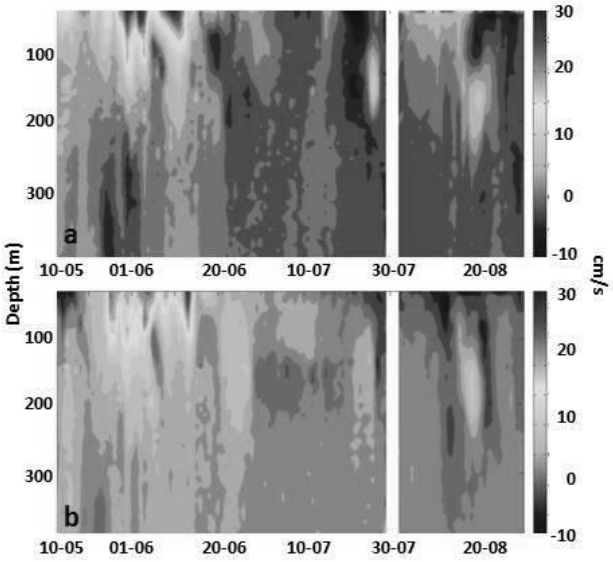

Fig. 2. Temporal evolution of zonal (a) and meridional (b) components of current North of the Strait of Messina.

BLACK SEA ANCHOVY *(ENGRAULIS ENCRASICOLUS PONTICUS)* TRANSPORT PATHWAYS

Ceren Guraslan [1]*, Bettina Fach [1] and Temel Oguz [1]
[1] IMS-METU - ceren@ims.metu.edu.tr

Abstract
Overwintering migration of Black Sea anchovy from the northwestern shelf to the southeast coast of the Black Sea is investigated using a Lagrangian particle-tracking model. By releasing drifters into surface currents calculated from satellite data, transport pathways of anchovy were simulated during different years and seasons. Simulations included different types of swimming behavior. Dominant pathways for anchovy to migration towards the southeast are suggested as direct transport from the Crimea south, transport along the Eastern Gyre following the Rim Current and transport across the Eastern Gyre.

Keywords: Black Sea, Migration, Models

Introduction
Anchovy migration in the Black Sea is not well understood and contrasting theories on overwintering migration exist. One theory is that anchovy are doing extensive overwintering migration from the spawning ground at the northwestern shelf to the southeastern coast of the Black Sea by beginning of October [1] or early autumn [2], while others suggests that anchovy spawning grounds are located in the southern region [3] and hence only local anchovy of the southern Black Sea migrate to this overwintering ground. Also it is know that anchovy migration is driven by ambient temperature criteria [1]. The present work focuses on elucidating which migration routes are feasible for anchovy to complete successful migration to the overwintering grounds depending on the interannual variability of ocean currents and sea surface temperature distribution.

Methods
Surface circulation fields were calculated from AVISO (Archivinig, Validation and Interpretation of Satellite Oceanographic data) sea surface height anomaly data. A Lagrangian particle-tracking model was used. Sea surface temperature optimal was obtained from AVHRR (Advanced Very High Resolution Radiometer) temperature product for the Black Sea. A total of 1026 drifters were launched along the northwestern shelf at different times during autumn of different years (2001-2003) that span a variety of environmental conditions in the Black Sea. To account for behavior, directional swimming with differential swimming speeds and directions (i.e. SE, ESE, SSE) were added on top of advection to test how many drifters arrive successfully to overwintering rounds and in what amount of time. Temperature thresholds of 13.5^{o}, 15^{o} and 17^{o}C were tested as the maximum allowable temperature for them to start active migration.

Results
Sea surface temperature varies greatly between years and is known to influence anchovy migration. Using 17^{o}C as threshold below which anchovy migration starts defines areas from which anchovy may start migration. Choosing lower temperature thresholds allowed no migration in the years of interest during fall. Directional swimming towards ESE at 1-2.5 body length per second is the most successful swimming behavior.

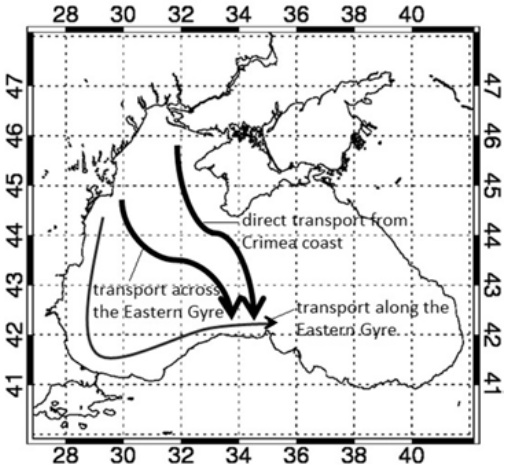

Fig. 1. Conceptual figure of anchovy pathways.

Three different pathways identified for anchovy migration (Fig.1): 1) direct transport from Crimea to the Turkish coast midway between the Eastern and Western Gyre, 2) transport along the eastern and then the southern edge of the Eastern Gyre following the Rim Current, and 3) transport through the Eastern Gyre. Moreover, anchovy located near the Danube plume, Kali-Akra and Constantsa regions of the NWS, prefer transport pathways 1, 2, and 3, respectively. Furthermore, the Danube and Sevastopol eddies and the cyclonic quasi-stable inner cell, as well as the Sinop and Kizilirmak eddies enhance anchovy transport.

EDDY TRACKING AND QUANTIFICATION IN THE EASTERN MEDITERRANEAN SEA: DATA AND MODELS

N. Mkhinini [1]*, K. Béranger [1], A. Stegner [2], T. Arsouze [1], A. Santi Coimbra De Oliveira [1] and I. Taupier-Letage [3]
[1] ENSTA-ParisTech - nadia.mkhinini@ensta-paristech.fr
[2] LMD
[3] MIO

Abstract
The aim of this study is to detect and quantify the eddies along the Lybio-Egyptian (LE) coast. We analyse the results of a regional ocean model adapted for the Mediterranean region. We extract characteristics of the LE eddies (size, intensity, trajectory, lifetime ...) using a tracking algorithm. These statistics are compared with drifter or altimetry data.

Keywords: Circulation models, Salinity, Mesoscale phenomena, Levantine Basin, Libyan Sea

Introduction - The circulation in the eastern Mediterranean is characterized by a high mesoscale activity. In particular, anticyclonic eddies are flowing along the Lybio-Egyptian coasts, mainly eastwards [1] but sometimes westwards [2]. In this study, we use a high resolution simulation to study the circulation in this area, and we apply an eddy tracking algorithm to identify the mesoscale eddy trajectories.

Tools - The eddy-resolving model is MED36, a 1/36 degree resolution configuration with 75 vertical levels, based on the NEMO system in a regional configuration of the Mediterranean Sea. This model is close to the MED12 model [3] with both higher horizontal and vertical resolutions. MED36 is forced by the atmospheric forcing ARPERA, which is obtained by performing a dynamical downscaling of ECMWF products above the Mediterranean Sea over the period 1998 to 2011 [4]. Then a tracking code [5] is used at 30 m depth to detect the core of the eddies and their trajectories. This code is based exclusively on the geometry of the velocity vectors.

Eddies tracking - An example of the preliminary results is shown in Figure 1. The core of eddies detected by the algorithm from the velocity fields are represented by elliptical close contours with a star for the center. Then to identify the trajectories of those eddies, daily analyses are made during the EGYPT-EGITTO compaign [4] in 2005-2006. Big structures as the Ierapetra eddy south-east of Crete are easily detected, but smaller or less recurrent eddies are more difficult to detect. Several parameters of the algorithm have to be modified to increase the accuracy of the algorithm. Some coastal eddies located in the Ionian Basin are flowing westwards. Large Libyo-Egyptian eddies are relatively permanent features while smaller eddies are flowing eastwards. The same tracking algorithm has been applied to the AVISO geostrophic currents and the model results were compared with it. The agreement is good between the two sets of data and the observed trajectories from EGITTO-EGYPT are well reproduced.

Conclusion - These analyses shows that in the Levantine basin, the model is able to reproduce a realistic circulation with the presence of both Ierapetra Eddy and Libyan eddies. Nevertheless the algorithm must be improved to better highlight and clarify the modelled eddy dynamics along the Libyan coast.

Acknowledgments - Modeling work was supported by Mercator Ocean. Computations were made at IDRIS from the CNRS (project i010227). Atmospheric forcing was made available by CNRM.

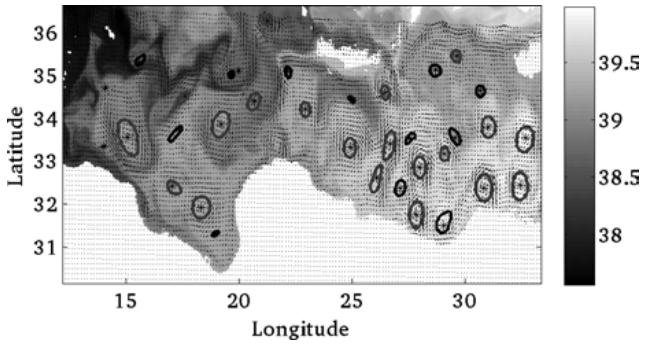

Fig. 1. Snapshot in November 2006 in MED36v75 simulation. Salinity (grey) and currents (vectors, $m.s^{-1}$) at 30 m depth. Eddies detected by the tracking algorithm are indicated with a star for the center and for their diameters with a black elliptical close contours for cyclones and grey close contours for anticyclones.

THE WINTER-SPRING TYRRHENIAN SEA SURFACE CIRCULATION

Ernesto Napolitano [1]* and Roberto Iacono [1]
[1] ENEA - ernesto.napolitano@enea.it

Abstract
Altimeter data and numerical results indicate that, from late winter to mid spring, a well-defined surface circulation is present in the eastern part of the Tyrrhenian Sea, made of a stream of Atlantic water that meanders around several cyclone-anticyclone couples, while progressing cyclonically along the Italian coasts. It is suggested that this circulation pattern may result from basin scale instability of the Atlantic stream.

Keywords: Circulation, Tyrrhenian Sea

A detailed understanding of the circulation structure in the central and eastern parts of the Tyrrhenian Sea (TYS) is still lacking. The area appears characterized by complex dynamics (see, e.g. [1]), but in the recent reconstruction of the spring 2004 circulation by Vetrano *et al.* [2] it was found occupied by large cyclonic and anticyclonic structures, also present in typical spring altimeter data. These structures could therefore be robust features of spring dynamics around which the flow and the transport organize. To gain further insight, we have analyzed the long time series of altimeter data now available (SALTO-DUACS data provided by AVISO; http://www.aviso.oceanobs.com/duacs/). Here we present results from this analysis, which confirm and extend the picture sketched in [2]. Our main finding is that in winter-spring a consistent mean flow can be individuated in the eastern TYS, formed by a stream of Atlantic water (AW) that meanders around several anticyclonic structures located along the Italian coast, having cyclonic companions offshore. The signatures of these vortices clearly appear in the maps of Sea Level Anomaly (SLA) and of Absolute Dynamic Topography (ADT). As an example, we show in the left panel of Figure 1 the March ADT map over the eastern TYS (average over 1993-2010), with a geostrophic reconstruction of the circulation superposed. The coastal anticyclonic cells (to the north of Sicily, off the Calabria coast, off Naples, and off Rome) are clearly seen in this map, as well as their cyclonic companions offshore.

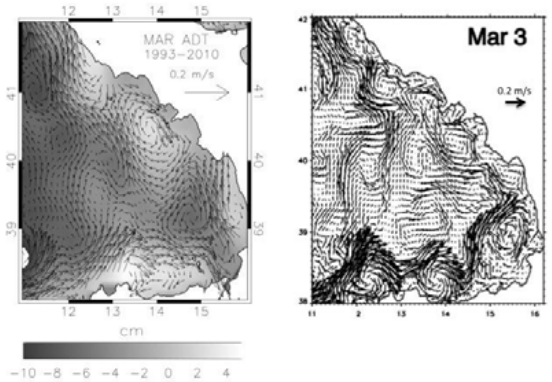

Fig. 1. Circulation in the eastern TYS. Left: average March ADT with geostrophic circulation superposed. Right: surface flow from an operationa model (March 3, 2009)

The signatures of these structures are seen from mid winter to mid spring, and become stronger and better defined towards the end of the winter, when the cyclonic wind forcing weakens. Analysis of the energy exchanges indicates that in this period eddies extract energy from the mean flow, suggesting the presence of a basin scale instability of the AW stream. Support to this picture also comes from the outputs of a high-resolution operational model of the TYS circulation (see [3]). The right panel in Figure 1 shows the surface flow (10 m of depth) of March 3, 2009, displaying strong meanders in which anticyclones (cyclones) are nested near shore (offshore) (the genesis and evolution of this structure is illustrated in Figure 6 of [3]).

An idealized experiment with the Princeton Ocean Model was also performed. The model has realistic bathymetry, but no surface forcing, and is initialized with zero velocity and typical winter stratification, with no horizontal gradients. Net barotropic transports are prescribed at the open boundaries (+ 0.7 Sv at the Sardinia Channel, - 0.7 Sv at the Corsica Channel, and 0 Sv at the Sicily Strait), together with realistic temperature and salinity sections. By day 150 (Figure 2) several robust vortices have formed, anticyclonic near shore, and cyclonic on the offshore side of the stream, in most of the places in which the altimeter anomalies are located. Thus, even in absence of surface forcing, baroclinic adjustment to the boundary conditions and to the bathymetry is capable of producing a circulation pattern similar to that observed in the eastern TYS.

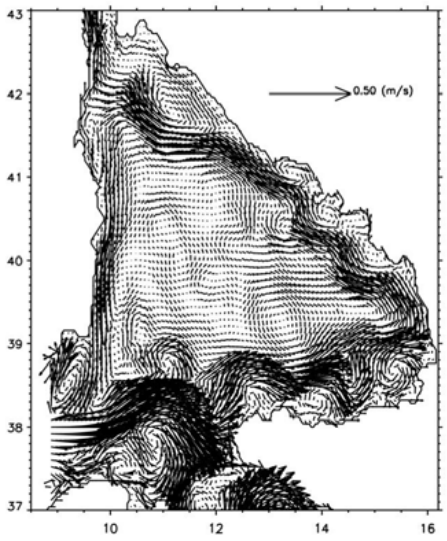

Fig. 2. Idealized POM experiment (details in the text). Surface flow at day 150.

Abstract
The dynamics of the bottom layer of the southern Adriatic Sea are investigated merging experimental data and numerical simulations. The observed continuous temperature and salinity increase, interrupted by the sudden intrusion of very dense water masses, is hypothesized to be one cycle of a general "saw-tooth" pattern: alternation of long-lasting linear increase (mixing phase) and sudden decrease (dense water intrusion phase) of temperature and salinity. Model results corroborate this theory reproducing the observed oceanographic features and giving a basin-scale view of the investigated process.

Keywords: South Adriatic Sea, Deep waters, Models

This study aims at exploring and understanding the dynamics of the bottom layer (below 1000 m) of the southern Adriatic Sea (SAS) merging direct measurements and numerical simulations. The SAS has been constantly monitored since November 2006 by means of the E2M3A deep mooring located in its central part (Lat. 41°32'N, Lon. 18°05'E, Fig. 1), and by several oceanographic cruises [1].

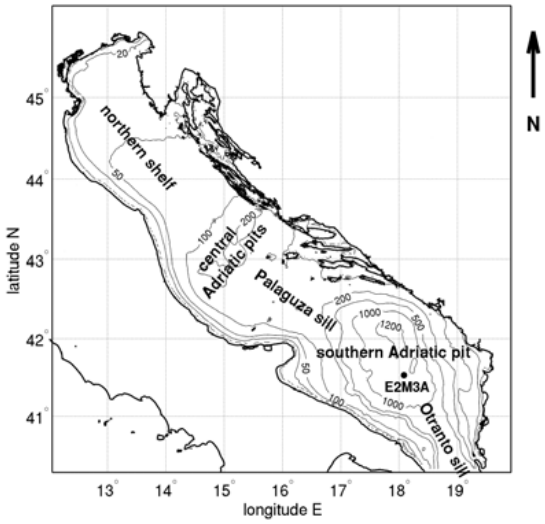

Fig. 1. Coastal and bathymetric map of the Adriatic Sea

Experimental time series running from November 2006 until March 2012 show that the bottom layer (~1200 m) was characterized by a continuous temperature (T) and salinity (S) increase (linear trend of ~0.05°C/y and ~0.004 psu/y, respectively), with a resulting density decrease. The positive trend was interrupted only in March 2012 by the intrusion of a very dense water vein (Northern Adriatic Dense Water, NADW), which was generated by an exceptional Bora event on the northern/central shelf. This sudden dense water intrusion modified abruptly the system, dropping both T and S.
In this study we demonstrate that the long-lasting (~5 years) "linear" increase is caused mainly by local mixing processes (i.e., mesoscale and sub-mesoscale turbulence). Moreover, we hypothesize a "saw-tooth" modulation of two main alternating phases: the long-lasting linear increase (mixing phase) and the sudden decrease of T and S (NADW intrusion phase). Under this assumption, the ventilation of the bottom layer of the SAS depends on the "return period" of exceptionally cold and dry winters.

We use a numerical model of the Adriatic Sea in order to have a basin-scale view of the observed oceanographic features and to corroborate the proposed interpretation of the experimental data. Numerical simulations are carried out customizing the MITgcm (Massachusetts Institute of Technology general circulation model), a three-dimensional, finite volume, general circulation model, with horizontal resolution of 1/32° (~3.4×2.4 km) and 60 unequally spaced levels [2]. Numerical results reproduce properly the spatial and temporal thermohaline variability in the SAS, as well as its main mesoscale features. When seeking an explanation for the long-lasting "linear" phase (T and S increase, density decrease) in the bottom layer, we can exclude possible thermal and chemical contributions from external sources (e.g., submerged volcanoes) because the model reproduces the bottom dynamics without considering any kind of external source. Moreover, the thermohaline trend can neither be ascribed to the open-ocean deep convection in the SAS, because deep convection is very limited in time and never reached depths greater than 1000 m. Conversely, the bottom of the SAS is a system surrounded by shallower sills (Palaguza (180 m) and Otranto (800 m) on the northern and southern side, respectively) and it is characterized by an almost permanent cyclonic circulation. Local mesoscale and sub-mesoscale turbulent processes, highlighted by model results, tend to slowly homogenize the deepest water masses there.

Abstract
The 2012 yearly maintenance of the HydroChanges moorings operated at Gibraltar jointly by Morocco (Faculté Polyvalente de Larache /FPL) and France (Mediterranean Institute of Oceanography /MIO/Aix-Marseille University/CNRS/IRD/USTV) had to be organized with a French research vessel. This was the opportunity to carry a hydrological campaign involving French, Moroccan and Spanish teams, focusing on high resolution, both in space and time. Seven transects across the strait yield an unprecedented detailed insight of the hydrological situation.

Keywords: Circulation, Hydrology, Alboran Sea, Gibraltar Strait, Water transport

Introduction

The time series recorded by moored instruments in the Strait of Gibraltar have shown the importance of the variability, from tidal to interannual scales, and the complexity of the hydrological situation (identification of the water masses exiting the Mediterranean, respective distribution in the cross-section…) [1, 2, 3].

The 4-day hydrological survey HydroChanges on board the R/V Tethys II (INSU/CNRS) was designed to address the issue of the very high spatial and temporal variability in the Gibraltar Strait. For the first time transects across the strait of Gibraltar have been performed with CTD casts spaced every ~1 mile, and /or with a Moving Vessel Profiler (MVP), a towed free-falling CTD down to ~500m that enables a ~800m-spacing interval, whenever possible occupying the same transects as GIBEX (Fig. 1). A total of 306 MVP profiles have been acquired along transects R1, R2, R3, R4, R7 and R7'. CTD profiles were interleaved when depth too great for MVP: 26 CTD casts have been recorded on transects R2, R5 and R7'. Transect R1 has been performed twice within ~6hours, and R2 3 times (1 with 11 CTD casts and 2 with MVP) within ~12 hours in order to capture different tidal situations. Thermosalinometer and ADCP data were recorded underway.

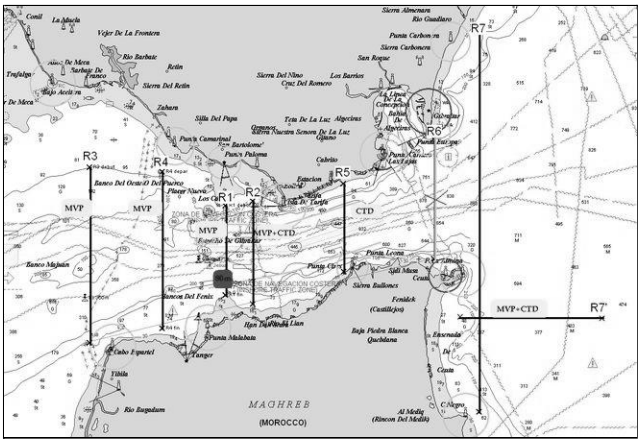

Fig. 1. Map of the sampling during the HydroChanges Gibraltar campaign in July 2012.

Results

The data processing is still underway at the time of writing. Nevertheless it is possible to see from now on the quality of the information about the waters stratification in the strait (Fig.2). The results of the CTD and MVP profiles will detailed, and this 5-day situation (a snapshot), will be analyzed in conjunction with the time series recorded on moorings.

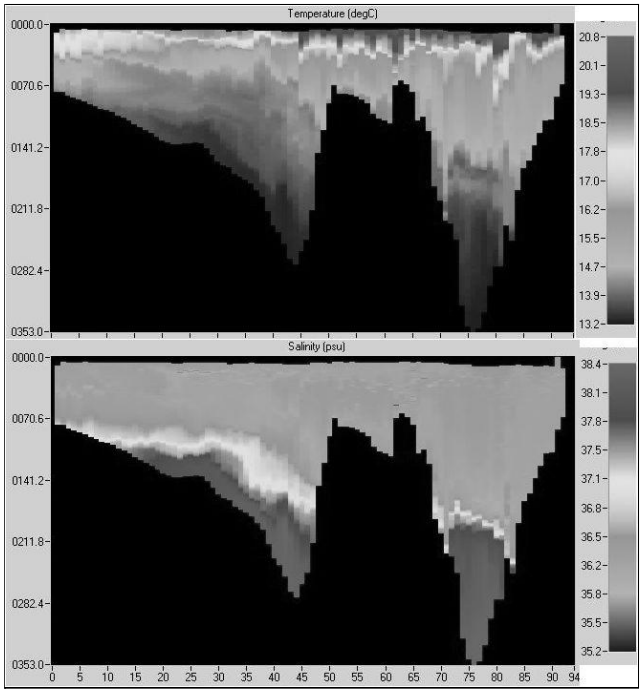

Fig. 2. MVP series of 94 CTD profiles across the R3 transect (from North (left) to South (right)).

Abstract
Investigation of submesoscale eddies having horizontal dimensions of 1-10 km at the narrow shelf of the north-eastern Black Sea was carried out in 2007-2013. *In situ* hydrophysical data were complemented by the remote sensing. Generation mechanisms of the submesoscale shelf eddies were studied by using laboratory models.

Keywords: Coastal processes, Black Sea

In the report we present some results of recent investigation of the fluid dynamics variability over the narrow north-eastern Black Sea shelf. It was revealed that short-term (1-100 hours) and submesoscale (1-10 km) variability of shelf currents depends on the coast orography and bottom topography and is strongly effected by fluid dynamics over continental slope and deep part of the sea.

The regular *in situ* observations were carried out and the satellite remote sensing data were analyzed for the north-eastern Black Sea (Gelendzhik region) during 2007-2013 as follows: the cross-shelf CTD sections; the towed ADCP surveys with submesoscale resolution; the bottom mounted ADCP measurements at selected sites; the moored profiler Aqualog surveys of vertical thermohaline structure and current velocity; the NOAA, MODIS-AQUA and MODIS-TERRA and MERIS-Envisat satellite imagery (sea surface temperature, chlorophyll "a", water leaving radiance. It was found that characteristic feature of the sea current variability is an intermittency of its along-shore and cross-shore components accompanied by rather intensive water exchange between the shelf zone and the open sea [1].

In general, the observed variability was associated with formation and alongshore transfer of the submesoscale eddies having diameter in the range of 1-10 km. These eddies were ageostrophic and non-stationary in nature and their life-time normally did not exceed several days. The main energy source for the submesoscale eddy generation was due to the open sea circulation – mesoscale and basin scale currents over the continental slope and deep part of the sea. On the base of observations two main physical generation mechanisms for the submesoscale eddies were suggested. The first one was the shear instability of the alongshore current. The second was associated with the alongshore current detachment from the shoreline at the cape which resulted in periodical formation of eddies behind the cape and their separation from the coast.

Both mechanisms were studied by means of laboratory modeling. Several experiments were conducted in the cylindrical tank on top of rotating platform filled by homogeneous fluid (distilled water) [2]. To study the first generation mechanism, the cases of cyclonic and anticyclonic shear between a core of alongshore current and a coast were reproduced in the rotating fluid. It has been shown that in the presence of a current with cyclonic shear, chain of eddies were formed in wide range of non-dimensional shear. In case of a current with the anticyclonic shear, chain of eddies was observed only at rather small values of shear and by contrast, the current had chaotic turbulent structure at large non-dimensional shear. An asymmetry in the conditions of the eddy-like structure formation in the alongshore current with cyclonic and anticyclonic shear was explained by simple physical model.

An investigation of the second mechanism indicated that the periodic eddy formation behind the cape and separation of eddies from the coast occurs only in the case of decelerating cyclonic alongshore current in rotating fluid (Fig. 1).

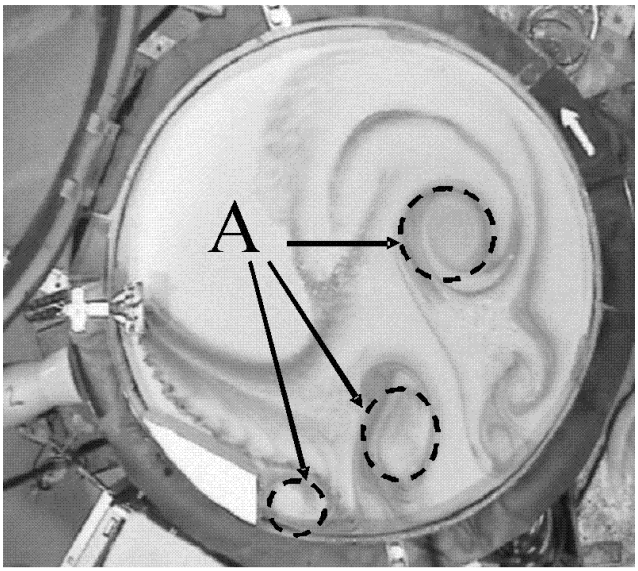

Fig. 1. Periodic formation of anticyclonic eddies (A, dotted circles) behined a cape in rotating fluid in the case of decelerating cyclonic alongshore current (top view).

An explanation for the physical nature of this effect was suggesteded. The dependences of eddy basic parameters (diameter, orbital and translational velocity, etc.) on time and other external parameters of the experiment were establised.

Results of the laboratory experiments were used to interprett the observations of the submesoscale eddies at the narrow shelf of the north-eastern Black Sea.

SURFACE CIRCULATIONS IN THE SICILY CHANNEL INFERRED FROM A NEURAL CLASSIFICATION APPLIED TO A 50-YEAR NUMERICAL EXPERIMENT

M. Jouini [1], K. Béranger [1]*, T. Arsouze [1], S. Thiria [2], J. Beuvier [3], S. Somot [4] and M. Crépon [2]

Abstract
As the surface circulation in the Sicily channel is highly variable, we have applied a neural clustering method on 30-m depth currents of a 50-year high resolution model to identify the different important circulation regimes. We have then showed that a part of the classes therefore obtained correspond to different seasonal modes and some others are the signature of an inter-annual variability.

Keywords: Water transport, Sicily Channel, Circulation models

Introduction - The circulation in the Sicily Channel (SC) can be described as a two-layer exchange of inflowing Atlantic Water (AW) and outflowing of dense eastern Mediterranean waters discharging in the Tyrrhenian Sea. At the SC entrance, due to topographic effect, the Algerian Current splits into three branches, one entering into the Tyrrhenian Sea while the two others pass through the SC and enter into the Eastern Mediterranean. These later branches are the Atlantic Tunisian Current (ATC), and the Atlantic Ionian Stream (AIS) (see [1] for a review). The variability of the SC surface circulation is therefore investigated using a 50-year simulation of a high resolution model of the whole Mediterranean Sea. To separate large and mesoscale variability, we first investigate the different important regimes by clustering 30-m depth currents into groups having close statistical properties. For each regime, we tried then to study its mesoscale activity.

Tools - The eddy-resolving MED12 model [2] was forced by daily atmospheric fields during the 1958-2011 period. Then we used a neuronal network classifier, the Self Organizing Algorithm (SOM) [3], which is an unsupervised classification method made of a competitive neural network structured in two layers. The first layer represents the input layer, which receives the data, L hereinafter, and made of the u and v velocities components at 30 m depth during 50 years taken on a SC subgrid. The second one is a 2D-classes grid composed of typical circulations, with a topological ordering and resuming at best the input data L. The objective of SOM is hence to summarize the information contained in one multivariate study set L of all daily situations by producing a small number of reference vectors ***rv***s statistically representative of the surface circulation. Each neuron represents a subset of L that gathers data having common statistical characteristics (not usually linear) and is associated to one ***rv***s.

Results - Once SOM is applied on L, we obtained a 5x6 SOM map providing 30 ***rv***s reference vectors corresponding to 30 typical circulations.The large number of classes allowed taking into account the complexity of the dataset and let to analyze the circulation regimes and their associated mesoscale variability. This high number of circulation regimes is difficult to interpret in term of physical processes. To counteract this difficulty, this large number was aggregated into a smaller number by using an Hierarchical Ascendant Classification method (HAC)[4]. The 30 situations were reduced to 7 typical circulation regimes . The inspection of the 7 typical circulation classes showed a strong seasonal signature. For example, classes 5 and 3 mainly occur in winter and present an enhancement of the ATC while classes 6 and 2 mainly occur in summer and characterize an enhancement of the AIS. Classes 4 and 1 are occurring during short time periods only. The atypical regime 7 seems to be associated with a change of the general circulation of the Mediterranean Sea. The regime variability inside each class reflects its mesoscale variability.

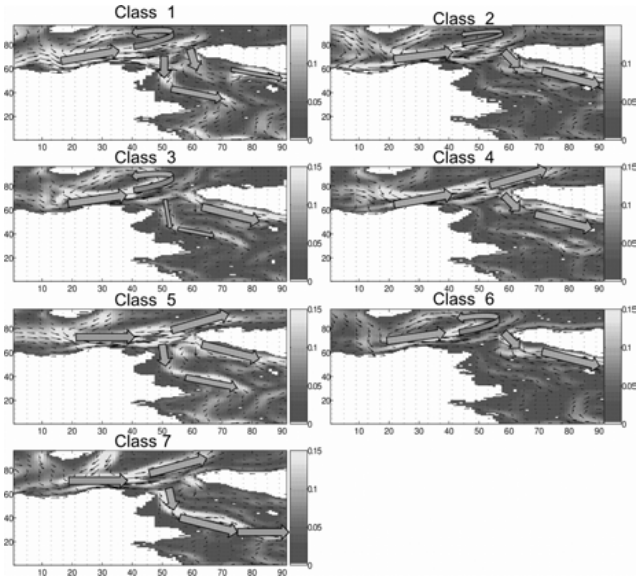

Fig. 1. The 7th typical circulation regimes.For each class,the color bar correspond to the current intensities and black arrows represent the current directions.

Conclusion – The classification method allows new analyses of the Sicily Channel circulation at the seasonal and interannual scales. The role of mesoscale features in reproducing typical circulation patterns could also be highlighted and quantified.

Acknowledgments - Modeling work was supported by Mercator Ocean. Computations were made at IDRIS from the CNRS (project i010227). Atmospheric forcing was made available by CNRM.

DENSE WATER BOTTOM CURRENTS IN THE SOUTHERN ADRIATIC SEA IN SPRING 2012

Abstract
Following the formation of very dense water in the northern Adriatic shelf during the severe cold spell in February 2012, a rapid-response cruise was organized by CNR-ISMAR to sample the flow and fate of the dense water in the Southern Adriatic Sea. In addition to the measurements carried out during the surveys, five moorings continuously monitored the bottom layer temperature, salinity and currents in selected sites in the southern Adriatic Sea. Data collected allowed to carry out a description of the veins of bottom density currents, both in time and space.

Keywords: South Adriatic Sea, Currents

In February 2012, the European region experienced a 2-weeks severe cold spell. This cold spell was triggered by a large Siberian high causing blocking of the Atlantic flow, forced northward, and retrogression of westward flow of dry and cold air masses from eastern Russia along the southern flank of the anticyclone all the way to Europe. This situation caused temperature as low as -40 °C in north-eastern Europe and –10° to –20°C in central Europe, with significant snowfall in southern Europe associated to deep lows in the Mediterranean Sea. The Northern Adriatic Sea was heavily impacted by this cold spell, with large decrease of surface temperature and the onset of severe north-easterly Bora wind, blowing almost continuously and intermittently reinforced by cyclogenesis in the western Mediterranean. A significant heat loss took place in the basin with surface water temperatures as low as 3-6 °C. The Lagoon of Venice partially froze. The impact of this extremely cold outbreak, the severe cold and dry Bora flow and the very limited discharge of the Po river in the preceding autumn, caused therefore the formation of extremely dense shelf water, with potential density anomaly as high as 30.5 kg/m^3 [1]. After few weeks, the dense shelf water reached the Southern Adriatic, where it sunk through successive cascading events. Rapid-response cruises were organized by CNR-ISMAR and the Southern Adriatic was extensively sampled by the R/V Minerva Uno (leg1, 23 March – 2 April 2012) and R/V Urania (leg2, 14-20 April 2012) with CTD-rosettes equipped with additional sensors for fluorescence, dissolved oxygen, LADCP as well as ship-borne ADCP and XBTs. In addition to the 3D snapshot carried out during the surveys, five moorings continuously measured temperature, salinity, currents and downward particle fluxes by means of SBEs, ADCPs and automatic sediment traps, respectively. CTD data sampled the veins in both legs, with dense water flowing on the shelf of the southern Adriatic as cold as 10.5 °C and sampled maximum density of 29.7 kg/m^3, relatively high in salinity (due to the unusually low discharge of rivers in the generation area) and rich in oxygen. Conversely, the bottom layer sampled by moorings and CTD casts off the shelf, few tens of meters thick, showed temperature seldom lower than 13 °C, yet significant velocities (above 50 cm/s several times). This is suggestive of significant mixing during cascading. Data collected allowed to carry out a description of the veins, both in time and space (Figure 1). The time series analysis showed significant differences in the behavior of the dense water flow at the mooring locations.

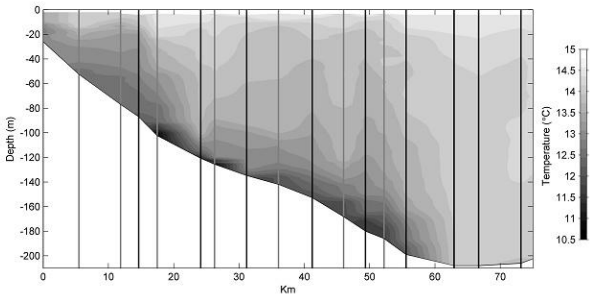

Fig. 1. Figure 1: vertical transect of in-situ temperature from CTD and XBT showing the vein of dense water flowing southward along the shelf in the Southern Adriatic Sea.

FLUCTUATIONS IN THE ADRIATIC: THE BIOS MECHANISM AT WORK IN THE LAST 130 YEARS

Abstract
In 1953, Buljan published the first detailed study on the salinity variability in the Adriatic Sea ("Fluctuations of salinity in the Adriatic"). Analyzing several oceanographic campaigns from 1875 to 1949, he hypothesized a mechanism called "Adriatic Ingression" at the base of the salinity oscillations in the Adriatic Sea. Here, the effects associated with the Adriatic ingressions are more appropriately explained by the recently discovered Bimodal Oscillating System (BiOS) mechanism, connecting the change of salinity with the circulation in the Ionian Sea. Our analysis is corroborated by the physical, biogeochemical and biological observations carried out in the past 130 years.

Keywords: Ionian Sea, Otranto Strait, South Adriatic Sea, Alien species, Salinity

The term "Adriatic Ingression" (AI), according to the original formulation, denotes the fluctuations of salinity in the southern and middle Adriatic (hereafter called Adriatic Sea, AS) due to the intensification of the flux of intermediate waters from the Ionian Sea through the Strait of Otranto. The term was first coined by Buljan [1], after an extended analysis of the results obtained by early oceanographic investigations in the Adriatic carried out in the first half of the 20th century. Together with the salinity increase, the AI implies a parallel increase of nutrients, since the Levantine Intermediate Water (LIW) is both the saltiest and the nutrients richest water mass in the Ionian as well as in the Eastern Mediterranean. Then, the AI mechanism impacts the thermohaline properties and the biogeochemistry of the AS. In addition, also the biology is affected by the increased availability of nutrients for the primary production during the ingression periods.

Recently, Civitarese et al. [2] have associated the periodical variation of salinity in the AS, in the period 1986-2012, with the upper layer circulation of the Northern Ionian Gyre (NIG), that in turn depends on, and influences the thermohaline properties of the Adriatic Dense Water (AdDW) produced in the AS. This mechanism was called Adriatic-Ionian Bimodal Oscillating System (BiOS) [3]. According to the sense of circulation of the NIG, the pathways of the Atlantic Water (AW) and of the water of Levantine/Aegean origin change on decadal scale, consequently changing the thermohaline properties of the water advected into the Adriatic through the Strait of Otranto.

Civitarese et al. [2] have shown that the change of salinity in the AS was accompanied by the change of the biogeochemical properties, and that nutrients variations were out of phase with the change of salinity. This is clearly in contrast with the AI view, where the variability of the LIW flux at the Strait of Otranto is responsible for the increase of both salinity and nutrients. On the other hand, in the BiOS perspective, the exchange at the Strait of Otranto is implicity considered stationary [4].

Results emerging from the literature of the 19th and 20th centuries and the available experimental data, suggest that the reported Adriatic ingressions can be considered as the past manifestation of the BiOS mechanism. Two results are worth mentioning: (i) the salinity variations in AS and Ionian Sea recorded from 1950 till now are mostly in phase (Fig. 1), in agreement with the advective impact of the Ionian circulation on the AS as expected in the BiOS mechanism; (ii) a number of biological recordings of alien organisms of the Western Mediterranean or Atlantic origin during the phases of minimum salinity in tha AS also suggests again the advection of those waters through the Strait of Otranto, a phenomenon not considered in the AI mechanism.

In conclusion, several signs confirm that the BiOS mechanism was already working in the past century, affecting the decadal variability of salinity, biogeochemical and biological properties of the Adriatic Sea. In his fundamental paper [1], Buljan stressed that in the AS "the ingressions leave a marked impression on both the quantitative and qualitative composition of populations". Although referring to a mechanism here revised, i.e. the AI, Buljan's words still hold their validity after more than fifty years, and should be guidelines for future research.

Abstract
A recent developed network of biogeochemical profiling floats in the Mediterranean Sea is used to confirm the biogeographical repartition of the basin obtained using phenological criteria and remote sensing data. Preliminary results are presented in the context of the relationship between the phytoplankton phenology, the circulation features of the basin and the biogeographical repartition of the basin; additionally, sensors calibration and coherence with ocean colour observations are also discussed.

Keywords: Biogeography, Ocean colours, Levantine Basin, North-Western Mediterranean, Ionian Sea

Satellite ocean colour observations of surface chlorophyll concentrations confirmed that several phytoplankton phenological regimes exist in the Mediterranean Sea [3]. The spatial distribution of these phenological regimes resulted in a biogeographical repartition of the basin, where each bioregion displays statistically similar seasonal cycles. Ocean colour observations are, however, limited to the ocean surface, calling into question the relevance of the proposed Mediterranean biogeography. The biogeography is dependent on the circulation features and its temporal variability, as shown for e.g. Ionian Sea [2]. Therefore, only by combining satellite observations with a significant consistent number of vertical in situ profiles could we shed light on the mechanisms inducing the existing phenological differences.Profiling floats (which are at the basis of the international Argo program, [6]) appear as a promising technology to obtain continuous and satellite-like (in terms of quantity of data) observations of open ocean biogeochemistry. In particular, a new generation of profiling floats equipped with biogeochemical sensors has recently emerged, demonstrating the capability of this technology for biogeochemical ocean studies [1,4,7]. In this work, we present data obtained with a recently developed network of biogeochemical profiling floats operating in the Mediterranean Sea. Floats are based on the Provor platform and are equipped with a complete suite of biogeochemical sensors (Chlorophyll and CDOM fluorescence, backscattering, three wavelengths irradiance, PAR, nitrate and oxygen, [5]). They were developed in the framework of French project NAOS (PIs P.Y. LeTraon and F. D'Ortenzio, www.naos-equipex.fr), although Mediterranean deployments and data analysis are organized on the basis of an international collaboration. We present here the results in the context of the relationship between the phytoplankton phenology, the circulation features of the basin and of the biogeographical repartition of the basin; additionally, sensors calibration and coherence with ocean colour observations are also discussed.

CLIMATE OF THE MEDITERRANEAN SEA

Paola Malanotte-Rizzoli [1]*
[1] Massachusetts Institute of Technology - rizzoli@mit.edu

Abstract
A Report written by a number of Mediterranean scientists acting as members of a newly formed Pan-Med group under the auspices of IOC/UNESCO and of CIESM was published in their respective web sites in September 2012. The major motivation for this Report was a call for a Pan-Mediterranean initiative bringing together the western and eastern oceanographic communities for the evolution and strengthening of a broad, interdisciplinary collaboration focused on the unique features of the Mediterranean Sea.

Keywords: Global change, North-Eastern Mediterranean

Paola Malanotte-Rizzoli Massachusetts Institute of Technology A Report written by a number of Mediterranean scientists acting as members of a newly formed Pan-Med Group under the auspices of IOC/UNESCO (Intergovernmental Oceanographic Commission/United Nations Educational, Scientific and Cultural Organization) and of CIESM (The Mediterranean Science Commission) was published in their respective web sites in September 2012.The Report in its turn stemmed from a workshop held in Rome in November 2011, on the occasion of the 25th anniversary of the POEM (Physical Oceanography of the Eastern Mediterranean) Programme. The objectives of the workshop were however rather more ambitious that having simply a memorial. First, the workshop was meant to provide a synopsis of the state-of-the-art of research and present knowledge of the Mediterranean Sea physical/chemical/biological properties. Secondly, it wanted to offer the opportunity to scientists working in different regions of the sea, both in the Western and Eastern basins, to meet and share ideas, and hence foster pan-Mediterranean collaborations. The importance of the Mediterranean Sea for the world ocean has long been recognized. First, the Mediterranean Sea has a profound impact on the Atlantic Ocean circulation. The Mediterranean salty water tongue exiting from the Gibraltar strait at intermediate depths and spreading throughout the Atlantic interior has been evidenced in the literature since long. Even more importantly, the Mediterranean sea is a laboratory basin for the investigation of processes of global importance, being much more amenable to observational surveys because of its location in mid-latitude and its dimensions. Both the western and eastern basins in fact possess closed thermohaline circulations. A unique upper layer open thermohaline cell, analogous to the global conveyor belt, connects the eastern to the western basin and, successively, to the north Atlantic through the Gibraltar strait. In it, the Atlantic water entering via Gibraltar in the surface layer, after travelling to the easternmost Levantine basin, is transformed into one of the saltiest water masses through air-sea heat and moisture fluxes. This is the salty water which, crossing the entire basin in the opposite direction below the surface Atlantic water, finally exits from the Gibraltar strait at mid-depths. The western and eastern basins are in turn endowed with deep/intermediate convection cells analogous to the polar Atlantic deep convection cells or to the intermediate mode water ones. Deep and intermediate water masses are formed in different areas of the basin. These convection cells are readily accessible to direct observational surveys and mooring arrays. Both wide and narrow shelves are present separated from the deep interiors by steep continental slopes. Cross-shelf fluxes of physical as well as biogeochemical parameters are crucial in determining the properties of the shallow versus deep local ecosystems and their trophic levels (chains). Most importantly, the Mediterranean Sea is a basin of contrasting ecosystems, from its strongly oligotrophic deep interiors to the fully eutrophic northern Adriatic, which is characterized by recurrent, anomalous algal blooms and related anoxia or hypoxia events. For reasons that may be linked to geographical locations and national scientific policies, the western and eastern basins have, in the past, been mostly investigated independently from each other. Recent international collaborative programs such as the Gibraltar Experiment, the Western Mediterranean Circulation Experiment (WMCE), the Programme de Recherche Internationale en Méditerranée Occidentale (PRIMO) and POEM itself, all have investigated separately the western and eastern basin or subbasins of them. Only in the last two decades the European research projects have addressed scientific issues related to the entire Mediterranean Sea, such as MATER, SESAME, PERSEUS etc. The major motivation for the Report was therefore a call for a Pan-Mediterranean initiative bringing together the western and eastern oceanographers and for the further evolution and strengthening of a broader, interdisciplinary collaboration to create a full integrated Mediterranean community of physical, chemical, biological oceanographers and of climate scientists.

AFTER DEEP WATER FORMATION: SINKING AND SPREADING OR REORGANISING PHASE, INCLUDING UPWELLING?

Jordi Salat [1]*, Mikhail Emelianov [1], Eugenio Fraile [2] and Mikel Latasa [2]
[1] Institut de Ciències del Mar (CSIC) - salat@icm.csic.es
[2] Instituto Español de Oceanografía

Abstract
Oceanographic data obtained by mid spring at open sea in the central part of the NW Mediterranean reveal evidences that almost two months after the open sea Deep Water Formation (DWF) process, there are still energetic mechanisms reorganising the water mass structure. Among those, clear indications of a relevant upwelling below the thermocline, that would contribute to maintain the early spring open sea phytoplankton bloom

Keywords: Circulation, Blooms, Deep sea basins, North-Western Mediterranean, Upwelling

Traditional description of the DWF cycle in the Western Mediterranean involves a final phase of sinking and spreading of the newly formed deep water. At the same time, the upper level is progressively recovering its stratification. Both mechanisms are well known. While the first has been obviously observed in the deep layers, the latter has been identified as the main driver for the typical phytoplankton blooms, especially in those areas where deep water formation was previoulsy active. These descriptions assume that on slacking the thermohaline DWF forcing, exerted by strong, dry and cold winds, the sea recovers its typical circulation patterns. Then, vertical motions are almost negligible and horizontal current intensity is decaying with depth, at least in the upper and intermediate layers. Spring phytoplankton blooms developing during this stage can stand for a couple of months, often depending on the intensity of the former DWF process and the, not so scarce, early spring storms [1]. However, to our knowledge, nothing has been reported about possible upwelling of intermediate waters into the upper layer as a mechanism contributing to sustain and perhaps extend the period of blooming.

Within the framework of the "Famoso" project (Fate of the Northwestern Mediterranean Open sea Spring bloom) two cruises were carried out in the NW Mediterranean, in March and early May 2009 respectively. Winter 2009 was considered to be "normal" to "cold" in terms of DWF [2]. At the beginning of the March cruise DWF was still active and, at the end of the cruise the phytoplankton bloom was clearly growing. In early May, several patches of high chlorophyll were still present in the vicinity of the formerly active DWF areas. A closed box around one of these chlorophyll patches was surveyed with the on-board ADCP and a SeaSoar towed system covering the upper 400 meters of the water column. The box was almost closed, from late 29 April to 2nd May, and the flow across the boundaries was estimated in two layers above and below the 29.0 isopycnal. Surprisingly, the results show that in the upper 400 m outflow was much higher than inflow (Figs 1 and 2). One can easily assume that the missing flow through the opening at the N corner of the box should compensate the output on its western side, since it falls under the path of the well know slope current. However, even with this assumption the outflow still remained much higher than inflow. Since the shape chlorophyll distribution at surface evidences that the SE corner of the box was almost at the centre of a cyclonic eddy, another part of the uncompensated flow could be explained if the eddy were moving towards the SW during the survey. However such situation would compensate not more than an additional 20%. Thus the remaining ~50% could only be explained assuming an additonal inflow from below 400 m. Although most of this flow left the box below the 29.0 σ_t surface, part of which would reach the upper layer above that isopycnal (~60-100 m) within the photic zone. In addition to this surprising result, during the cruise there were additional evidences (not shown) for relatively strong currents at depths below 400 m as well as the presence of LIW at less than 200 m depth in several stations. The region thus, at early May, was still involved in a reorganising phase after DWF.

Summarising, the results show evidences that the last phase of the DWF would not only include sinking and spreading of the newly formed DW but also other energetic processes leading to the reorganisation of the dynamic structures, including upwelling pulses that would contribute to maintain the spring phytoplaknton bloom in NW Mediterranean open sea.

Abstract
Recent intensive observation field campaigns and reanalysis of past observations allow an intensive evaluation of the North-Western Mediterranean open-sea deep convection process in the fully-coupled CNRM regional climate system model. Both case study for specific Winter (e.g. 2011-2012) and interannual variability are well reproduced. Using the model, a comprehensive description of the interannual variability of the process is proposed as well as a first analysis of the main driving factors.

Keywords: Deep waters, Water convection, Open sea, Models, North-Western Mediterranean

Introduction
The North-Western Mediterranean Sea is known as one of the only place in the world where open-sea deep convection occurs (often down to more than 2000m) with the formation of the Western Mediterranean Deep Water (WMDW). At the event scale, the WMDW formation is characterized by different phases (preconditioning, strong mixing, restratification and spreading), intense air-sea interaction and strong meso-scale activity but, on a longer time scale, it also shows a large interannual variability with impact on the regional biogeochemistry. Simulating and understanding the temporal variability of this open-sea deep convection is thus a challenging task for the ocean and climate modelling community.

Modeling approach
In order to achieve such a goal, we developed a Mediterranean Regional Climate System Model (RCSM) that includes high-resolution representation of the regional atmosphere (ALADIN, 50km), land surface (ISBA, 50km), rivers (TRIP, 50km) and ocean (NEMOMED8, 10km). All the components are interactively coupled daily without any constraint at the air-land-river-sea interfaces and a simulation over the period 1979-2012 has been performed using the atmosphere ERA-Interim reanalysis and the ocean NEMOVAR1° reanalysis as 4D lateral-boundary conditions. Spectral nudging technique is applied in the atmosphere to better constrain the large-scale atmospheric circulation.

Winter 2011-2012 case study
We first evaluate the ability of the model to simulate one of the most recent and best observed WMDW formation events: Winter 2011-2012. Time series of air-sea flux, surface water characteristics, mixed layer depth dynamics, convective surface, water mass characteristics and deep water formation rate are analyzed and compared to in-situ observations (Durrieu de Madron et al. 2013) of the programs MOOSE, HyMeX and MERMEX. The model is able to match well the available observations (see for example the mixed layer depth chronology in Fig. 1) despite a slight underestimation of the newly-formed deep water density (29.12 maximum value instead of 29.13 kg/m^3) and of the estimated deep water formation rate (0.44 Sv instead of 1.1 Sv).

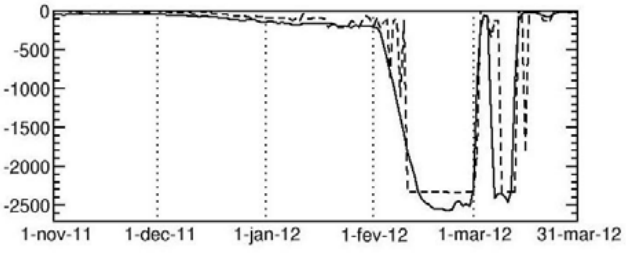

Fig. 1. Daily mixed layer depth time series (1st Nov. 2011 – 31st March 2012, in meter) in the center of the convective area (near 42°N-5°E) for the observations (dashed line) and for the model (full line).

Understanding the interannual variability
The model shows a very good ability to reproduce the observed past chronology of the mixed layer depth in the Gulf of Lions with 75% of the years showing maximum mixed layer depth higher than 1500m. In addition, the model shows about 50% of the years with a deep water formation rate higher than 0.1 Sv (for waters > 29.10 kg/m^3) with three years above 1 Sv (1981, 1999, 2005). The 1980-2012 interannual variability of this open-sea deep convection is then analyzed comparing the relative role of the water column preconditioning before Winter and of the Winter (DJFM) accumulated buoyancy loss in driving the annual maximum depth of the mixed layer and the deep water formation rate. The variability of the intensity of the deep convection is strongly related to the buoyancy loss but it is also correlated to the preconditioning of the water column (see Fig. 2). As an illustration, a Winter buoyancy loss less than 0.6 m^2/s^2 leads to negligible annual deep water formation rate whereas November stratification index higher than 0.9 m^2/s^2 are likely to prevent intense deep convection.

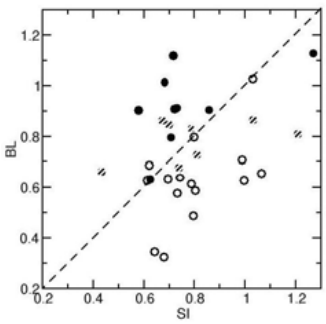

Fig. 2. Scatter-plot (1 circle per year) of the preconditioning stratification index (SI in m2/s2) versus the cumulative Winter buoyancy loss (BL in m2/s2), white/dashed/plain circles show deep water formation rate respectively <0.1 Sv / [0.1-0.4] Sv / >0.4 S.

FACTORS FAVORING LARGE ORGANIC PRODUCTION IN THE NORTHERN ADRIATIC: TOWARDS THE NORTHERN ADRIATIC ECOLOGICAL MODEL

Romina Kraus [1], Nastjenjka Supic [1]* and Robert Precali [1]
[1] Rudjer Boskovic Institute - supic@cim.irb.hr

Abstract
The high interannual variability in the primary production of the northern Adriatic possibly reflects on the secondary production of the entire Adriatic. Although phytoplankton blooms are usually high in summer, the winter phytoplankton blooms are of special interest as in that period of low stratification especially large amounts of organic matter can be produced. Applied PCA analyses show that interannual variability in the winter production is primarily related to circulation, while the one in the spring/summer production is an immediate response to the Po River discharge. In addition, forcings from the previous period, up to a year, play a significant role in interannual changes of bioproduction.

Keywords: Circulation, Organic matter, Monitoring, Models, North Adriatic Sea

Introduction
The northern Adriatic (NA) is held to be one of the most productive regions of the Mediterranean Sea. However, its productivity is high only when influenced by the Po River, whose impact on the region significantly varies on seasonal and annual scales (Fig. 1). If waters of the Po River do not reside in it, the NA is oligotrophic like the rest of open Adriatic areas. Long-term changes in the NA organic production are therefore highly pronounced, and, most likely reflect on the secondary production of the entire Adriatic region or even wider.
An ecological model could explain and eventually predict long-term changes in the organic production of the region. In order to prepare grounds for it, we have tried to distinguish the main factors responsible for large organic production of the NA, throughout empirical analysis of long-term measurements in the region.
Although phytoplankton blooms are very high in summer, we have mainly focused to the winter ones [1]. When, in conditions of low stratification the nutrient rich Po River waters spread across the NA, they can fill volumely large spaces and induce exceptionally large organic production in general (as observed in 2004). Such events could probably result in an exceptional increase in the secondary Adriatic production.

Data and methods
Oceanographic data were collected monthly to seasonally in the 1990-2000 interval at six stations at a section in the NA (Figure 1). PCA and simple linear correlations were used to investigate relations between phytoplankton blooms and surface geostrophic currents relative to 30 dbar between the stations, Po River discharge rates, and atmospheric fluxes.

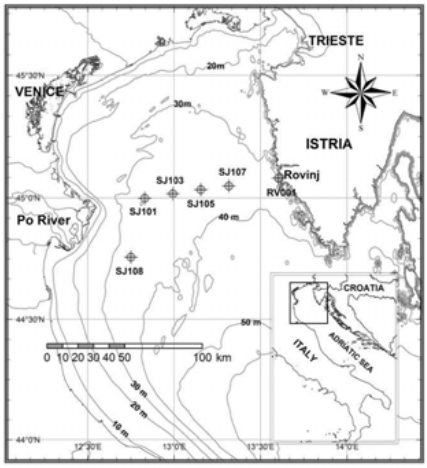

Fig. 1. The northern Adriatic with map of sampling stations.

Results and discussion
Long-term changes in phytoplankton abundances at the section between the Po River delta and Rovinj in winter (Jan and Feb) significantly depend on the circulation patterns, while in spring/summer (May-Jul) a direct Po River influence could be attributed (Table 1). However, discharge in the previous period, up to 45 days earlier, reflected possibly on winter blooms (Table 1).
High Po River discharge rates in the preceding summer along with intense evaporation and low Po River rates in the preceding autumn favoured large winter (Feb) blooms at st. SJ108, SJ101 and SJ107 (not shown). On the contrary, intense blooms in summer (Jul) at the same three stations were favoured concomittantly by high Po River rates in previous summer, autumn and winter, by heavy rain in the preceding autumn, and by enhanced insolation in the previous spring.

Tab. 1. Correlation coefficients between the first (F1) or second (F2) mode of interannual changes in phytoplankton abundance at 6 stations of Figure 1 in a chosen month (I to XII; abundances were normalized before performing PCA) and first two modes of geostrophic current distribution across the Po section at the sampling time (C1 and C2), Po discharge rates on the same day (Po), as well as cumulative values of Po discharge rates in period preceding the sampling, up to 1 (Po-1), 5 (Po-5), 10 (Po-10), 30 (Po-30) or 45 (Po-45) days. Correlations significant at 95% CL are bolded.

	F2	0,41	0,12	0,61	0,58	0,61	0,62	0,58	0,58

Conclusion
The obtained results, showed that oceanographic forcing at the time of sampling and in previous periods, are important for the understanding of the long-term variability of the NA organic production, and can be used to forecast such events. In addition, they can be used for development of the NA ecological model.

AN INTERNAL MECHANISM ALTERNATIVELY DRIVES THE PRECONDITIONING OF BOTH THE ADRIATIC AND AEGEAN SEAS AS DENSE WATER FORMATION SITES IN THE EASTERN MEDITERRANEAN

Dimitris Velaoras [1]*, George Krokos [1] and Alexander Theocharis [1]
[1] Hellenic Center for Marine Research Institute of Oceanography - dvelaoras@hcmr.gr

Abstract
Dense water produced in the Aegean Sea during the late 2000's supports the existence of a rather permanent thermohaline pump mechanism that regulates the production of dense/deep waters in the Adriatic and Aegean Seas. The mechanism disturbs the Eastern Mediterranean (EMed) upper thermohaline cell modifying their hydrological structure which alternatively preconditions each Dense Water Formation (DWF) source. The role of this internal mechanism seems to prevail over the long-term atmospheric influence in DWF events.

Keywords: Aegean Sea, Levantine Basin, Circulation, Deep waters

The Adriatic and the Aegean Seas are the two dense/deep water producing sources in the EMed. It has been shown [1] that during the 1960 - 2000 period these two areas presented alternating competitive cycles of DWF which were followed by periods of less intense activity. The mechanism responsible for the alternation of dense water production is based on their antagonistic functioning in controlling the EMed deep thermohaline cell at almost decadal time intervals. The massive outflow of dense water through the deepest layers of these two marginal seas during their active phases is balanced by increased inflow from the upper layers. Thus, a thermohaline pump is created that advects upper layer available water masses towards the active areas through their straits and gradually disturbs the upper thermohaline cell of the EMed finally modifying the main water mass pathways. This disturbance is portrayed in two different modes: Following the activation of the Adriatic Sea, the Atlantic – Ionian Stream (AIS) is deflected towards the North Ionian with limited eastward flow resulting in the recirculation of the Levantine Intermediate Water (LIW) in the Levantine. Therefore salinity gradually increases in the eastern part of the EMed which leads through preconditioning to DWF in the Aegean Sea. Respectively, the activation of the Aegean Sea re-establishes the AIS eastward flow and consequently restores the LIW westward return flow. The mechanism modifies the thermohaline structure of the water column, alternatively preconditioning each source area.

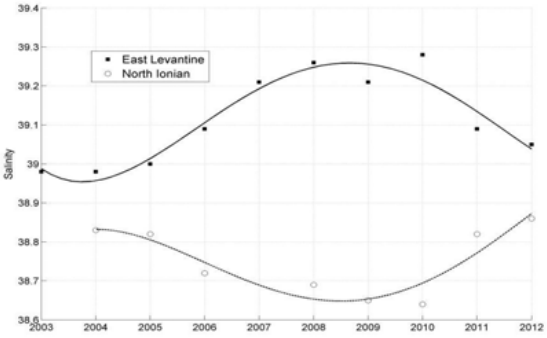

Fig. 1. Yearly mean integrated salinity values for the first 300m in the N. Ionian and E. Levantine Seas (2003-12). Polynomial curves have been added for clarity

Recent field studies [2] have provided solid indication of dense water formation taking place in the Aegean Sea a few years after the 2006 AIS deflection towards the North Ionian [3]. Dense water outflow has been monitored in the Western Cretan Straits during 2007, 2008 and 2009 characterized by high temperature and salinity values and with potential densities occasionally reaching up to 29.21 kg/m3.
Using ARGO and Glider data from the MyOcean project's data pool [4], yearly mean integrated salinity values in the first 300m were produced for the eastern Levantine basin (east of 31ºE) and the North Ionian Sea (north of 37ºN) for the available data period 2003-12. The results (figure 1), show a clear anti-correlated behavior between them with an apparent almost decadal signal. Following the 2006 AIS deflection upper thermocline salinities in the North Ionian decrease, while the eastern Levantine salinities are enhanced. In order to estimate the contribution of the atmosphere we examined the net heat flux derived from the ERA Interim reanalysis dataset [5]. Results presented in figure 2, show that the recent activation of the Aegean is not characterized by any significant thermal interaction with the atmosphere. The same conclusion can be reached by examining the E-P budget (not shown). The role of the air-sea interactions should nonetheless not be underestimated since severe winter atmospheric events can modulate the intensity of the DWF, as in the case of the Eastern Mediterranean Transient.

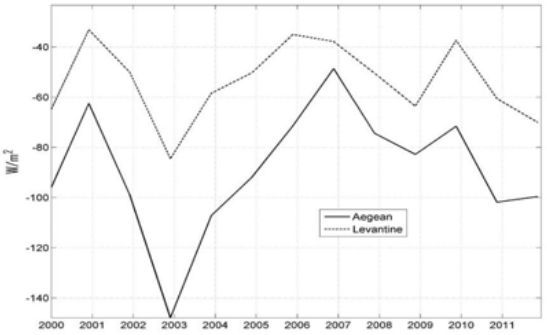

Fig. 2. Winter net heat budget (December to March) in the Aegean and Levantine Seas (2000-12)

[3] Dept of Physics, National Kapodistrian University of Athens

Abstract
In the framework of the European Marine Strategy Framework Directive, the mixing characteristics and residence times of the Hellenic seas are reviewed and analyzed. To that purpose, analysis of Lagrangian observations is used, as well as other methods, wherever applicable. The method of Optimum Multiparametric Analysis is also used and compared to Lagrangian and hydrographic estimates, to assess mixing of water masses and age of deep waters. The above methods compare quite well in the intermediate and deeper waters. Both Lagrangian analysis and a variety of other methods, including velocity shear measurements, buoyancy budgets, density overturn analysis and specially planned Lagrangian experiments are also employed in an assessment of horizontal and vertical mixing in the Hellenic Seas.

Keywords: Surface waters, Turbulence, Circulation, Currents, Aegean Sea

In the framework of the Greek response to the European Marine Strategy Framework Directive (EMSFD), a review of mixing assessments and water residence times is attempted for the parts of the Mediterranean surrounding Greece, hereby referred to as the Hellenic Seas. For the purposes of the EMSFD, the seas surrounding Greece were divided into four major sub-basins, i.e. the North, Central and South Aegean, the NW Levantine and NE Ionian Seas. In each of these basins, estimation of mixing rates and residence times was based on the availability of surface drifter (in the surface layer) and ARGO float tracks (in deep waters), as well as other methods, whenever applicable. Regarding residence times, surface estimates were obtained through drifter tracks provided by the MedSVP project (http://nettuno.ogs.trieste.it/sire/medsvp/) and by the data set of the University of Athens. The residence times for each of the above sub-basins were estimated by averaging the times over which the drifters remained within the sub-basin, normalized by the ratio of zonal or meridional extent of the basin to zonal or meridional extent of each drifter track, to account for limited drifter lifetimes.

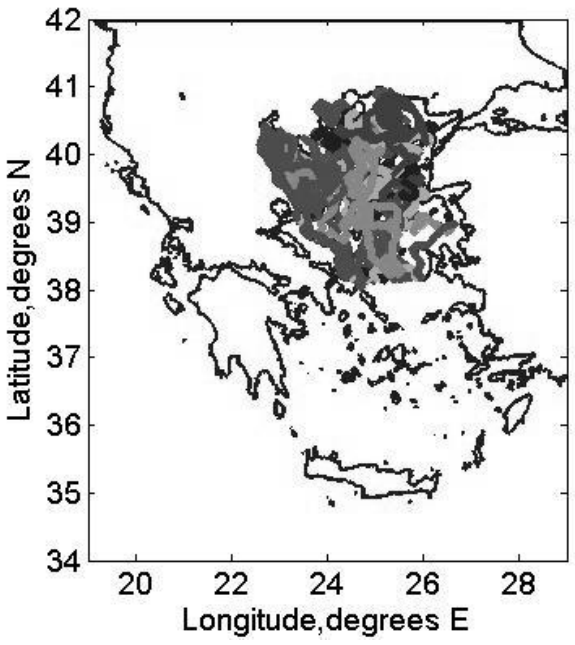

Fig. 1. Spaghetti diagram of the drifter tracks used for the estimation of mixing and residence times in the North Aegean sub-basin

The same method was applied on a much smaller data set of ARGO floats for the deeper layers.
The method of Optimum Multiparametric Analysis (Karstensen and Tomczak, 1998; Leontiou, 2010) has been exploited for the estimation of residence times in intermediate and deep waters. The surface residence times based on drifter tracks in the surface layer naturally increased with basin size, ranging from 20 days in the Central Aegean to 150 days in the Northwestern Levantine. In the deeper layers of the Aegean the ARGO float tracks, whenever available, provided estimates comparable to the OMP method results. In the Ionian and Levantine Seas, residence time increased with distance from the Cretan Straits, ranging from 1 year to 30 years, based on the OMP method. ARGO float estimates should provide significantly smaller numbers, as the OMP method inherently incorporates the mixing taking place within a whole basin. The description of mixing processes in each sub-basin was also assessed via a range of methods. Horizontal mixing was addressed via the surface drifter and ARGO float observations, by estimating the eddy diffusivities through calculating Lagrangian decorrelation scales. Again, these estimates were applied over the whole sub-basins reported above, thus the considered mixing processes include all sub-basin scale circulation. Our results vary from 350 m^2s^{-1} in the North Aegean to more than 3000 m^2s^{-1} in the Levantine for the surface layer, and from 80 m^2 s^{-1} in the South Aegean to 140 m^2 s^{-1} in the Levantine Sea for the deep layers. A review on vertical mixing estimates provides values ranging from 10^{-5} to 10^{-3} m^2s^{-1}, based on a spectrum of methods ranging from direct shear measurements via microstructure profilers (Gregg et al., 2012), to buoyancy budget estimations (Zervakis et al., 2003), to mixing assessment observed through Lagrangian experiments (Zervakis et al., to be submitted) as well as obtained via analysis of density overturns (Kioroglou et al., manuscript under revision).

Abstract

Four companion eddy-resolving simulations, obtained by running the NEMO code in regional Mediterranean configurations differing only by the horizontal or the vertical resolution grid, are compared during the 1998-2011 period with a focus on the Western Mediterranean Transition event in 2004-2006. The increase of the model resolution highlights the models skills in simulating such processes as the water mass formation and spreading towards the southern boundaries of the basin.

Keywords: Circulation models, Water convection, Mesoscale phenomena, Gulf of Lyon, Algerian Basin

Introduction - The Western Mediterranean Transition (WMT) is a strong event [1] occurring during the winter 2004-2005 in the Western Mediterranean resulting in the formation of a large amount of Western Mediterranean Deep Water (WMDW). The newly formed WMDW then invaded the whole Western Mediterranean in a relatively short period of time. Our modeling study compares four companion eddy-resolving simulations obtained by running the NEMO code in regional Mediterranean configurations differing only by the horizontal or the vertical resolution grid. The first configuration MED12v50, considered as our reference, is well described in [2] and refers to a 1/12° ORCA grid with 50 vertical levels. The second configuration MED12v75 refers to a 1/12° ORCA grid with 75 vertical levels. The third and the fourth configurations refer to a 1/36° ORCA grid with 50 and 75 vertical levels, MED36v50 and MED36v75 respectively. All the simulations used MEDATLAS climatology [3] in October 1998 as an initial condition and were forced from 1998 to 2011 by the ARPERA atmospheric fields, at about 50km resolution [4].

Results - The first study of the reference simulation MED12v50 has shown the role of deep mesoscale cyclones in transporting a large amount of new WMDW in the southwestern Mediterranean, in agreement with altimetry data [5]. The companion simulations are compared to the reference simulation on the 2004-2006 period and the differences are quantified in terms of horizontal patterns and WMDW formation rate, mesoscale eddy characteristics and drift, and bottom spreading towards the Channel of Sardinia and the Strait of Gibraltar.

The increase in the horizontal resolution consequences an increase of the formation rate for density higher than 29.11 $kg.m^{-3}$ (Table 1) in particular in 2006. The increase in the vertical resolution consequences an increase of the formation rate, more pronounced for density higher than 29.12 $kg.m^{-3}$ (Table 1). The horizontal resolution increase consequences a decrease in the diameter of deep cyclones transporting WMDW southwards by 20km (80 km against 100 km in the reference run) , while the vertical resolution increase consequences an increase of the deep cyclone southern drift velocity with higher bottom speed, in better agreement with the satellite data [5] and observations of [1].

Conclusion - The MED36v75 model shows a realistic formation rate and characteristic time for southward spreading in the basin, although the newly formed WMDW caracteristics are a little too cold and less salty than when compared to the observations of [1], partly due to the influence of the modeled shelf waters coming from the Cap Creus. In both MED36 simulations, as for 2005, the winter 2006 shows intense deep convection and WMDW formation, contributing to the fast spreading southward observed.

Acknowledgments - Modeling work was supported by Mercator Ocean. Computations were made at IDRIS from the CNRS (project i010227).

EVOLUTION OF THE DISSOLVED OXYGEN IN THE CENTRAL PART OF THE NW MEDITERRANEAN SEA: NEW RESULTS ABOUT THE WATER MASS PROPERTIES CHANGE OVER THE LAST 20 YEARS

Laurent Coppola [1]*, Dominique Lefevre [2], Louis Prieur [1] and Vincent Taillandier [1]
[1] Laboratoire Océanographique de Villefranche CNRS UPMC - coppola@obs-vlfr.fr
[2] Institut Méditerranéen d'Océanologie Université Aix-Marseille CNRS, France

Abstract
Recent studies evidenced that intermediate and deep water masses properties in the western Mediterranean Sea are affected by the propagation of the EMT signal and the deep convection events. The long oceanic time series operated at the DYFAMED site (Ligurian Sea) since 1993 recorded recent and rapid change of the water mass properties. We present here new results from the dissolved oxygen, more sensitive to the dynamic processes, to detect deep convection process and intrusion of new water mass that occurred over the last 20 years in the Ligurian Sea and affecting the biogeochemical budget.

Keywords: Oxygen, Time series, Ligurian Sea

Recent studies evidenced that climatic changes does not only occur at centenary and millenary scales, but may also occur at much shorter time scales. This is particularly important for the Mediterranean Sea, where the spatial and temporal scales are one order of magnitude smaller than in the global ocean. Since the late 80s a rapid and extended change of the deep water formation cell in the eastern basin has been observed (Eastern Mediterranean Transient event). More recently, modifications of the deep and intermediate water masses properties have been also observed in the western basin suggesting a propagation of the EMT event (so called the Western Mediterranean Transient) and more intense local deep convection events with a probable impact on marine ecosystems. This change shows the importance for a continuous monitoring of the Mediterranean circulation in strategic area to estimate the impact of the water circulation on biogeochemistry cycles. The DYFAMED time series (Ligurian Sea) represents one of the longest oceanic time series in the Mediterranean Sea where water mass changes have been already observed [1]. To detect hydrodynamic change, T and S parameters are currently used. Here we propose to use the dissolved oxygen concentrationsand more sensitive to the physical processes and which has been acquired at the DYFAMED site since 1993 (EUROSITES, PERSEUS and MOOSE since 2010). These new results allow us to observe the variability of the deep convection events, the water mass ventilation and the intrusion of new water mass that occurred in the Ligurian Sea over the last 20 years and affecting the biogeochemical budget. For example, since 1993, the dissolved oxygen concentrations showed the lowest values in the Levantine Intermediate Water at the DYFAMED site (from 170 to 190 umol/kg) with a strong variability due to mixing process. In the deeper waters (~2,000m depth) O2 concentrations showed less variability (from 200 to 215 umol/kg) with the maximum could be related to the deep convection processes that appeared some winters in the Ligurian Sea.

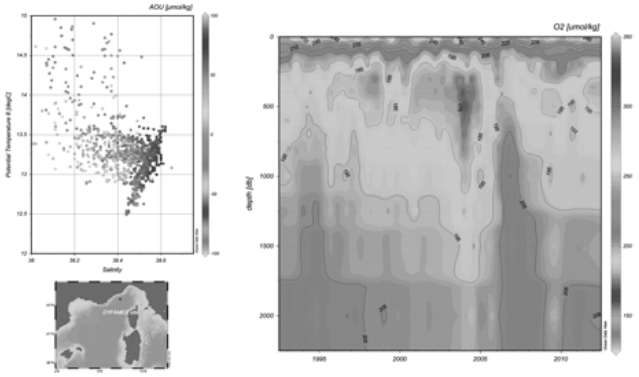

Fig. 1. Time series of the dissolved oxygen concentrations measured at the DYFAMED site. Data have been acquired from bottles sampling and Winkler method.

SEASONAL VARIATIONS OF ORGANIC MATTER AND NUTRIENTS IN THE NORTHEAST MEDITERRANEAN (MERSIN BAY)

Emine Erdogan [1]*, Süleyman Tugrul [2] and Özden Bastürk [1]
[1] Mersin University, Faculty of Fisheries - emineerdogan@mersin.edu.tr
[2] Middle East Technical University, Institue of Marine Sciences, Erdemli 33731, Mersin, Turkey

Abstract
In the present study,4 field studies,in the April 2010 – February 2011 period,were conducted in the eastern region of Mersin Bay extending from Mersin city up to Seyhan River delta.In the river-fed coastal waters, nitrate values were high (1.1 -9.2 µM);the low phosphate(0.06-0.16 µM)values result in higher N/P ratios (35-50) in nearshore waters.Surface total phosphorus, chlorophyll-a and particulate organic matter displayed similar spatial distributions, decreasing 5-10 times in the offshore waters, exhibiting seasonal variations. POM values were as high as 10.9-88.4 µM for POC, 1.5-8.3 µM for PON and 0.05-0.27 µM for PP in the polluted shallow zone, with the POC/PON: 7.1-10.6 and PON/PP: 18-35 ratios.These ratios generally ranged between 7 and 10 as the concentrations decreased markedly in the oligotrophic offshore waters of the bay.

Keywords: Eutrophication, Nutrients, Particulates, Mersin Bay

Shelf waters of NE Mediterranean (Cilician basin) have been polluted by discharges of the major rivers (Seyhan, Ceyhan) and domestic wastewaters of the big cities in the region. Therefore, eutrophication phenomena have increased in the Mersin bay shallow waters fed by polluted river and domestic water discharges. On the other hand, open surface waters of the Eastern Mediterranean is a typical example for the oligotrophic seas [1-2]. This study aims to assess inpacts of land based inputs on the distributions of eutrophication- related biochemical parameters in the bay, covering the affected coastal zoen and offshore waters (Fig. 1). Four field surveys were conducted by R/V BILIM during the April, 2010-February, 2011 (funded TUBITAK within 107G066 project). Conventional methods were followed in the measurements of chemical parameters. Concentrations of dissolved inorganic nutrients, POM, biomass, CHL-a were expectedly high in the nearshore waters of the bay fed by nitrate-rich rivers (with high N/P) and domestic wastewater discharges. Impacts of land-based inputs weaken markedly in the offshore waters due to limited water exchanges between the shallow inner bay and deeper (>50 m) offshore (Fig. 1). Typical surface distributions of nitrate and CHL-a (algal biomass indicator) in the bay show the highly impacted water body in the nearshore zone. In spring-autumn period, surface nutrient values were consistently low in the central and outer bay waters (0.02-0.05 µM for PO_4 and 0.05- 0.67 for NO_3) with relatively low N/P molar ratios (8-15) which increased up to 35-50 in the nearshore waters fed by river discharges.

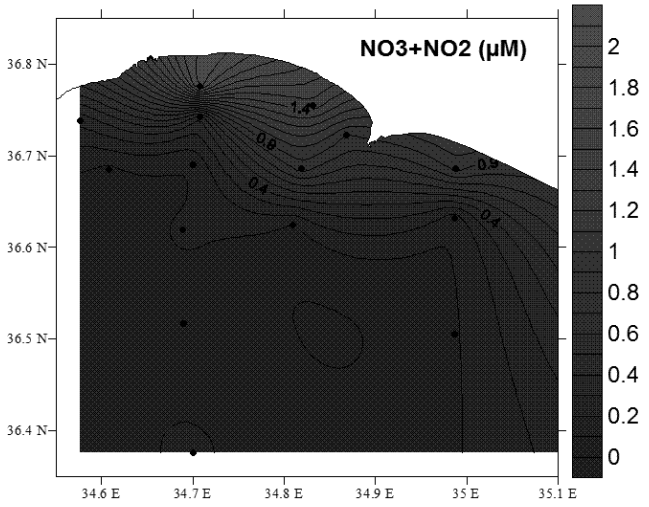

Fig. 1. Surficial distribution of nitrate in the bay in April 2010.

Surface water N/P ratios appears to decrease in spring-autumn period due to decreasing nitrate values of the surface waters. Surface CHL-a concentrations, as low as 0.05-0.15 µg/L in offshore waters displaying oligotrophic properties, increased steadily to 2.7 µg/L level in the river-fed nearshore waters. Apparent increase in the POM conetrations coastal waters with low C/N ratios indicate that the enhanced eutrophication dominates the POM pool in the inner shelf compared to the POM of regenerative origin in the open sea during spring-autumn period. Particulate P and PO4 constituted merely 10-35 % and 8-25 % of TP pool in the nearshore; the rest by DOP which dominate in the TP pool in the euphotic zone of the open sea.

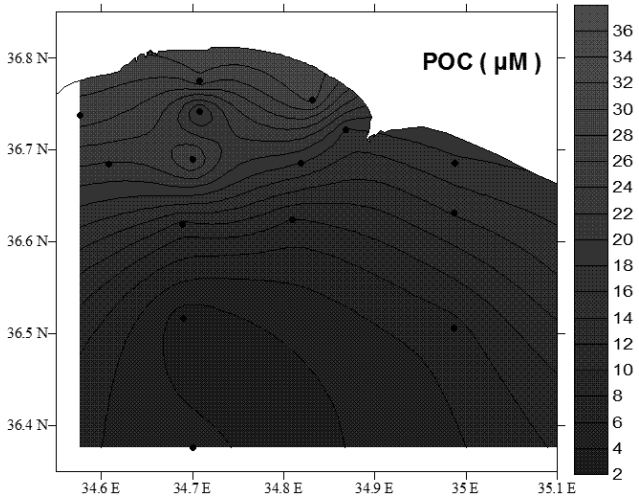

Fig. 2. Surficial distribution of POC in the bay in April 2010.

VARIABILITY OF NUTRIENT CONCENTRATION PROFILES IN RELATION TO SEASONAL PHYSICAL AND BIOGEOCHEMICAL PROCESSES: DATA FROM THE DYFAMED STATION (LIGURIAN SEA)

Orens Pasqueron de Fommervault [1]*, Christophe Migon [1], Fabrizio D'Ortenzio [1] and Laurent Coppola [1]
[1] Université Pierre et Marie Curie, CNRS, UMR 7093 Laboratoire d'Océanographie de Villefranche - orens.de-fommervault@obs-vlfr.fr

Abstract
Nutrient (nitrate, phosphate and silicate) concentrations profiles were continuously measured at the DYFAMED time-series station (Ligurian Sea) between 1991 and 2011, and underwent quality control. Concentration profiles showed seasonal patterns in relation to physical and biogeochemical processes (winter convection, spring bloom, and summer stratification). The interannual variability of nutrient concentrations was examined, which permitted to figure composite years of nutrient concentrations from surface to 200m depth. Nitrate to phosphate ratios permitted to assess the seasonal variability of chemical limitation in this region.

Keywords: Time series, Nutrients, Ligurian Sea

The knowledge of physical and biogeochemical processes that control the availability of nutrients is a key point for the understanding of the chemical limitation of primary production. However, time-series data on nutrient dynamics are still scarse in the Mediterranean Sea. From 1991 to 2011, nutrient concentrations were measured at the time-series DYFAMED site (central Ligurian Sea, 28 nautical miles from the continental French coast, 2350m deep, 43°25'N, 7°52E), now in the framework of the French Service d'Observation MOOSE (Mediterranean Ocean Observing System on Environment). After quality control on the whole data set, outliers and aberrant values were removed. Remaining data permitted to evidence clear patterns in relation to seasonal physical and biogeochemical processes: Winter convection homogenises nutrient concentrations along the water column, resulting in rectilinear profiles. The convection process yields the fuelling of nutrients to the photic layer, which triggers the subsequent phytoplankton bloom, in spring. Then, nutrients are progressively consumed by biota, while the stratification of the water column increases. The depletion of surface waters characterises the oligotrophic season, resulting in typical surface-depleted profiles. Such reproducible patterns permitted to draw composite years of nutrient concentrations, e.g. nitrate concentrations (Fig. 1).

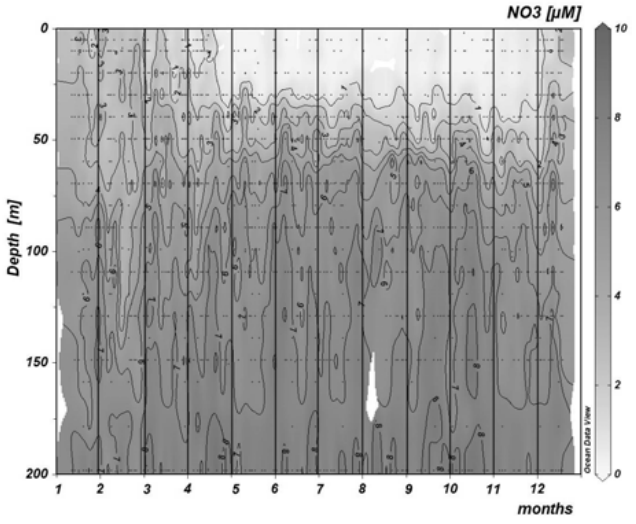

Fig. 1. Seasonal plot of nitrate concentration in the 0-200m layer for a composite year (1991-2011), after quality control at the DYFAMED site.

Ultimately, this data set permitted to assess the seasonal variability of nitrate to phosphate ratios, which evidences the seasonal variability of the chemical limitation of primary production: a shift from nitrate (spring) to phosphate (summer and fall) is characteristic of the north-western Mediterranean [1] (Fig. 2).

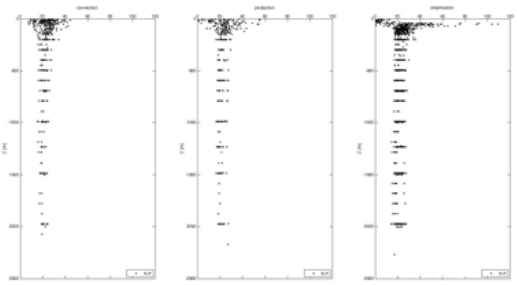

Fig. 2. N:P ratio for the 0-2500m layer at the DYFAMED site. Data are gathered according seasonal patterns: Left, middle and right graphs represent the convective, productive, and stratified periods, respectively. The seasonal variation is clearly marked in the surface layer. Below 500m depth, the ratio is around 21-22, and much less variable. Note that low values calculated at the surface during the stratified period are due to very questionable estimates of the N:P ratio when nitrate and phosphate concentrations are low.

IMPACT OF P VS SAHARAN DUST/AEROSOL ADDITIONS ON THE MICROBIAL FOOD WEB OF THE EASTERN MEDITERRANEAN SEA - A MESOCOSM APPROACH

Paraskevi Pitta [1]*, T. Frede Thingstad [2] and Barak Herut [3]
[1] Institute of Oceanography, Hellenic Centre for Marine Research, Heraklion, Crete, Greece - vpitta@hcmr.gr
[2] Department of Biology, University of Bergen, Bergen, Norway

Abstract
Atmospheric aerosols have been found to supply not only phosphorus but also macro- and micro-nutrients (N, Fe and other) to the Mediterranean. The impact of P alone and Saharan dust/aerosol additions on the microbial food web of the oligotrophic Eastern Mediterranean Sea was studied by means of two mesocosm experiments carried out at the new mesocosm facility of the Hellenic Centre for Marine Research in Crete, Greece, during September 2009 and May 2012, respectively. During both experiments, a wide range of chemical and biological rate and state variables was measured. The results of the two kinds of addition are discussed in terms of their effects on the phytoplankton and bacterial component of the food web.

Keywords: Atmospheric input, Phosphorus, Food webs, Cretan Sea, North-Eastern Mediterranean

The Eastern Mediterranean Sea (EMS) receives high dust fluxes, with maximal inputs, especially from the adjacent Sahara desert, during the spring and early summer periods. Since Saharan dust has been shown to contain bioavailable phosphorus (P) but also macro- and micro-nutrients (N, Fe and other trace metals) [1], dust deposition events could stimulate the biological activity at the Low Nutrient Low Chlorophyll EMS. During the past years, many efforts have been carried out to understand the effect(s) of P-addition on the entire pelagic food web of the P-limited EMS, through a Lagrangian [2] as well as a mesocosm study [3]. However, this kind of ecosystem-level approach has not been used in the case of dust/aerosol in the Eastern Mediterranean.

The impact of Saharan dust and mixed aerosols on the microbial food web of the oligotrophic Cretan Sea was studied during a mesocosm experiment in May 2012 (ATMOMED project), at the new mesocosm facility of the Hellenic Centre for Marine Research in Crete, Greece (http://mesoaqua.eu/cretacosmos). Saharan dust (1.6 mg l^{-1}) and mixed aerosols (1 mg l^{-1}), collected in Crete and elsewhere, were each added to 3 mesocosms of 3 m^3, while 3 more mesocosms were used as control (no addition). A wide range of biological state (abundance and biomass of all biota from viruses to mesozooplankton, bacterial, microplankton and mesozooplankton community composition) and rate (primary, bacterial, viral and mesozooplankton production, bacterial respiration, phosphorus uptake, N2 fixation, photosynthetic efficiency, microzooplankton grazing) variables were measured during 9 days of experiment.

The results of primary production and phytoplankton biomass (mainly *Synechococcus*) indicated a net response of the autotrophic community to both Saharan dust and mixed aerosol additions between days 1 and 4. The response of the heterotrophic bacterial community to both dust and mixed aerosol treatments was also clear but faster than the one of the phytoplankton and lasted only from day 0 to day 2. This would suggest that Saharan dust and mixed aerosol stimulated the auto- and hetero-trophic sides in different time scales and probably triggered interactions between them.

The above-mentioned biological parameters were related to the temporal distributions of numerous chemical species, such as inorganic and organic nutrients, total proteins, total mono- and poly-saccharides and their molecular composition profiles, in order to highlight the production and degradation dynamics of organic matter.

The results of this experiment are compared to the ones of a previous mesocosm experiment with addition of P alone that took place at the same facility, in September 2009 (Nutritunnel project).

The impact of dust and aerosol additions on the microbial food web was spectacularly more significant than the one of addition of P alone and it was evident in the case of both bacteria and phytoplankton whereas only bacteria were found to benefit when P was added to the pelagic ecosystem of the Eastern Mediterranean. This differential response is not unexpected given that atmospheric inputs contain P and N and also that phytoplankton has been found to be N&P co-limited in the area, at least during the warm period [2,3].

TROPHIC STATE OF THE NORTHERN ADRIATIC

Robert Precali [1]* and Tamara Djakovac [1]
[1] Rudjer Boskovic Institute Center for Marine Research - precali@cim.irb.hr

Abstract
The annual mean trophic index and efficiency coefficient were used to address the trophic state of the northern Adriatic in the last forty years. Differences in the efficiency of nutrients use between the western (more eutrophied) and eastern (more oligotrophic) part were identified at the beginning of the investigated period. Later, after the ban of polyphosphates in detergents (mid-eighties) the NA ecosystem showed similar patterns in the whole area.

Keywords: Eutrophication, North Adriatic Sea

Introduction
The trophic state of the northern Adriatic (NA) is mainly under the influence of the Po River (70 % of the inflow), one of the largest Mediterranean rivers. The trophic index (TRIX) and the Efficiency coefficient (EFCO) are widely used to address the trophic state of an area [1]. As the NA undergoes changes in the nutrients availability and the ecosystem responds to that *stimulus* [2], it is important to understand if the trophic state of the area shows same patterns.

Methods
Water samples for nutrients (ammonium, nitrite, nitrate and total phosphorous) and chlorophyll *a* concentration measurements were collected on a monthly scale from 1972-2011 at five oceanographic depths at stations SJ107 (13 Nm off Rovinj) and SJ108 (13 Nm SE off Po River mouth; Fig. 1). Parameters were determined by standard oceanographic methods described in previous authors' publications.

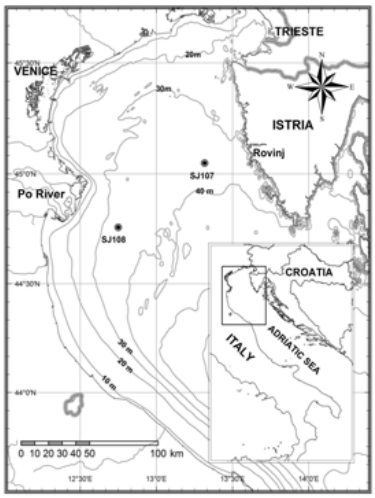

Fig. 1. Northern Adriatic map and station locations.

To understand the changes of the trophic state of NA two indexes (TRIX and EFCO) were calculated as originally stated by Giovanardi and Vollenweider [1]. Data for the surface layer (depth<11 m) were only considered. Cumulative anomaly of those two indexes was calculated summing cumulatively their differences from the average value for the whole investigated period.

Results and discussion
Stations SJ107 and SJ108 (Fig.1) are situated at the opposite ends of the trophic gradient in the NA [1]. The overall mean TRIX at the western station SJ108 is 3.92 and 2.97 at eastern SJ107, indicating that the western one is mesotrophic while the eastern oligotrophic. These differences are maintained through the whole period (Fig. 2). The overall mean EFCO differed at the beginning of the investigated period showing a more efficient use of the available nutrients up to the mid-eighties in the mesotrophic western part. Later, after the ban of polyphosphates in detergents in the eighties no difference between the two stations in nutrient use was detected (Fig. 2).

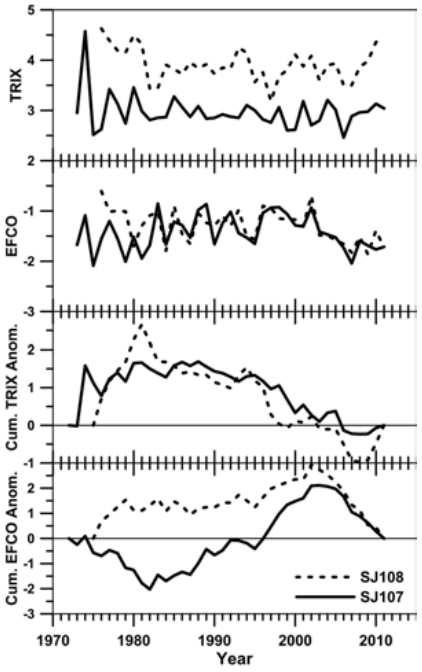

Fig. 2. Mean annual trophic index (TRIX) and Efficiency coefficient (EFCO), Cumulative TRIX and EFCO Anomaly at stations SJ107 and SJ108 for the period 1972-2011 in the surface layer (depth<11 m).

Cumulative TRIX and EFCO anomaly are more difficult to understand because this type of data presentation is a good indicator of systematic behaviour rather than trend. After the eighties they (Fig. 2) show similar patterns on both stations, indicating that the trophic state of the NA after the ban of polyphosphates in detergents and with that lowering the phosphorus pressure, is in the whole controlled by the same processes (nutrient availability – Po River input, forcing from southern basin - intrusions, general circulation - open or closed etc…).

INFLUENCE OF MESOSCALE ACTIVITY ON DOC DYNAMICS: THE TYRRHENIAN SEA CASE

Chiara Santinelli [1]*, Ernesto Napolitano [2], Roberto Iacono [2] and Maurizio Ribera D'Alcalà [3]
[1] Biophysics Institute, CNR - chiara.santinelli@pi.ibf.cnr.it
[2] ENEA, C.R. Casaccia, Roma, Italy

Abstract
Vertical distributions of Dissolved Organic Carbon (DOC) were studied along a section in the southern Tyrrhenian Sea sampled in seven cruises from 2006 through 2011. DOC showed the highest concentrations in the surface layer (0-150 m) with an interesting variability strongly influenced by mesoscale circulation features. Persistent anticyclonic eddies appear to provide a favorable environment for DOC accumulation.

Keywords: Circulation models, Mesoscale phenomena, Carbon, Organic matter, Tyrrhenian Sea

Dissolved Organic Carbon (DOC) represents the largest reservoir of organic carbon on the Earth and plays a key role in the global carbon cycle. Almost all biological processes occurring in the oceans concur to determine its concentration which is also affected by external inputs (e.g., atmosphere, rivers, sediments). Physical processes (water masses circulation, winter convection), on the other hand, redistribute DOC in the Mediterranean Sea and in the Oceans. DOC data were collected along a selected section, starting off the Gulf of Naples and reaching a central location in the eastern Tyrrhenian Sea (39.5°N, 13.5°E), during seven cruises (2006-2011 conducted in different seasons) in the framework of the Italian Project "VECTOR". Altimeter data and maps of surface velocity from an operational model of the Tyrrhenian Sea circulation [1] were studied for the same periods, in order to figure out if the variability in surface DOC distribution could be mainly explained by mesoscale activity. DOC distribution showed a decoupling between the surface layer (0-150 m), where the highest concentrations (57-80 µM) were observed throughout the year, and the intermediate and deep waters, where DOC ranged between 33 and 49 µM. This feature can be explained by the basin's seasonal cycle which, to some extent, may be characterized as permanently stratified. In this basin late winter mixing seems to rarely exceed 120-150 m. This is consistent with the low nutrients concentrations observed in this area even in winter [2], and supports the idea of a basin with a subtropical-like behavior. Surface DOC distribution showed different patterns during the various cruises, without a clear seasonal cycle. DOC vertical distribution superposed to isopycnals is shown for three periods representative of the different patterns (Fig.1). In April 2007 DOC showed high concentration (69-78 µM) down to 100 m in the middle of the section, in August 2010 two maxima (60-73 µM) were observed towards the edges of the section. Low concentrations (53-60 µM) were found in January 2009 above the pycnocline. The structure of the isopycnals suggests the occurrence of an anticyclonic circulation in both April 2007 and August 2010 (even if in this month the high stratification masks this feature in the upper 100 m). No such feature is present in January 2009.

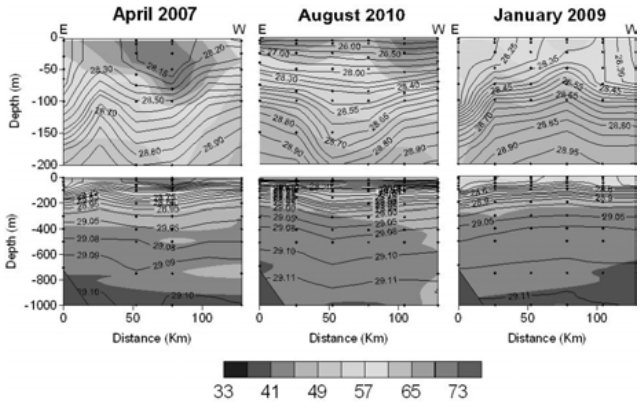

Fig. 1. DOC (µM) vertical distribution along a section in the southern Tyrrhenian Sea. Black lines are isopycnes. CTD data were kindly provided by DiSAm, "Parthenope" University, Napoli and CNR-ISMAR, La Spezia.

To get further information on the horizontal structure of the circulation in the area and to confirm possible effects on the DOC distribution, maps of average Absolute Dynamic Topography from AVISO, with geostrophic circulations superposed, are shown for the same periods (Fig. 2). In April 2007 the section cuts the edge of a strong anticyclonic eddy, that is perfectly centered on the section in August 2010. In January 2009 no such structure is visible and the area is occupied by a coherent northwestward current. These data confirm that mesoscale structures play a major role in shaping DOC distribution in the surface layer of the Tyrrhenian sea as already reported for other areas in the Mediterranean Sea [3] and in the subtropical NE Atlantic Ocean [4]. The presence of a persistent anticyclonic structure may provide favorable conditions for the establishment of high DOC concentrations. However our repeated surveys suggest that the DOC maximum is located on the edge of the structure and not in its core. All the above asks for an in depth analysis of the mechanisms by which mesoscale activity affects DOC accumulation and redistribution in the Thyrrhenian Sea.

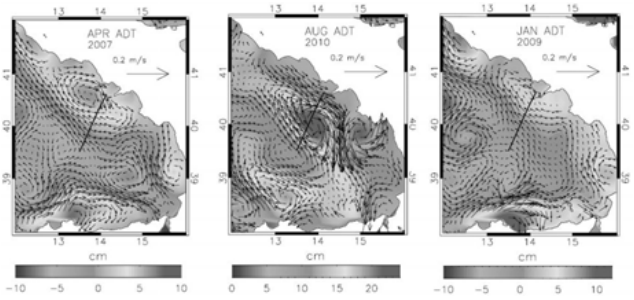

Fig. 2. Maps of average Absolute Dynamic Topography from AVISO for April 2007, August 2010, and January 2009, with geostrophic circulations superposed The section is indicated with a black line.

DISSOLVED ORGANIC CARBON DYNAMICS IN THE MEDITERRANEAN SEA

Chiara Santinelli [1]*
[1] Biophysics Institute, CNR - chiara.santinelli@pi.ibf.cnr.it

Abstract
Dissolved Organic Carbon (DOC) data collected in the Mediterranean Sea during 15 cruises (1999-2011) allow to study the basin-scale DOC distribution and to estimate DOC stocks and fluxes at the straits. This study will also report new information about the metabolic state of the basin.

Keywords: Carbon, Geochemical cycles, Organic matter, South-Central Mediterranean, North-Western Mediterranean

To date the contribution of the Mediterranean Sea (MS) to the global carbon cycle is still under debate. This basin shows some peculiar characteristics that make it a good model to assess Dissolved Organic Carbon (DOC) dynamics. It is characterized by (1) unique thermohaline circulation including deep water formation; (2) short ventilation rates and residence times for deep waters (20-126 years); (4) Deep water temperatures ~10°C higher than in deep oceans; (5) enhanced respiration rates (6) high DOC mineralization rates and (7) different patterns of stratifications in areas located within close proximity.
The main goal of this work is to give a snapshot of the basin-scale DOC distribution, its fluxes at the straits and external inputs. This is the first attempt to combine stocks, fluxes and mineralization rates by merging data and information regarding the whole basin. The increased number of DOC data has facilitated a large progress in the knowledge of DOM spatial distribution and dynamics on a basin-scale.
The vertical distribution and concentration of DOC in the Med Sea are similar to those observed in the oceans. DOC ranges between 31 and 128 µM, values higher than 128 µM have been observed in coastal areas impacted by river input (e.g. the Gulf of Lions and northern Adriatic Sea). DOC vertical profiles show the highest concentrations in the mixed layer, with a gradual decrease to reach a minimum of 40-48 µM between 200 and 500 m, in the core of the Levantine Intermediate Water (LIW). Below 500 m DOC shows almost constant values (34-43 µM) with a slight increase close to the bottom. Figure 1 shows surface (5 m) contour plot of temperature and DOC from the data collected during 15 cruises (1999-2011).

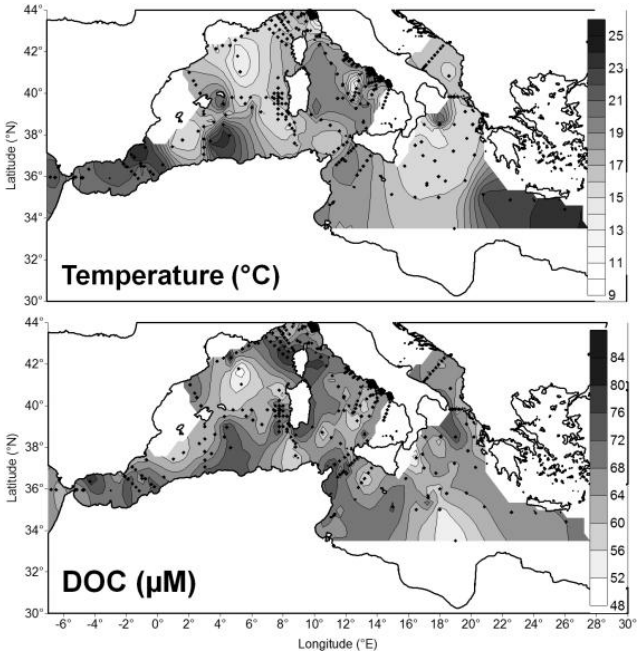

Fig. 1. Surface (5 m) contour plot of temperature and DOC from the data collected during 15 cruises (1999-2011).

There is an interesting correspondence between the two distributions, with the lowest DOC concentration in correspondence of the coldest areas, that are the areas where the water column is completely mixed due to winter convection or to the occurrence of cyclonic eddies. DOC shows high values in the warmer areas, that is in the mixed layer of high stratified waters, and in the core of anticyclonic eddies (Fig. 1). In the intermediate and deep water physical processes (water masses circulation, winter mixing and deep water formation) play a key role in shaping DOC distribution [1].
DOC plays an important role in carbon export down to meso- and bathy-pelagic layers by deep-water formation. The amount of DOC exported by deep-water formation is $0.85\text{-}1.19\cdot10^{12}$ g C year^{-1} in the Adriatic Sea and $0.54\text{-}18.24\cdot10^{12}$ g C year^{-1} in the Gulf of Lions [1]. By the same process, the LIW formation may carry $8.3\text{-}12.5\cdot10^{12}$ C year^{-1} from the surface to intermediate layer.
The large data set available allows for a re-assessment of DOC stocks in the different depth-layers of two sub-basins [2]. Total Mediterranean DOC stock is $1692\cdot10^{12}$ g C ($660\cdot10^{12}$ g C in the West Med and $1032\cdot10^{12}$ g C in the East Med). Net inputs supply a high fraction of DOC to the Mediterranean Sea each year (1% of total stock). On the basin scale, primary production is $178\cdot10^{12}$ g C y^{-1} [3]. Estimated PER is 38% [4], so $68\cdot10^{12}$ g C y^{-1} are released as DOC by phytoplankton and $12.9\text{-}18.5\cdot10^{12}$ g C y^{-1} are supplied by external inputs. In order to give information on the metabolic state of the basin three assumptions were made (i) a steady state, (ii) a BGE of 50% and (ii) the average value of BCD estimated for the Ligurian, Tyrrhenian and Ionian Sea [5, 6, 7] could be representative for BCD in the whole basin. Based on these assumptions, we can roughly estimate that BCD is $81\cdot10^{12}$ g C y^{-1} in the upper 100 m and $61\cdot10^{12}$ g C y^{-1} between 100 m and the bottom. In this scenario about $55\text{-}61\cdot10^{12}$ g C y^{-1} are still missing to satisfy bacterial carbon demand, confirming the importance of other mechanisms of DOC production and/or DOC inputs to the Mediterranean Sea.

INFLUENCE OF DEEP WATER FORMATION ON THE NUTRIENT STOICHIOMETRY OF THE NORTHWESTERN MEDITERRANEAN SEA

Abstract
The stoichiometry of the northwestern Mediterranean Sea depends largely on the formation of dense water during winter. Observations collected in the center of the MEDOC area [1], in March 2011, allowed to follow the evolution of N:P ratios at the end of the convection period and at the beginning of the restratification. While the convection episode led to homogeneous nutrients concentration with deep N:P value of 22 over the entire water column, the stratification allowed the mineralization of fresh organic matter exported during the convection. These processes could be partly responsible to enhance the known phosphate depletion of the Northwestern Mediterranean sea.

Keywords: North-Western Mediterranean, Water convection, Nutrients, Phosphorus, Chlorophyll-A

The winter convection is an important process for the northwestern basin of the Mediterranean Sea. While sinking dense water entrains dissolved and particulate organic matter to the deep layer, upward motions transport nutrients to the surface layer. This refueling is a key factor for the ensuing spring bloom [2], and a significant evolution of the stoichiometry of the nutrients is expected during the transitional period between the unstratified and stratified conditions. The CASCADE cruise succeeded in sampling a late convection episode during the winter 2011, and followed the rapid restratification of the water column.

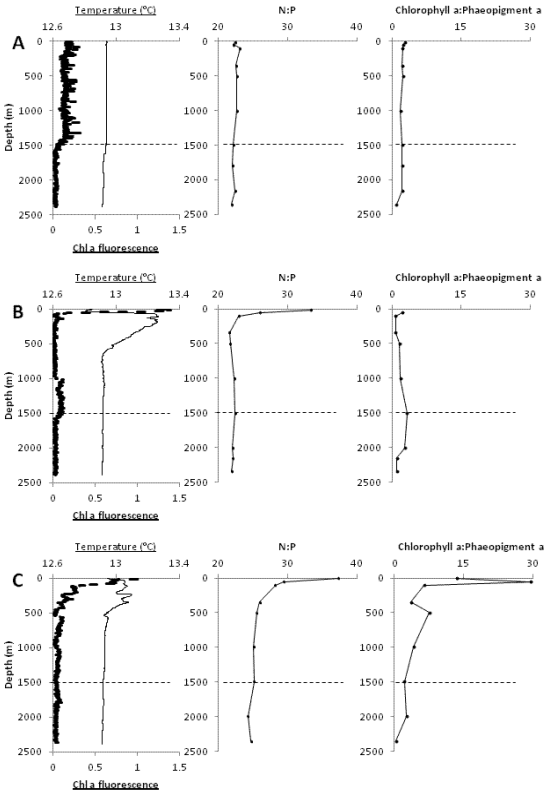

Fig. 1. Profiles of potential temperature (bold line), chlorophyll a concentration (thin line), DIN-DIP ratio (noted N:P), and chlorophyll a : phaeopigments a ratio at the station 42°00N 4°40E, during the convection event (A), 5 days after (B) and 12 days after (C). The dashed line is the mixed layer depth of 1500m.

The convection event produced a mixed layer of 1500m depth (Fig. 1A). It followed a bottom-reaching convection event that occurred a couple of weeks earlier. A N:P ratio of 22, similar to the few known values for the deep layer in the northwestern basin [3], was observed on the entire water column. Chlorophyll a was also detected throughout the mixed layer. The chlorophyll a to phaeopigments ratio indicated that the phytoplanktonic community was still healthy despite its advection well below the euphotic depth.

Five days later, the water column restratified due to the rapid advection of Levantine Intermediate Water over the convection area (Fig. 1B) that isolated the newly formed deep water from the surface layer. The nutrient load in the surface layer supported a phytoplankton development (1.95 µgChl.L^{-1}), which rapidly consumed the nutrient and led to a relative phosphate depletion (high N:P ratio). The newly-formed deep water and the older bottom waters preserved their biogeochemical properties.

Then, a short wind event destabilized the first 500m of the water column (Fig. 1C), but was enabled to induce a new convective event. Twelve days after the convection event, the N:P ratio increased on the whole water column i.e. from surface to the bottom. Considering the steadiness of nitrate and decrease of phosphate concentrations, we hypothesized that mineralization of fresh organic matter by bacteria occurred within a redfieldian N:P ratio. Phosphate consumed by this mineralization process rapidly led to its limitation.

Following this hypothesis, the northwestern Mediterranean convective region is possibly an area where surface and deep N:P ratio are significantly altered at the end of the mixing period due to mineralization of fresh organic matter present in the winter deep mixed layer. Hence, this process possibly contributes to the reinforcement of the existing Mediterranean phosphate depletion.

PHYSICOCHEMICAL INTERACTIONS BETWEEN THE ADRIATIC AND THE IONIAN SEAS

Ekaterini Souvermezoglou [1]* and Evangelia Krasakopoulou [1]
[1] Hellenic Centre for Marine Research Institute of Oceanography - katerinasouv@hcmr.gr

Abstract
The ability of the Adriatic in renewing the deep waters of the Eastern Mediterranean is investigated in relation to the properties of the LIW entering from the Ionian Sea. This study is based on oxygen and nutrient data collected in the Otranto strait and the surrounding area between 1987 and 2000.

Keywords: Oxygen, Nutrients, Intermediate waters, Otranto Strait

The Adriatic Sea is a semi-enclosed basin shallow in the north and deep in the south. It communicates with the Ionian Sea thought the Strait of Otranto, a 70 km wide and 800 m deep channel. The general circulation in the Adriatic basin is cyclonic [1] consisting from a rather weak current along the eastern coast (the Eastern Adriatic Current - EAC) and a fast mainly coastal current along the western coast (the West Adriatic current - WAC).

The Ionian Sea is a deep (up to 4000m) and wide basin which receives salty and warm waters from the easternmost part of the Mediterranean and fresher and relatively colder water from the western Mediterranean. The EAC bring Levantine Intermediate Water (LIW) and Ionian Surface Water (ISW) into the Adriatic [2]. Adriatic is prone to strong winter outbreaks of cold dry northerly winds which induce extended heat losses and evaporation, that drive to deep water formation events. During cold winters and restricted fresh water input, the densest water in the whole of the Mediterranean, the North Adriatic Dense Water (NAdDW) is formed over the shallow northern shelf of the Adriatic [3]. In addition, in the Southern Adriatic Pit, the Adriatic Deep Water (ADW) is produced through open ocean deep convection [4].

The capacity of the Adriatic Sea to form dense water depends to:
- the incorporation of saline intermediate waters
- the intensity of the winters.

During the Eastern Mediterranean Transient (EMT) the salinity of the intermediate layers (200-700 m) entering in the Adriatic Sea became reduced by the upwelling of the deep waters in the Eastern Mediterranean, due to the massive dense water supply from the Cretan Sea [5]. The reduction of salt content in combination with milder winters limited the capacity of the Adriatic Sea to form dense water [6].

The systematic study of the nutrient and oxygen regime from 1987 in the Otranto strait in the frame of national and international research programs permitted to follow the temporal evolution of oxygen and nutrients in the Strait of Otranto (Fig. 1 & 2) and the surrounding area [7] and [8].

Our observations show that the ability of the Adriatic in renewing the deep waters of the Eastern Mediterranean is closely linked to the properties of the LIW entering from the Ionian Sea. The modulation of the LIW characteristics entering in the Adriatic Sea due to the reversal of the North Ionian Gyre (NIG) from anticyclonic during the period of 1987-1995, to cyclonic during the period of 1996-2005 [9] is also examined.

Abstract
We performed 21st century climate change scenario simulations with a Mediterranean regional ocean model in order to assess the sensitivity of changing Mediterranean water masses to boundary forcings. Our study aims to quantify the uncertainty linked to the choice of boundary conditions such as the Atlantic hydrography at the western margin, the river runoffs or the surface fluxes. We particularly focus on changes in mean sea level and thermohaline circulation. Results show that the near-Atlantic hydrographic changes have the strongest influence on the evolution of the Mediterranean water masses.

Keywords: Circulation models, Sea level, Deep waters, Stratification, Gibraltar Strait

The Mediterranean climate is expected to become warmer and drier during the 21st century [1]. This typical response and the associated changes may vary, depending on the chosen scenario. However, the regional ocean model behaviour could also be sensitive to the choice of the boundary conditions such as Atlantic hydrography, runoffs and air-sea fluxes.

To assess and quantify the sensitivity of the Mediterranean Sea to boundary forcings, a set of numerical experiments was carried out with the regional ocean model NEMOMED8 set up for the Mediterranean Sea. The model is forced by air-sea fluxes derived from the regional climate model ARPEGE-Climate on a 50-km stretched grid. Freshwater inputs from the rivers and the Black Sea are prescribed. At the Atlantic boundary, temperature and salinity are relaxed towards values derived from a global model.

Historical simulations representing the climate for the period 1961-2000 were run to obtain a reference state. From this baseline, various sensitivity experiments were performed for the period 2001-2100, following IPCC-A2 scenario. In these simulations, the three main boundary forcings (river runoff, near-Atlantic water hydrography and air-sea fluxes) were alternatively changed to better identify the role of each forcing in the way the ocean responds to climate change.

Our numerical experiments suggest that the choice of the boundary forcings substantially impacts the response of the Mediterranean Sea to an IPCC-A2 scenario. The range of mean SSS anomalies (2070-2099 vs. 1961-1990) spreads between 0.6 and 0.9 psu depending on the boundary conditions applied. The near-Atlantic surface water evolution, which is very uncertain in global ocean scenario simulations, has the strongest influence on the evolution of the Mediterranean water masses and dense water formation. Significant differences of the future thermosteric mean sea level trends are thus simulated, with a range of increase between 40 and 60 cm. This uncertainty is mainly driven by Atlantic boundary conditions. We also analyse the changes in the Mediterranean thermohaline circulation (MTHC). Finally, we address the question of the influence of the initial MTHC state on the ocean climate projections.

WESTERN MEDITERRANEAN DEEP WATER ANOMALY: PREVIOUS TRENDS, TEMPORAL EVOLUTION AND SPREADING AFTER 2005

Rosa Balbín [1]*, Jose Luis López-Jurado [1], Alberto Aparicio-González [1] and Mª Del Mar Flexas [2]

Abstract
With the help of IBAMar data base new deep water (DW) formed in the Western Mediterranean (WM) after winter 2005 is tracked all along the Spanish Mediterranean coast since it was formed to nowadays. After winter 2005 an abrupt uplift of isopycnals of the order of hundreds of meters was observed in the DW formation areas. No clear trend of isopycnals is observed since then. Using MEDAR, CORA and MATER databases, isopycnal trends during the previous decades will be analyzed in the same area, trying to understand the processes that induce the new DW formation.

Keywords: Deep waters, North-Western Mediterranean

1. Introduction After winter 2005 an abrupt change was observed in the Western Mediterranean Deep Water (WMDW), with the apparition of a complex thermohaline structure due to the contribution of different water masses, that could be observed from the north of the WM to the Argelian sub-basin [1]. It has been denoted as the Western Mediterranean Transition (WMT), to distinguishing it from the Eastern Mediterranean Transient (EMT), and is described in [2] and references therein. Different hypothesis have been proposed to explain the new properties of the WMDW: a progressive increase of salinity and heat in the intermediate levels due to EMT advection, a progressive increase of salinity and heat of the Atlantic Water (AW) entering through Gibraltar, or an extreme winter forcing. Long term trends on the increase of salinity and temperature have been observed in the DW in the eastern and westerm sub-basins during the second half of 20th century but there are no clear results in the intermediate and surface waters that participate in their formation [3]. Those studies have been done on isobaric surfaces and it is necessary to do the same analysis on isopycnals [4] to better understand the impact of salinity and temperature tendencies of intermediate and surface waters on the new WMDW formation.

2. Data and Methodology IBAMar 2.0 is a new data base created from the oceanographic data obtained during the development of different oceanographic projects by the Balearic Center of Spanish Institute of Oceanography (IEO) and conducted from 1974 and ongoing in the Western Mediterranean basin (Balearic Sea and Algerian Basin) [5]. The main goal of this data base is to establish a climatology for the most significant variables to study the existence of decadal cycles or long term trends, trying to better understand the behaviour of the hydrographic conditions of the Spanish Mediterranean coast, at both seasonal and interannual time scale and long term. Using IBAMar database it is possible to characterize the temporal evolution of the thermohaline anomaly since 2005 to nowadays. With the help of MEDAR [6], CORA [7] and MATER [8] it is possible to study the thermohaline characteristics of the WMDW before 2005. Using all databases together, figure 1 shows potential temperature and salinity versus pressure and time from 1972 to the end of 2012 for stations between 40.0 ºN and 42.5 ºN, 3.5 ºE and 7.0 ºE, area that corresponds to DW formation in the WM. Data was interpolated over a regular grid every 100 days and 10 dbar. Interpolated isopycnals are also shown. Similar plots can be done for selected areas along the Spanish Mediterranean coast down to the Alboran sea to characterize the spreading of the anomaly along the west of the WM sub-basin.

3. Discussion After winter 2005 an abrupt uplift of isopycnals of the order of hundreds of meters was observed in the DW formation areas. This uplift seems to be faster than previous observed events, and remains on time since nowadays. No clear trend of isopycnals is observed since then. With the help of IBAMar data base it is expected to characterize the isopycnals behavior along the Spanish Mediterranean since 2000. Using the MEDAR, CORA and MATER data bases it should be possible to analyze the isopycnal trends during the previous decades in the DW formation area to help to understand the processes that induce the new DW formation.

Abstract
Autonomous underwater gliders provide accurate, high-resolution datasets that can unlock hidden variability in ocean processes at critical control points, as demonstrated for a 'choke' point between two ocean sub-basins in the Western Mediterranean Sea. This high-resolution observation skill is important for characterizing sub-mesoscale and sub-seasonal variability in order to detect future climatic change, improve our constraint of models and understand ecosystem response to physical process.

Keywords: Mesoscale phenomena, Circulation, Coastal processes, North-Western Mediterranean

It is becoming increasingly important to understand sub-mesoscale and sub-seasonal variability in our ocean circulation system: in order to place historical observations in context, to detect future climatic change and to improve our modeling and forecast capability. The in-situ monitoring of this variability at inter-basin 'choke' points, narrow channels and straits that exert a controlling influence on the exchanges of watermass such as Drake Passage in the Southern Ocean and the Fram Straits in the North Atlantic, is particularly important [1]. The Ibiza Channel in the Western Mediterranean is one such 'choke' point in the basin-scale thermohaline circulation of the Western Mediterranean Sea, where an important north/south exchange of watermasses is known to affect local ecosystems of economic importance, e.g. the spawning grounds of Atlantic bluefin tuna [2]. From January 2011, within the framework of SOCIB activities [3] and now also within the framework of PERSEUS (an EU funded project), autonomous underwater gliders have been deployed on a regular basis across a standard transect at this narrow 'choke' point and have proved particularly effective at capturing the signature of a high sub-seasonal variability (days-weeks) in the inter-basin exchange of watermasses [4], a variability that had previously only been observed at a seasonal level through ships surveys or at a coarse resolution with moorings [5]. Combining the data from these recent glider missions (now from 2011-2012) with a historical timeseries of ships CTD surveys (1996 – 2012) from the IBAMar database [6], enables us to define a new more detailed seasonal cycle of transports. This, in conjunction with the glider data, clearly demonstrates the contribution of sub-seasonal variability to the seasonal pattern of transports (Figure 1), indicating that mesoscale processes are as important as the seasonal cycle in governing the North/South exchange at this Mediterranean 'choke point'. The links between this observed high variability, atmospheric forcing and mesoscale indicators are investigated to determine the key dynamic processes governing this sub-basin exchange and resolve the links between basin-scale and mesoscale processes.

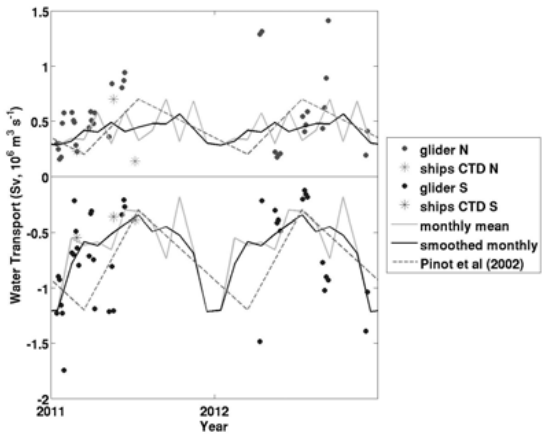

Fig. 1. Geostrophic transports of water mass volumes, both north (positive values) and south (negative values), per transect of Ibiza Channel; glider transects (dots) and CTD transects (stars). The new seasonal cycle (black line) is shown, with the mean monthly values (grey line) and an earlier [5] simple seasonal signal (dashed line). The high sub-seasonal variability in transports captured by the repeated glider transects is clearly visible.

OCEAN COLOUR AND OTHER OPTICAL SATELLITE DATA VERSUS IN-SITU DATA

Mira Morovic [1]*, Branka Grbec [1], Žarko Kovac [1] and Živana Nincevic Gladan [1]
[1] Institute of Oceanography and Fisheries - morovic@izor.hr

Abstract
Different optical data are available at JRC database, covering partly the same time period. The idea of this paper was to extract monthly mean data from the geoportal from different satellites for the same location in the open middle Adriatic Sea and compare them with each other and with the in-situ optically weighted monthly chlorophyll pigments. The correlation coefficients were calculated between various optical data retrieved from the satellites like Chlorophyll data from SeaWiFS, MODIS and MERIS diffuse attenuation coefficient, absorption coefficient, particulate backscattering coefficient and euphotic zone depth with the monthly in-situ chlorophyll and Secchi disk transparency.

Keywords: Remote sensing, North-Central Mediterranean

The data series of the Institute of Oceanography (Split, Croatia) especially in the Middle Adriatic has long tradition of almost monthly oceanographic measurements. Among these data we used transparency and in-situ chlorophyll from the station located at 43N; 16.33E for the period 1997-2007 (Fig 1).

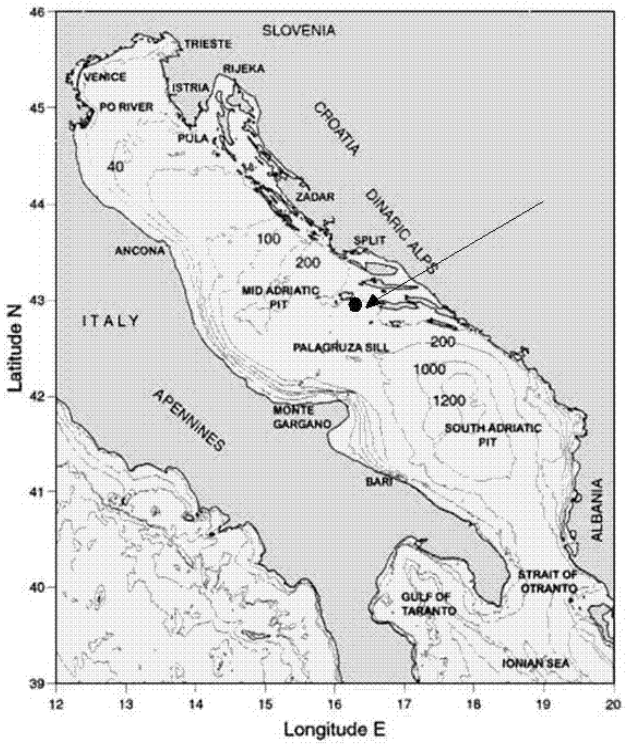

Fig. 1. Investigated location.

From the same point all the available satellite optical data were retrieved form www.jrc.it geoportal.
Recent comparison of in-situ to satellite colour data from the same area at the monthly scale has shown rather high differences, especially in summer when satellites often show higher values (1). In some earlier analysis high seasonal differences were also found (2). Daily pixel values also show in some periods large differences relative to the same day and location in-situ data (3). The question is how to handle these differences, if we wish to complement one data type with the other?
Besides anylsing the annual course of the differences, the correlation analysis was performed to see to what extent the data from different sources, the satellite and the in-situ, correspond and also to what additional parameters, retrieved from the satellites, are they best related.
In spite of the differences, high correlation coefficients were obtained between in-situ optically weighted chlorophyll (OPW) with chlorophyll values from satellite sensor MODIS and somewhat less with the data from MERIS (Table 1).
Also high correlation was obtained between OPW and diffuse attenuation coefficient Kd490 (MODIS). The correlation coefficients, although significant, are lowest with the Secchi disk depth, which is understandable due to their dependence not only on water properties.
Euphotic zone depth is highly correlated to absorption coefficient and both euphotic zone depth and absorption coefficients are highly correlated (0.96) to MERIS Kd490, while correlation of these with particulate backscattering coefficient is somewhat lower (0.7).
The correlation coefficients between the chlorophyll satellite data from the three satellites are very high while correlations among Kd490 from the three satellite sources are little lower.
Although the analysis of long-term series of both in-situ and satellite data often lead to similar and comprehensive results, the differences in data require particular attention in order to take the advantage of frequent optical satellite data measurements.

Tab. 1. Correlation coefficients between diffuse attenuation coefficient Kd_{490}, Chlorophyll pigments from different sensors (MERIS, MODIS and SW-SeaWiFS), transparency (SD), optical data from MERIS: euphotic zone depth (Z_{eu}), absorption coefficient at 443 nm (a_{443}), particulate backscattering coefficient at 443 nm (bb_{443}) and optically weighted in-situ chlorophyll pigments (OPW). N-data number, p-significance level <0.01 for all unmarked coefficients, and p<0.045 for coefficient marked with *. Only the significant correlation coefficients are shown.

VALIDATION OF CLIMATOLOGICAL MAPS IN THE ADRIATIC SEA

E. Partescano [1]*, M. Lipizer [1], A. Crise [1], A. Giorgetti [1] and A. Rabitti [2]
[1] Ist. Naz. Oceanografia e Geofis. Sperimentale-OGS - epartescano@ogs.trieste.it

Abstract

The interpolation error and the uncertainty degree associated to the updated climatology of oceanographic properties of the whole Adriatic Sea, based on campaigns from a large temporal range (about a century), have been estimated in order to provide information on the reliability of the products obtained and on the stability of the climatological fields. The updated climatologies have been produced using the Variational Inverse Method (VIM) and a resolution by Finite Element Method; error and uncertainty maps associated to each climatological field approximation have been obtained by calculating the error associated to data interpolation and by comparing climatology with measured data. The uncertainty associated to the climatology provides an estimate of the importance of mesoscale processes in the Adriatic Sea.

Keywords: Mesoscale phenomena, Global change, North Adriatic Sea, Central Adriatic Sea, South Adriatic Sea

Climatological maps provide valuable information for different purposes such as optimization of regional and subregional numerical prediction models, validation of new datasets and as baseline information to identify possible modifications in the marine environment related to global climate changes. However, the climatology *per se* provides only an estimate of average fields without explicitly showing the intrinsic dynamics connected to the short and long term variability (from submesoscale to decadal) that *insitu* data do contain. In this study we provide updated climatologies of temperature and salinity for the Adriatic Sea produced using the Variational Inverse Method (VIM) [1]. We applied successfully different quality assessment procedures of VIM field approximation (cross-validation, SST comparison with satellite data, real *vs* synthetic T-S profiles) with good results. There is yet a strong discrepancy in some areas between the interpolation error associated to the method (used as a measure of the reliability of field approximation) and the uncertainty degree calculated from the average difference between the spatial distributions obtained using the VIM and the original data acquired *in situ* (a measure of the persistence of the climatological fields). Error field (Fig. 1) and uncertainty maps (Fig. 2) of winter surface salinity are reported as an example. The comparison shows that in the North Adriatic Sea, near the Po River outflow, the interpolation error is low due mostly to the good spatial data coverage and, accordingly, the reliability of the field reconstruction is high. On the other hand, in the same area the uncertainty is high, with large deviations from the climatology (differences > 20%) which indicate intrinsic high temporal variability due to the mesoscale processes, that is properly reflected in the dataset used. In comparison with earlier climatologies [2], [3], [4], the climatology presented in this paper covers the whole Adriatic Sea, includes data spanning over a century (1900 – 2009) and provides estimates of the interpolation error and the uncertainty associated to the climatology.

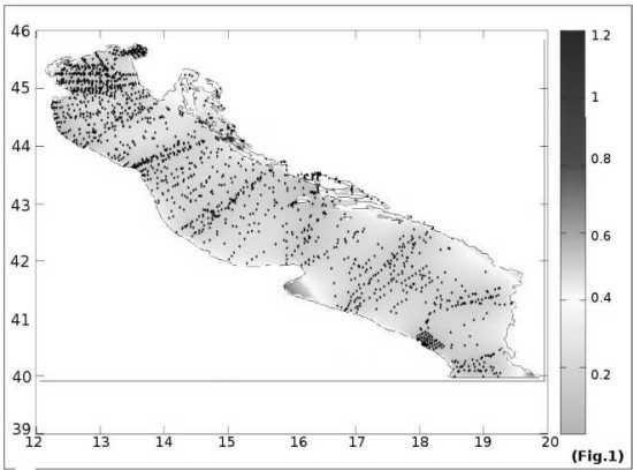

Fig. 1. Interpolation error field map of winter surface salinity (in salinity units)

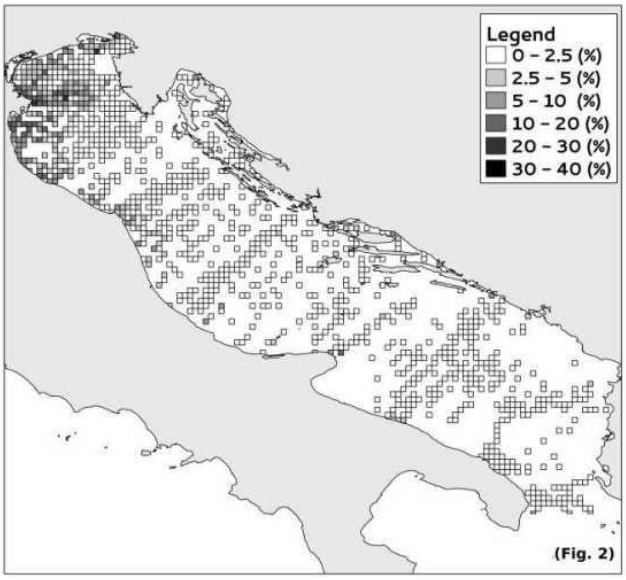

Fig. 2. Uncertainty map of winter surface salinity (units are average difference from the climatology, expressed in percentage).

LONG-TERM CHARACTERISTICS OF SEA LEVEL, WAVE, WIND AND CURRENT AT CENTRAL MEDITERRANEAN COAST OF ISRAEL FROM 20 YEARS OF DATA AT GLOSS STATION HADERA

Sergiu Dov Rosen [1]*, Lazar Raskin [1] and Barak Galanti [1]
[1] Israel Oceanographic & Limnological Research - IOLR - rosen@ocean.org.il

Abstract
We present the long term main meteo-marine characteristics at the central Mediterranean coast of Israel, based on monitored wind, sea level, wave and current data during April 1992 to March 2012 at IOLR's GLOSS station 80 Hadera, 2.1 km offshore.

Keywords: Currents, Sea level, Waves, Wind, South-Eastern Mediterranean

The long-term main meteo-marine characteristics at the central Mediterranean coast of Israel, were determined based on wind, sea level, wave and current data gathered during April 1992 to March 2012 at IOLR's GLOSS station 80 Hadera, about 2.1 km offshore the Hadera coast.
The data were analyzed in hydrographic years (from April of first year to March of following year), to ensure events independence occurring in winter season, versus normal splitting at calendary year start on 1st of January. Thus, each year was characterized by contiguous winter and summer seasons.
It was found that the sea level rose on the average about 6mm/year, about twice the global sea level rise average. By comparing yearly changes in the monthly averaged values of the wind speed, significant wave height and current speed, the fluctuations of these parameters on monthly to yearly scales were investigated. An example of the outcome is presented in Figure 1 showing the monthly averaged sea level change during the monitored period.

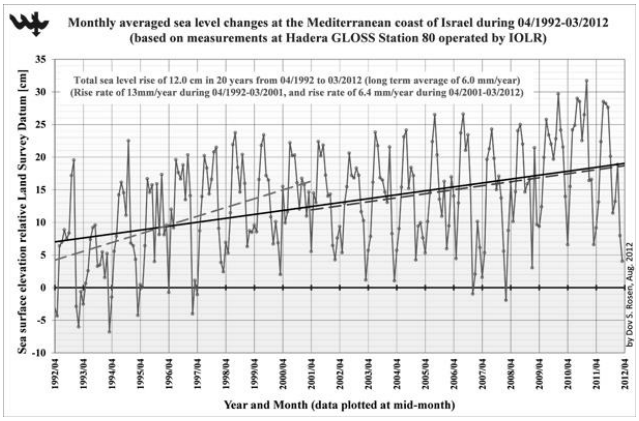

Fig. 1. Sea Level change at Hadera, Israel during 04/1992 -03/2012

THE ROLE OF TELECONNECTION PATTERNS ON CLIMATE VARIABILITY IN THE AEGEAN SEA, EASTERN MEDITERRANEAN

Alexandra Spyropoulou [1]*, Effie Kostopoulou [2] and George Tsirtsis [1]
[1] Aegean University, Department of Marine Sciences - spyropoulou@marine.aegean.gr
[2] University of the Aegean, Department of Geography, University Hill, Mytilene 81100, Greece

Abstract
The aim of this study is to investigate the possible role of the most representative atmospheric oceanic modes on climate variability of Aegean Sea. The North Atlantic Oscillation-NAO, the East Atlantic/West Russian Pattern-EA/WR, and the Scandinavian Pattern-SCAN indices from the NOAA Climate Prediction Centre were taken into account along with NCEP-Reanalysis data.

Keywords: Temperature, Aegean Sea, Time series

1. Introduction
Several regional studies have revealed negative trends in precipitation over the Mediterranean during the past decades (New *et al*. 2001), while air temperature has shown an increasing trend especially during summers. Especially, the eastern Mediterranean region is characterized by cooler and drier conditions during the positive phase of NAO, while the negative phase is related to anomalously warm and wet conditions (Xoplaki *et al*. 2000). Moreover, during the negative (positive) phase of EAWR wetter (drier) than normal weather conditions prevail over a large part of the Mediterranean region. Although many studies have been carried out for the Mediterranean, only few have emphasized on the Eastern Aegean Sea, where trends in both precipitation and air temperature have been identified locally during the last decades (Spyropoulou *et al.* 2013).

The aim of the present work is to analyze the climate trends in the Aegean region from 1950 to 2008 and to link possible background variations of the meteorological fields with the dominant atmospheric modes expressing the most prominent patterns of atmospheric circulation variability in the Northern Hemisphere.

2. Data and Methodology
The time series for the atmospheric modes NAO, EA/WR, EA and SCAN were obtained on a monthly basis from the NOAA Climate Prediction Center (CPC, http://www.cpc.ncep.noaa.gov/data//eledoc//nao.html) for the period 1950-2008. Similarly, the NCEP-Reanalysis data (air temperature at 2m) were extracted for a window-area extending from 44.76°N to 31.42°S and from 13.12°W to 35.62° E on a monthly basis. In order to exclude seasonality, anomalies were calculated for both the Reanalysis data and the teleconnection indices on a monthly basis. To determine the relative influence of the various modes on climate variability, the time series of temperature were analyzed statistically. Linear correlations were calculated between the monthly, yearly and seasonally means and the ocean modes series. The relationship between monthly temperature means and the large-scale atmospheric circulation indices was investigated using Canonical Correlation Analysis (CCA), after extracting the empirical orthogonal functions (EOFs) for temperature. The latter was performed in order to more clearly reveal signals in both time and space.

3. Results
The leading EOF of temperature pattern accounts for 52%, the second for 15.9% and third for 12% of the total variance. CCA revealed 3 statistically significant pairs of canonical variables, therefore 4 physically relevant pairs of patterns that describe the responses of monthly temperature in the Eastern Mediterranean seems that it is connected with the considered Ocean Modes. The first pair of canonical variables has a correlation coefficient of 50%, showing a relatively strong negative effect of EAWR and NAO on air temperature, with CCA coefficients of -0,80 and -0,50, respectively.

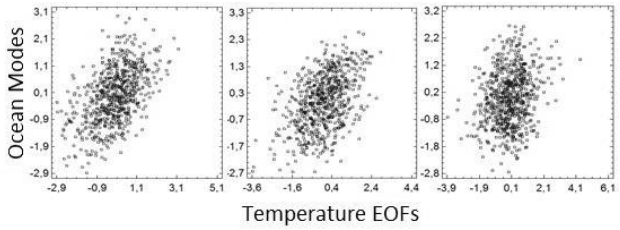

Fig. 1. Fig1. Canonical Correlations Between air temperature in Eastern Mediterranean and Ocean Modes

The second pair has also shown a high correlation coefficient (46%), however EA was the ocean mode with the higher contribution, being positive and with a coefficient of 0.96. The third pair although it was also found statistical significant, had a low correlation coefficient of 22%. In conclusion, the observed trends of warming of air temperature over the Aegean region, Eastern Mediterranean during the last decades seem to be related with three Ocean Modes (EA, EAWR, NAO), showing the effect of teleconnection on climate variability over Eastern Mediterranean

Abstract

The North Ionian circulation is subject to decadal reversals of direction of rotation. From the altimetric data and surface geostrophic currents a "premature" inversion of the North Ionian circulation from cyclonic to anticyclonic was documented in the second half of the year 2012. This can be caused by the very cold and dense Adriatic Dense Water (density anomaly > 29.25 kg/m^3) formed during the severe winter in the Adriatic in 2012, representing an example of climatic impact on the BiOS rhythm.

Keywords: Circulation, Ionian Sea, Deep waters

The Ionian circulation is characterized by the presence of the North Ionian Gyre (NIG) which reverses its direction of rotation on a decadal scale. These circulation variations were explained in terms of the internal mechanism denoted as Bimodal Oscillating System (BiOS) associated with the feedback between the Adriatic and Ionian [1]. The mechanism has a Mediterranean basin-wide importance since it determines thermohaline properties of the Levantine, Adriatic and even the western Mediterranean [2]. Altimetric data and meridional components of the surface geostrophic currents along the eastern and western Ionian flanks, which show clearly decadal inversions of the NIG (Fig. 1), also reveal that seasonal variations are relatively weak resulting rarely in reversals at the intra-annual scale. A sudden decrease of the northward geostrophic flow (along the west coast) and the concomitant increase of the southward flow (along the east coast) is evident in the year 2012 as a sign of the weakening/reversal of the preceding year (cyclonic) circulation.

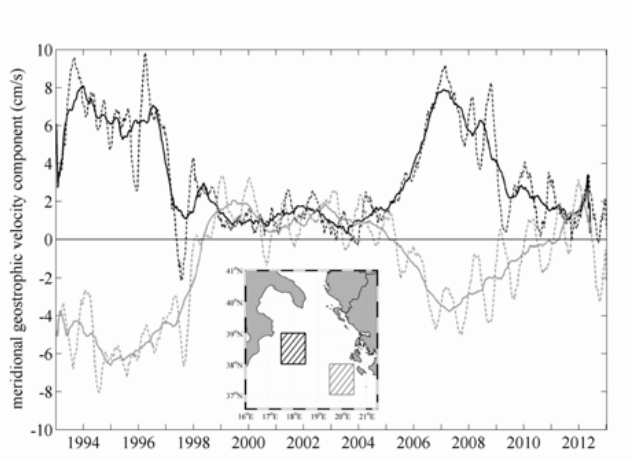

Fig. 1. Time-series of the spatially averaged meridional geostrophic surface velocity components (area of averaging shown in the insert). Continuous lines represent thirteen-month moving average while the dashed lines are monthly time series.

We hypothesized that this "premature" circulation inversion was due to the inflow of the very dense water formed during the winter 2012. In order to evidence differences in the thermohaline properties of the AdDW spreading in the Ionian, we collected all available hydrographic data for the two years, i.e. 2011, considered "normal" winter and 2012, an extremely cold one. More specifically, we used T-S profiles from both Argo floats and oceanographic campaigns and grouped them together for each year separately, implicitly neglecting the seasonal signal which is a rather realistic assumption for the layer below the seasonal pycnocline. The data show the first occurrence of the dense AdDW in the Ionian having density anomalies over 29.24 kg/m^3 in July 2012. Consequently, the horizontal density distribution reveals the presence of the denser water along the Ionian flanks with respect to the centre of the basin. This fact explains the sea level being lower along the boundaries than in the center and thus the occurrence of the anticyclonic surface geostrophic circulation. The opposite pattern was evident in 2011 when the density gradient reversed with the density maximum in the centre of the basin. The reversed density gradient is associated with the surface cyclonic flow. The linear relationship between the altimetric data and the isopycnal depths was sought from the calculations of the linear regression between the sea surface absolute topography and the depths of the 29.00 and 29.18 kg/m^3 isopycnals. The dispersion diagram (Fig. 2) between the two variables suggests a linear relationship for the 29.00 isopycnal (being at a depth of about 200 m). This confirms the impact of density changes in shaping the Ionian circulation. For the 29.18 kg/m^3 isopycnal (depth around 1200 m) the linear relationship is not statistically significant which is probably due to the very weak vertical density stratification in deeper portion of the water column.

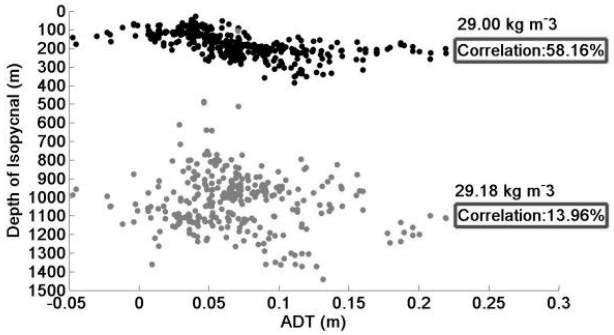

Fig. 2. Dispersion diagram of the depth of 29.0 and 29.18 kg/m^3 ispycnals versus absolute sea-level height.

THE CASE FOR A SEA-SURFACE-HEIGHT CONTROL BARRAGE ON THE STRAIT OF GIBRALTAR

Jim Gower [1]*
[1] Institute of Ocean Sciences - jim.gower@dfo-mpo.gc.ca

Abstract
Global sea level rise is now seen as one of the most significant impacts of long term climate change. A dam on the Strait of Gibraltar would provide long-term protection for the entire Mediterranean and Black Seas against every conceivable future global sea level rise for the next few millennia. The dam would be designed to cause a height difference between its two sides of only a few metres, and would therefore have a limited impact on shipping, requiring lock gates at the dam and on the Suez canal. This paper discusses arguments for and against a dam, including long-term effects connected to Mediterranean salinity. The dam would be a major project, requiring international agreements and resources. It will probably not be built soon, but it would be useful to start discussions now to quantify costs, benefits and impacts.

Keywords: Global change, Salinity, Water transport, Messinian, Gibraltar Strait

Introduction
The word "dam" suggests a wall of concrete holding back water many metres deep. Although we use the word here, discussion is of a sea-level-rise barrage as in the title, designed to cause a relatively minor sea level difference between its two sides. A dam at Gibraltar allows a Mediterranean Sea level to be chosen and maintained. Choosing a level that is 30 to 40 cm below the present average would probably be best for a coastal city like Venice, returning their sea level to the average for the last century. However, this might not suit everyone in the Mediterranean. Also, a 35 cm drop in Mediterranean Sea level implies a 3 mm rise in the global average level (Mediterranean and Black Seas together represent about 0.8 % of global ocean area). This might be hard for non-Mediterranean nations to accept. Perhaps they would also object to the 0.8% extra rise rate they would experience if Mediterranean countries decide to defend themselves by building a Gibraltar dam. This would seem a less reasonable objection, since any prevention of coastal flooding must cause some increase in global sea level. If world opinion allows Mediterranean countries to defend themselves with a dam, but not to lower the level of the Mediterranean below its level at the time the dam is built, then there is a major incentive to build the dam soon.

Dam history
A Gibraltar dam was most famously proposed for the much more radical German Atlantropa project of the 1930s (see for example Cathcart 2006, and references therein), designed to lower Mediterranean Sea level by 200m, provide new land, and allow power generation from the resulting inflow at the Strait. Proponents did not explain how the world would cope with the resulting 2 metre global sea level rise, and I have not seen this discussed in historical descriptions of the proposal. More recently, Johnson (1997) urged constructing of a dam across the Strait of Gibraltar to prevent what the author saw as a coming ice age induced by the building of the Aswan Dam on the Nile. However, the claimed effects of Mediterranean salt water outflow appeared exaggerated (Rahmstorf, 1998).

Oceanographic implications
The Strait of Gibraltar is 340 m deep and 13 km wide. Damming it would be a major project. The dam would not need to withstand a large head of water pressure, though as global sea level rises, the head would increase in future centuries. Lock gates would be needed for shipping and would also be needed on the Suez Canal, where presently there are none. The amount of power generated at Gibraltar could still be significant, since the flow of water needed to stabilize the depth of the Mediterranean is large. The water deficit is due to the excess of evaporation over the combination of precipitation and river flow. Since only fresh water is removed, the main effect of replacing the 1200 km^3/year deficit with salty (37 psu) Atlantic water will be that Mediterranean average sea water salinity will increase at an initial rate of about 0.012 psu per year (Mediterranean total volume is 3,700,000 km^3), or 1 psu every 80 years. Without control measures, Mediterranean salinity would eventually get very high, with an equivalent smaller reduction in global ocean salinities. We need to understand and quantify the long term effects of this salinity rise. If a 5 psu rise in Mediterranean salinity is acceptable, then we have 400 years before this value is reached, and time to plan responses. High salinity has significant effects on fish at present levels, with major harm by about 50psu. These effects need to be quantified.

Cost of the dam
This would be a major project, costing tens of billions of Euros. Johnson (1997) shows a map of the dam site, and estimates that it would require about 1.4 cubic km of rock material. This is about 4 billion tons, less than half of annual world coal production, for example, so the Gibraltar dam is not beyond imagination. The project could use local rock, transported and dumped by ship. The resulting loose rock structure might be slightly permeable at first, but could easily be filled with finer material and will tend to solidify by marine fouling. A rail link between Spain and Morocco has been proposed (http://en.wikipedia.org/wiki/Strait_of_Gibraltar_crossing). Local tectonic activity is a severe problem for a deep tunnel, and would also be a concern for the dam, but the dam would make a surface rail and road link possible, which could be a major positive factor. The dam would cross the Azores-Gibraltar Transform Fault, which moves at about 4 mm per year. This would be a severe problem for a solid concrete dam, but less significant for a loose rock structure.

Conclusion
The proposed Gibraltar dam can maintain the Mediterranean and Black Seas at their present level for many centuries, during which time global sea levels are expected to rise by several metres. Such a rise is expected to have huge impacts on all other coasts. The project is going to cause increasing Mediterranean salinity, though this can be limited by remedial action. This would be a major project, but the benefits in terms of coastal protection are very large. Discussions should start now on feasibility and impacts.

CLIMATE CHANGE IMPACTS ON SEA SURFACE TEMPERATURE IN THE EASTERN MEDITERRANEAN, LEVANTINE BASIN

Y. Samuel-Rhoads [1], G. Zodiatis [1], D. Hayes [1]*, G. Konnaris [1] and G. Georgiou [1]
[1] Oceanography Centre University of Cyprus - dhayes@ucy.ac.cy

Abstract
Increases in SSTs have been recorded to occur in the Mediterranean at about twice the rate as that of the global oceans. Here we analyze and compare satellite remote sensing SST data with in-situ data from 1996 to 2012 in the Levantine. Further, SST profiles from oceanographic cruises and gliders were processed to study the variability at the surface layer (0-10m). These data were collected during several CYBO research cruises that the Oceanography Centre has conducted, as well as during missions of the gliders owned and operated by the OC. We show that the Levantine has undergone SST increases, and that satellite and in-situ SST data are correlated. The driving mechanisms of these changes need to be investigated, in order to understand the future trends and impacts of climate change in the region.

Keywords: Temperature, Remote sensing, Surface waters, Levantine Basin

Several studies have reported regional temperature increases in the Mediterranean Sea for each of its two basins [1-5]. Changes occurring in the eastern and western basins are frequently out of phase as a consequence of different processes that affect the climate of the two [6-7]. Overall, SSTs across the Mediterranean as a whole have been rising about twice as much as those of the global oceans [8-9]. The objective of this work is to investigate the increase in SST due to climatic changes in the Eastern Mediterranean Levantine basin from 1996 until 2012, with the use of satellite remote sensing data as well as with in-situ data.

Analyses of annual mean satellite sea surface temperature (SST) data indicate that over the last years a general warming has occurred over the Levantine Basin, and occurred at an average rate of approximately 0.065°C per year. This increase in average SSTs is also seen in the seasonal averages, especially during the summer. Spatial variability in the decadal warming is depicted in the satellite SST anomalies, with positive anomalies dominating most of the Levantine during the years 1999, 2001, 2002, 2003, and 2008. The highest sea surface temperatures appear in 1999, 2003, and 2008. An area southeastern of Cyprus is seen during some years to be warming up much more strongly than the rest of the Levantine Basin. Empirical Orthogonal Function (EOF) analysis was performed on the annual and seasonal satellite SST data to examine their spatial and temporal patterns of variability. The spatial eigenfunctions of mode 1 show that the seasonal and annual SSTs across the entire Levantine share high positive eigenfunctions and thus varied in a spatially coherent manner over time. Therefore, the SST variability is characterized by a broad, basin-wide warming (mode 1). The seasonal principal component (PC) of the same mode (PC1), which depicts the time variation of the first mode, varied over the years supporting the fact that the Levantine is experiencing a strong seasonal cycle. The PC1 of the annual data supports the fact that higher than average SSTs were observed across the Levantine during the later part of the time period. An asymmetry in the N-to-S direction is depicted in the spatial eigenfunctions of mode 2. Areas in the northern Levantine are out of phase from areas in the southern parts of the basin, creating a dipole pattern of heating and cooling at interannual and interseasonal time scales. Analyses of annual and summer in-situ SST data reveal similar increases in temperatures to the ones recorded by satellites in the region. The average rate of increase of SSTs is 0.53°C, which is approximately three times higher than the recorded 0.18°C rate of increase of global SSTs [10]. During the year 2010, the highest temperatures were recorded up to date, which were much higher than the recorded ones from summer of 2003 (mean values for the summer of 2010 for T=29.57°C). Analyses of monthly in-situ SST data collected during glider expeditions from 2009 until 2012, and calculated for the top 10 meters of the water column, reveal the monthly variability in temperatures in the Levantine basin. However, the time series in some cases does not represent well the entire region of interest, as the gliders may have been in an area with a local effect, which is then affecting the regional averages. Further examination, processing and analysis of these data is needed.

The present study has shown that an increase in the Levantine Basin sea surface temperatures (SSTs) has taken place from 1996 to 2012. The SST variability is characterized by a broad, basin-wide warming (mode 1) occurring at both seasonal and interannual time scales, and a weaker dipole pattern that fluctuates at similar time scales (mode 2). Further, satellite SST data are correlated with in-situ CTD SST data, especially during the summer months. The warming in the Levantine, which is revealed by the satellite SST data, as well as by the recorded increases in in-situ SSTs, occurred at both seasonal and interannual time scales. The fact that in 2010 the highest temperatures have been recorded so far, which were even higher than the record values of 2003, indicates that the increasing trend is expected to continue. The driving mechanisms of these changes need to be investigated, as they may be driven by changes in annual latent heat losses and by the variability in regional wind speeds.

IS THE MEDITERRANEAN SEA LEVEL RISING AGAIN?

Mirko Orlic [1]* and Miroslava Pasaric [2]

Abstract
Sea-level data collected in a wider Mediterranean area since 1920s are analyzed with the aim of separating changing trends from decadal-scale and interannual variability. During the second half of the twentieth century the trends were close to zero in the West Mediterranean and the Adriatic, and they resembled the global trends in the Atlantic off Gibraltar and the Black Sea. There are some indications that over the last twenty or so years the rate of sea-level rise considerably increased in the Black Sea and thus surpassed the Atlantic rate, while it became similar to the Atlantic rate in the West Mediterranean and the Adriatic.

Keywords: Sea level, North-Western Mediterranean, Central Adriatic Sea, Black Sea

It is well known that a pronounced sea-level deceleration was observed at the Adriatic and West Mediterranean tide-gauge stations in 1960s and 1970s [1, 2]. Subsequently and until the end of the twentieth century, mean sea level was almost stagnant in the area. There are now some indications that the quiet interval is over and that the Mediterranean sea level is beginning to accelerate. Although rather preliminary, the indications deserve to be presented to the Mediterranean research community.

In the analysis we use annual mean values recorded at sixteen tide-gauge stations in the Mediterranean and Black Sea region and the Iberian coast of the Atlantic, taken from the Permanent Service for Mean Sea Level database [3]. The stations are chosen such that the correlation coefficient between buddy stations exceeds a threshold value, in order to eliminate records with some anomalies due either to the measurement problems or the local tectonic activity. We construct time series of regional sea level (for the Atlantic, West Mediterranean, Adriatic and Black Seas) by averaging tide-gauge data over each basin, in order to obtain signals that are coherent over wider areas and to minimize local effects; prior to the averaging, zero level at each station was set to long-term mean value, the mean being calculated over interval with simultaneous data from all stations within a basin. Gaps not longer than one year were linearly interpolated within the time series. The regional sea-level time series eventually obtained cover the interval from 1928 to 2008. They are subjected to interannual and decadal-scale variability that has to be minimized in order to determine the trends. Interannual variability is eliminated by smoothing all the time series with a 5-year moving average. As for the decadal-scale variability, it is reduced by fitting a third-degree polynomial to the time series.

The result of the analysis is depicted in Figure 1. It is obvious that the decadal-scale variability was most pronounced and was characterized by the shortest periods in the Black Sea, while it had smaller amplitudes and was shifted towards the longer periods in the other regions. Of more interest for the present study is the longer-term variability, illustrated by the cubic fits. It shows a different behavior in the Atlantic as compared to the Mediterranean and, to a lesser extent, the Black Sea. In the Atlantic the sea level was rising and was slightly accelerating throughout the interval considered, whereas in the remaining regions the sea-level rise slowed down in the second half of the twentieth century. The deceleration was most obvious in the West Mediterranean and the Adriatic, where the sea-level rise almost tapered off, and there was a slight deceleration in the Black Sea, where, however, the rise remained similar to that in the Atlantic. Over the last twenty or so years the rate of sea-level rise considerably increased in the Black Sea and thus surpassed the Atlantic rate, while it became similar to the Atlantic rate in the West Mediterranean and the Adriatic. It should be stressed that this last finding may be strongly influenced by sensitivity of cubic fits to decadal-scale variability at the edges of time series, and that therefore the finding should be regarded as preliminary until confirmed by some independent methods.

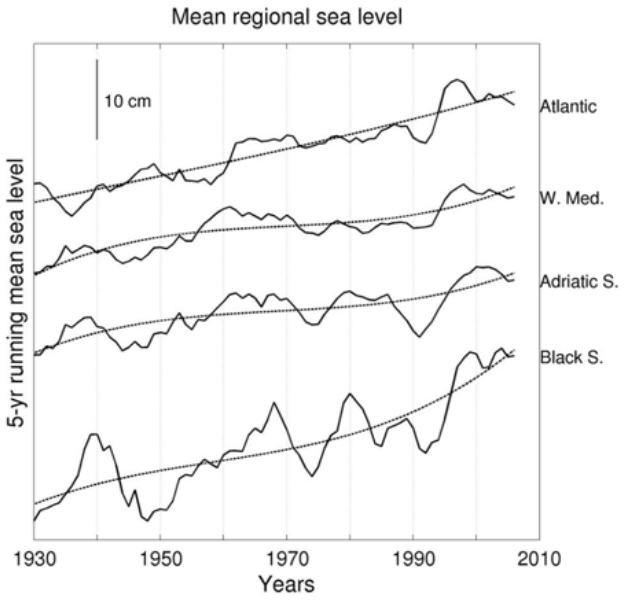

Fig. 1. Time series of sea level registered by tide gauges in the Atlantic close to Gibraltar and in the West Mediterranean, Adriatic and Black Seas and smoothed by a 5-year moving average (full lines). Cubic fits are superimposed to the time series (dashed lines).

IS GLOBAL WARMING RESPONSIBLE FOR MASS MORTALITIES IN THE UPPER LAYER OF THE MEDITERRANEAN SEA?

Abstract
The thermal structure of the shallow water column over the past 65 years is reconstructed from a large dataset of temperature profiles at basin scale. Data do not support a consistent signal of climate change for the upper layer of the Mediterranean Sea, but identify areas more exposed to thermal anomalies than others. Areas subjected to mass mortalities correspond to positive thermal anomalies, suggesting a causal link between higher temperatures and mass mortalities. Methodological concerns in deriving conclusions on climate change require systematic assessment of thermal anomalies in the future. <\/div>

Keywords: Global change, Mortality, Temperature, Vertical profile, Mediterranean Ridge

Introduction The Mediterranean Sea is changing, but both the magnitude of change and the identification of areas more exposed to thermal anomalies are idiosyncratic [1, 2]. The increasing mass mortalities of temperate sessile invertebrates suggest their vulnerability to rises in seawater temperature [3]. We combined and compared the thermal structure of the uppermost part of the water column both at regional scale and at the smaller scale of mortality events, using all the high vertical resolution data (bottles, CTDs, XBTs, MBTs) available for the basin over the period 1945-2011 [4].

Methods
The thermal structure of the uppermost part of the water column has been assessed by using two approaches: first at the spatial scale of Mediterranean regions and at the temporal scale of seasons; second at the spatial and temporal scale of mortality events. For the first approach Mediterranean sub-basins were combined into five regions and the seasonal temperature anomalies at 10, 30, 50, and 100 m depth were estimated in four 15-year-long periods. For the second approach, in those areas where mass mortalities were observed average temperature profiles in the periods 1945-1982 and 1992-2011 in the months when mass mortalities were reported at least once have been considered together with the temperature profiles in the months when mass mortalities occurred. This analysis was been made for the Ligurian Sea, the Provence Coast, the Western and Eastern Tyrrhenian and the Balearic and Columbretes Islands.

Results and discussion
The available data for the upper layer of the whole Mediterranean Sea, at regional scale and at the temporal scale of season, do not show a coherent signal at basin scale. Temperature increased in the Western and in the Central Mediterranean, but not in all other areas. The Eastern Mediterranean shows larger positive and negative temperature anomalies (Fig. 1).

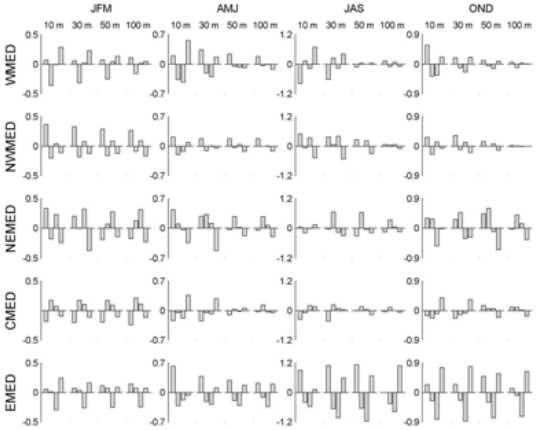

Fig. 1. Temperature anomaly for depth and seasons for the periods 1945-1959, 1960-1974, 1975-1989, 1990-2011 in the five Mediterranean regions.

At locations where at least a mortality event was recorded, mean temperature profiles document a systematic warming since the early 1990s. Here, changes of mean monthly temperature caused a rise of the upper limit of interannual temperature fluctuations, sharply associated with mass mortalities (Fig. 2).

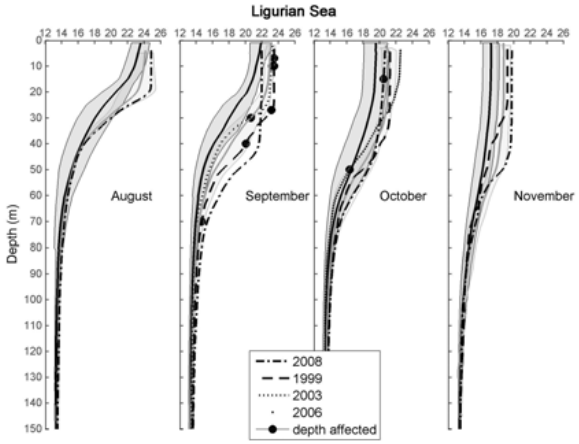

Fig. 2. Monthly average temperature profiles for the periods 1945-1982 (black lines) and 1992-2011 (grey lines) and average temperature profiles for the years and months in which mass mortalities occurred, in the Ligurian Sea. <\/div>

Though biota represent a reliable proxy for ecological responses to global change, since mass mortalities occurred especially in areas with no clear signals of climate warming at regional scale (see the N-W Mediterranean), caution in interpreting changes only in terms of thermal anomalies is needed. The lack of systematic assessment of thermal anomalies can be partly responsible for our contrasting results. Implementing monitoring programs to understand the magnitude of this phenomenon, together with specific conservation actions, should be the core of future management strategies for the whole Mediterranean Sea.

LONG-TERM VARIABILITY OF THE EXCHANGES BETWEEN THE TYRRHENIAN SEA AND THE LIGURIAN SEA THROUGH THE CORSICA CHANNEL

K. Schroeder [1]*, M. Borghini [1], S. Sparnocchia [1], G. Gasparini [1], A. Vetrano [1] and J. Chiggiato [1]
[1] CNR ISMAR, Venice, La Spezia, Trieste, Italy - katrin.schroeder@ismar.cnr.it

Abstract
The aim of this study is to investigate the interannual signal of the time series (1985-2012) of temperature and water transport through the Corsica Channel, connecting the Tyrrhenian Sea with the Ligurian Sea. The variability from the annual to the interannual scale is explored and an investigation of the possible forcing mechanisms determining the long-term variability of transports is carried out, trying to correlate transports through the channel with large scale atmospheric modes as well as other atmospheric forcings. There is a striking similarity between the annual cycles of transport and temperature with high winter transports associated to a larger portion of purer LIW in the outflow through the Corsica Channel.

Keywords: Ligurian Sea, Circulation, Water transport, Time series

The north-western Mediterranean Sea is a region of dense water formation (DWF). It is characterized by a cyclonic circulation, which is fed by the Western Corsican Current (WCC), flowing northeastward on the western side of the island of Corsica, and the Eastern Corsican Current (ECC), flowing northward on the eastern side of Corsica. The ECC is forced to cross the narrow Corsica Channel (430 m depth), making this location ideal for the monitoring of a choke point of the Western Mediterranean circulation (Figure 1).

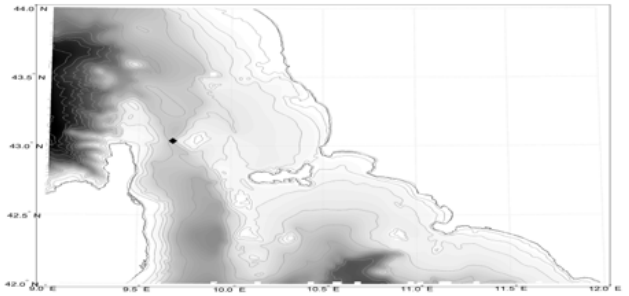

Fig. 1. Location of the mooring in the Corsica Channel. The site is part of the CIESM HYDROCHANGES Programme.

The 27-years long time series of current velocities and thermohaline properties within the water flowing through the Corsica Channel provides now a unique chance to evaluate the temporal variability, at different scales, of the exchanges between the Tyrrhenian and the Ligurian Sea. Given the extension of this time series, the focus is on periods ≥ 1 year, including the annual cycle, keeping in mind that there are also important sub-annual periodicities, as reported e.g. by Astraldi and Gasparini (1992).
Since early research efforts in the region, it is known that a two-layer shear flow crosses the Channel, where the upper layer is occupied by Atlantic Water (AW) and the lower layer by Levantine Intermediate Water (LIW) (Astraldi and Gasparini, 1992). Air–sea fluxes and steric differences between the two basins, also related to DWF events in the NW-Mediterranean, are possible candidates to explain the variability of the exchanges at the interannual scale. According to Astraldi and Gasparini (1992), a link can be established between the winter increase of currents inside the channel and the cooling of the Ligurian Sea. Other parameters are found to have a correlation with the interannual variability of transports, such as the North-Atlantic Oscillation (Vignudelli et al., 1999), the sea level pressure, net heat loss and wind speed in the Ligurian Sea.
The integrated transport over the whole water column ranges between -0.5 Sv (i.e. southward) and 2.3 Sv (Fig. 2a). The flow shows a clear annual cycle, directed northward and intensified in winter, as it has been already discussed by, e.g., Astraldi and Gasparini (1992), who estimated that the winter transport is about 60% of the annual transport. This behaviour is even more evident considering the integrated transports for each individual season, as shown by the bar plots in Figure 2b. Winter transports are always very strong, compared to the other seasons, while in summer there are a few cases of current inversions. Considering only the winter transports, a strong interannual variability is evident as well, with increased throughflow during the mid-80s, the mid-90s and mid-2000s.

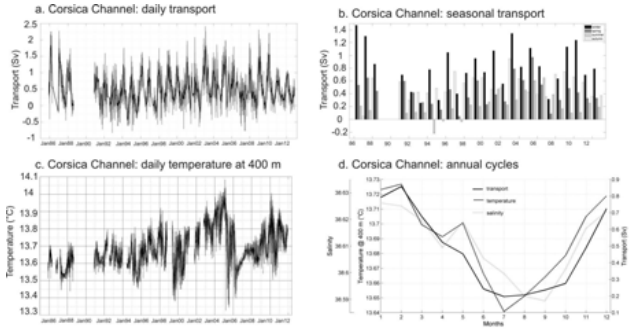

Fig. 2. A. Daily time series of the integrated transport throught the Corsica Channel; b. seasonal transport; c. daily time series of the temperature at 400 m depth; d. annual cycles of integrated transport, temperature at 400 m and salinity at 400 m.

Also the temperature time series has a clear annual cycle (Fig. 2c). The data at 400 m are proxy of the hydrological variability of the LIW (Schroeder et al., 2013). The maximum temperature was recorded in early 2005 (more than 14° C): compared to the mid 1980s, when the average was 13.6 °C, up to 2005 there has been an increase of +0.4°C. It is interesting to note that within one year (2005–2006) the highest and lowest values of the 1985–2012 time series were observed. There is a striking similarity between the annual cycles of transport, temperature and salinity (Fig. 2d). Maxima are in January-February, and minima in summer. High transports thus seem to be associated to a larger portion of purer LIW in the outflow through the Corsica Channel. Being the LIW core (i.e. the T and S maximum) in the Tyrrhenian Sea located at 500-600 m, and the sill depth at Corsica only 430 m, according to the Bernoulli principle (see its application to the Mediterranean Outflow at Gibraltar, by Stommel et al., 1973), the higher the flow, the deeper the level of "aspiration". This means that in winter the strong transport is able to "aspire" water more close to the LIW core (i.e. warmer and saltier) than in summer, when the transport is reduced, and thus also the "aspiration" depth: a behaviour that has been found also by Astraldi and Gasparini (1992), analyzing the 1985-1988 time series.

SEASONALITY IN INTERANNUAL VARIABILITY OF MEDITERRANEAN SEA SURFACE TEMPERATURE AND ITS LINKS TO REGIONAL ATMOSPHERIC DYNAMICS

Igor Zveryaev [1]* and Klaus P. Koltermann [2]
[1] Shirshov Institute of Oceanology, RAS - igorz@sail.msk.ru
[2] Faculty of Geography, Moscow State University

Abstract
Sea surface temperature (SST) data from the NOAA OI SST V2 High Resolution dataset for 1982-2011 are used to investigate intraseasonal and interannual variability of Mediterranean SST, their relationships and links to regional atmospheric dynamics during winter and summer seasons.

Keywords: Temperature, Surface waters, North-Western Mediterranean, South-Eastern Mediterranean

Sea surface temperature (SST) data from the NOAA OI SST V2 High Resolution dataset (Reynolds et al., 2007) for 1982-2011 are used to investigate intraseasonal and interannual variability of Mediterranean SST, their relationships and links to regional atmospheric dynamics during winter and summer seasons.

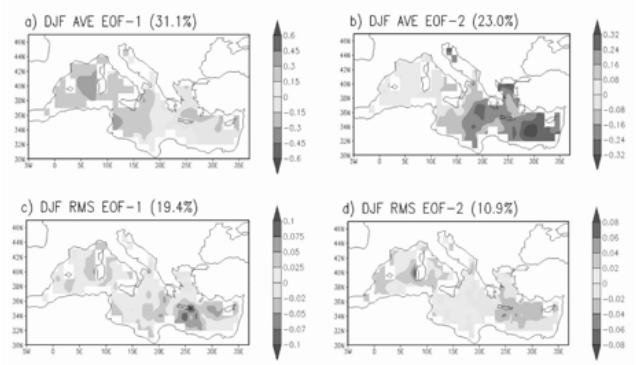

Fig. 1. Spatial patterns of the EOF-1 (a, c) and EOF-2 (b, d) of the winter (December-February) seasonal mean SST (a, b) and its intraseasonal STDs (c, d).

An empirical orthogonal functions (EOF) analysis has revealed that both in winter and summer the leading EOFs of the seasonal mean SSTs and the intensities of their intraseasonal fluctuations (expressed by standard deviations (STD) of the daily SST data) are characterized by the principally different spatial patterns. For example, in winter EOF-1 of SST is characterized by east-west dipole with the largest variability in the western Mediterranean Sea (Figure 1). Wintertime EOF-1 of intraseasonal STD, however, is characterized by the monopole pattern with the largest variability in the eastern Mediterranean Sea. Note, the EOF-1 of winter evaporation is characterized by monopole pattern (Zveryaev and Hannachi, 2012). Interannual variability of the leading principal components was also different for SSTs and intraseasonal STDs. Therefore, present analysis did not reveal significant links between interannual variability of Mediterranean SST and that of the intensity of intraseasonal fluctuations of SST.

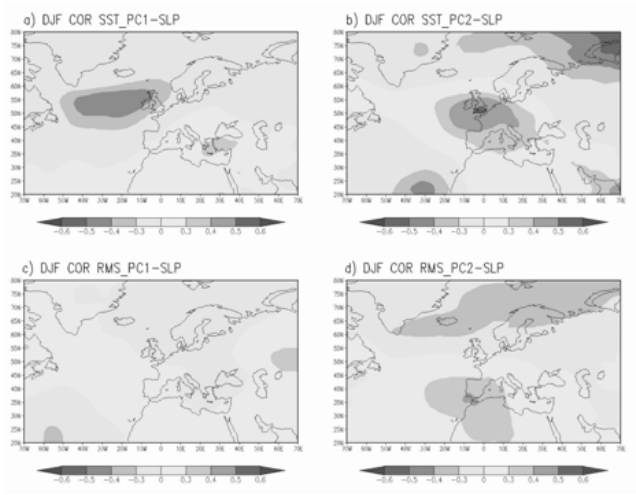

Fig. 2. Correlations between principal components (PC) of the EOF-1 (a, c) and EOF-2 (b, d) of the winter seasonal mean SST (a, b) and its STDs (c, d) and respective sea level pressure fields.

Analysis of the links to the regional atmospheric dynamics has revealed quite different patterns of correlations between leading principal components (PCs) and sea level pressure fields obtained for seasonal mean SSTs and intraseasonal STDs. In particular, it was found that during winter EOF-1 and EOF-2 of seasonal mean SST are associated respectively with the East Atlantic and the East Atlantic/West Russia teleconnections (Barnston and Livezey, 1987). Wintertime EOF-2 of intraseasonal STDs is linked to the North Atlantic Oscillation. Overall, results of the present study suggest that interannual variability of Mediaterranean SST is not associated with variations in the intensity of its intraseasonal fluctuations, and that they are driven by the different modes of regional atmospheric dynamics.

EFFECTS OF 2012 WINTER CONVECTION ON THE DEEP LAYER OF THE SOUTHERN ADRIATIC SEA

M. Bensi [1]*, V. Cardin [1], A. Rubino [2], G. Notarstefano [1] and P. M. Poulain [1]

Abstract
Winter convection occurred during 2012 in the Northern Adriatic produced an exceptionally dense water, which caused abrupt thermohaline changes in the bottom layer of the Southern Adriatic after its arrival as a bottom-arrested current. We investigate this phenomenon merging data from a fixed point observatory and from drifting profiling Argo floats.

Keywords: South Adriatic Sea, Deep waters, Circulation experiments, Deep sea processes

An unusually harsh and long-lasting (~20 days) episode of Bora wind, which occurred from 24 Jan to 14 Feb 2012 in the Adriatic Sea, was responsible for a large production of very dense water (σ_θ > 30 kg m^{-3}) in the northern basin, where maximum depth does not exceed 250m. Here, we merge Temperature (T), Salinity (S), and current time-series collected at the E2M3A deep-ocean observatory of the Southern Adriatic (41°32' N, 18° 05' E) with CTD (Conductivity-Temperature-Depth) profiles obtained from freely drifting Argo profiling floats to analyse the drastic thermohaline changes which occurred in the deep layer (>1000m depth) of the Southern Adriatic Pit (SAP) after the arrival of the dense water formed on the northern shelf. The signal of that water mass arrived in the Jabuka Pit (middle Adriatic) by the end of February 2012, and its effect was clearly evident in the bottom layer (Fig. 1).

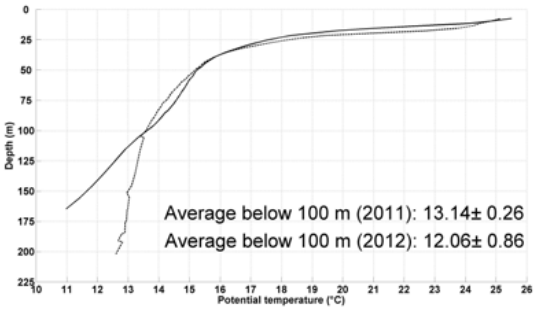

Fig. 1. Average pot. temperature profiles obtained from float data in July-August 2011 (dashed line) and 2012 (solid line) in the Jabuka Pit (middle Adriatic).

Afterwards, its arrival in the SAP interrupted the positive T and S bottom trends observed during the last 5 years, which were quantified by ~0.05°C y^{-1} and ~0.004 y^{-1}, respectively (Fig. 2).

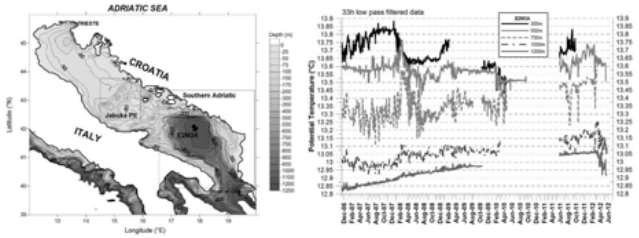

Fig. 2. Map of the Adriatic Sea (left panel) and temperature time series (right panel) at the fixed point observatory E2M3A from 2006 to 2012.

Previous studies report that, presumably, these trends were associated to the combined effect of local mesoscale eddies, large scale circulation changes, and dense water formation processes ([1], [2], [3]). The descent of dense waters of Northern Adriatic origin (NAdDW) caused an abrupt bottom T and S decrease (~0.15 °C and ~0.015, respectively). The corresponding density increase was ~ 0.02 kg m^{-3}. Our data confirm that the deepest part of the SAP undergoes intense modifications only when harsh winter conditions are able to produce a high volume of NAdDW with different properties from those of the previous years. Moreover, they show that the exceptionally dense waters produced on the northern shelf arrived in the central, deepest part of the SAP as a series of individual pulses not earlier than 10 March 2012, while a stronger and prolonged signal that significantly modified the deep water stratification arrived after 10 April 2012. CTD float profiles collected in the Strait of Otranto, which connects the Adriatic Sea with the Ionian Sea, reveal that the Adriatic outflow in July 2012 was characterized by relatively cold and dense water (θ ~13.08°C, S~38.71, and σ_θ~29.25 kg m^{-3}). This fact clearly indicates that the harsh winter conditions, responsible for an exceptional production of very dense water in the Northern Adriatic, caused also strong modifications in the thermohaline properties of the Adriatic outflow with respect to those observed in the previous years ($\Delta\theta$~ -0.2°C, ΔS~ 0.01, $\Delta\sigma_\theta$~ +0.02-0.03 kg m^{-3}).

INTERANNUAL CHANGES IN THE THERMOHALINE STRUCTURE OF THE SOUTH EASTERN MEDITERRANEAN

Abstract
CTD data shows long term increase of the Levantine Surface Water salinity (0.01 per year) and temperature (0.1ºC/year) during the last 33 years. Fluctuations of salinity and temperature in the Atlantic Water and Levantine Intermediate Water do not show substantial long term tendencies.

Keywords: Levantine Basin, Stratification, Salinity, Temperature

The South Eastern Mediterranean (SEM) is the region with the highest temperature and salinity values in the upper layer. The so called Levantine Surface Water (LSW) originates from Atlantic Water (AW) whose properties change through evaporation and heating in the course of their eastward propagation. During summer the LSW is bounded from below by overturning halocline and stabilizing seasonal thermocline. The later prevents vertical mixing of LSW with the less transformed (cold and less saline) AW. During winter, the overturning halocline sinks as a result of winter cooling. However, AW signal (minimum salinity) is not typically destroyed. Levantine Intermediate Water (LIW) formation occurs when LSW cools down and sinks along isopycnals into intermediate depths. This usually occurs as LSW reaches Rhodes Gyre regions (Lascaratos et al., 1999). Nevertheless, some indications of intermediate water formation were observed on continental shelves of Israel and Turkey (Oszoy et al., 1989). When sufficiently saline LSW propagates further to the Aegean it can cool down to reach densities of Eastern Mediterranean Deep Water (EMDW) and cause intensive deep water formation, as occurred during the Eastern Mediterranean Transient (EMT) (Roether et al., 2007; Gertman et al., 2006). In this study we estimated interannual variability of thermohaline structure in the region where LSW circulates and accumulates before it propagates further to LIW and EMDW formation regions

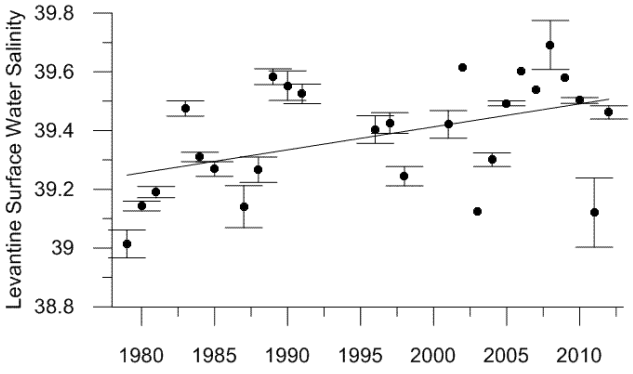

Fig. 1. Long term changes in LSW salinity. Confidence interval (Emery & Thmoson, 2001) is shown when number of observations is more than 3.

Thermohaline structure was obtained by analysis of CTD profiles from a regional cast database containing data from the SESAME project cast DB along with recent observations made by IOLR and OCUCY. For the analysis we used only CTD profiles in the SEM which are at least 50 km away from the coast. This was done in order to eliminate influence of coastal upwelling. To characterize the thermohaline structure variability we derived the following parameters from the vertical profiles of potential temperature, salinity and density: depth of the seasonal mixed layer and its temperature and salinity (LSW parameters); thickness of minimal salinity layer, location of salinity minimum as well as water temperature and salinity of the minimum (AW parameters); thickness of intermediate maximal salinity layer, location of salinity maximum as well as water temperature and salinity of the maximum (LIW parameters). In order to increase the robustness of the estimated parameters, all CTD profiles were smoothed initially by low pass median filter (effective to eliminate spikes) and then by running average filter to finalize the smoothing. The depth of the seasonal mixed layer was defined as the size of the upper layer where total increase in potential density was less than 0.08 kg/m^3. The same depth was used as the upper boundary of AW layer. The low AW boundary was defined as the depth of isopycnal surface 28.5 kg/m^3. The low boundary of the LIW layer was defined as the depth of isopycnal surface 29 kg/m3.

Thickness of LSW during summer fluctuates between 10 m and 50 m and between 20 m and 350 m during winter. Time series of summer and winter salinity show long term increase of the LSW salinity with a rate of about 0.01 per year (Fig. 1). In the summer salinity time series, two periods of salinity increase can be observed: from 1978 (39.10) to 1991 (39.55) and from 1996 (39.4) to 2008 (39.7). The first period preceded the EMT. It is not yet clear whether the second increase in salinity will cause another EMT, however data observed during 2010-2012 shows some decrease of the LSW salinity. The winter salinities of LSW show the similar behavior. Summer and winter temperature series shows a long term tendency of the LSW warming with the rate of about 0.1°C/year (Fig.2). Fluctuations of salinity and temperature in the AW and LIW does not show substantial long term tendencies.

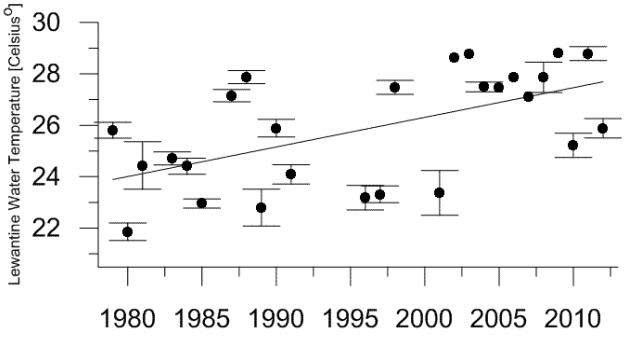

Fig. 2. Long term changes in LSW temperature.

Abstract
Hydrographic data have been collected for 17 years in the northeastern Levantine by the Cyprus Basin Oceanography (CYBO) initiative of the Oceanography Center, University of Cyprus. Twenty-three cruises have covered the region extensively, and have shown significant changes in the salinity of the Levantine Intermediate Water (LIW: 250 m depth) from values of around 39.1 to 39.3 since 2007. Profiling float data since 2003 and glider data since 2009 show agreement. LIW temperature shows a very small change at the same time from all three platforms.

Keywords: Intermediate waters, Levantine Basin

LIW is primarily formed in February and March in the cyclonic Rhodes Gyre [1]. It is signified by a sub-surface maximum in salinity, around 250 m. During and after buoyancy driven convection, LIW spreads laterally around the Levantine basin, eventually finding its way into the Western Mediterranean, and to the Atlantic Ocean. Salinity and temperature values at the time of formation are reported to be 38.95-39.1 and 15-16 deg C [2]. In this paper, the properties of LIW from 1995 to present is examined.

Since 1995, the CYBO program has carried out 23 hydrographic cruises of up to ninety stations to 1000 m over 9 days (Fig. 1). For the last 10 years or so, profiling Argo floats have been deployed in earnest in the Mediterranean Sea [3]. While coverage is not the same every year, a significant portion of the region is covered in any given year. The last three years gliders have been used: over 4000 profiles have been collected, most to 1000 m (Fig. 1). The salinity and temperature at the depths of the LIW have been extracted from floats and gliders for the Eastern Levantine each year in order to be compared to the CYBO data.

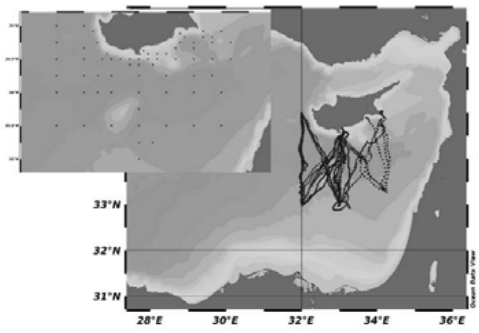

Fig. 1. Location map of standard Cyprus Oceanography hydrographic stations (zoom) and Cyprus glider fleet missions (2009-2012).

Results from CYBO show a significant increase in LIW salinity and temperature from 39.0 to 39.15 and 15.4 to 16.0 deg, around 2009 (Fig. 2).The glider data (connected symbols) also show higher salinity and temperature in recent years, in agreement with CYBO. Maps of salinity at 200 m (Fig. 2) from floats also indicate a sudden change in LIW salinity around 2009, with the years before and after not exhibiting large-scale changes.These results could indicate a change is taking place on the fresh water budget of the Mediterranean. Besides the slow changes over the last century because of the damming of major rivers, it could be that different sites for LIW formation are favored in recent years. The geographic extent outside the eastern Levantine is not yet known, nor is the mechanism for this change. Further analysis of the in situ data, as well as model re-analyses will shed light on the mechanisms at work.

OBSERVATIONS OF DENSE WATER FORMATION AND DEEP WATERS CHANGES IN THE NORTHWESTERN MEDITERRANEAN OVER THE RECENT PERIOD (2007-2012) FROM IN-SITU MEASUREMENTS.

Loïc Houpert [1]*, Xavier Durrieu de Madron [1] and Pierre Testor [2]

[2] LOCEAN, CNRS-IRD-Université Pierre Marie Curie-MNHN, Paris, France

Abstract
We present here new in-situ observations collected since 2007 in the Gulf of Lions that enable to characterize the variability of the different phase of the deep water formation and the subsequent thermohaline changes.

Keywords: North-Western Mediterranean, Air-sea interactions, Deep waters, Deep sea processes, Water convection

Open-ocean deep convection is a key process that transfers the heat and salt contents from the surface to the deep ocean. In the Northwestern Mediterranean Sea, this leads to the formation of the Western Mediterranean Deep Water (WMDW) which underwent in 2005 an abrupt increase in its thermohaline properties, and an important modification in the deep stratification (known as the Western Mediterranean Transition, WMT [1]).

A mooring line was setup since 2007 in the Gulf of Lions (42°N-4.6°E) to monitor the deep convection process. This observation system is composed by 20 temperature sensors, 10 salinity sensors and 5 current meters between 150m depth and the bottom (2330m depth). Theses recent measurements reveal the temporal evolution of the physical processes interfering in the phases of deep convection (deepening of the mixed layer depth, violent vertical mixing and restratification [2]).

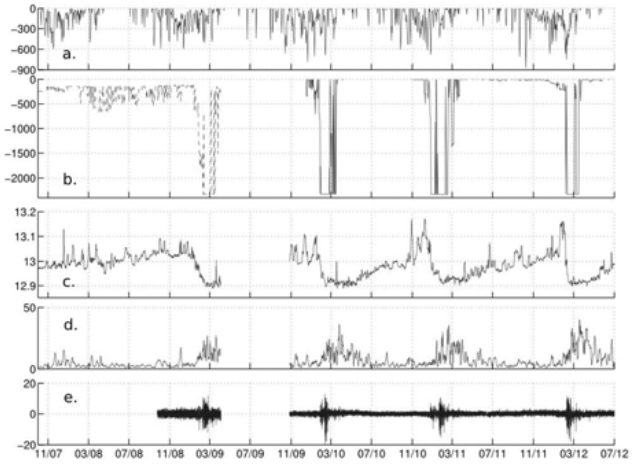

Fig. 1. (a) Daily net heat fluxes (W.m-2) from ERA-Interim reanalysis, (b) daily MLD (m) calculated with a 0.08°C criterion and a 10m depth reference level (continuous line from November 2009 to July 2012) and with a 0.05°C criterion with a 150m depth reference level (dashed line from October 2007 to April 2009), (c) daily θ (°C) at 750m depth, (d) daily horizontal speed (cm.s-1) at 1000m depth, (e) bi-hourly vertical current (cm.s-1) at 1000m depth

Some remarkable features point out from the analysis of four deep convection events observed between 2009 and 2012. The time for the mixed layer deepening is comprised between 1 and 2 months, while the violent vertical mixing is in the range of 7-10 days. Due to the strong heat losses, the mixed layer can reach the bottom (Fig 1.) and its temperature may undergo a 0.02°C decrease.
Strong currents were also recorded during the different events of deep ocean convection: high frequencies vertical velocities exceeded 10 cm.s-1 during the violent vertical mixing phase and strong mesoscale horizontal currents reached 40cm.s-1 during the restratification phase (Fig. 1). Horizontal currents were strongly barotropic during each deployment. The first EOF dominate the variability, containing 85% to 95% of the variance, while the second mode contains 5% to 10%.
Dense shelf water cascading also contributed to deep water formation during winter 2012 [3]. Each of these five deep water formation events modified the deep stratification by producing a new deep water. The thermohaline changes of the bottom water between 2007 and 2012 corresponds to a potential density (σ) increase of 0.015 kg.m-3 in 4 years, linked to a salinity (S) increase of 0.03 and a potential temperature (θ) increase of 0.03°C (Fig. 2). These stepwise increases in bottom water characteristics are marked by postivie jumps in θ , S and σ, and correspond to the mixed layer reaching the bottom in February. We interpret the 0.02°C decrease in temperature after each jump, already seen in [4], as the effect of the persistent net heat losses after that the MLD reached the bottom (Fig. 1). A remarkable signal corresponding to a strong decrease in θ and S can be seen in March 2012, indicating the arrival of dense shelf water to the mooring location [3].

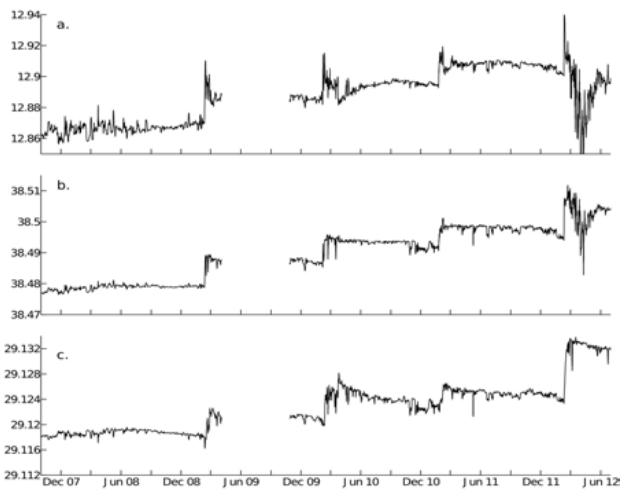

Fig. 2. (a) Potential temperature (°C), (b) salinity and (c) potential density anomaly (kg.m-3) from the mooring line at 2300m depth.

A COMBINED NUMERICAL AND ANALYTICAL MODEL STUDY OF DENSE WATER FORMATION IN THE NORTH AEGEAN SEA DURING THE YEAR 1987

Ettore Salusti [1]* and D. Gasbarra [2]
[1] ISAC-CNR - ettore.salusti@gmail.com
[2] Univ. of Rome "La Sapienza"

Abstract
We investigate the role of year 1987 in a kind of preconditioning the EMT, being the first of a series of increasingly cold winters affecting the Aegean Sea. Due to the scarceness of direct in situ observations in this sea during 1987, we implement satellite and in situ data with numerical simulations from Protheus, a coupled ocean-atmosphere model. We use just such numerical temperature and salinity data to simulate lacking observations in some transects to infer dense water formation sites, evolution and mixing during this pre-EMT year. We so obtain a detailed description of North Aegean dynamics but that around Cyclades plateau looks a more complex situation.

Keywords: Deep sea processes, Models, Aegean Sea

The numerical simulation of transects and heuristic T/S diagrams Information from the simulated Protheus transects is synthesized in some heuristic hydrologic maps of monthly data, that allow one to infer some dynamics of the dense waters [Fig 1]. Unfortunately no Lagrangian version of the Protheus model data has been available. For the PROTHEUS data, the densest Northern Aegean Sea (NAS) water appears during January over the shelf of transect M15. From the deep M15 densities, no dense water cascade is evident, so we assume that such densest M15 water flows geostrophically over the NAS slopes. Its effect is evident over the O1 sill , at ~ 200 m depth, where σ decreases of ~ 0.1 in February and ~ 0.2 in March. In the following months the O1 sill dense water increases slightly its temperature, perhaps due to a mild mixing with the fresher and colder O3 waters. No evident effect of such dense surface M15 water appears on the O3 nor M15 deep data, that anyway are ~ 0.5 denser than the sill waters. We therefore assume that M15 flows as a density current into the sill, while probably the fresher and colder O3 water diffuses over the NAS bottom.

In these NAS density evolutions two important effects can be seen. First the time delay between surface dense water formation and bottom waterdensity increase (about two months) can be explained by considering the dense water evolution over a slope with its mild alongflow deepening due to bottom friction. Considering the distance along isobaths from the M15 shelf and the O1 sill as ~ 200 Km and a water velocity of ~ 4 cm/s, one indeed has a time delay of 57 days. The second important physical effect concerns again the sill deepest point (O1 at 200m depth): the dense water over the sill bottom is increasingly mixed with the dense M15 (and O3) shelf January waters while no relation with the Turkish shelf dense water (O1, 30 m) is evident. All this supports the idea that Turkish dense water (O1, 30m) has no important effect in the NAS dynamics but most probably flows around Limnos into the central Chios Basin.

The most important question about the thermodynamics of the central basin concerns the origin of the dense water near the Cycladic Plateau, where in January, February and March σ ~ 29.25, then ~29.36 in June to finally reach 29.5 in August . We examine hydrologic data of the possible sources, i.e. the O1 sill and shelf, the NE O7 shelf and deep points, the Z5 transect shelf or the northward flow of salty water along the Turkish shelf during January, February and March.

In these deep layers, salinities for both NE O7 (~ 500 m deep) and Z5 (at ~ 250 m depth) increase during January, February and March. At the deep O7 point near the Cyclades it looks reasonable that such NE O7 deep water during March is mixed with new salty water. This could come from the O1 sill (at a distance of ~ 180 Km from the NE O7 deep point, with model velocity u ~ 2 cm/s), or from the Limnos/Gokçeada shelf (~ 320 Km from the NE O7 deep point, with u ~ 3 cm/s), or to dense water formed over the same NE O7 Turkish shelf at a distance of ~ 160 Km (about 50 m deep , with u ~ 3 cm/s). It could also have been influenced by a violent storm.

In the following 3 months, S of this deep NE O7 water increased to ~ 38.2 and T decreased giving a density of about 29.35, most probably due to the mixing with O1 and salty waters. So in August a very dense water (σ ~ 29.48) was there found. In synthesis, a general increase of the water salinities and densities was evident, but no clear effect of the Z 5 transect on NE O7 can be found.

A similar effect holds in the other point of interest, the Z5 sill water. Its σ increased to ~ 29.2 in March, from 29.1 in January, while its salinity increases from 39.72 in January to 38.84 in March. In April, May and June its densities remained constant but S and T both show a mild decrease, with a large σ ~ 29.40.

CHANGES IN VENTILATION IN A VIEW OF TRANSIENT TRACERS TIME SERIES AND A CONSTRAINED TRANSIT TIME DISTRIBUTION MODEL

Tim Stoeven [1]*, Toste Tanhua [1], Anke Schneider [1] and Wolfgang Roether [2]
[1] Helmholtz Centre For Ocean Research Kiel - GEOMAR - tstoeven@geomar.de

Abstract
Measurements of transient tracer in the Mediterranean Sea cover the time frame between pre Eastern Mediterranean Transient (EMT) state in 1987, the EMT during the 1990's and post EMT progress as well as the Western Mediterranean Transit (WMT) up until 2011. The transient tracers can be used to determine the tracer age and mean age of water masses, i.e. the Transit Time Distribution, and thus provide a significant insight into the temporal variability of the ventilation processes in the Mediterranean Sea.

Keywords: North-Central Mediterranean, South-Central Mediterranean, Circulation, Time series, Models

The time series of transient tracer surveys includes several expeditions in the Western and Eastern Mediterranean Sea (WMed, EMed) between 1987 and 2011: Meteor 5/6 in 1987, Meteor 31/1 in 1995, Urania MAI2 and Poseidon 234 in 1997, Aegaeo M4WF in 1988, Urania MAI7 in 1999, Meteor 44/4 in 1999, Meteor 51/2 in 2001 and Meteor 84/3 in 2011 (Fig. 1). Transient tracers can be used for water mass analysis in terms of tracer age calculations and mean age modeling. The data sets consist of different combinations of CFC's, Helium isotopes, Tritium and SF_6 whereat the extent of the tracer data and sampling area are relatively similar. Changes in the composition of transient tracers resulting from changes in ventilation have a direct impact on the different ages, rates of age growth and age shifts. This provides a versatile and powerful tool to describe ventilation and transport processes in the ocean. According to this age applications the classical approach of tracer ages like the $^3He/^3H$-age [1] and the Inverse Gaussian - Transit Time Distribution (IG-TTD) [2] were used for the analysis of the time series. The ventilation of the Mediterranean Sea has direct implications for several biogeochemical processes, such as storage of anthropogenic carbon, oxygen and nutrient distribution, and transport of labile dissolved organic matter to the deep interior waters.

The comparison of apparent tracer ages and mean ages over the period of 25 years shows changes in circulation (like the EMT [3,4,5] and WMT [6]) as well as shortcomings of the different methods and to use them as such. Furthermore, the relation between the SF_6 ages in 2011 and the CFC-12 ages in 1997 of the same oceanic region give additional insights to changes in circulation. This approach is based on the almost identical atmospheric increase functions of both tracers with a time shift of 14 years [7]. In a steady-state system the tracer age of SF_6 in 2011 should match the tracer age of CFC-12 in 1997. In most tracer age shifts this was not the case. Increased ages for the eastern basin can be found below ~1500 m in 2011 and younger waters at depth in the western basin, respectively.

The comprehensive data set of the latest Meteor cruise M84/3 in 2011 consisting of CFC-12, SF_6, Helium isotopes and Tritium indicates that the EMed returns into the pre EMT state with the Adriatic Sea as major deep water source. Young water masses with higher tracer concentrations intrude the deep water layer in the Ionian Sea. Nevertheless, the Cretan Sea Outflow Water (CSOW) is still present in the bottom layer of the Levantine Sea shown by younger mean ages beneath the Tracer Minimum Zone (TMZ) in the intermediate layer. The WMT between 2005/06 leads to a complete renewal of the deep and bottom layer in the Western Basin by tracer rich water masses. Parts of the newly formed deep water spill over the shallow sill between Sicily and Sardinia intruding the old water masse of the Tyrrhenian Sea along the continental slope of Italy. Furthermore, the data set allows in addition to the standard investigation of ventilation processes to constrain the Inverse Gaussian (IG) - TTD model with either one (1IG) or two (2IG) main water masses, or transit time distributions. The obtained parameters like D/G-ratios ratios (the ratio of diffusion over advection) and alpha (the relative contribution of one water mass in a 2IG model) in the EMed give an insight into the advective/dispersive behavior of the water masses. Based on a constrained TTD model the mean age can be determined considering the particular water mass properties. The used tracer couples to constrain the 1IG-TTD were CFC-12 / SF_6 and Tritium / SF_6. However, not all data points were constrainable by those two couples and there were also small but distinctive differences in mean ages of the constraints. Therefore, the 2IG-TTD was applied to the tracer data which provides possible solutions describing one mean age by three transient tracers. Building on these results the anthropogenic carbon (C_{ant}) column inventory might be better estimated compared to the results of the standard TTD model. A further examination of the practical use and the improvement of the 2IG model within field data will be part of future work.

Rapports des modérateurs

Acidification

Patrizia Ziveri, UAB, Spain

Résumé

The introduction covered the concept of ocean acidification and the unique characteristics of Mediterranean acidification and biological impacts. It was followed by communications covering diverse topics related to the chemistry, past carbonate chemistry dynamics, biological impacts and modelling. Several presentations contributed to the on-going European project (MedSeA-project.eu) focusing on acidification in the Basin.

During the debate many important issues were discussed:

1. Data on seawater carbonate chemistry are still few, particularly in the southern Mediterranean and there is a need of long-term time-series stations for monitoring ocean acidification and other biogeochemical and physical parameters. The MedSeA project, among others, is collecting many new carbonate chemistry and biological data related to elevated CO2 conditions.

2. Ocean acidification training activities for scientists and laboratories starting to work on this research field was promoted. There is a need of method standardization for both chemistry (pH, AT, DIC, pCO2) and experimental biological work testing the impacts of acidification. It is particularly important to have long term monitoring time-series on the seawater carbonate chemistry and target biogeochemical processes, because only with a long record it is possible to identify trends in seawater pH and relative impacts. During the presentation new data were presented from the DYFAMED site (North Western Mediterranean) and the LTER-C1 (North Adriatic Sea). Time series stations should be established, especially in the eastern and southern Mediterranean and the Black Sea. They should follow the same standard operational protocols for measuring the basic carbonate system parameters

3. The negative impacts of acidification could be much more relevant in coastal ecosystems, where marine life is concentrated and biogeochemical processes are more active. However, changes in pH in these areas are difficult to study due to the multitude of physical and biological drivers, including watershed processes, nutrient inputs, and changes in ecosystem structure and metabolism. The next challenge for the ocean acidification research is to focus on these environments, using a multidisciplinary approach; chemical, physical and biological aspects should be well investigated and integrated.

4. Different kinds of impacts by acidification could exert themselves in the near future. Not only chemical and biological impacts were discussed, but also the importance of socio-economic aspects arose; collectively these highlight a transversal way that integrates the main decision making components in a holistic approach.

5. The last point discussed was the potential effects of acidification on metal and contaminant speciation. The MedSeA project only partly covers this topic, which also bears on the biota and on human health itself. This is an important issue that is just at its infancy. In the Mediterranean some initial work has been performed in MedSeA project mesocosm experiments. It would be also interesting to understand the effect of acidification on dust input and elemental availability.

6. An international ocean acidification coordination was launched recently. It provides important information about research status and OA collaborators (OA-ICC web site: www.iaea.org/ocean-acidification News Stream: news-oceanacidification-icc.org).

7. A dedicated information outlet on Mediterranean Sea acidification, climate and environmental changes is available at http://medseaclimatechange.wordpress.com.

Bioaccumulation, methodology

Bourhane Belabed, Univ.d'Annaba, Algérie

Résumé

La protection de la Méditerranée s?était fixé plusieurs objectifs, dont un était la création d?un programme de surveillance de la pollution marine. Depuis, le programme MEDPOL s?est développé, et remodelé plusieurs fois. Les États membres du bassin méditerranéens se sont engagés à fournir des données sur la qualité des eaux côtières. Les travaux réalisés restent insuffisants pour estimer l?état des écosystèmes marins. De plus, la situation est rendue complexe par une forte urbanisation, une explosion démographique et surtout des usines le long du littoral. Ces zones présentent des habitats riches et variés, un réservoir de biodiversité, et des espaces de développement d?activités : portuaires, industrielles, urbaines et touristiques et jouent un rôle nourricier pour de nombreuses espèces de poissons. Face aux risques environnementaux générées par l?introduction de substances chimiques dans le milieu marin il est urgent de mettre en place des outils pertinents- notamment des bio indicateurs quantitatifs- afin d?évaluer les perturbations des écosystèmes.

Les participants de la session 82 ont proposé de suivre, à l?échelle internationale, les concentrations de contaminants dans les organismes vivants en vue de surveiller le milieu. Les stratégies de surveillances présentées sont diverses ; l?utilisation de mollusques, et surtout de poissons- mulet et thon- dans les programmes de surveillance, ont rencontré le plus de succès.

La douzaine de travaux présentés lors de cette session ont montré que les métaux lourds et certaines substances radio-nucléiques entrainent des modifications du comportement et des perturbations du métabolisme et des réponses génétiques, pouvant avoir des répercussions à toutes les échelles trophiques, affectant ainsi le fonctionnement des écosystèmes. Lors du débat les participants ont pu conclure:

- qu'il n?existe pas de bio-indicateur universel. L'utilisation d?indicateur biologique répond à une problématique appliquée;

- à l'intérêt d'indicateurs basés sur l?individu comme les indices de croissance et de condition.

- que la création d?un réseau de suivi de la contamination littorale était donc un objectif socio- économique vital pour la région considérée.

Chemical fluxes - 1

Chemical fluxes - 2

Christian Tamburini, MIO, Université Aix-Marseille, France

Résumé

In this session, 12 speakers presented their results in front of a large audience (the room was full). The short introduction presentation provided a brief overview of the different presentations focused on: (i) eutrophisation in the Black Sea leading toward anoxic conditions in the water column (three talks: A. Alkan, S. Trugul and A. Alkan); (ii) benthic nutrient fluxes in Adriatic and Aegean Seas and geochemical characteristics in recent deep sediments under influence of open sea convection in the Gulf of Lion (three talks: F. Spagnoli, C. Dumas and M. Stabholz,); (iii) the silica budget at the scale of the Mediterranean Basin (one talk: M. Krom); (iv) production of dissolved organic matter (DOM) in culture experiment and in coastal zone and its degradation (three talks: E. Sanchez-Perez, B. Charriere and C. Tamburini).

While the panel of presentations was relatively large, the discussion was rich, active, well distributed through the different presentations and crossing the many themes.

Coastal lagoons status

Michèle Forestier, Univ. Genève, Suisse

Résumé

Durant cette session, 4 auteurs ont présenté leurs résultats, après une courte introduction de la modératrice sur les lagunes côtières: (i) H. Chalghmi, Suivi de la réponse des biomarqueurs de métabolisation de phase I et II dans le Lac de Tunis (Tunisie); (ii) D. Munaron, Assessment of chemical contamination of french coastal lagoons using passive sampling techniques; (iii) U. Sunlu, Distribution of Some Heavy Metals in Surface Sediments From The Homa Lagoon (Izmir Bay, Turkey). (iV) M. Forestier, Historical trace metal contamination assessment of Orikum Lagoon, Albania, based on dated recent sediments record.

Ces présentations ont contribué à la mise en lumière de différentes méthodes d'évaluation des systèmes lagunaires selon diverses approches (biologique, géologique et chimique). La discussion fut riche et pertinente, rappelant les difficultés que les auteurs ont pu rencontrer à travers l'étude de tels systèmes dynamiques complexes.

Ecosystem modelling

Estuaries status

Ana-Marija Cindric, Ruder Boskovic Institute, Zagreb, Croatia

Résumé

The session ?Estuaries status? hosted in total eight presentations covering specific, but quite different topics: the intrusion of seawater into the surrounding aquifer, lithogenic and biogenic particle fluxes, distribution of water masses and nutrients, distribution and behavior of metal contaminants, application of specific techniques for the speciation of trace elements, the intrusion of alien species and their use as possible bio-indicator of pollution. The use of radon and radium isotopes for estimating submarine groundwater discharge (SGD) and the study of anchialine caves were presented as particular environments with freshwater and seawater mixing.

All these systems present environments in which freshwater and seawater are mixed, causing dramatic changes in physical, chemical and biological properties. Significant differences in hydrology as well as chemical properties between estuaries in the south and in the north of the Mediterranean were clearly exemplified by the Mafragh estuary with periodic offshore bar causing closure of the estuary?s mouth and the permanently highly stratified Krka River estuary. Contrary to these mostly ?pristine? estuaries, untreated discharges to Dil Creek estuary increase the level of inorganic and organic contaminants. Particularity of estuary hydrodynamics is presented by the Alexander River estuary where partial salinization of the adjacent aquifer takes place. Populated, industrialized and touristic regions are prone to threaten the sensitive estuary ecosystems.

Biological responses as well as chemical changes of contaminants occurring within estuarine salinity gradient affected by the anthropogenic pressure were identified as topics of primary research interest. Identification of the specific physico-chemical processes, increase of the sampling frequency as well as number of samples and sites, was highly recommended in order to better understand and to predict the behavior of contaminants. Finally, modeling of contaminants transport and behavior across the salinity gradients was pointed as one of the tasks which would help in predicting their negative effects.

Fouling, status and novelties

Christine Bressy, University of Toulon, France

Résumé

This session focused on (i) the fouling communities which could colonize any substrata immersed in the Mediterranean Sea and (i) antifouling strategies.

The moderator outlined that surfaces immersed in seawater are subjected to biofouling, i.e. the settlement of undesired marine micro- and macroorganisms. This leads to negative economic consequences on marine structures such as vessels, offshore platforms, sensors and fishnets in aquaculture. Ocean-going vessels have been plagued by the deleterious effects of biofouling for centuries. In addition to marine 'bio' risks from non-invasive species transfers, biofouling reduces vessel speed due to a reduction in hydrodynamics and maneuverability, causing increased fuel, gas emissions and maintenance costs.

The design of more environmentally-friendly coatings and the use of non-toxic active molecules extracted from sponges, macroalgae and metabolites of macroalgae as promising antifouling strategies were discussed. Taxa of micro- and macro-organisms which colonize surfaces immersed in Mediterranean Sea were reported and the microbial processes were shown to be spatially and temporally variable.

It was concluded that developing antifouling surfaces presents a major challenge due to the environmental impact on the marine environment. New environmental concerns related to antifouling strategies have been highlighted for marine renewable energy resources including tidal marine turbines, wave energy and ocean thermal energy converters where fouling could degrade performances over time.

Marine litter

François Galgani, France

Résumé

11 presentations/posters were planned for this first session on Marine litter in a CIESM meeting. The presentations covered all fields on the topic, including (i) the processes of degradation of polymers at sea , (ii) assessments of marine litter on beaches, sea floor and deep sea floor from various regions of the Mediterranean sea, (iii) the evaluation of densities of microplastics on beaches and at sea , (iv) methodological developments , including monitoring protocols and new methods, (v) monitoring within the Marine Strategy

Framework Directive and finally (vi) social awareness, reporting about the impact of marine litter, in order to support the reduction of the litte at sea.

The session was followed by more than 50 attendants. It was very active, with a dense and open discussion on the different aspects of the issue, demonstrating the importance of this new topic, especially in CIESM related seas. The presentations and discussion enabled to identify the scientific questions to be

addressed in the future and the specific issues in both the Mediterranean and black seas. Typically, a consistent evaluation of densities , a better understanding of harm and degradation pathways, the importance of circulation in driving the transport of litter and the transborder transportation within the CIESM areas, the occurence of trophic transfer or not, will facilitate the investigations on processes and help to understand why the Mediterranean and Black seas are the most affected basins in the world.

Overall, the session provided a basis for the networking of scientists

from both the Mediterranean and Black seas, the support of further research,

the harmonisation of common projects and the implementation of monitoring.

Mercury in the Mediterranean

Donata Canu, Italy

Résumé

Seven presentations were given in this session, addressing different aspects, such as the state of mercury contamination in its different forms, in different substrates, including biota, at different sites such as local hotspots located in Turkey, Tunisia, Croatia, Italy, Slovenia, and sampling stations in the Adriatic and in the Mediterranean basins. Mercury budgets, isotopes tracking and dynamic model results were also presented.

The open discussion touched general and specific aspects of the biogeochemistry of mercury, highlighting knowledge gaps and open scientific questions. It emerged that -in general- the information regarding transformation rates and processes is still highly uncertain and -in particular those involved in methylation- need to be better evaluated in order to improve the general understanding of the global mercury cycle. Examples of open issues were cited, such as the observed increasing mercury concentration in open sea fishes and un-correlation between mercury concentration in sediment and in the corresponding biota.

More information is needed regarding the environmental variables influencing mercury transformations and speciation, and their synergistic effects, also including the role of the microbial community. The identification of new methylation potential of various microbial taxa could also benefit of recent advances in genomics. It was generally agreed that the integrative analysis of mercury transport and transformation processes should be improved, also considering biogeochemical and physical oceanographic processes, such as DOC complexation or the and dawn-ward transport of mercury during the dense water formation and spreading in the North Adriatic.

The same integration should be viewed as a medium-long term goal of mercury modeling, improving current mercury modelling performances with a full coupling with physical and biogeochemical models. The modeling approaches should be developed and used in parallel with measurements to investigate the effects of changes in given parameters, forcing and inputs, and to evaluate the effects of future natural and anthropogenic changes in environmental variables.

Methods and technics - chemical and toxicological monitoring

David Sánchez Quiles, IMEDEA, Esporles, Spain

Résumé

The Mediterranean Sea is under intense pressure because of the anthropogenic impacts caused by population growth, which inevitable leads to the introduction of organic and inorganic chemicals in the marine environment. In that context, some studies presented during this session focused on human activities proper, such are the dredging of polluted coastal sediments, the effects of a common insecticide as permethrin over the acetylcholinesterase activity in Chelon labrosus, or the use of sunscreens in touristic beaches of the Mediterranean. The other communications, indicated or suggested specific organisms (i.e. protists, ragworms, Paracentrotus lividus, and Pinna nobilis among others) for the monitoring of specific contaminants or for signaling contamination in a given area (i.e. near Rovinj, Croatia).

While monitoring and biomonitoring programs are powerful tools to know the level of pollution in the Mediterranean, there is an urgent need to improve the analytical processes and analytical techniques in order to obtain results of high quality. In that sense, the importance of the Proficiency Test for trace elements, the problematics of an inappropriate pre-treatment of the samples and the need of increase the number of laboratories participating in these tests were highlighted.

Oxygen depletion

Nadira Ait-Ameur, Algérie

Résumé

This session dealt with the problem of oxygen depletion in Mediterranean sea at two scales- the coastal area and the open sea. The Mediterranean Sea is very sensitive to anthropogenic pressure and to Climate change and warming. The dissolved O2 in sea water is important for the viability of the ecosystems. The anthropogenic and river input in the coastal area could lead to eutrophication and hypoxia. In the open sea, the surface warming could induce a stratification which could lead to a decrease in the ventilation of intermediate and deep water, and so deoxygenating.

The coastal areas studied included a presentation on the Black sea (A. Capet), were it is shown, using a biogeochemical model, that climatic stressors intensify the response of hypoxia to nutrient discharge, and affect the seasonal dynamics of hypoxia. For the North Adriatic Sea (T. Djakovac), marked hypoxia has been often observed in bottom layers during autumn. This feature seems to be related to the circulation in the area and not exclusively to eutrophic pressure. In the southwesternMediterranean Sea (Algerian coast, N. Ait-Ameur), the anthropogenic input in phosporus (enrichment from domestic waters and fresh water input) reduces the N/P ratio but the amount in dissolved O2 seems to be above the critical limit of eutrophication. In the bay of Algiers, where the air-sea CO2 exchange is mainly controlled by the fresh water input, the circulation may ventilate the waters.

For the open sea, the time series (D. Lefevre) collected since 2008 at the ANTARES fixed moored site has shown a decrease of 2.5 µM O2 during three years of observation. This depletion is associated to hydrological and biological events at the basin scale. The ensuing debate concerned mainly the lack or paucity of accurate data for dissolved O2 in sea water. The need for time series in open sea in the eastern and southernwestern sectors of the Mediterranean Sea is critical.

The importance of using sensitive and accurate sensors for O2 and the need for calibration with standardized protocols and to intercalibrate the method and protocols were stressed. The problem of O2 depletion in intermediate and deep water in open sea remains. Observation and the implementation of long-term monitoring sites appear necessary to understand this phenomenon. Comparing both basins in terms of the processes affecting the O2 content of intermediate and deep waters, and investigating the impact of climate forcing are also needed. Another question, still open, was raised: the possible link between the downward trend of O2 in the intermediate waters of the Western basin and the EMT (Eastern Mediterranean Transient, deep change in the flow of water in the Eastern basin).

[3] ICREA, Barcelona

[4] ICTA-UAB, Barcelona

Abstract

Corallium rubrum is an octocoral endemic to the Mediterranean Sea. Slow growing and long living, it has been harvested since ancient times determining overexploitation due to the high economic value of axial skeleton. Moreover the Mg rich calcite skeleton make it vulnerable to ocean acidification. To understand the effects of elevated pCO_2, colonies of *C. rubrum* were maintained for 314 days in aquarium tanks at 2 pH levels (8,16 and 7,84). Buoyant weight, biochemical balance (protein, carbohydrates and lipids) and spicules morphology were measured. Buoyant weight increment was significantly different between controls and acidified treatment. Aberrant spicule shapes were observed only in acidified treatments. Total organic matter was higher in acidified treatments while no difference was found in carbohydrates, lipids and proteins contents

Keywords: Global change, Conservation, Mediterranean Ridge, Cnidaria, Ph

Introduction: Mediterranean Sea is is considered one of the world's most sensitive regions to Ocean Acidification (OA) [1]. OA is a threat for calcifying organisms and can also have regional socio-economic effects related with the reduction in the harvest of high commercial interest species [2]. Red coral, *Corallium rubrum* is a long-lived, slow-growing gorgonian endemic to the Mediterranean Sea, where it dwells between 10 and 600 m depth. The high economic value of the skeleton used for jewelry, determined overexploitation [3]. The axial skeleton and the sclerites, coated with living tissue, are both composed of Mg-rich calcite [4] which solubility is greater than that of aragonite or calcite [5], moreover the seawater saturation state with respect to carbonate minerals decreases with increasing latitude [6]. Thus *C. rubrum* is expected to be highly susceptible to OA. We evaluated the effects of OA on $CaCO_3$ deposition, sclerites morphology and biochemical balance.

Methods. 48 colonies of *C. rubrum* (from 40 m depth) were distributed among 6 aquaria, further subdivided into 2 treatments (3 replicates): control (~8.10) and low pH (~7.81), simulating, respectively, seawater in equilibrium with ~380 and ~800 ppm CO_2 (current and projected levels for year 2100). Seawater pH was adjusted by bubbling CO_2 and monitored by glass electrodes connected to a pH controller. Additionally, total alkalinity was analyzed by potentiometric titration and pH using spectrophotometry. Buoyant weight, sclerites morphology, organic matter (OM) content and biochemical balance were measured quarterly during 314 days (Time 0 to Time 3). At the end of the experiment, specific microdensity and porosity were estimated on 6 colonies (1 from each aquarium). Sclerites (photographed at SEM) were categorized in 3 morphological types (I, II and aberrant) and the ratio area/perimeter, width/height and circularity were calculated and analysied by PERMANOVA. OM content was determined as the difference between dry and ash weight. Total carbohydrates, protein and lipid content were quantified colorimetrically and results analysed by ANOVA.

Results and discussion. No significant differences were observed, neither in microdensity nor on porosity, indicating that the structural material composition of skeleton was not affected by treatment. Calcification rates in low pH treatment was significantly lower (59%) with respect to control, confirming the expected detrimental effect on skeletal formation. Sclerites morphology was significantly different at Time 3, and aberrant shapes were detected only in low pH treatments. According to [7] the main function of sclerites is the mechanical protection, although [4] suggested a role in $CaCO_3$ temporary stocks. Therefore, in the long term, OA should affect *C. rubrum* compromising the $CaCO_3$ stocking capacity and skeleton biomechanical properties. OM content was significantly higher in the low pH treatment with stable values through time while changed in control treatments from T0 to T3. According to [8] metabolism is affected under low pH conditions and the energetic cost of calcification is higher. Therefore we hypothesize that *C. rubrum* respond to low pH by increasing the formation of OM, consequently decreasing calcification rates. Total protein, carbohydrate and lipid content were not different between treatments but the Coefficient of Variation (CV) was lower in low pH treatments indicating a more dimmed seasonal trend, probably due to endogenous processes or dormancy activated to save energy. A decrease in calcification rate together with a metabolic depression could have negative rebounds on the economy of the jewellery industry linked to this species leading to a price deflation. Furthermore some populations may suffer local extirpation due to the combined effects of climate and athropogenic threats. Projections of population structure under OA scenarios based on our results can be used to give advices for management and conservation [9] to preserve *C.rubrum* with the associated biodiersity and the economy linked to its exploitation.

Abstract
We evaluated the biogeochemical impact of planktonic related processes on the space-time distribution carbonate system variables (e.g. alkalinity, pH, air-sea CO2 fluxes) in the Mediterranean Sea and related economic implications by using a validated 3D coupled transport-biogeochemical model (OPATM-BFM). Simulations provided a reconstruction of the state and variability of contemporary carbonate system and an assessment of the relative impacts of the biogeochemical processes on the carbonate system dynamic and on the sea-air CO2 fluxes. Basing on these data a microeconomic valuation of the economic impacts of changes in marine carbon sequestration was then performed.

Keywords: Air-sea interactions, Economic valuation, Ecosystem services, Geochemical cycles, North-Western Mediterranean

The Mediterranean Sea shows alkalinity and dissolved inorganic carbon concentrations much higher than those observed in the Atlantic Ocean at the same latitude and strong spatial gradients [1]. Estimating the scale of variability of carbonate system and the processes involved may help in understanding the amplitude of the acidification processes due to atmospheric carbon sequestration and its possible evolution. In this work we use a validated biogeochemical model in order to estimate the scale of spatial-temporal variability of the carbonate system properties and to estimate the impact of physical and biological processes involved. The physical-biogeochemical model OPATM-BFM [2] has been coupled with the OCMIP2 carbonate system model and initial condition and boundaries conditions have been estimated from existing dataset. The reference simulation covers the contemporary conditions (1998-2005) forced by ECMWF fields and an atmospheric pCO2 ranging from 360 to 380 ppm. Results of the simulation show that a spatial gradient from the Gibaltrar strait to the marginal seas (Aegean and Adriatic seas) of DIC and Alkalinity is a permanent structure along the water column (Fig. 1) although it is less marked in the intermediate and deep layers. Vertical profiles are generally characterized by lower values at surface, a sharp increase between surface and 200 meters and almost stationary values below 500 meters. At surface, alkalinity dynamics are driven by the terrestrial input, mainly located in the eastern marginal seas and the basin wide surface circulation, dominated by the intrusion toward east of the surface atlantic water and the two thermoaline cells of the western and eastern sub-basin.

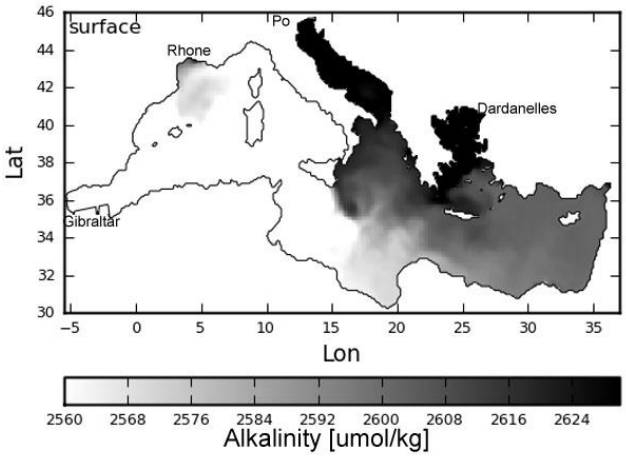

Fig. 1. Alkalinity distribution in the surface layer of the Mediterannean Sea.

The results show that primary producers affect the carbonate system by fixing CO2 into organic carbon that eventually sinks under the mixed layer as particulate organic matter. Organic carbon is then respired within the deep layers, contributing to carbon oversaturation especially in the western Mediterranean sub-regions. The carbon pumps combined with the inverse estuarine Mediterranean circulation results in a net carbon export toward the Atlantic sea of about 45TgC per year. This net carbon loss is compensated by the sinking of atmospheric CO2 through the water-air exchange (20TgC per year) and by the input from rivers (25TgC per year). Further, primary production processes, such as nutrient uptake, alter the alkalinity at surface and consequently the carbonate system equilibrium by increasing the solubility of CO2 and the sinking of atmospheric CO2. Results of the numerical simulation show that the most productive areas such as mixing and coastal areas (i.e. the Gulf of Lion, the Adriatic Sea and the Alboran Sea) present the highest seasonal variations of alkalinity (up to more than 20 mmol/kg) and the highest rate of atmospheric CO2 sequestration. Additional simulations were then run aiming at evaluating the impacts of the biogeochemical processes on CO2 sequestration.

Monetizing the loss of the environmental service, in this specific case under sea acidification scenarios, can be performed applying different economic theories and valuation methodologies. Notwithstanding the ample variability, the assessment literature can be grouped into two large streams: "partial equilibrium" and "general equilibrium" methodologies. Both are widely applied in the area of climate-change economics. Partial equilibrium analysis is based upon appropriate microeconomic-econometric valuation techniques, including market-based economic valuation tools (e.g., market price, direct-costing analysis) as well as non-market valuation tools (such as contingent valuation method, travel cost method, meta-analysis and value transfer). Its main characteristic is to quantify a damage without considering the potential feedback and rebound that this damage can trigger onto the macroeconomic context. The micro-economic element of the study relies on the use of market-based, unitary values for carbon, which are multiplied by the carbon flux estimates resulting from the biogeochemical model to obtain a spatially explicit estimate of the yearly flow of values. In other terms, the air-sea CO_2 exchanges are regarded as additional, spatially distributed, sources (or sinks) of CO_2 for the atmosphere, which therefore translate into a social cost (or benefit). In order to value the carbon sequestration services in the Mediterranean Sea in monetary terms and reflect the uncertainties in the damages caused by different degrees of climate change, we consider in this study a range of estimates of the Social Costs of Carbon, and a set of simulation scenarios aimed at varying the biogeochemical properties of the Mediterranean Sea system, in order to take into account the socio-economic and the natural variability, also in response to future climate changes impacts.

Abstract
To assess the ability of communities to adapt following prolonged exposure to locally elevated CO_2 and temperature levels, phototrophic and heterotrophic benthic communities were analysed at the natural seepage site of Panarea Island. Preliminary results highlight that microalgal proliferation seems to be stimulated by gas emissions and warm temperatures as shown by the elevated abundances and the high primary production rate. In contrast, the low densities of meiofauna suggest that this community could be less tolerant to higher CO_2 concentration and temperature.

Keywords: Tyrrhenian Sea, Diatoms, Hydrothermal vents, Copepoda

Introduction
Carbon capture and storage (CCS) is considered as a valid option to 'permanently' store carbon dioxide (CO_2) from large anthropogenic point sources, providing a short-term approach for mitigating potential global climate change due to anthropogenic CO_2 emissions. Nevertheless, several concerns exist regarding the long term safety of sub-seabed CO_2 storage, including the potential impact of CO_2 leakage on the biota. In marine environments the potential leakage could cause local high concentrations of CO_2 and consequently a pH decrease, with possible significant impact on marine organisms. Although laboratory experiments can be performed [1], the study of natural analogue systems likely provides a more complete (and realistic) understanding of the potential hazard associated to CO_2 leakage from CCS. In the framework of the "Sub-seabed CO_2 Storage: Impact of Marine Ecosystems" (ECO2) project (EU project FP7 n. 265847), OGS and the University of Rome "La Sapienza" performed two field campaigns near the island of Panarea (Aeolian Islands, Italy) in June and October 2012. The site is characterised by natural, thermo-magmatic CO_2 leakage from the seafloor at water depths ranging from 5 to 30 m. Early surveys showed that the system is relatively stable in both gas chemistry (i.e. 98% CO_2, 1.7% H_2S plus other trace gases) and flux rates (7-9 x 10^6 L/d) [2]. Although from most release points only gas leaks, various points also release water of different origin, ranging from geothermal to seawater end-members that are mixed to variable degrees [3]. On the bases of these peculiarities, Panarea represents an exceptional location to study natural processes and impacts related to shallow seabed CO_2 leakage. Both structural and functional parameters have been considered and integrated following a holistic approach directed to the study of the overall benthic ecosystem functioning.

Materials and Methods
During both campaigns, sediments were sampled at two points at a shallow site to the NE of Panarea Island: one characterised by the emission of hot water from the coarse sand and one, located 1 m away, where sediments were characterised by *in situ* temperatures (St. Hot-Cold). Two benthic chamber experiments were performed at both points to measure the flux of dissolved CO_2, heat and the main carbonate system parameters from the sediments to the overlying water. Temperature and pCO_2 were measured *in continuum* using a probe while the water for the other parameters was sampled thrice (once every 10 minutes). Sediment samples were collected for the analyses of abiotic parameters (sediment grain-size, Total Organic Carbon, Biopolymeric Carbon) and benthic communities (microphytobenthos and meiofauna). Along with the biological and chemical structural characterisation during both campaigns, in October 2012 some preliminary estimates of functional parameters, i.e. Primary Production and Prokaryotic C Production (PCP), were also carried out at this site.

Results
During the benthic chamber experiments the hot part of St. HC was characterised by a gradual increase of both temperature and CO_2 concentration while the cold counterpart did not show any evident variation for these parameters. The microphytobenthic assemblage in the hot gas/fluid emission site was more abundant particularly in June 2012, when the densities were two orders of magnitude higher than in the cold sediments nearby. Pennate diatoms belonging to the family Naviculaceae dominated the microalgal community in both periods. The species *Navicula* cfr. *cancellata* alone exceeded 30% of the total abundance, whereas in the nearby cold site its density was negligible. Primary production rates which strongly depend upon the microphytobenthic abundances were six times higher in the hot site (42.88 ± 5.75 mg C m^{-2} h^{-1}) than in the cold one (7.16 ± 0.13 mg C m^{-2} h^{-1}). During both campaigns, meiofaunal abundances in the cold part of St. HC were higher than those within the sediments exposed to high temperatures, characterised by the almost absence of organisms. From a qualitative point of view, the community of the cold part of St. HC was dominated by Copepoda, followed by Nematoda and Ostracoda. In October 2012, lipids were the dominant fraction of the biopolymeric carbon pool, followed by proteins while carbohydrates were negligible. Both lipid and protein contents were 2-fold higher in hot sediments than in cold ones.

Discussion
Preliminary results highlight that benthic communities at different trophic levels could respond differently to gas emission and warm temperatures. The elevated abundances of microalgae inhabiting the hot sediments suggest that higher CO_2 concentration and temperatures could exert a stimulatory effect on this community which seems also active as shown by the elevated primary production rates. The organic enrichment observed in the sediments, particularly in terms of proteins and lipids, could be ascribable to the proliferation of microalgae. On the contrary the meiofaunal contribution was an unimportant source of carbon due to extremely low densities. These organisms in fact showed a limited tolerance to increased CO_2 concentration and temperatures. The integration of these results with others, particularly those related to benthic prokaryotes, is expected to shed more light on the benthic ecosystem functioning in this natural analogue system.

SOME EVIDENCES OF ACIDIFICATION IN THE MEDITERRANEAN SEA

Paul Geri [1]*, Franck Touratier [1] and Catherine Goyet [1]
[1] Institut de Modélisation et Analyse en Géo-Environnement et Santé (IMAGES) University of Perpignan, Laboratoire IMAGES EA 4218 52, Avenue Paul Alduy. F-66860 Perpignan cedex, France - paul.geri@univ-perp.fr

Abstract
The Mediterranean Sea is one of the most impacted ecosystems by anthropogenic pressure. Several published papers have shown that all Mediterranean waters (from surface to the bottom) are already contaminated by significant concentrations of anthropogenic CO2. The accumulation of anthropogenic CO2 contributes for a large percentage of the pH decrease in seawater (phenomenon of acidification). However, since anthropogenic CO2 cannot be measured at sea, this property is estimated using various models. Since uncertainties still exist on the concentration of anthropogenic CO2, it is difficult to precisely estimate the level of acidification. In the present poster, another approach is proposed to assess the level of acidification. It consists in the reconstruction of times-series using data from the 2002 Medar/Medalas and Dyfamed databases.

Keywords: Surface waters, Ph, Ligurian Sea

The ocean acidification is under interest by the scientific community for his effects on our environment. This study presents an approach to asses the level of acidification in the Mediterranean Sea. Results highligth the importance of the phenomenom is this sea.

pH evolution
The ocean acidification is under interest by the scientific community for his effects on our environment. According to several studies around the world, acidification of seawater has increased since the beginning of the industrial era. For instance, pH measured at the times-series stations during several decades, and located in the Pacific Ocean (station HOT) and in the Atlantic Ocean (station BATS) indicate significant pH decreases of -0.0019 ± 0.0002 yr-1 (Dore et al., 2009) and -0.0017 ± 0.001 yr-1 (Bates, 2007), respectively.

Medar/Medalas database (82-92)
For the present study, we focus on pH data within the surface layer (0-10m) located in the area close to the Mediterranean Dyfamed site. Figure 1 shows the map (using the Ocean Data View software) with the localization of the measurement spots. Figure 2 draws the corresponding pH according to the period of time (from 1982 to 1992), with the linear regression on this period.

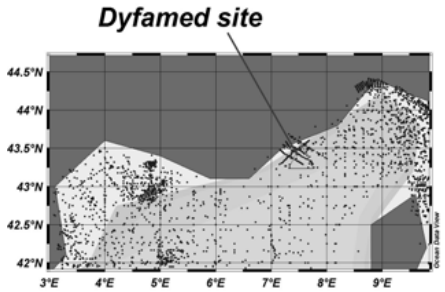

Fig. 1. Localizations of the data sites used in the estimation
The figure presents pH measurements in the surface water around the Ligurian Sea. The Linear regression shows a decrease of 0.009 pH unit per year (6599 points considered).

Dyfamed database (95-2011)
The Dyfamed site is located in the North Mediterranean Sea (see Figure 1). The location is part of the previous map to allow us to compare or complete the observations. A study made using the Dyfamed database (Yao, submitted to Ocean Acidification) to rebuild pH time-series from 1995 to 2011 has underlined an average decrease of -0.003 pH units.yr-1. The evolution is calculated from total dissolved inorganic carbon, total alkalinity, temperature, salinity and some incomplete pH data. The results are indeed more accurate than the previous one thanks to the precision of the values.

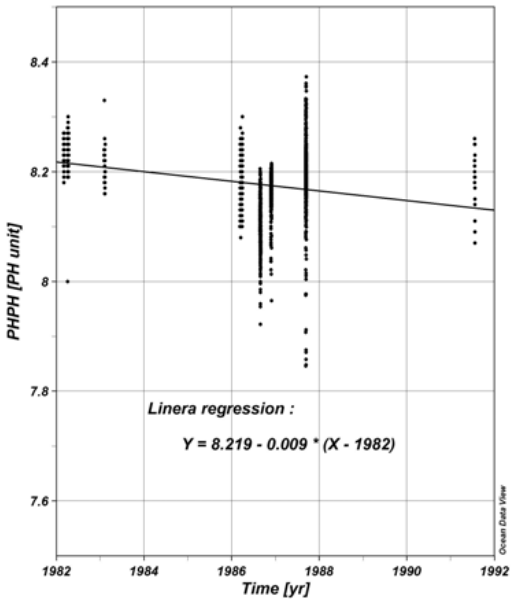

Fig. 2. Medar/Medalas pH data and linear regression from 1982 to 1992

Conclusion
Observations between Medar/Medalas and Dyfamed databases present an important difference, from -0.009yr-1 to -0.003 yr-1. These results show that this decrease is much higher than those observed in other oceanic region. It clearly strengthens the need to develop projects to study the impact of acidification in the Mediterranean Sea.

Abstract

Microbial processes can be affected either directly or indirectly through changes in seawater pH. The results presented here are part of the MedSea project -Mediterranean Sea Acidification in a changing climate-obtained through laboratory microcosm experiments. The main aim was to describe the effect of acidification on bacterial and virus communities as well as on microbial metabolism. Natural bacterial populations exhibited increased production under more acidic conditions and changes on the reaction velocity of extracellular enzymes could affect the processing of organic matter in the sea.

Keywords: Bacteria, Enzymes, Organic matter, Aegean Sea

Bacterial communities play an important role in organic matter cycling and the carbon balance in the future ocean [1]. The oceanic uptake of CO_2 emissions leads to an alteration of seawater carbonate chemistry, manifested as a drop in seawater pH. This process, called "ocean acidification" have direct and indirect effects on the growth and physiological processes of a range of marine organisms [2]. Little is known about the response of marine microbes to increasing pCO2 [3].

The effect of lowered seawater pH was investigated during a microcosm experiment, on bacterial and viral communities as well as on microbial metabolism in natural bacterioplankton communities. Our study included a laboratory 10-day incubation experiment, with natural 0.8μm filtered seawater, under past -8.13, present-day -8.04 and predicted for the year 2100-7.83 pH conditions.

Bacterial production was remarkably enhanced after the start of the experiment (up to 342 $ngCl^{-1}h^{-1}$) under the more acidic conditions.

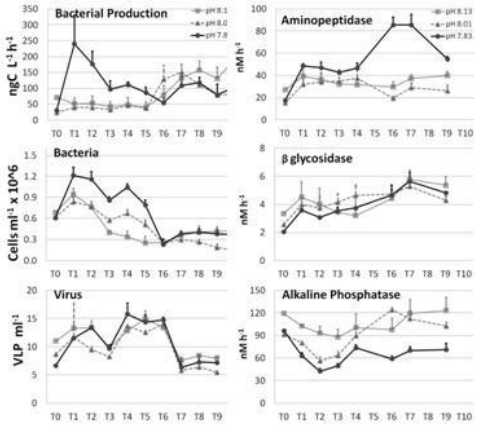

Fig. 1. Changes in bacterial production, bacterial / virus abundance, and enzymatic activities during the experimental period. Error bars correspond to standard deviation.

Values were progressively decreased similar or lower, compared to the past and present-day pH treatments. The same trend was observed for bacterial abundance that reached quickly high values (up to $1.34x10^6$ cells ml^{-1}) under the acidified conditions. Viral abundance was not significantly different among treatments (varied from $6.67x10^6$ - $1.88x10^7$virus ml^{-1}) (Fig.1) In agreement with bacterial production data, increased dissolved organic carbon (DOC) concentration was observed in low pH microcosms, possibly due to increased exudation of photosynthetic cyanobacteria. Dissolved monosaccharide (MCHO) concentration decreased with time in experimental bottles, showing no influence from the different pH concentration. On the contrary dissolved polysaccharide (PCHO) rose as the pH value lowered, with two peaks on day 1 and 4, acting also as precursors for the abiotic formation of transparent exopolymer particles (TEP), rich in acidic polysaccharides. TEP-C formation peaked on days 3-4 (Fig.2).

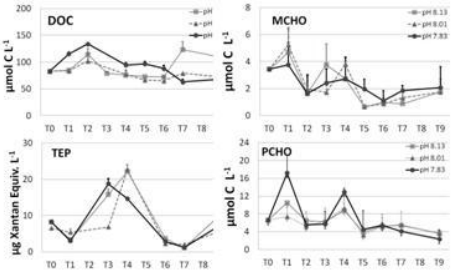

Fig. 2. Dissolved organic carbon (DOC) , monosaccharide (MCHO), polysaccharide (PCHO) concentration and Transparent Exopolymer Particles (TEP) during the experimental period. Error bars correspond to standard deviation.

β-glycosidase specialised in the degradation of polysaccharides showed no significant variation in activity among different pH's and an increasing trend towards the end of the experiment. For alkaline phosphatase lowered activity was recorded in acidified environments, translated to a potential inhibition of phosphate turnover whereas leucine aminopeptidase (protease) activity which degrades polypeptides was enhanced under lower pH conditions (Fig.1).

The ongoing pH decline has the potential to cause changes at the bottom of the food web and consequent shifts in plankton community composition and food web functioning. The impact of ocean acidification on the reaction velocity of extracellular enzymes could affect the processing of organic matter. An increase in bacterial concentration could increase the transfer of carbon between bacteria and protists, alter the community composition of microbial top predators and give an advantage to the heterotrophic food web.

PHYSICAL AND BIOLOGICAL INFLUENCES ON THE VARIABILITY OF PH AND CARBONATE SYSTEM IN THE GULF OF TRIESTE (NORTHERN ADRIATIC SEA)

G. Ingrosso [1]*, M. Giani [1], M. Celussi [1], T. Cibic [1], C. Comici [1], P. Del Negro [1], C. De Vittor [1], C. Fabbro [1], A. Karuza [1] and M. Kralj [1]

Abstract

A 2 years surveys showed that the variations of pH and of the carbonates system in a coastal area of the northern Adriatic sea resulted mainly affected by the seasonal thermal cycle, by the inputs of carbonates from riverine waters of karstic origin and from degradation processes taking place below the main pycnocline in the warm season. The CO_2 air – sea exchanges showed that the gulf was a sink during cold months and a source during the warm period.

Keywords: Ph, Carbon, North Adriatic Sea, Coastal processes

The effects of acidification, caused by the uptake of anthropogenic CO_2 from atmosphere, can be additional to those produced by natural biological processes such as respiration and organic matter degradation [1]. The Gulf of Trieste, which lies in the northernmost part of the Adriatic (Fig. 1), is a region of freshwater influence under the inflow of the eastern Adriatic Current. Seasonal variations of the carbonate system and of the seawater biogeochemistry, were investigated in the framework of MEDSEA (Mediterranean Sea Acidification in a changing climate) FP7 Project, for 2 years along a transect (Z1-Z4 stations) from the Isonzo River mouth to the centre of the Gulf, on a 2-months sampling frequency, and monthly at coastal site (C1-LTER site, Fig.1).

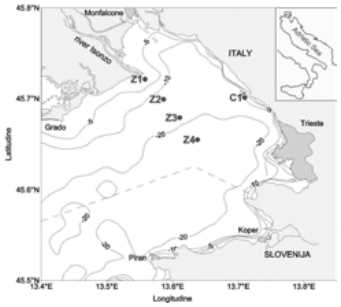

Fig. 1. Sampling sites in the gulf of Trieste (Northern Adriatic Sea).

Total alkalinity (A_T) was measured by open cell potentiometric titration [2]. The titration has been carried out in a cell thermostated at 25 °C. Dissolved Inorganic Carbon (DIC) and the partial pressure of CO_2 (pCO_2) have been calculated by CO2SYS program [3]. Certified reference materials (CRM Batch 107 supplied by University of California, San Diego USA) for DIC were used to check the accuracy of the results. pH ($pH_{T)}$ was measured by m-cresol violet colorimetric method iby a double beam spectrophotometer with cell thermostated at 25 °C [4]. Prokaryotic Carbon Production (PCP) was measured by the incorporation of ^{3}H-Leucine [5]. Seawater temperature ranged from 2.88 to 26.98 °C whereas the salinity variations were comprised between 27.04 and 38.50. The A_T varied from 2663 to 2933 µmol kg^{-1} and was inversely correlated with salinity ($p<0.0001$) due to the inputs of local rivers with karstic watersheds. The contribute of riverine inputs to the increase of A_T and DIC resulted particularly evident in surface waters. The annual pH_T variations ranged from 7.878 to 8.259. Strong seasonal variations of pCO_2 occurred in the water column due to the thermal effect, to primary productivity and to the degradative processes. The thermal effect was predominant, the biological drawdown of CO_2 occurred mainly from March to July and was more relevant in the waters above the pycnocline. From August to September in the oxygen depleted bottom waters, the remineralization processes prevailed increasing the pCO_2 and nutrients and, notwithstanding the lowering of pH, the waters remained always oversaturated in carbonates with respect to the more soluble biogenic carbonate form (i.e. aragonite). The seasonal thermal effect resulted the main driver of variations in the carbonates system, whereas the not-thermal effects prevailed in the bottom water during late summer where the respiration processes consume O_2, regenerate nutrients and increase CO_2. The air-sea CO_2 exchanges showed a marked sink during the winter dense water formation which can act as a physical pump transporting the CO_2 towards the southern Adriatic sea and the Eastern Mediterranean Deep Waters. The winter CO_2 atmosphere-seawater invasion determined an increase of dissolved inorganic carbon (DIC) which gradually decreased with warming (Fig. 2). The strong seasonal thermal increase (ΔT up to 22.4 °C) shifted the carbonate equilibria towards the dissociate species with the effect of lowering the pH. On this process superimposed the CO_2 produced by degradation processes, particularly evident in bottom water during late summer-autumn. This resulted supported by a negative linear correlation ($p<0.001$) between pH_T in situ and secondary carbon production (PCP). The PCP maxima occurred in late summer whereas the pH_T minima were temporally delayed. The seasonal changes of this shallow semi-enclosed sub-basin showed a strong temporal and spatial dynamics of the carbonate system due to the complex coupling of circulation patterns, heat exchanges, riverine inputs and biological processes.

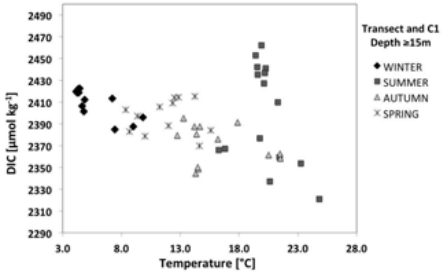

Fig. 2. Variations of dissolved inorganic carbon (DIC) as a function of seawater temperature.

TOWARD THE ASSESSMENT OF MEDITERRANEAN SEA CARBONATE SYSTEM CLIMATOLOGIES

Tomas Lovato [1]*, Marcello Vichi [1], William J. McKiver [1] and Patrizia Ziveri [2]
[1] CMCC - Centro Euro-Mediterraneo sui Cambiamenti Climatici, I-40127 Bologna - tomas.lovato@cmcc.it
[2] Institute of Environmental Science and Technology, Universitat Autònoma de Barcelona, E-01893 Barcelona

Abstract
A monthly climatological dataset is proposed to model the seawater carbonate system in the Mediterranean Sea. We exploit gridded objective analysis of hydrochemical parameters and literature-based empirical relationships to estimate total alkalinity and total dissolved inorganic carbon. The comparison of the reconstructed fields with the experimental data of two oceanographic cruises highlighted the consistency of the total alkalinity field, while the estimate of total carbon was more uncertain.

Keywords: Carbon, Pelagic, South-Central Mediterranean

The Mediterranean Sea is characterized by high values of alkalinity [1], which are likely to contrast the impacts of anthropogenic acidification on the carbonate system. Nevertheless, the scarcity of long-term basin-scale observations and the lack of knowledge of the response of Mediterranean key species have increased concern on the vulnerability of this system to acidification. The EU FP7 project MedSeA (www.medsea-project.eu) has been conceived to investigate this vulnerability by combining new observations of the carbonate system and numerical models that will allow analyses of acidification at the basin scale.

The historical observations of the carbonate system are sufficient to describe the east-west distribution for total alkalinity (TA) and total dissolved inorganic carbon (TC), and to provide the first estimates of the concentration of anthropogenic CO_2 [2]. The available experimental datasets are however confined to very short time windows and are not evenly distributed across the basin. These limitations become a critical issue when dealing with numerical models, as they require spatially continuous data for initialization and validation.

As a mandatory first step to the modelling of the carbonate system in the Mediterranean Sea, a monthly climatology has been developed. The reconstruction of TA and TC fields was achieved through the application of empirically estimated relationships available in the literature [see 1,2,3], which make use of temperature, salinity and dissolved oxygen as input data. The backbone of the carbonate system data climatology is composed of the objectively analysed monthly climatologies of ocean hydrochemical parameters from the SeaDataNet project (www.seadatanet.org). These gridded products cover the period 1985-2007, with a horizontal resolution of 1/8 of degree and 33 vertical levels.

A comparison with the experimental data collected in the METEOR51 (October-November 2001) and METEOR82 (April 2011) trans-Mediterranean cruises was carried out to assess the skills of the reconstructed carbonate system fields. Data were extracted from the corresponding monthly fields by interpolating the values at the same depth of each sample for the nearest grid point to the considered sampling station. Only data below a threshold depth of 400 m were used, according to literature findings on the reliability of the empirical relationships [1,2].

The Mean Absolute Error (MAE) and the standard deviation of absolute errors (SD) were computed for each reconstructed field and the two oceanographic cruises. The following relationships lead to the smallest differences with the experimental data: $TA=76.631*S - 369.51$ [3] and $TC=3915.55 + 4.30*\theta - 0.33*AOU - 43.54*S$ [2]. In particular, a good agreement was obtained with the METEOR51 data (TA: MAE=6.01, SD=4.30 µmol/kg; TC: MAE=18.85, SD=6.02 µmol/kg), while the statistics indicated larger differences for the METEOR82 cruise (TA: MAE= 13.55, SD=8.09 µmol/kg; TC: MAE= 44.83, SD=57.07 µmol/kg).

The reconstructed TA (Fig.1) compared well with the data thus indicating the robustness of the adopted formulation. Conversely, the empirical relation used to estimate the TC (not shown) was in a better agreement with the METEOR51 cruise rather than METEOR82. This was clearly related to the use of the data from the first cruise to estimate the coefficients of the multiple linear regression. Nonetheless, the large discrepancy in the MAE of the TC can also be attributed to the accumulation of anthropogenic CO_2 within the Mediterranean Sea, as the two cruises were made ten years apart. Further non-parametric statistics were also applied to extend the skill assessment and provide a broad picture of the differences within the different sub-basins.

This preliminary analysis of the reconstructed carbonate system monthly climatology showed that the TA can be reliably derived from the salinity data and it can be used to initialize predictive biogeochemical models, while the determination of the TC from other hydrochemical parameters is affected by larger uncertainties.

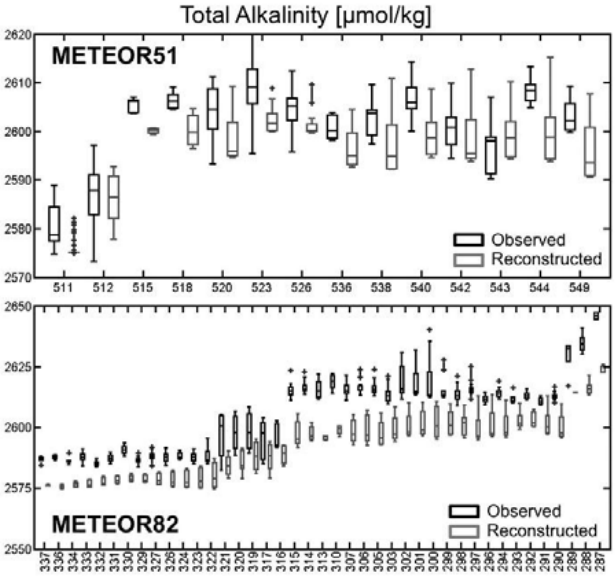

Fig. 1. Comparison of the total alkalinity (µmol/kg) between the experimental data of the METEOR51 (top) and METEOR82 (bottom) cruises and the reconstructed fields for the months of October and April, respectively. Data for each sampling location (east-west going from left to right) is described by means of box-whiskers and outliers are indicated by the cross symbol.

AIR – SEA CO_2 FLUXES IN THE ADRIATIC SEA: TWO SEASONAL SNAPSHOTS IN FEBRUARY AND OCTOBER 2008

Carolina Cantoni [1], Stefania Sparnocchia [1] and Anna Luchetta [1]*
[1] CNR - Istituto di Scienze Marine Italy - anna.luchetta@ts.ismar.cnr.it

Abstract
We present the air-sea CO_2 fluxes in the Adriatic Sea calculated from shipboard pH_T and alkalinity measurements, under two contrasting seasonal conditions. During February 2008 the whole basin was undersaturated with respect to the atmosphere and acted as a CO_2 sink, with higher fluxes on the Northern Adriatic shelf, where dense water formation was occurring. In October 2008, under late summer stratified conditions, the North Adriatic was still a CO_2 sink, with weaker fluxes, while the central South Adriatic was acting as a weak CO_2 source.

Keywords: North Adriatic Sea, Air-sea interactions, Carbon, South Adriatic Sea

Inorganic carbon cycle and air - sea CO_2 exchange in the Mediterranean basin have received, in the past, little attention by the oceanographic community. In the last years some studies have started to fill this gap [1, 2, 3, 4] and they put in evidence that the signal of anthropogenic CO_2 has already reached the interior of the basin. The Mediterranean is hence emerging as one of the basins more impacted by acidification process and where a faster carbonate ion concentration decrease is likely expected in response to anthropogenic CO_2 invasion.

Within this framework, all authors underpin the potential role of the dense waters formed in the Adriatic sea (NAdDW and ADW) as preferred pathways for transferring atmospheric CO_2 into Mediterranean deep layers, but the air-sea CO_2 fluxes available are limited to two fixed stations in the northernmost part (the Gulf of Trieste) [5,6].

The state of the art presented in this work derives from two cruises carried out in February and October 2008, in the framework of SESAME-EU-FP6 and Italian VECTOR projects and presents the first air-sea CO_2 fluxes data (FCO_2), at sub-basin scale, both for North and the South Adriatic sea.

The fluxes were calculated from the sea – air gradient of fCO_2 across the sea – air interface ($DfCO_2 = fCO_{2SW} - fCO_{2atm}$) according to Wanninkhof, (1992); fluxes towards the sea are denoted with a negative sign.

Sea surface fCO_2 values have been calculated from experimental determinations of pH_T (SD ± 0.002) and total alkalinity (SD ± 2 µmol/kg) using the CO2SYS program; the accuracy of both parameters was assessed by measurements of certified reference materials. Wind field at 10 m and mean sea level pressure were derived from the atmospheric model COSMO-I7 (courtesy of ARPA – SIMC Emilia Romagna). Atmospheric fCO_2 values were calculated from XCO_2 concentrations measured during the February 2008 cruise, SST and SSS from cruise CTD data and pressure derived from model.

During the winter season, cooling and evaporation trigged mixing leading to dense water formation over the northern shelf (sigma-t > 29.3 kg m^{-3}), and deep convection in the Southern Adriatic (SA). Under these conditions all the Northern Adriatic shelf (NAs) was strongly undersaturated in CO_2 (avg $DfCO_2$ = -92 µatm). During the cruise bad weather conditions prevailed and average daily wind speeds recorded were up to 10.3 ms^{-1}. Air-sea CO_2 fluxes reached values up – 23 mmol m^{-2} d^{-1}, in the middle of the basin, off the Po delta (Fig 1) with an average value of -8.3 mmol m^{-2} d^{-1} over the whole shelf (depth< 80 m).

In this period the convection reached 700 – 800 meter depth in the SA allowing mixing and outcropping of older LIW water masses enriched in CO_2; nevertheless the area remained undersaturated with respect to the overlying marine air (avg $DfCO_2$ = -33.9). The lower undersaturation and the absence of strong wind events sustained lower CO_2 fluxes (avg FCO_2 = -1.9 mmol m^{-2} d^{-1}) and during February 2008 the SA acted as a moderate CO_2 sink.

In October 2008 the water column presented a marked thermal stratification with production processes prevailing in the upper water column. The effect of biological CO_2 drawdown in the NAs prevailed over the fCO_2 increase determined by the SST increase and the whole area remained undersaturated with respect to the overlying marine air (avg $DfCO_2$ = - 50 µatm). As already observed in February, also in October the NAs acted as a CO_2 sink, but the lower wind speeds (< 3.97 ms^{-1}) resulted in weak CO_2 fluxes (avg. FCO_2 = -1.34 mmol m^{-2} d^{-1}).

In the central part of the SA, the temperature driven fCO_2 increase was only partially compensated by biological CO_2 drawdown and the area resulted slightly oversaturated (avg $DfCO_2$ = 8.0 µatm), on the contrary to the more productive western shallower area ($DfCO_2$ = -27.1 µatm). Air-sea CO_2 fluxes were low in the central part of the basin (FCO_2 = 0.31 mmol m^{-2} d^{-1}) and directed to the atmosphere while the more coastal area, also in fall, acted as a weak CO_2 sink (FCO_2 = -1.6 mmol m^{-2} d^{-1}).

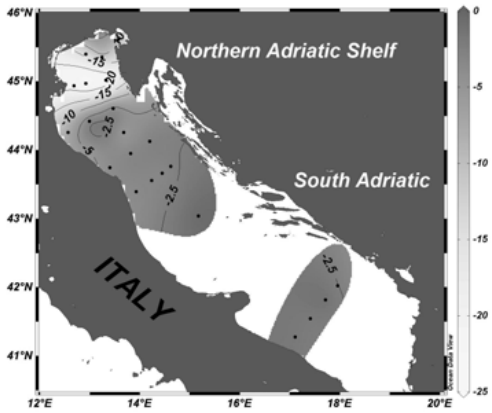

Fig. 1. Spatial distribution of air-sea CO_2 fluxes [m mol CO_2 m^{-2} d^{-1}] in the Adriatic Sea during 16-27 February 2008.

Abstract

The main aims of this study were to quantify the response of a marine planktonic system to increasing CO_2 levels as well as to identify the potential changes of key biological processes (e.g. primary production, secondary production, copepod grazing) to ocean acidification. In order to address these overall goals, experiments were carried out in small volume enclosures (200 l) during April 2012 in a Mediterranean coastal station. Two different CO_2 levels were tested: (1) present pCO_2 (380 µatm) and (2) future pCO_2 (750 µatm). The obtained results showed that the different functional groups of plankton and biological processes presented diverse response to increased CO_2.

Keywords: Food webs, Plankton, Biomass, Global change, Aegean Sea

Rising atmospheric carbon dioxide (CO_2) is causing global warming and ocean acidification (e.g. [1]), which are increasingly recognized as important drivers of change in biological systems ([2]). During this study we quantified the effects of increased CO_2 on the stock and composition of several functional groups of plankton, attempting to investigate the impact of OA on planktonic food web processes in a coastal area of the Eastern Mediterranean Sea.

For this purpose, four small volume (200 L) enclosures were used, filled with filtered (through 200 µm to exclude grazers) sea water collected from a station in Saronikos Gulf (Greece) during April 2012 (period of maximum copepod abundance). Targeted pCO_2 levels in the mesocosms were: 1) present pCO_2 (380 µatm) and (2) future pCO_2 (750 µatm) and were regulated via CO_2 injections controlled automatically by a continuous pH-stat system (IKS, Karlsbad, Germany). The measured chemical and biological parameters were nutrients, C_T and pH (pH_T, expressed on the total hydrogen ion concentration scale), DOC, bacteria, viruses, picoplankton, Chlorophyll a (<2.0 µm and >2.0 µm), phytoplankton pigments, nanoflagellates and ciliates, whereas the measured biological processes were phytoplankton production (<2.0 µm and >2.0 µm), copepod feeding and copepod fecal pellet production.

The results showed that nutrients and DOC exhibited similar variation in both treatments. Also, the abundances of bacteria and virusespresented similar trend regardless of pCO_2 levels. Chlorophyll *a* and PP didn't reveal any significant difference between treatments, and the observed values were similar to those recorded in oligotrophic ecosystems. However, phytoplankton pigments differentiated considerably in both pCO_2 levels. Copepod feeding rates and fecal pellet production were lower in the future pCO_2 conditions compared to the current environmental state (Fig.1). Our findings revealed that the different functional groups of plankton and biological processes presented diverse response to increased CO_2 that might have impact on the structure of the pelagic food web of the Mediterranean Sea.

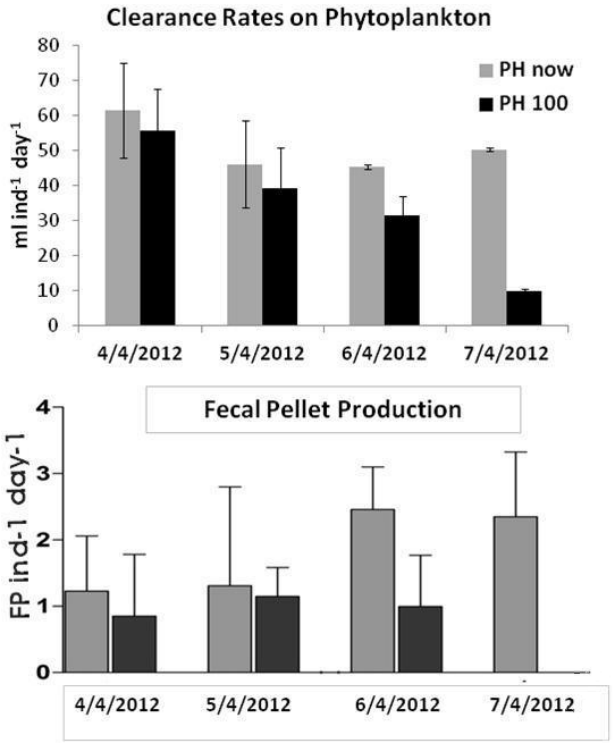

Fig. 1. Clearance rate on phytoplankton and fecal pellet production of *Acartia clausi* in both treatments (pH_{now} and pH_{100}).

Abstract
The dynamics of marine carbonate chemistry and biocalcification in the Mediterranean Sea are to date poorly understood, mainly due to a dearth of observational data of sufficient length and spatial coverage to document the biogechemical response(s) of the basin to the ongoing rise in atmospheric CO_2 concentrations. To fill this gap in our understanding we use a paleoceanographic approach. We present a suite of new micropaleontological and geochemical results portraying the variability of the carbonate system parameters and the attendant response of the main planktonic calcifying organisms across key intervals of the recent palaeoceanographic history of the Mediterranean Sea, such as the last interglacial period (~125,000 years ago), the last glacial-interglacial transition (19,000 to 8,000 years ago), and the last millennium.

Keywords: Ocean history, Carbon, North-Western Mediterranean, South-Central Mediterranean, South-Eastern Mediterranean

The Mediterranean Sea is a semi-enclosed marginal sea connected via the Strait of Gibraltar to the Atlantic Ocean, with which it exchanges water and chemical properties, such as, nutrients and carbon [1]. Multiple sites of intermediate to deep convection and a vigorous basin-wide thermohaline circulation [2] result in a relatively short residence time of the waters in the basin. These features collectively account for the observed invasion throughout the water column of the so-called "anthropogenic carbon" [3], i.e., the excess carbon injected into the atmosphere by fossil fuel burning, cement production, and deforestation since the beginning of the industrial era. High alkalinity levels and a prominent $CaCO_3$ supersaturation are observed throughout the basin with the former partly balanced by carbonate sedimentation [4]. However, the response of the carbonate chemistry changes and their impacts on biocalcification during the rapid rise of atmospheric CO_2 concentrations of the last several decades remains elusive, mostly because only few time-series are available (e.g., DYFAMED) and their spatial and temporal coverage are insufficient to provide a conclusive picture. As part of the EU-funded project MedSeA (Mediterranean Sea acidification under changing climate) we have generated several geochemical (e.g., boron isotope-pH proxy) and micropaleontological (e.g., planktonic foraminiferal shell weight and coccolith mass) time-series to reconstruct carbonate chemistry and biocalcification changes across the Mediterranean Sea (Figure 1) during key intervals of the Late Pleistocene featuring different magnitude of atmospheric CO_2 and climate forcing. A pertinent feature of our results is the marked decrease of both foraminiferal shell weight and coccolith mass at different locations of the Mediterranean Sea during intervals of increasing atmospheric CO_2 concentrations, such as the last deglaciation. This alludes to considerable changes in biocalcification also in an "supersaturated" basin like the Mediterranean Sea. These results will be further discussed in the contexts of similar "proxy records" from open ocean settings to provide a first order assessment of the main factors controlling the variability of the Mediterranean Sea carbonate chemistry and biocalcification on decadal to millennial timescales.

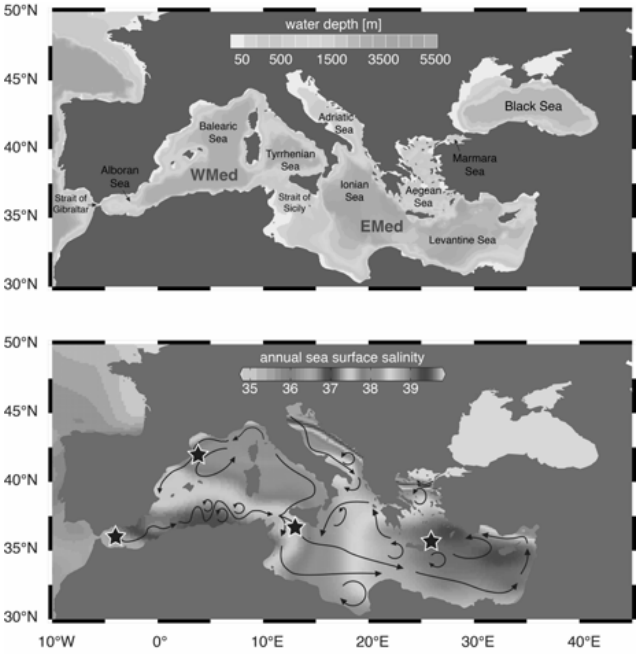

Fig. 1. time-series to reconstruct carbonate chemistry and biocalcification changes across the Mediterranean Sea

RESEARCH TURNS TO ACIDIFICATION AND WARMING IN THE MEDITERRANEAN SEA: THE MEDSEA PROJECT

Patrizia Ziveri [1]* and MedSeA Project Members - [2]
[1] Universitata Autonoma Barcelona - patrizia.ziveri@uab.cat
[2] -

Abstract

The *Mediterranean Sea Acidification in a changing climate* (MedSeA), a project funded by the European Commission (EC) under the 7th Framework Programme, is assessing uncertainties, risks and thresholds related to Mediterranean acidification and warming at organism, ecosystem and economic scales. A main goal is to identify where the impacts of acidification on Mediterranean waters will be more severe, taking into account the complete chain of causes and effects, from ocean chemistry through marine biology to socio-economic costs. As a practical outcome, it proposing policy measures for adaptation and mitigation that may geographically vary and at the same time requiring coordination between regions or countries.

Keywords: Carbon, Temperature, South-Central Mediterranean, North-Western Mediterranean, South-Eastern Mediterranean

Although the general impact of acidification on water chemistry is globally well understood, fine-scale regional models are needed to resolve the complexity of the physical and ecological interactions of small and complex basins, such as the Mediterranean Sea. The Mediterranean Sea is considered a small-scale ocean with high environmental variability and steep physicochemical gradients within a relatively restricted region. Its circulation is characterized by zonal gradients of physicochemical variables, with salinity, temperature, stratification and alkalinity all increasing towards the east. The generally low-nutrient (from oligotrophic to ultraoligotrophic) waters offshore stand in contrast to many near-shore regions, often containing coral and seagrass ecosystems, which are affected by human-induced eutrophication. Thus acidification is an additional anthropogenic pressure on Mediterranean Sea ecosystems, already suffering from overfishing, increasing sea surface temperatures, and alien species invasions. To properly project how key biogeochemical and ecosystem processes will change, it is fundamental to adequately represent the general circulation of the Mediterranean basin, i.e., both the fine-scale processes that control it (e.g. eddies and deep convection), and the highly variable atmospheric forcing. With their relatively short residence times, Mediterranean Sea deep waters are likely to lag changes in surface waters by a few decades at most. Changes in deep-water formation sites, such as characterized by the dramatic shift with the Eastern Mediterranean Transient, are likely to coincide with changes in the hot spots where much of anthropogenic CO_2 is taken up from the atmosphere and transferred into the deep sea (where it is stored for longer periods). The efficiency of carbon uptake and export from the surface waters to the basin interior depends on the relatively rapid time scales for surface-to-deep water exchange and the Mediterranean general circulation. Thus the combined effect of Mediterranean seawater acidification (absorbing anthropogenic CO_2 per unit area), with low tropospheric warming on Mediterranean biogeochemistry, ecosystems, and the ecosystem services they support, through direct impacts on its highly adapted calcareous and non-calcareous organisms, may be large.

The EC MedSeA project (medsea-prject.eu) is assessing the chemical, climatic, ecological, biological, and economical changes of the Mediterranean Sea driven by increases in CO_2 and other greenhouse gases (ocean acidification (OA) and ocean warming). Our findings suggest that the degree of OA and warming expected over the next 100 years may have major consequences for the biodiversity and biogeochemistry of endemic and keystone species of Mediterranean coastal ecosystems, such as coralline algae. Other habitats such as sea grass meadows are expected to suffer from elevated seawater temperature and invasion by non-indigenous algae species, which benefit from increased pCO_2 and elevated temperature. A central goal is to provide science-based projections of Mediterranean acidification under the influence of climate change as well as associated economic impacts. Projections will be based on new observations of chemical conditions as well as new observational and experimental data on the responses of key organisms and ecosystems to OA and warming, which will be fed into existing ocean models that have been improved to account for the Mediterranean ´s fine-scale features. These scientific advances will allow us to provide the best advice to policymakers who must develop regional strategies for adaptation and mitigation. A MedSeA strategy is to focus on a selected set of key ecosystem and socio-economic variables that are likely to be affected by both acidification and warming, studying the combination of both effects through ship-based observations, laboratory and mesocosm experiments, physical-biogeochemical-ecosystem modeling, and economical analyses. It aims to provide best estimates of future changes, and related uncertainties, in Mediterranean Sea pH, $CaCO_3$ saturation states, and other biogeochemical-ecosystem variables. In addition, it assesses the changes in habitat suitability of relevant ecological and economically-important species.

Here we are presenting an overview of the project and of selected important scientific achievements. Initial project results confirmed that the concentration of anthropogenic carbon extrapolated from Mediterranean field measurements is high and penetrating the deep sea. It is clear that due to the complexity and high variability of the basin, this process will have different regional impacts. This is anticipated to occur in regions where future model projections of sea surface temperature indicate a mean increase of winter and summer temperature of up to 2-4 degrees by the year 2050 if anthropogenic emissions remain unchanged. In terms of impacts on Mediterranean marine species and ecosystems, the extensive work using Mediterranean CO_2 vents as natural acidification laboratories showed consistently a decrease in benthic species biodiversity. Ocean warming and/or acidification impact *Posidonia oceanica*, coralligenous reef, *Corallium rubrium*, and vermetids. Experimental work is also showing that there is a strong influence of temperature on jellyfish.

Finally to convey acquired scientific knowledge to a wider audience of policy-makers, decision-makers, marine managers and other stakeholders, we are developing the formation of the Mediterranean Reference User Group (MRUG). We will suggest policy measures for adaptation and mitigation that will vary from one Mediterranean area to another. As a result, project managers and stakeholders in the different Mediterranean areas will have, for the first time, a set of up-to-date vulnerability maps upon which future action plans can be designed.

Abstract
New results concerning Cu, Zn, Cd, Pb accumulation rate in algae and alginate extracted from algae *Cystoseira barbata* collected in March 2012 from Mangalia, located in the southern part of the Romanian Black Sea coast, are reported. The patterns of heavy metal accumulations rates of contaminated algae and alginate extracted from contaminated algae, in increments, were for algae Zn < Cd < Cu < Pb and for alginate Pb < Cd < Cu < Zn.

Keywords: Algae, Black Sea, Metals

Introduction
The ecosystem of the Romanian Black Sea coast has been damaged as a result of metal contamination. Marine algae are frequently used as biological indicator of heavy metal pollution [1]. The results of heavy metal accumulation in algae of the Romanian Black Sea coast are reported [2]. Brown algae are known to have high concentration of alginate, which is extracted and largely exploited in various domains. Evaluation of metal accumulation rate in alginates isolated from contaminated algae is highly important, considering the diversified usage of alginates in food industry and medicine. No studies have been carried out in Romania concerning heavy metal accumulation in alginate extracted from contaminated algae, correlated with contamination rate of algae with metals.

The aim of this study was to determine the accumulations rates of Cu, Cd, Zn, and Pb in algae *Cystoseira barbata* and in the alginate extracted from the contaminated algae.

Materials and methods
Samples of algae *Cystoseira barbata* have been collected in March 2012 from Mangalia Gulf, located in the southern part of the Romanian coast. The accumulations rates of Cu, Cd, Zn, and Pb in algae *Cystoseira barbata* were realized by means of contamination procedure of algae with metals. Batch contamination experiments of algae were carried out using the following materials: fresh biomass, contaminated sea water with heavy metal ions such as Cu (I), Cd (II), Zn (II), Pb (II) (60mg/L for each metal). Alginates were extracted from contaminated algae by a specific method [3]. The algae and alginate have been carefully prepared (washed, dried) and subjected to dissolution with nitric acid and hydrogen peroxide in a Digesdhal device. Metal concentrations were determined by atomic absorption spectrophotometer (GBC Avanta). The accumulation rate of heavy metals in fresh algae was calculated considering the initial concentration of this metals in algae (uncontaminated). Analyses were made three times in the same conditions and the mean values were reported.

Results and discussion
Results obtained in this experiment are shown in Table 1.

Tab. 1. The metal concentration and accumulation rates in algae and alginate

Cu	Zn	Cd	Pb
The mean metal concentration in uncontaminated[a] and contaminated[b] algae (mg/Kg dry wt)			
5.72 ± 0.38[a]	26.00 ± 2.05[a]	0.95 ± 0.07[a]	7.73 ± 1.49[a]
365.00 ± 24.38[b]	107.25 ± 8.45[b]	185.50 ± 13.74[b]	1206 ±233.00[b]
The mean metal concentration in uncontaminated[a] and contaminated[b] alginate (mg/Kg dry wt)			
2.35 ± 0.16[a]	4.52 ± 0.36[a]	0.19 ± 0.01[a]	1.44 ± 0.28[a]
6.84 ± 0.46[b]	6.82 ± 0.54[b]	1.22 ± 0.09[b]	7.61 ± 1.47[b]
The mean accumulation rates of contaminated algae[a] and contaminated alginate[b] (%)			
19.96[a]	4.51[a]	10.25[a]	66.50[a]
0.45[b]	1.02[b]	0.21[b]	0.19[b]

In a study of Chirila et al (2006) the heavy metals concentrations in the algae *Cystoseira barbata* collected from Romanian coast of the Black Sea were higher than the concentrations obtained for uncontaminated algae of our study (2012) [4]. *Cystoseira barbata* is a biological indicator of heavy metal pollution and our results obtained for the uncontaminated algae suggests that pollution rate on the Romanian Black Sea coast decreased at the end of the period 2006 – 2012. Zn and Pb concentrations were higher than Cd and Cu in uncontaminated algae probably because of sulphur water springs existing in the Mangalia gulf coastal area. Concentrations of metals were higher in contaminated algae and alginate than concentrations found in uncontaminated algae and alginate. On the other hand, Pb accumulation rate was higher in algae and lower in alginate and Zn accumulation rate was lower in algae and higher in alginate. The lead is a toxic metal for human body and our results showed that the accumulation rate of Pb in alginate extracted from contaminated algae was lower than contaminated algae (0.19 versus 66.5). This fact is very important for human health.

Conclusions
Accumulation rates of the heavy metals in algae and alginate increases as follows: for algae Zn < Cd < Cu < Pb and for alginate Pb < Cd < Cu < Zn. It is very important for human health that accumulation rate of Pb in alginate extracted for contaminated algae to be lower versus contaminated algae. There is no evidence in current literature to confirm or invalidate the results obtained through this experiment, regarding accumulation rate of metals in alginate extracted from contaminated algae.

Abstract
Les teneurs en fer, cuivre, zinc, chrome, nickel, plomb, cadmium et mercure ont été déterminées par SSA dans les sédiments, les moules et les poissons. La pollution montre un degré de contamination inquiétant; résultat de l'activité portuaire et à l'exposition directe aux effluents d'origine anthropique. Ils ont aussi permis de valider l'utilisation de deux organismes, un mollusque (*Perna perna*) et un poisson (*Mugil cephalus*) pour un biomonitorage.

Keywords: Pollution, Algerian Sea, Metals

Introduction
Ce travail s'intéresse à une pollution chimique par les métaux lourds, ces métaux sont présent naturellement et au dessus d'un certain seuil ils deviennent toxiques **[1].** Les éléments retenus dans cette étude sont au nombre de 8 métaux (Fe Cu, Zn, Ni, Cr, Pb, Cd et Hg). Certains sont essentiels à la vie comme le cuivre et le zinc et d'autres toxiques comme le plomb, le cadmium et le mercure. Ces éléments sont des produits d'usages domestiques, urbains, industriels et agricoles, ces métaux on les retrouve aux niveaux des eaux les sédiments et les organismes vivants drainés par les eaux ou par voie atmosphérique. Ces derniers sont bio accumules et bio amplifies, dans la chaîne alimentaire et par conséquent à certains seuils ils deviennent dangereux. La présente étude se propose de déterminer le degré de contamination par les huit éléments traces au niveau des principales matrices du complexe industrialo–portuaire de Annaba à savoir les moules (Perna perna), les poissons (le mulet Mugil cephalus) et les sédiments. Cette zone est exposée à divers polluants de différentes origines.

II. Matériel et Méthodes : II.1 Présentation de la zone d'étude : Le golfe d'Annaba est limité à l'Est par le cap Rosa (8° 15'E et 36° 58'N) et à l'ouest par le cap de garde (7° 47'E et 36° 58'N) . Six stations ont été choisies, dont six pour les sédiments et les moules et deux pour ceux des poissons.

II.2 Stations de prélèvement : Station ST1 « Sidi Salem » : à proximité de l'embouchure de l'oued Seybouse et de l'ensemble des rejets industriels et urbains de toute la plaine de la ville d'Annaba. Station « ST2 » la petite Darse. Station « ST3 » la grande Darse. Station « ST4 » 3ème bassin. Port de pêche Station ST5 « Lever de l'aurore » se trouve du côté ouest du port. Station ST6 «La kyenne» en dehors de la zone urbanisée. L'échantillonnage du sédiment a été effectué au cours d'une seule campagne de prélèvement par site durant l'année 2011 ; des moules d'une campagne mars, avril 2011 ; pour les poissons 'une campagne en période printanière de l'année 2012. Le calcul de l'indice de contamination selon l'agence du bassin du Rhône(1990) : a établit trois classes de pollution en fonction de l'indice de contamination Ic, qui est le rapport entre la valeur considérée comme normale **[2]** et celle observée dans le sédiment , Ic< 3 sédiment de référence 3 <Ic<10 sédiment pollué Ic> 10 sédiment à risque.

II.3 Préparation et analyse des échantillons : La minéralisation est effectuée selon les méthodes : **[3]-** sédiments, **[4]-** moules, et **[5]-** poissons. Les teneurs des ETM sont déterminées par spectrophotométrie d'absorption atomique à flamme de type PERKIN-ELMER Analyst 100 ; Pour le mercure selon la méthode IAEA/UNEP (1984). Les analyses statistiques ont été effectuées à l'aide du logicie STATISTICA.

III. Résultats et discussion :

Dans les sédiments on observe un degré de contamination inquiétant. On note à cet effet des indices de contamination élevés, en plomb 20.45-7.95, en mercure 19-5.50,en zinc 11.84-3.42, en chrome 9.22-4.22, en cuivre 7.84-3.07, en cadmium 7-4.16, en fer 3.60-3.06, résultat probable de l'importance activité au niveau de port ; et à l'exposition directe aux effluents d'origine anthropique, classant les sédiments de ces stations de sédiments pollués par le zinc, le chrome, le cuivre ; le cadmium et le fer et de sédiment à risque par le plomb au niveau des stations 1,2, 3,4 et 5 et pour le mercure au niveau des stations 2, 3 et 4 .Les teneurs en métaux relevées dans la chair de moules , on observe une contamination dominée le plus souvent par les métaux toxiques tels que le plomb (1.67–2.68) mg.kg^{-1}, le mercure (0.16–0.20) mg.kg^{-1}, le cadmium (0.25-0.90) mg.kg^{-1} et le chrome (2.24–2.80) mg.kg^{-1} · comparées aux médianes Françaises. Quant aux teneurs relevées dans les muscles de poissons ; on note des teneurs élevées ;notamment par le plomb (1.19-1.99) mg.kg^{-1}, le mercure (0.02–0.15) mg.kg^{-1}, le cadmium (0.040-0.08) mg.kg^{-1} et le chrome (0.79-0.90) mg.kg^{-1}.Quant aux basses teneurs relevées dans la station 6, elles s'expliqueraient par l'éloignement de toute activité.

IV. Conclusion : Les résultats obtenus font état d'une contamination métallique. La consommation des moules et des poissons peuplant, l'intérieur du port et l'embouchure est dangereuse notamment pour le plomb. Ces résultats ont aussi permis d'identifier les principales sources de pollution, et de valider l'utilisation de deux organismes marins, un bivalve Perna perna et un poisson Mugil cephalus pour un biomonitorage.

HEAVY METALS BIOACCUMULATION IN TWO SPECIES OF MOLLUSCS IN N.EVOIKOS GULF-GREECE

Leila Bordbar [1]* and Manos Dassenakis [1]
[1] University of Athens, Department of Chemistry, Laboratory of Environmental Chemistry, - leila.bordbar@gmail.com

Abstract
Two different species of Molluscs (*Monodonta turbinata* and *Patella caerulea*) from seven stations around the smelting plant in the bay of Larymna (N.Euvoikos Gulf-Greece) were sampled seasonally from Autumn 2009 to Autumn 2010. Iron, Mn, Zn and Cu were determined in the soft tissues of organisms using Atomic Absorption Spectrometry (AAS). The highest concentration of Fe, Mn in both species were detected at the station near the smelting plant .All metals measured in *M. turbinata* were higher in spring 2010, while in *P. caerulea* the highest Fe and Mn concentrations were measured during the cold period of the year (winter 2010). Higher mean levels of Cu (six fold) and Mn (two fold) were measured in soft tissues *M. turbinata* than in *P. caerulea.*

Keywords: Bio-accumulation, Metals, Mollusca, Monitoring, Aegean Sea

Introduction: aquatic environments are highly impacted by human activities, either by its use for resources exploitation, transportation, recreational proposes or as dumping .The heavy metal pollution of the marine environment has long been recognized as a serious environmental concern (2) The bay of Larymna in the N. Evoikos Gulf (Central-Greece), receiving huge a mount of waste from the most important ferronickel smelting plant in the country (3) since 1963. The by-product of smelting plant is deposited in Gulf includes iron oxides, silicon dioxide as well as Fe, Al, Mn, Cr, Ni and Co (5). The Hellenic Centre for Marine Research (HCMR) has been charged for monitoring the impact of dumping slag in N. Evoikos gulf, since 1983 (4). The aim of the present study is to select the most appropriate sentinel species naturally growing in the area to use for the monitoring of the metal pollution in the coastal environment.

Material and Methods: two different mollusc species (*Monodonta turbinata* and *Patella coerulea*) from seven stations around the smelting plant and two stations from the other side of Gulf as a reference area have been collected .(120 individuals from each species per each station) figure1.

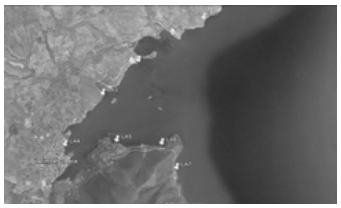

Fig. 1. The location of stations around the smelting plant.

Ten individuals from *P. caerulea* and 15 from *M. turbinata* were pooled; freeze dried. One gram of sample was digested with 6 ml of concentrated HNO_3 (65%) (Merck, Germany) and 2 ml of concentrated H_2O_2 (30%) (Merck,Germany) in microwave digestion system and diluted to 20 ml with Milli-Q water (blank digest was carried out in the same way).Four heavy metals" i.e." Fe, Mn, Cu and Zn measured by Atomic absorption spectrometry AA20. The accuracy of our measurements were verified by analysis of certified reference materials.(Ulva (CRM NO 279)) and IAEA (NIST 2976). More than 90% recovery for all metals were obtained.

Results and discussion: the box plot distribution of Fe and Mn in *P. coerulea* and M. *turbinata* were presented in table 1. It is detected that Fe and Mn were in their highest concentration in the station near the smelting plant (LA4) in the both species, suggesting the direct water discharging from the smelting plant in the Gulf and the metal dust around the smelting plant cause the high concentration of mentioned metals as form of dissolved and particulate in water samples (1). Zn & Cu, metals not directly related to slag (5).The highest concentration of Cu was detected in LA5, in *M. turbinata*, while in *P. coerulea* the highest concentration was found in LA6.both stations are near to an aquaculture farm and the high concentration of this metal would probably due to the antifouling used in fish farm. LA5 station is located near village of Larymna and Zn concentration is significantly high in this station. Zn and Cu are known to be related to direct anthropogenic inputs such as sewages, aquaculture and agriculture activities. (3), therefore the high concentration of this metal could be attributed to vicinity of this station to the rural area . For all metals the highest concentration in *M. turbinata* were determined in Spring 2010, while in *P.caerulea* the highest Fe and Mn were measured in Winter 2010, and Zn and Cu were marked in Autumn 2010.Comparision of metal concentration in the two species showed Significantly higher level of almost all measured metals in M. *turbinata* expect for Fe in *P. caerulea* which was two times more than *M. turbinata.*

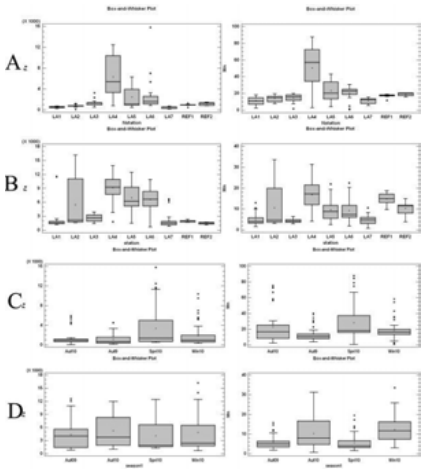

Fig. 2. Fe and Mn (µg/g dw) box-plot distribution of *P. coerulea* (B&C) and *M. turbinata* (A&D).

Abstract
Bluefin tuna accumulated ^{134}Cs and ^{137}Cs released from the Fukushima nuclear power plant in Japan and transported these isotopes to the eastern Pacific. Radiation doses to the tuna and to human seafood consumers are below doses from natural radiation background, but these isotopes can be used to trace migratory routes and timing in large pelagic animals.

Keywords: Fishes, Radionuclides, Pollution, North-Central Mediterranean

The damage to the Fukushima Da-ichi nuclear power plant in Japan in March 2011 resulted in a the largest accidental release of radioactivity to the oceans in history. The principal radionuclides released into the Pacific were ^{131}I, ^{134}Cs, and ^{137}Cs, but others were also found in biota and marine sediments. Nearly all the short-lived ^{131}I decayed away within a few months, but ^{134}Cs ($t_{1/2}$ = 2 y) and ^{137}Cs ($t_{1/2}$ = 30 y) are detectable in water and biota in coastal regions near Japan. We used gamma spectrometry to analyze biota in Japanese waters in June 2011, 2.5 months after the date of maximal release of radioactivity. We found that zooplankton were contaminated with equal quantities of ^{134}Cs and ^{137}Cs (~15 Bq kg^{-1} each), as well as ^{110m}Ag (~8 Bq kg^{-1}). Small myctophid fish were found to have both Cs isotopes (~10 Bq kg^{-1} each) but no Ag [1]. In August of 2011, we also collected Pacific bluefin tuna from waters off California; this species spawns in the western Pacific and migrates eastward to California, often at the age of 1-2 years.

All 15 bluefin tuna that were new arrivals to California in August 2011 were found to have both Cs isotopes in their muscle, resulting in concentrations that were over ten times the amount of radioactivity from anthropogenic radionuclides prior to the accident [2]. Yellowfin tuna, a residential species, also collected off California had no ^{134}Cs and only "background" ^{137}Cs (from nuclear weapons testing in the 1960s), indicating that the radioactivity in the bluefin tuna off California was accumulated in waters off Japan and transported via migration to the eastern Pacific. The radioactivity in bluefin tuna caught off California that derived from Fukushima was only about 3% above the radioactivity from the naturally occurring ^{40}K.

Using a simple model, we calculated that the radioactivity from ^{134}Cs and ^{137}Cs in these tuna prior to their departure from Japanese waters was about 15 times higher than at the time of capture in California waters [2], matching independent measurements of tuna radioactivity near Japan. The decrease during the migration across the Pacific was attributable to excretion of the Cs, which has an efflux rate constant from marine teleosts of ~2% d^{-1}. We also evaluated the radiation risks to human consumers of the contaminated bluefin tuna in Japan and in the USA. Japanese eat more seafood, on average, than Americans (57 vs. 24 kg y^{-1}). The total estimated annual dose from consumption of these fish in August 2011 from $^{134+137}$Cs would be 0.9 µSv in the US and 33 µSv in Japan in April 2011 [3]. By comparison, the annual dose to tuna eaters from the naturally occurring ^{40}K and ^{210}Po in the same fish would be 570 µSv in the US and 1340 µSv in Japan (Table 1) [3]. Doses from ^{210}Po to the tuna exceed doses from radiocesium by 2-3 orders of magnitude [3].

The radioactivity from the Fukushima reactor to human consumers of Cs-contaminated tuna would thus be well below the natural radiation background to which we are all exposed, and estimated additional cancers from tuna consumption would be ~2 per 10 million people, although this estimate is highly uncertain. Other species of fish in Japanese coastal waters have also been reported to be contaminated with ^{134}Cs and ^{137}Cs, particularly benthic species [4]. As with the tuna, consumption of most other contaminated species would not exceed human safety limits, although some greenlings are extremely contaminated (7400 times the Japanese legal limit for Cs), and although banned, fishermen who ignore regulations and eat them would exceed human safety limits. In 2012, 50 additional bluefin tuna off California had $^{134+137}$Cs concentrations < half the levels found in 2011 [5], reflecting the dilution of the radioactive wastes in the Pacific. By studying the ^{134}Cs:^{137}Cs ratios in the fish, it is possible to discern the timing of migration of these fish and to assess the fraction of total fish in the eastern Pacific that are recent migrants [2, 5]. Such information is vital for proper management of this imperiled fishery. One positive outcome of this accident is that the application of radioactive tracers for evaluating migration routes and timing could be extended to understanding dynamics of other migrating animals, including other fish, turtles, birds, and mammals.

Tab. 1. Radioactivity in biota (Bq kg^{-1} dry wt) and radiation doses to tuna and humans

	Zooplankton	Bluefin tuna-US	Bluefin tuna-Japan	Dose to tuna (nGy h^{-1})	Dose to human tuna eaters (µSv y^{-1})
$^{134+137}$Cs	33	155	10	0.5-1.7	0.9: US; 33 Japan
^{40}K, ^{210}Po	199	347	347	600	570: US; 1340: Japan

This study highlights the possibility of using point sources of contamination, not restricted to radioactivity, to trace migration patterns of animals in any body of water, including the Mediterranean. The Mediterranean and Black Seas have numerous point sources of chemical contaminants whose background concentrations in uncontaminated seawater are negligible; bioavailable contaminants can be used to trace the movement of animals in these waters, as exemplified by tuna transporting Cs. Thus, any future radioactive releases from nuclear installations or accidents could be used to better understand animal migrations in these waters. And, importantly, detectability of contaminants in seafood does not necessarily imply significant risk for consumers.

RECENT ADVANCES IN THE BIOMONITORING OF TRACE ELEMENTS USING POSIDONIA OCEANICA (L.) DELILE

Sylvie Gobert [1]* and Jonathan Richir [1]
[1] Université de Liège - sylvie.gobert@ulg.ac.be

Abstract
One of the most studied bioindicator in the Mediterranean is the seagrass *Posidonia oceanica*. Trace element (TE) monitoring surveys using that species have however mostly focussed on a few elements (e.g. Pb, Cd), while numerous others, efficiently bioconcentrated by the plant and potentially toxic, have been barely or not studied (e.g. Ag, V, Bi). Furthermore, although *P. oceanica* bioaccumulation behaviour relies on synergistic effects between the sampling environment and its ecophysiology, this aspect has been mostly underestimated until now. This study presents recent advances in the biomonitoring of TEs using *P. oceanica* and insists on the necessity of developing consensual monitoring protocols in order to improve its use as bioindicator.

Keywords: Trace elements, Bio-indicators, Ecotoxicology, North-Western Mediterranean

Coastal ecosystems are submitted to numerous anthropogenic pressures: among them, the chemical pollution by traces elements (TEs). Biomonitoring surveys using the marine magnoliophyte *Posidonia oceanica* (L.) Delile, endemic to the Mediterranean, have mainly focussed on contaminations by Cr, Ni, Cu, Zn, Cd, Pb and Fe. However, other TEs like As, V, Ag, Be, Al, Mn, Co, Se, Mo, Sn, Sb and Bi, categorized as elements of "environmental emerging concern", have been subject to nearly no ecotoxicological survey with that species. As the worldwide evolution of our technologies and of our lifestyle increases the extraction and production of most of the listed TEs, their environmental monitoring remains a topical subject. Furthermore, little is known about TE kinetics within *P. oceanica* meadows. The respective importance of the plant ecophysiology and its sampling environment henceforth needs further investigations in order to properly use this bioindicator in intercomparative monitoring surveys. We firstly monitored TE mean annual levels in *P. oceanica* shoots sampled during 3 years (2008-2010) in front of the oceanographic station STARESO (Calvi Bay, Northwestern Corsica, France). Results showed that *P. oceanica* shoots bioaccumulated TEs of emerging concern to levels ranging from 0.001 (e.g. Bi) to 100 (e.g. Mn) $\mu g.g_{DW}^{-1}$ of shoot [1]. A spatial monitoring survey (April 2007) along the French Mediterranean littoral further pointed out that many of these TEs effectively threatened its chemical integrity: the observed spatial variability of *P. oceanica* shoot TE levels (in $\mu g.g_{DW}^{-1}$ of shoot) could be linked to specific anthropic activities like agriculture (Mo: up to 27 ± 14), mining (Sb: up to 0.70 ± 0.13), storage and refinement of oil products (V: up to 23 ± 7), or the presence of major urban centres (Bi: up to 0.049 ± 0.004). Their monitoring, along with the one of TEs classically studied in that species, turned out to be essential [2]. A complementary small-scale study (May 2010) of TEs contents in *P. oceanica* shoots sampled along a radial located at the back of the Ajaccio Bay (western Corsica) further demonstrated that the spatial variation of their TE contents (e.g. Bi, in $\mu g.g_{DW}^{-1}$ of shoot) could vary as much at the scale of 1 km (from 0.009 ± 0.004 to 0.061 ± 0.012) than at the scale of the French Mediterranean littoral (from 0.004 ± 0.000 to 0.049 ± 0.004; Richir, 2012). The election of a representative monitoring site to characterize the global health status of a wider area (e.g. a Bay) is thus a very important step when planning a monitoring survey based on benthic (and rooted) organisms. We also studied the physiological mechanisms of accumulation, storage and excretion of a mix of 15 TEs by *P. oceanica* though the *in situ* contamination of seagrass bed portions (June 2009). Realistic low TE concentrations within the experimental setup (from 0.018 ± 0.004 $\mu g.L^{-1}$ for Ag to 16 ± 8 $\mu g.L^{-1}$ for Zn, as measured with DGTs) were similar to pollution levels recorded in contaminated coastal areas of the Mediterranean. Plant compartments responded differently to TE exposures: adult senescent leaves assimilated TEs less rapidly than young intermediate actively growing ones. Mean contamination factors were3.0 ± 1.7 for *P. oceanica* intermediate leaves (min. = 1.2 for Fe; max. = 7.4 for Bi) and 2.0 ± 0.9 for adult leaves (min. = 0.95 for Cd; max. = 3.7 for Bi), at the levels of contamination tested. TEs, once accumulated, could be redistributed between plant compartments, notably towards rhizomes buried in sediments. Rhizomes could therefore play the role of storage organs, in particular for essential nutrients such as Cu or Zn, and thereafter supply plant demands during the moment of maximum leaf growth [3]. TE levels and kinetics in *P. oceanica* beds will thus evolve seasonally and spatially according to the synergistic effect of both environmental bioavailable TE levels and the plant ecophysiology. However no general sampling rule and/or protocol prevails nowadays when using that species in biomonitoring surveys, contrary to other species (e.g. *M. galloprovincialis*). In the light of our observations, we strongly recommend developing consensual monitoring protocols in order to improve the use of *P. oceanica* as bioindicator of TE pollution, although we are conscious of the difficulty of such a task.

PECULIARITIES OF MACRO- AND MICROELEMENTS ACCUMULATION IN *CYSTOSEIRA* SPP. IN THE COASTAL WATERS OF SOUTH-WESTERN CRIMEA (THE BLACK SEA)

Alexandra Kravtsova [1]*
[1] Institute of Biology of the Southern Seas - alexkravtsova@yandex.ru

Abstract
The peculiarities of 26 macro- and microelements accumulation in the thalli of brown algae *Cystoseira* from the coastal waters of south-western Crimea (the Black Sea) were studied using instrumental neutron activation analysis (INAA). The possibility of using brown algae *Cystoseira* as a biomonitor of coastal waters pollution was shown.

Keywords: Black Sea, Algae, Bio-indicators, Trace elements

Macroalgae can accumulate trace elements in concentrations that are orders of magnitude greater than their content within the environment. This ability allows them to indicate the level of coastal waters pollution [1]. Although features of macro- and microelements accumulation by Black Sea macroalgae (Chlorophyta, Rhodophyta and Ochrophyta) have been described by a number of authors [2], the data about relationship between concentrated elements and plant age, morphostructural elements of the thalli and seasons are scarce. Therefore it is difficult to give a science-based recommendation for their use as biomonitors of the coastal waters pollution. The aim of our work was to study features of accumulation of macro- and microelements by brown macroalgae *Cystoseira barbata* C. Ag. and *Cystoseira crinita* (Desf.) Bory from the coastal waters of south-western Crimea (Sevastopol region) and relate their concentrations with the seasons, ages and different parts of the thalli. The study was carried out at five aquatic sites in Sevastopol area with different degree of anthropogenic pollution. The plants of *Cystoseira* species were sampled at the depths of 0,5–1,5 m during spring and summer seasons in 2012. The concentrations of 26 macro- and microelements (Na, Mg, Al, Cl, K, Ca, Sc, V, Mn, Fe, Co, Ni, Zn, As, Br, Rb, Sr, Sb, I, Cs, Ba, Sm, Nd, Ag, Au and U) were determined by means of INAA, which is widely used in current ecological studies [3]. INAAwas performed in the radioanalytical laboratory at the fast pulsed reactor IBR-2 of the Frank Laboratory of Neutron Physics, JINR (Russia). Average concentrations of macro- and microelements in the thalli of *Cystoseira barbata* and *C. crinita* widelydiffer and are dependent on ecological conditions. The results showed a tendency to increase concentrations towards more polluted waters. The highest concentrations of trace elements were found in young plants less than one year old at all stations, regardless of their degree of pollution (figure 1).

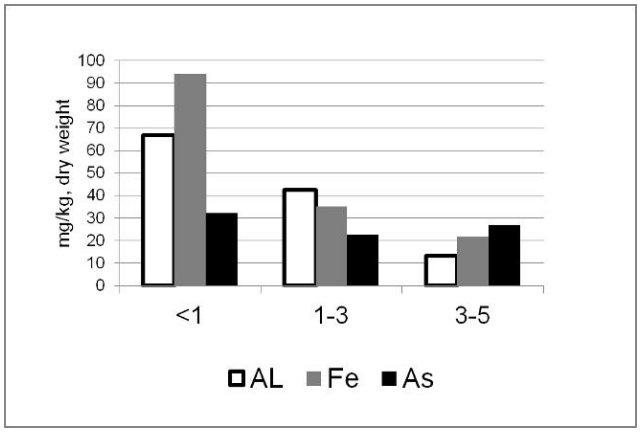

Fig. 1. Average concentrations of Al, Fe and As (mg/kg) in *Cystoseira* spp. stems at various ages in summer season 2012 (Sevastopol region).

The content of trace elements in the stems and branches of the thalli from the same station differed by a factor of 1,5-7. In the spring, the greatest concentration of elements in stems was higher than in the summer; the reverse was observed for the branches (figure 2). In the summer season the epiphytic macroalgae are an additional source of elemental sorption from the aquatic environment resulting in raised concentrations in the branches of *Cystoseira barbata* and *C. crinita.*

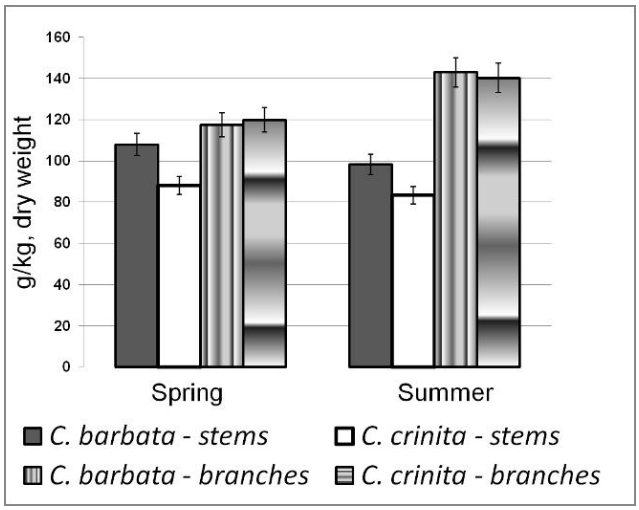

Fig. 2. Total concentration of elements (g/kg, dry weight) in *Cystoseira barbata* and *Cystoseira crinita* thalli in spring and summer season 2012 (Sevastopol region).

Taking into account a wide range of variation in concentrations of elements in *Cystoseira* species thalli and their relationship with ecological factors, structure and the age of the thalli, it was recommended to use stems and branches of the same age for biomonitoring purposes that were sampled in the same season. The stems of 2-3 year old plants of *Cystoseira barbata* and *C. crinita*, sampled in the summer season, could be the biomonitors of water pollution in the Sevastopol coastal zone. Acknowledgements. This research has received funding from the EC (FP7/2007-2013) under Grant Agreement No. 287844 for the project CoCoNet ("Towards Coast to Coast NETworks of marine protected areas (from the shore to the high and deep sea), coupled with sea-based wind energy potential").

ASSESING HEAVY METALS IN THE MARINE BIVALVE *PINNA NOBILIS* IN THE BALEARIC ISLANDS (WESTERN MEDITERRANEAN)

M. Morató [1]*, S. Deudero [1], M. Vázquez-Luis [1], C. Guitart [2] and J. Campillo [2]
[1] Centro Oceanográfico de Baleares-IEO - merce.morato@ba.ieo.es
[2] Centro Oceanográfico de Murcia-IEO

Abstract
Heavy metals (Cd, Cu, Hg, Pb and Zn) concentration were determined in the marine bivalve *Pinna nobilis* along the Balearic Islands, comparing a protected area with two sites with strong anthropogenic influence. Analyses of Cabrera and Mallorca indicated that heavy metal concentration were generally higher in the most of samples, specially in Santa Maria bay (Cabrera, MPA), and Magaluf (Mallorca, with strong anthropogenic influence). *Pinna nobilis* appears to efficiently bioaccumulate heavy metals exhibiting large differences in a range of anthropic scenarios. The results on *P. nobilis* metal accumulation show that the concentrations decrease according to order: Zn > Cu >Pb> Cd > Hg.

Keywords: Balearic Islands, Bivalves, Metals, Bio-accumulation

Introduction
Heavy metals in marine biota have natural and anthropogenic origin, and are regarded as serious pollutants of the aquatic environment because of their toxicity, persistence, low biodegradability and their tendency to concentrate in aquatic organisms [1]. Many benthic organisms accumulate trace metals to the levels reflecting those in the environment, and the molluscs in particular may therefore be sensitive biomonitors of metal inputs. *Pinna nobilis*L., 1758 is a fan mussel endemic to the Mediterranean Sea and is consideredthe biggest bivalve mollusc of this area [2]. It is commonly found within the seagrass meadows, especially those of *Posidonia oceanica* [3], and the species is a long-lived filtering bivalve. There are numerous studies on heavy metals in the Mediterranean Sea, especially in sediment [4], seagrass meadows [1] and benthic invertebrate species [11], but there are few studies on large filter feeders like *P.nobilis*.

Materials and methods
The study area is the Balearic Islands coast, includes two islands, Mallorca (Andratx and Magaluf) and Cabrera (Santa Maria bay) included within a zone of integral protection. Fourteen *P. nobilis* samples were taken in October 2011 with scuba diving. Concentrations of Cd, Cu, Pb and Zn were determined by atomic absorption spectrometry (AAS), and Hg was determined by an Advanced Mercury Analyzer AMA 254. For comparison of total metals at the sampling sites, the metal pollution index (MPI) was applied ([8]; [9]; [1]): $MPI= (Cf_1 \times Cf_2 \ldots Cf_n)^{1/n}$; where the Cf_n is the metal concentration *n* in the sample.

Results and discussion
Metal concentrations in soft tissues of *P. nobilis* samples (dry weight) range from 1.21 to 33.1 mg/Kg for Cd, from 4.1 to 319.2 for Cu, from 0.247 to 1.158 mg/Kg for Hg, from 0.58 to 39 mg/Kg for Pb and from 1244 to 4529 mg/Kg for Zn (Table 1).

Tab. 1. Mean SD (min-max) mg/Kg dry weight and metal pollution index (MPI) by site. (n= number of samples)

sites	1.Andratx (n= 4)	2.Magaluf (n= 4)	3.Santa Maria bay (n= 6)
Metals			
Cd	1.613± 0.606 (1.21-2.5)	8.918 ± 3.002 (5.82-13.03)	26.435 ± 6.966 (15.03-33.1)
Cu	6.05 ± 2.204 (4.1-9.2)	197.85± 88.084 (127,1-319,2)	57.25 ± 30.405 (20.9-96.5)
Hg	0.297± 0.044 (0.25-0.35)	0.795 ± 0.22 (0.56-1.09)	0.957 ± 0.133 (0.82-1.16)
Pb	0.895 ± 0.21 (0.58-1)	20 ± 6.272 (12-27)	22.67 ± 5.164 (15-29)
Zn	4034.25± 358.71 (3670-4529)	1763± 607.879 (1244-2631)	2708.33±347.757 (2364-3224)
MPI	6.22 ± 0.528	34.446 ± 11.55	38.171 ± 8.2

All examined metals had maximal concentration in Santa Maria bay in Cabrera, excepte for Cu at Magaluf, and Zn in Andratx. The obtained concentrations are comparable with those reported for Pinnidae elsewhere ([4]; [5]; [6]; [7]). We compared the concentrations of all heavy metals by metal pollution index (MPI), and the MPI reaches the maximal value for site 3 (Santa Maria bay) linked to the highest concentrations of three metals (Cd, Pb and Zn).

Conclusions
Elevated metal concentrations can cause a severe reduction or elimination of intolerant species, thereby having a significant effect on the diversity and trophic structure of the biological community [10]. In view of the range of concentrations that can be found in the soft tissues of bivalves species, the magnitude of metals in the *P. nobilis* can be considered high. The species shows a high bio-accumulation capacity, thus further analysis are needed to assess their tolerance ranges to metal pollution and monitoring data indicate that the bioacumulation potential is sufficient to be of concern.

TRACE METAL CONCENTRATIONS IN THE DATE MUSSELS, *LITHOPHAGA LITHOPHAGA* (L., 1758) FROM IZMIR BAY (EASTERN AEGEAN SEA)

Meral Özsüer [1] and Ugur Sunlu [1]*
[1] Ege University, Faculty of Fisheries - ugur.sunlu@ege.edu.tr

Abstract
This study determined zinc (Zn), cadmium (Cd), lead (Pb) and copper (Cu) in the bivalve *Lithophaga lithophaga* from Izmir Bay (Aegean Sea) in 2011 seasonally. All values were measured by voltammetry. Mean values of trace metals for all seasons were 49.07 µg Zn g^{-1}, 0.34 µg Cd g^{-1}, 1.69 µg Pb g^{-1} and 12.65 µg Cu g^{-1} as wet weight.

Keywords: Trace elements, Bio-accumulation, Izmir Bay, Bivalves

Introduction
Aquatic organisms are in a fragile equilibrium with the aquatic environment which they inhabit and they can biologically represent its level of pollution The aim of the study was to determine the concentrations of Zn, Cd, Pb and Cu accumulated in *L. lithophaga* in the middle part of Izmir Bay.

Materials and Methods
Izmir Bay is a part of the eastern coast of the Aegean Sea. Yassica Ada is an island located at the middle part of the bay (Fig. 1).

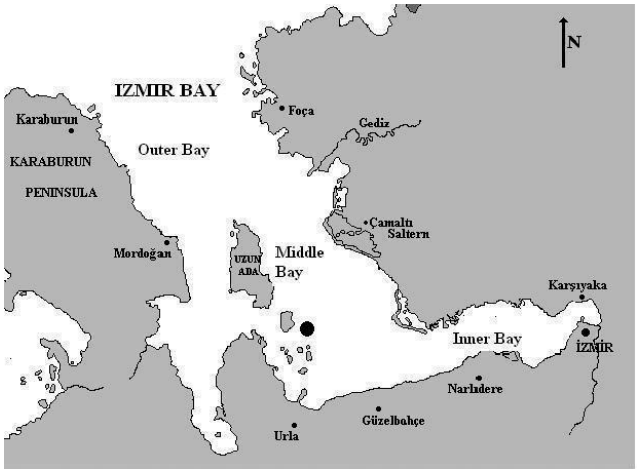

Fig. 1. Izmir Bay and the sampling area (*).

A bivalve of the Mytilidae family, *L. lithophaga* is an endolithic species inhabiting limestone rocks.The species has been protected by the Bern Convention and Barcelona Convention – Genoa Protocol. Only consuming by local fishermen they are not commercially exploited and there aren't any legal restrictions on harvesting and collecting them in Turkey.
Individuals of *L. lithophaga* were collected by SCUBA diving from the coastal area of the Isle of Yassica Ada between August 2010 and May 2011 in a seasonal study. The metal contents of individuals were extracted according to international standard methodology[1] Trace metal concentrations were measured using a hanging drop electrode voltammetric analyzer. Inter-calibration homogenate samples (IAEA-142/TM) for mussel, from the IAEA, Monaco Laboratory were used as a quality control for the analytical methodology. Detection limits for 5 g wet weight (ww) were 0.001 ppm for Cd and Pb and 0.02 ppm for Zn and Cu.

Results and Discussion
Voltammetric analyses of extracted forms of *L. lithophaga* are presented as mean values in Table 1. Our results showed that the pattern of trace metal occurrences in the mussel was Zn>Cu>Pb>Cd. Only one study [2] could be found in the literature concerned about the same species as in our study. Keeping in the mind that trace metal levels and their bioavailibity in water are affected by numerous variables (both anthropogenic and natural); differences in concentrations might be expected. Dissimilar results of the two studies also could stem from different device and methods of the measurement. The table further shows the permissible upper limits of metals in edible bivalves, as published in the Turkish Food Codex [3], European Regulations EC1881 [4] and the world Health Organization [5].

Fig. 2. Results of another study and legally permissible amounts of trace metals as well as mean concentrations measured in the present study (ppm ww).

The results from our study for Pb are not below the established EC or Turkish Food Codex guidelines and level for Cd is not below the WHO guideline. High Zn concentration is just below the guidelines, suggests a need for further monitoring of seafood species from this immediate area that are harvested for human consumption.

THE MEDITERRANEAN MUSSEL WATCH, TEN YEARS AFTER: SUCCESS AND END

Hervé Thébault [1]*
[1] Institut de Radioprotection et de Sûreté Nucléaire Antenne de Radioécologie Marine - herve.thebault@ifremer.fr

Abstract
A regional monitoring program - the CIESM Mediterranean Mussel Watch (MMW) - has been running for 10 years, using the mussel *Mytilus galloprovincialis* as unique bio-indicator specie. The network consists of some 20 marine environmental laboratories from 18 different Mediterranean and Black Sea countries. As of today, more than 100 sites have been sampled to produce the first distribution map of ^{137}Cs in coastal waters at the Mediterranean basin scale. Despite repeated efforts to set up more permanent monitoring on this basis, the second phase of the program did not found the necessary institutional and financial support which brought the project to its end.

Keywords: Monitoring, Bio-indicators, Radionuclides, Mediterranean Ridge

Introduction
Coastal management requires complete information on baseline levels of contaminants for any impact assessment, especially for semi-enclosed Mediterranean and Black Seas with very long water residence time. Although included in the Barcelona Convention protocol, radioactivity monitoring was not implemented in the MEDPOL program. Then, as part of its observation and monitoring programs, the CIESM launched in 2002 a regional "Mediterranean Mussel Watch (MMW)" to record levels and trends of radioactivity in the environment. In addition to some existing monitoring activities at the national levels, the objective of the MMW was to promote the common production of large and reliable datasets, on a long term basis, throughout the network of Mediterranean marine research institutes. This was achieved during the course of a dedicated workshop resulting in a consensual agreement on monitoring strategy, procedures and methods [1].

Methodology and implementation
The Mediterranean mussel *Mytilus galloprovincialis* was selected as unique bio-indicator specie, widespread in the region and capable of accumulating many contaminants including radionuclides. In sectors where natural populations are rare, samples were obtained from transplanted mussels, a technique initiated in France and successfully extended to the entire Mediterranean Sea [2]. Trace level measurements of radionuclides are performed by direct gamma spectrometry as a routine technique. Intercalibration of all participating analytical laboratories was achieved with the making of a specific reference material, AIEA-437 [3]. Some 20 marine environment laboratories from 18 Mediterranean countries have been involved in the MMW and more than a 100 sites have been sampled so far. The database of radionuclides measurements comprises some 500 original values. Results have been discussed among participants within dedicated round-tables during the course of CIESM congresses from 2004 to 2010.

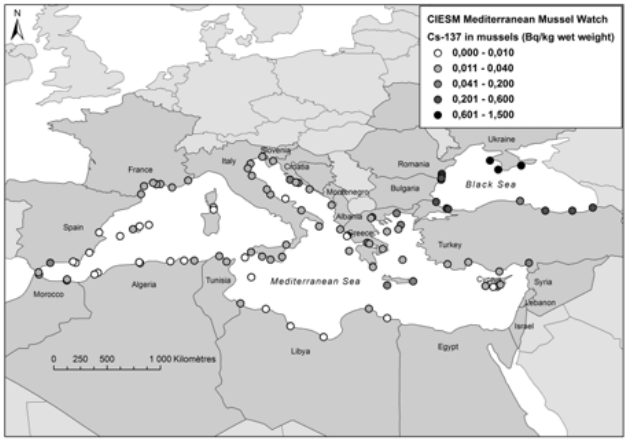

Fig. 1. Distribution of ^{137}Cs concentrations in mussels collected in 2004-2009.

Results and conclusion
Among artificial radionuclides, ^{137}Cs is the main element regularly detected in mussel tissues. By 2009, the MMW network has been able to produce the first comprehensive distribution map of ^{137}Cs at the regional level (Fig. 1). This artificial radionuclide, mostly originated from global fallout of former nuclear weapons tests, is now detected at very low level in all Mediterranean coastal waters [4]. The mean value is 0,085 Bq.kg^{-1} wet weight, which is three orders of magnitude below the compliance level for human consumption of seafood products. However, in the Black Sea and North Aegean Sea, ^{137}Cs activity in mussels is still remarkably higher than in the Western basin (max value of 1,5 Bq.kg^{-1} w.w.), showing the remaining impact of Chernobyl accident. The MMW was quite successful in its implementation phase and brought much interest from monitoring activity of other regional seas (i.e. ROPME in the Gulf). In European countries of the Mediterranean basin, this program is also considered as a good basis for the mandatory radionuclides monitoring provided for by the European Marine Strategy Framework Directive. The second phase of the program was planned to set up more permanent monitoring and to extend the network activity to emerging contaminants [5]. However, despite repeated efforts from the coordination team and many participants, the program did not found the necessary institutional and financial support to go beyond the initial involvement of CIESM. This action was not considered with high priority for the Mediterranean marine environment, possibly due to the low level of artificial radionuclides.

Aknowledgements
The author, as coordinator of the program on behalf of CIESM, deeply thanks all participants for their scientific involvement and personal enthusiasm over the last ten years. The group is grateful to the CIESM staff, to MEDPOL program, to IAEA for technical support and to the team of Ifremer-coordinated EC projects Mytilos/Mytimed/Mytior for ship opportunity and efficient logistic support.

ETUDE PRÉLIMINAIRE DES MÉTAUX TRACES AU NIVEAU DE *CYMODOCEA NODOSA* À PROXIMITÉ DU PORT DE PLAISANCE EL KANTAOUI

Rym Zakhama-Sraieb [1]*, Yassine R. Sghaier [1], Ahmed Ben Hmida [1] and Faouzia Charfi [1]
[1] Unité de Recherche de Bio-écologie et Systématique Evolutive - zakhamarym@yahoo.fr

Abstract
Les herbiers de Magnoliphytes sont reconnus comme un outil efficace pour l'étude de l'environnement côtier car ils sont très répandue dans le bassin méditerranéen, sont fixés sur le fond et ils sont sensibles à la pollution. Dans la présente étude, on a analysé la concentration de cinq éléments traces (Cd, Zn, Pb, Cu et Ni) au niveau des différentes parties de *Cymodocea nodosa*. C'est au niveau des stations à proximité du port et du point de rejet d'eau usé de Hammam Sousse que l'on enregistre les concentrations les plus élevés en éléments traces. Par ailleurs, la comparaison des teneurs des différentes parties de la plante en métaux traces montre que c'est au niveau des feuilles de la *C. nodosa* que la concentration est la plus élevé en particulier pour le Cd, le Pb et le Cu.

Keywords: Metals, Phanerogams, Tunisian Plateau

Introduction
Cymodocea nodosa est une phanérogame marine abondante au niveau des faibles profondeurs des côtes tunisiennes (Sghaier *et al*., 2011) où elle constitue des herbiers denses durant les saisons estivales et printanières; par ailleurs, les angiospermes ont un pouvoir accumulateur des polluants dans leurs tissus. Pour toutes ces raisons, *C. nodosa* semble une candidate intéressante pour l'étude des métaux traces au niveau des zones côtières Tunisiennes. La présente étude s'intègre dans le projet de recherche MAPMED (Management of Port Area in the Mediterranean Basin). Ce projet vise a développer des indicateurs rapides et simples à identifier de la qualité des eaux côtières autours des ports touristiques en Méditerranée.

Matériels & méthodes
L'échantillonnage a été effectué par plongée sous-marine en mars 2012, au niveau de 4 stations aux alentours du port touristique d'El Kantaoui entre 2 et 3m de profondeur (Fig. 1). La densité des faisceaux a été estimé *in situ* en utilisant un cadre de 20cm de coté avec 10 réplicas. Trois échantillons de 15 faisceaux de *C. nodosa* chacun ont été collectés pour l'analyse des métaux traces. Les faisceaux sont séparés en différents compartiments (feuilles, pétioles et rhizomes). Après séchage, les échantillons de *C. nodosa* ont été calcinés à 450°C, digérés avec l'eau régale dans un système fermé ensuite analysés par la méthode de spectrométrie d'émission atomique ICP.

Fig. 1. Localisation des stations d'étude

Résultats
La densité des faisceaux (Fig. 2) montre un gradient croissant des stations à proximité de l'émissaire d'eau traité de Hammam Sousse (C1 et C2) vers les stations les plus éloignées (C3 et C4) avec une différence significative. Les échantillons de *C. nodosa* collectés au niveau des quatre stations contiennent des traces des 5 métaux étudiés et ce dans les différents compartiments (Feuilles, Pétioles et Rhizomes).
C'est au niveau des stations à proximité du port et du point de rejet d'eau usé de Hammam Sousse que l'on enregistre les concentrations les plus élevés en éléments traces en particulier pour le Cadmium, le Cuivre et le Plomb (Fig. 2). Par ailleurs, la comparaison des teneurs des différentes parties de la plante en métaux traces montre que c'est au niveau des feuilles de la *C. nodosa* que la concentration est la plus élevé en particulier pour le Cadmium, le Plomb et le Cuivre.

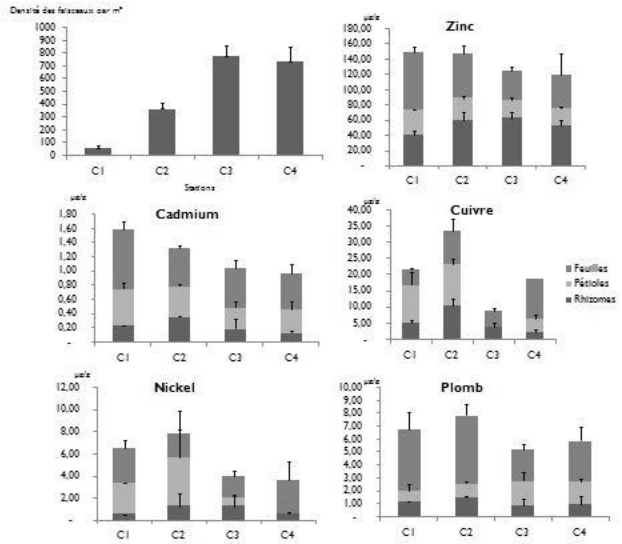

Fig. 2. Variation spatiale de la densité de *Cymodocea nodosa* et de la concentration en métaux traces dans les différentes parties de la plante

Discussion et Conclusion
Les métaux lourds analysés dans cette étude (Cd, Ni, Pb, Cu et Zn) ont été sélectionnés car ils représentent des métaux traces les plus communs dans les communautés côtières (Roberts et al., 2008). Tous ces métaux ont été détectés avec des concentrations plus ou moins importantes au niveau des échantillons de *C. nodosa* collectés dans les herbiers étudiés. Les concentrations trouvées sont comparables avec ceux enregistrées dans d'autres pays de la Méditerranée (Llagostera et al., 2011). Ces résultats préliminaires montrent que la *C. nodosa* peut être utilisé dans les études d'impact et le monitoring des aires portuaires touristiques. Pour une meilleure conservation de la plante, les feuilles peuvent être le seul tissu prélevé pour les analyses de métaux traces.

PERSISTENT ORGANIC POLLUTANTS (POPS) IN OPEN SEA SURFACE WATERS AND ATMOSPHERE ACROSS THE MEDITERRANEAN AND IN THE BLACK SEA

Javier Castro Jiménez [1]*, Berrojalbiz Naiara [1] and Jordi Dachs [1]
[1] IDAEA-CSIC Department of Environmental Chemistry - javier.castro-jimenez@idaea.csic.es

Abstract
The most complete and comprehensive assessment of base line atmospheric and water concentrations and derived atmospheric deposition fluxes of PCDD/Fs, PCBs, PAHs and OCPs across the Mediterranean Sea open waters and in the South-West Black Sea is presented in this work. The main findings from this extensive investigation based on samples collected during two West-East oceanographic cruises in the Mediterranean Sea will be presented. Key processes controlling the air-water exchange of the studied POPs, spatial variability and potential sources will be also discussed.

Keywords: Atmospheric input, Air-sea interactions, Open sea, Black Sea, Pollution

The Mediterranean and Black Seas are two semi-enclosed marine environments under an intense anthropogenic pressure, which have resulted into different degrees of chemical contamination of their waters as well as the overlying atmosphere, among other compartments. One of the many contaminant classes occurring in these two environments are organic chemicals, in particular persistent organic pollutants (POPs) and related compounds. In this work we present a synthesis of various investigations reporting on baseline atmospheric and water concentrations of polychlorinated dibenzo-p-dioxins and dibenzofurans (PCDD/Fs), polycyclic aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCBs) and selected organochorine pesticides (OCPs) in all Mediterranean Sea basins and in the South-West Black sea. Air-water exchange and atmospheric deposition of the studied POPs, their spatial variability across the Mediterranean as well as potential sources will be also discussed. The presented data set was produced from the analysis of a large number of atmospheric (gas and aerosol phases) and water (dissolved and particulate phases) samples collected across the Mediterranean Sea and in the SW Black Sea during two sampling cruises undertaken on June 2006 and May 2007. In both campaigns, Barcelona was the initial and final port, with Istanbul and Alexandria being the intermediate stops, respectively (Figure 1). Air samples were taken by using high volume samplers. Particulate phase collection was performed by quartz fiber filter (QFFs) whereas gas phase trapping was achieved by polyurethane foams (PUFs). Seawater was pumped on board and low/high sampling systems were used achieving the retention of the particulate water phase by glass fiber filters (GFFs) or QFFs and the dissolved water phase by XAD columns. [1-5]. One of the main findings was that the Mediterranean Sea open waters may act both as sink or source for most of the studied contaminants, depending on the regions and the specific chemical. The total atmospheric loading of organic contaminants (PAHs + OCPs + PCBs + PCDD/Fs) to open Mediterranean sea waters is estimated to varied from 2100 to 4360 tons each year.

ATMOSPHERIC LEVELS OF ORGANOPHOSPHATE ESTER (OPE) FLAME RETARDANTS ACROSS THE OPEN MEDITERRANEAN AND IN THE BLACK SEA

Javier Castro Jiménez [1]*, Berrojalbiz Naiara [1] and Jordi Dachs [1]
[1] IDAEA-CSIC Department of Environmental Chemistry - javier.castro-jimenez@idaea.csic.es

Abstract
First measurements of organophosphate esters (OPE) flame retardants in the atmospheric aerosol over the Mediterranean open waters and in the South-West Black Sea are presented in this work. sum5OPE atmospheric concentrations across the open Mediterranean Sea ranged from 60 to 700 pg m-3, whereas levels in the atmosphere over the SW Black sea varied from 150 to 400 pg m^{-3}.

Keywords: Air-sea interactions, Atmospheric input, Open sea, Black Sea

Organophosphate esters (OPEs) are a group of organophosphorus flame retardants which are currently used in many industrial applications as substitutes of polybrominated diphenylethers(PBDEs) due to their recent ban [1]. Recent investigations pointed to the global occurrence of OPEs in the atmosphere of marine environments, even in remote regions of the world [2]. However, no data have been reported on the presence of OPEs over the open Mediterranean Sea and in the Black Sea to date. This work fills this gap providing with the first data on atmospheric levels of OPEs in these two semi-enclosed marine environments. Atmospheric aerosols across the Mediterranean Sea and in the SW Black Sea were collected during two sampling cruises performed on June 2006 and May 2007 on board of the oceanographic vessel R/V García del Cid (CSIC). In both campaigns, Barcelona was the initial and final port, with Istanbul and Alexandria being the intermediate stops, respectively. The samples were analyzed for tris-(dichloroisopropyl)phosphate (TDCP), triphenyl phosphate (TPhP), 2-ethylhexyl diphenyl phosphate (EHDPP), tris(2-ethylhexyl)phosphate (TEHP) and trycresyl phosphate (TCrP). sum5OPE atmospheric concentrations across the open Mediterranean Sea ranged from 60 to 700 pg m^{-3}, whereas levels in the atmosphere over the SW Black sea varied from 150 to 400 pg m^{-3}. This levels are comparable with measurements undertaken in the atmosphere over the North Sea waters in 2010 (sum8OPE ranging from 110 to 1400 pgm^{-3})[3]. Atmospheric dry deposition fluxes are under calculation and will allow to estimate the main atmospheric loading pathway of OPE to Mediterranean and Black sea waters.

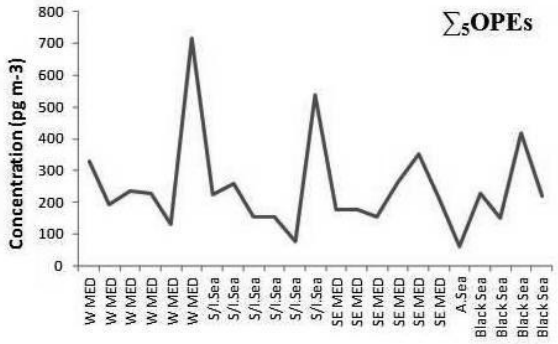

Fig. 1. Spatial variability of OPEs across the studied marine basins

The highest ∑OPE level was found in a sample collected in the Western Mediterranean, while the lowest in a sample collected in the Aegean Sea. ∑OPE atmospheric concentrations showed a high within-basin spatial variability.

FLUORESCENT DISSOLVED ORGANIC MATTER IN COASTAL WATERS FROM THE NORTH-WESTERN MEDITERRANEAN SEA UNDER THE INFLUENCE OF RHÔNE RIVER INPUTS

Nicolas Ferretto [1]*, Marc Tedetti [2], Stéphane Mounier [2] and Madeleine Goutx [1]
[1] MIO - nicolas.ferretto@univ-amu.fr
[2] PROTEE

Abstract
The characteristics of FDOM from waters sampled in the Rhone River and at different distance from the river mouth in Marseille Bay were contrasted. In the Rhone River, the terrigenous material was the most abundant with elevated protein-like material contribution. In marine waters, the biological activity significantly contributed to the FDOM pool. The Rhone River impacted sporadically the coastal water with an increase of humic-like material in FDOM. This signature was coupled to an increase of protein-like material due to the biological activity when simultaneous nutrient input occurred.

Keywords: Coastal waters, Estuaries, Geochemistry, River input, North-Western Mediterranean

The Rhone River is the major source of freshwater and terrigenous material to the Mediterranean Sea (*1, 2*). Generally, the plume of the Rhone River moves toward the west due to the North Current, but under particular meteorological conditions, it may reach the Bay of Marseilles (*3*). The objective of this work is to characterize and to assess the seasonal variation of fluorescent DOM (FDOM) in the Rhone River and in marine coastal waters potentially under the influence of freshwater inputs. Three stations were sampled bi-monthly from February 2011 to January 2012: one in the Rhone River and two stations in the Bay of Marseilles (Fig.1). Two PARAFAC analyses were performed, one on the Rhone water and another on the marine water dataset. In freshwaters, the PARAFAC analysis validated a model at three components, two humics and one protein. In marine water, a model at three components including one humic and two proteins was validated. In the Rhône River, humic-like material dominated, while protein-like fluorophores were the most abundant in the marine waters. These fluorophores displayed a seasonal pattern. The humic-like fluorophores in the Rhone River were more abundant in winter. This would be due to the higher inputs of terrigenous material from higher plants and soil to the river in relation to rain events. The tryptophan followed an opposite pattern with higher concentrations during the summer compared to the winter that most probably related to the phytoplankton activity (*4*).In marine waters, both humic-like and protein-like materials exhibited the highest concentration values during the summer and weaker values during the winter due both to the plankton activity (*4*) and to the freshening events that occurred mostly during the warmest seasons. The influence of Rhône River in marine waters was evidenced by the decrease in salinity and changes in the marine FDOM composition. At Couronne, the Rhone plume intrusion increased the humic acids proportion whereas the nutrient-rich intrusions increased the amount of proteins. At Sofcom, the plume effect on FDOM composition was limited because of its location in the south Bay,far from the Rhone river mouth.

Abstract

Recent nutrient budgets for the Eastern Mediterranean Sea (EMS) indicate a significant role of Mediterranean aerosols as a net supplier of macro- and micro- nutrients to the Low Nutrient Low Chlorophyll EMS. A mesocosm experimental study was performed in Crete during May 2012 examining the overall response of the oligotrophic EMS (Cretan Sea) to two different types of aerosol additions, "pure" Saharan dust (1.6 mg/L) and mixed (polluted and desert origin) aerosols (1 mg/L). Generally, the additions triggered an increase in several of the performed rate (primary production, bacterial production, phosphate turnover time, N_2-fixation) and state measurements, showing relatively larger impacts by the mixed aerosols.

Keywords: Air-sea interactions, Cretan Sea, Aerosols, Atmospheric input, North-Eastern Mediterranean

Significant quantities of leachable nutrients from dry atmospheric inputs become potentially bioavailable and may influence bacterial production and abundance, primary production rates, chlorophyll *a* (or other phytopigments), diversity of pico and nanophytoplankton communities, and may also affect diazotrophs and nitrogen (N_2) fixation rates [1 ,2]. To date, these influences were assessed by on-board, dust enrichment, microcosm experiments, while no previous mesocosm experiment has been performed in the EMS. A mesocosm experiment in the Western Mediterranean examined the addition (~0.8 mg/L) of a dust analog (treated Saharan soil) to surface seawater (Corsica, www.obs-vlfr.fr/LOV/DUNE). Here we present preliminary results of a mesocosm experimental study performed in Crete in May 2012 examining the overall response of the oligotrophic EMS (Cretan Sea), during a transitional spring season, to two different types of aerosol additions, "pure" Saharan dust (1.6 mg/L) and mixed aerosol (1 mg/L) containing a natural mixture of desert dust and polluted aerosols. The second treatment represents an aerosol with more leachable nutrients and metals, and somewhat higher N/P ratios. The two treatments, run in triplicates (3 m^3 each), were compared to control runs. Preliminary measurements show an average addition of approximately 2-3 and 65-75 nM dissolved inorganic phosphorous (DIP) and dissolved inorganic nitrogen (DIN), respectively, representing 30% of the ambient concentrations. Converting the estimated nutrient addition to potential carbon production (or chlorophyll *a* increase) reveals values similar to the observed changes. The additions triggered an increase in several of the performed rate and state (Table 1). Considering similar aerosol/dust particle concentrations, larger biological impacts were observed in the polluted aerosols treatment (Figure 1).

ACCURACY OF ANNUAL AND MONTHLY LUMPED WATER BALANCE MODELS FOR THE ASSESSMENT OF RIVER DISCHARGE IN THE MEDITERRANEAN AND BLACK SEAS DRAINAGE BASINS

Wolfgang Ludwig [1] and Olivier Montreuil [1]*
[1] CEFREM, UPVD-CNRS - olivier.montreuil@univ-perp.fr

Abstract
Accuracy of 16 annual and monthly water balance models (WBM) for modelling annual river discharge were assessed on an extended discharge series data set for Mediterranean and Black Sea rivers. Results indicate a better accuracy of some monthly models to reproduce inter-annual mean, variability and trends. Using gauged discharge filled with monthly WBM and extrapolating to the whole drainage basins, freshwater discharge to the Mediterranean Sea (excluding the Nile) significantly decreased in 1960-2009 (-22%, $p<0.05$), while decrease was not significant for the Black Sea.

Keywords: North-Western Mediterranean, Hydrology, Black Sea, South-Eastern Mediterranean, River input

Materials and Methods: A previous data set of discharge series [1] in Mediterranean and Black Sea rivers was extended through data mining from national and international water agencies. This new data set includes 467 monthly or annual series within the 1960-2009 period for downstream stations and sub-catchments greater than 1000 km². If possible, gaps in time series were completed using linear regression with neighboring stations ($r^2 > 0.80$). The corresponding rainfall and potential evapotranspiration time series were extracted from the CRU TS 3.10 climatologies. For water discharge modeling, we tested the accuracy of 16 monthly and annual WBM: 3 free-parameter annual WBM, 6 one-parameter annual WBM and 8 monthly multiparameters WBM. Parameters were calibrated by maximizing an objective function (Favg) which is the average of Nash-Sutcliffe model efficiency coefficient (NS), the NS of logarithmically transformed flow, the Pearson correlation coefficient and the bias score. The magnitude of discharge trends was estimated using the slope of the Kendall-Theil robust line. We used the Kolmogorov-Smirnov test (KS) to compare the equality of observed and modeled trend distributions. The Pearson correlation coefficient and the mean absolute error were used to test the similarity of trend patterns. For extrapolation of the water budgets to the entire 1960–2009 period, we combined observed and modeled discharge values in order to fill the data gaps in the observed time series. We extrapolated to the whole drainage basins using ratio between discharge modeled with free-parameter annual WBM in and outside gauged catchments.

Results: For the Mediterranean Sea drainage basin, the mean coverage of the whole basin by gauged catchments is only about 20% (excluding the Nile). Taking account spatial variation in precipitation depth, this coverage increases to 36% for total precipitation. Using the 3 free-parameter annual WBM, gauged discharge account for about 50% of the total freshwater discharge. For the Black Sea, the mean coverage by gauged catchments is better and reaches 73% of the whole drainage area, 77% of total rainfall and 85% of the total freshwater discharge. Model calibration of WBM for discharge series >10 years allow to increase the spatial coverage with 26% for the Mediterranean Sea and 81% for the Black Sea. This coverage represents 43% of precipitation and about 55% of freshwater discharge for the Mediterranean Sea and, respectively, 84% and 91% for the Black Sea. WBM performances are highly dependent on the model type. The lowest Favg scores are observed for the three free-parameter WBM, with only 1 to 7% of the discharge series having Favg > 0.60. For one-parameter WBM, these percentages increase to 13-20%. The WBM performing best are multi-parameters monthly models. Here, Favg > 0.6 could be reached for 51 to 54% of the discharge series with the models GR2M [2], ABCD [3] and ZH3 [4]. Using observed discharge series filled with these three monthly WBMs and extrapolating discharge to the whole Mediterranean (excluding the Nile) and Black Sea drainage basins, we computed an interannual mean of freshwater discharge of 365-367 $km^3.yr^{-1}$ and 351-355 $km^3.yr^{-1}$ for the 1960-2009 period. Correlations between observed and modeled absolute trends are significant ($p < 0.05$) for all WBM. Best Pearson correlation coefficient reaches 0.75 for two monthly WBM: ZH3 and GR2M. Lowest mean absolute error was about 1.4 $mm.yr^{-1}$ for 3 monthly WBM: GR2M, ZH3 and ABCD. The hypothesis of the KS test for similar distributions was rejected for all WBM. All WBM slightly overestimate the occurrence of weak negative trends (74-87% for modeled discharge and 60% for observed discharge) but underestimate occurrence of strongest negative trends. Looking the cumulative trends at downstream gauging stations, observed and modeled value for the Mediterranean Sea are very closed with respectively -38 km^3 and -34 to -36 km^3 for GR2M, ABCD and ZH3. For the Black Sea, the cumulative trends is <-1 km^3 for observed discharge but between -34 and -36 km^3 for this three models. This difference is mostly explained by the difference between observed and modeled trend for the Donau. Using gauged discharge filled with monthly WBM and extrapolated to whole drainage basin, a 22-23% decrease in river discharge was calculated for the Mediterranean drainage basin ($p<0.05$, excluding the Nile) while no significant trend was detected for the Black Sea drainage basin.

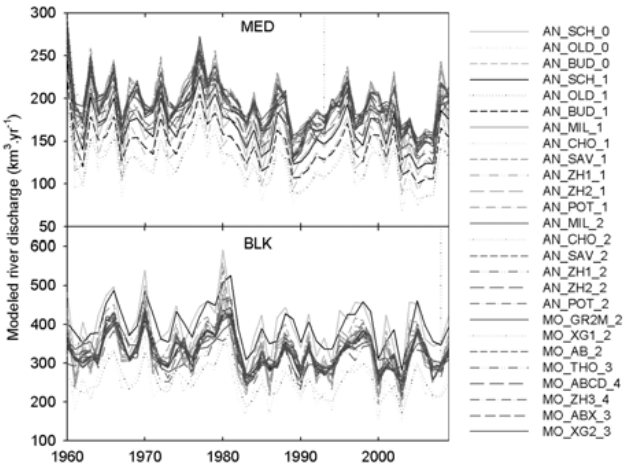

Fig. 1. Modeled annual river water discharge from 1960 to 2009 for 26% and 81% of the whole Mediterranean (MED) and Black Sea (BLK) drainage basins. AN: Annual water balance, MO: Monthly water balance. The last number specifies the count of calibrated parameters.

DISSOLVED ORGANIC MATTER DYNAMICS IN THE GULF OF NAPLES DURING SUMMER 2012

A. Paluselli [1]*, E. Zambianchi [2], M. Gonnelli [1], S. Vestri [1] and C. Santinelli [1]
[1] CNR- Istituto di Biofisica, Pisa, Italy - andrea.paluselli@hotmail.it
[2] DiSAm, Università "Parthenope" & CoNISMa, Napoli, Italy

Abstract
The data collected in the Gulf of Naples in summer 2012 indicates that dissolved organic matter distribution is strongly affected by the complex pattern of circulation typical of the Gulf. Interestingly, freely dissolved extracellular enzymatic activity showed different values of Vmax depending on DOC concentrations. Mineralization experiment indicated a 10 µM DOC removal in two months in the stations characterized by the highest DOC concentrations. These data suggest that the surface water masses circulating in gulf of Naples show different biogeochemical properties.

Keywords: Gulf of Napoli, Organic matter, Enzymes, Coastal waters, Coastal processes

The Gulf of Naples is a semi-enclosed bay, strongly affected by anthropogenic pressures. It is characterized by a marked spatial and temporal variability in hydrodynamic processes, that make it a natural laboratory to investigate the interaction between physical and biogeochemical processes [1].
The main goal of this study is the biogeochemical characterization of different water masses in the Gulf of Naples during summer 2012. Surface distribution of dissolved organic carbon (DOC) and chromophoric dissolved organic matter (CDOM) were combined with the information coming from mineralization experiments and determination of freely dissolved microbial extracellular enzymatic activity (leucine aminopeptidase and β-glucosidase), in order to gain information about the biogeochemical properties of this area.
DOC and CDOM data were collected in 64 stations during July/August 2012 during the GELaTo (Gulfofnaples Eulerian/LAgrangian TOsca) 2012 experiment, carried out in the framework of the MED TOSCA project. Mineralization experiments and microbial extracellular enzymatic activity measurements were carried out in 7 stations, representative of the different water masses circulating in the Gulf.
DOC showed a surface distribution consistent with the occurrence of different water masses as indicated by salinity and temperature distributions (Fig. 1). The lowest DOC concentration (50-60 µM) was observed in the southern side of Bocca Grande, in the water mass incoming from the Tyrrhenian Sea and characterized by the highest salinity. Surprisingly the highest DOC values (85-90 µM) were not found in proximity to the Sarno river mouth, but in front of Naples city and in the northeastern part of the Gulf. High DOC values (75-80 µM) were also found in the northern side of Bocca Grande in correspondence with the salinity minimum. In the southern part of the Gulf, near the coast and in front of the Sarno river, DOC showed concentrations of 70-75 µM (Fig. 1).
Information on CDOM pool were obtained through absorption spectra and fluorescence excitation-emission matrix (EEMs) associated with parallel factorial (PARAFAC) analysis. Four fluorophore groups were identified and their emission/excitation spectra suggested the occurrence of protein-like, humic-like, fulvic-like compounds and of a fourth group with spectral properties similar to phenols. The distributions of CDOM was consistent with the temperature and salinity distributions, suggesting the occurrence of different fluorophores and/or different CDOM concentrations in the different water masses. In particular, the incoming water from the Tyrrhenian Sea was characterized by very low values of absorption and fluorescence, while the highest values were found close to the coast, in front of the Sarno river mouth and the Naples city, especially for humic and fulvic-like. This pattern is clearly due to terrestrial input.
Extracellular enzymatic activities can give indirect information about the substrates that are readily transformed and metabolized. Vmax of β-glucosidase (0.72-2.87 nM h-1) and leucine aminopeptidase (1.15-5 nM h^{-1}) were in agreement with the total enzymatic activity reported for the Mediterranean Sea [2], but surprisingly they showed a contrasting pattern. Vmax of β-glucosidase was maximum in the southern part of the Gulf in correspondence with the lowest DOC values and it progressively decreased until a minimum in front of Naples, where the highest DOC concentration were observed. In contrast, the Vmax of leucine aminopeptidase showed the highest value in front of Naples.
Mineralization experiments suggested the occurrence of variable concentrations of labile DOC. In the samples collected in the northern stations (characterized by high DOC concentrations), 10 µM of DOC were removed in two months, while in the stations with DOC concentrations of 65 µM 2-4 µM were removed during the same period.

These data suggest that the surface water masses circulating in Gulf of Naples show different biogeochemical properties (DOC, CDOM, enzimatic activity, mineralization experiments) and that CDOM is a very good tracers of fresh water.

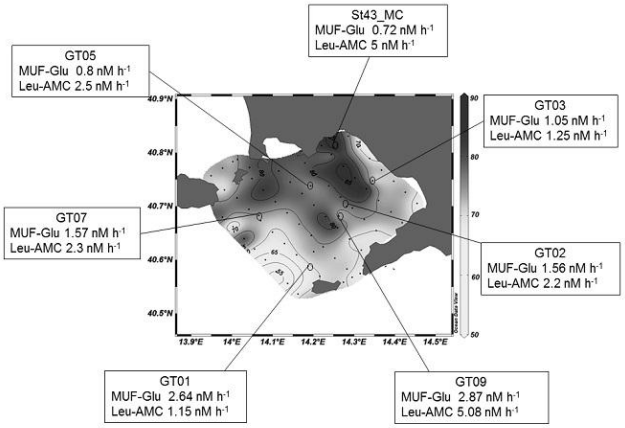

Fig. 1. Surface distribution of DOC in the Gulf of Naples. The Vmax of leucine aminopeptidase and β-glucosidase is reported for the seven stations investigated.

DISSOLVED ORGANIC MATTER DYNAMICS IN A COSTAL AREA OF THE TYRRHENIAN SEA STRONGLY IMPACTED BY RIVER INPUTS

Simona Retelletti Brogi [1]*, Margherita Gonnelli [1], Rosario Lavezza [1] and Chiara Santinelli [1]
[1] Biophysics Institute, CNR, Pisa - simona.rb86@gmail.com

Abstract
This study report the first Dissolved Organic Carbon (DOC) and Cromoforic Dissolved Organic Matter (CDOM) data for a large coastal area of the southern Tyrrhenian Sea strongly impacted by river inputs. The input of both DOC and CDOM is well visible at the mouth of all rivers and it is correlated to the river discharge. CDOM optical properties show the occurrence of humic-like, fulvic-like and protein-like fluorophores in the riverine plumes. This work was supported by the Italian Project RITMARE.

Keywords: Geochemical cycles, Coastal processes, Bacteria, Tyrrhenian Sea, Organic matter

Dissolved organic matter (DOM) is the main reservoir of reactive carbon on the Earth and represents the main source of energy for heterotrophic prokaryotes. The fraction that absorbs light (UV and visible) is defined chromophoric DOM (CDOM) and affects the penetration and diffusion of the UV and visible light in the water, in particular in the costal environment. In coastal areas, riverine DOM undergoes to different physical-chemical (dilution, photodegradation, flocculation [1]) and biological (consumption and transformation by microbes [2]) processes.

The main goal of this work is to study DOM dynamics in a large coastal area of the Tyrrhenian Sea (from the Gulf of Salerno to the Tevere river) strongly impacted by river inputs, with particular regards to the physical and biological processes affecting riverine DOM at the river mouth.

More than 600 samples were collected for DOC analysis in October-November 2010. CTD data were kindly provided by CNR-ISAC. Information about CDOM pool were obtained on 260 selected samples, through absorption spectra and fluorescence Excitation Emission Matrix (EEM) combined with parallel factorial analysis (PARAFAC). EEM showed the occurrence of 4 different components with spectral characteristics similar to proteins, humic and fulvic acids [3].

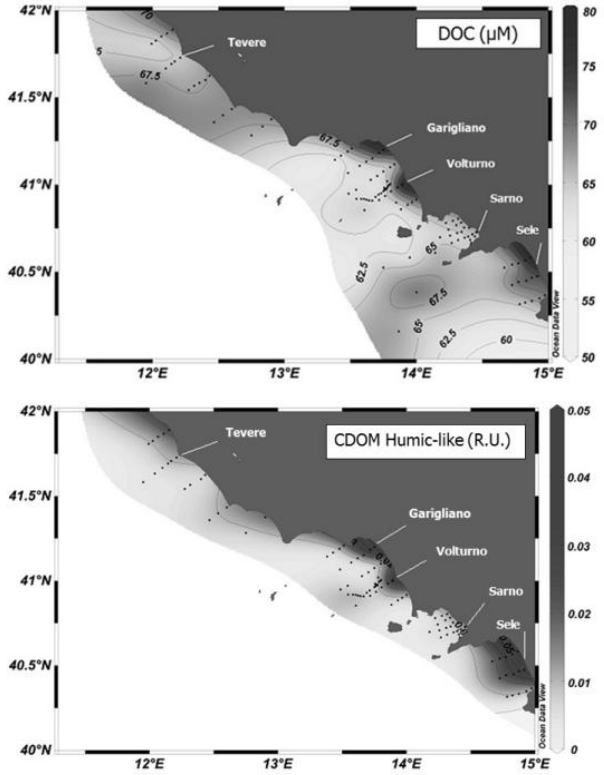

Fig. 1. Surface map of DOC and humic-like component of CDOM, individuated by EEM combined with parallel factorial analysis (PARAFAC).

The input of DOM was well visible at the mouth of all the rivers and was correlated to river discharge. DOC (73-89 µM) and CDOM (both humic and protein-like component) showed their maximum in the river plume (salinity minimum) and decreasing values going far from the coast (Fig. 1). The four groups of fluorophores showed a similar distribution confirming that rivers are an important source of CDOM in coastal areas.

The good linear correlation between DOC and salinity allowed a rough estimate of the DOC concentration in the rivers. This estimate indicates that the carbon input due to these rivers is about 50.000 ton C yr^{-1}, and represents the 21% of the whole riverine carbon input in the Western Mediterranean Sea [4, 5, 6].

In the samples collected in the riverine plume, microbial mineralization experiment showed a 6-7 µM DOC decreases in 2 months, suggesting removal rates of 3 µM $month^{-1}$. A decreasing gradient in DOC removal rate was observed going from the costal to the open sea. CDOM, in particular the fulvic-like component, showed an increase in all the mineralized samples. This suggests that microbes can be a source of CDOM in both coastal areas and open sea water, in agreement with previous studies [7].

Our data indicates that: (1) DOC and CDOM distribution are clearly affected by river input; (2) minor rivers are important in the western Mediterranean Sea carbon budget and (3) CDOM could be released by heterotrophic prokaryotes during mineralization.

This work stress the necessity of intensifying the studies in coastal areas impacted by river inputs and improving experiments with estuary microbial communities to better understand the role of heterotrophic prokaryotes in DOM transformation.

Abstract
In this study the speciation, the sources and the biogeochemical significance of soluble atmospheric P and N over the North-Western Mediterranean is investigated. Our results show that the annual average atmospheric deposition of TDN and DIN are estimated at 62.9 and 51.9 mmol m^{-2} y^{-1} respectively, while the average percentage contribution of DON to TDN was 25%. The annual average atmospheric deposition of DIP was calculated to 0.6 mmol m^{-2} y^{-1}, while the average TDP was 2.9 mmol m^{-2} y^{-1}.

Keywords: Atmospheric input, North-Western Mediterranean, Nutrients

The Mediterranean Sea (MS) has any of the most oligotrophic surface waters in the world, but displays a great heterogeneity, especially in the Western Basin [1]. The average annual productivity in the Mediterranean Sea is typical of oligotrophic waters, ranging from 80–90 g C m^{-2} y^{-1} estimated by the classical methods [2] to 130-140 g C m^{-2} y^{-1} given by satellite images [1]. Previous studies have shown that atmospheric inputs are an important source of nutrients (N and P) to the MS [3,4], even in productive zones such as the NW Mediterranean [5]. Atmospheric dissolved inorganic nitrogen (DIN) input to the Western Mediterranean is of the same order of magnitude as riverine input [6]. During the last decades, special attention has been drawn to the inorganic forms of nitrogen and phosphorus and particularly to the inorganic forms of nitrogen (NO_3^- & NH_4^+).
This study aims to investigate the sources, forms and the biogeochemical significance of soluble atmospheric P & N over the North Western Mediterranean Sea. Bulk deposition samples (n=84) have been collected at Cape Bear (Perpignan, France) during a seven year period (2005-2011)and analyzed for P and N speciation. The dissolved inorganic nitrogen (DIN) was measured by ionic chromatography. The dissolved organic nitrogen (DON) was determined by subtracting DIN from the total dissolved nitrogen (TDN), measured as NO_3^- after persulfate oxidation. Details about the methodology can be found elsewhere [7]. Total dissolved phosphorus (TDP) was measured on the acidified samples following by persulfate digestion method. Dissolved organically bound phosphates (DOP) were determined by subtracting TDIP from TDP. Details about the analytical protocol can be found elsewhere [8]. Our results show that the annual average TDN and DIN atmospheric deposition fluxes are 62.9 and 51.9 mmol m^{-2} y^{-1}, respectively, while the average percentage contribution of DON to TDN is 18%. The dominance of inorganic nitrogen species in Total nitrogen pool N is presented in Fig.1.

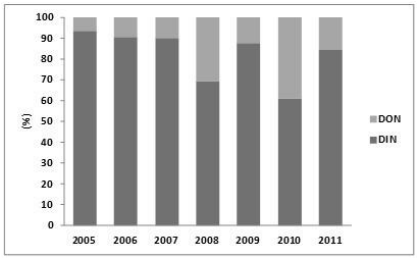

Fig. 1. The percentage contribution of nitrogen species to TN during the years 2005-2011.

The annual average atmospheric deposition of DIP is 0.6 mmol m^{-2} y^{-1}, while the average TDP is 2.9 mmol m^{-2} y^{-1}. The average DIN/DIP ratio in atmospheric deposition samples is calculated at 86, which is in agreement with previous study (Markaki et al., 2010). Almost equal contribution of organic and inorganic forms of total phosphorus has been observed as depicted in Fig.2.

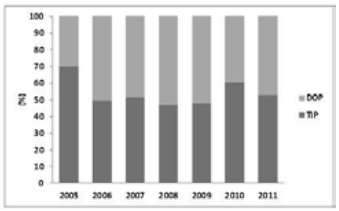

Fig. 2. The percentage contribution of phosphorus species to TDP during the years 2005-2011.

A source apportionment analysis is performed from the chemical speciation for the major ions. The results will be presented and the factors controlling the P & N concentration levels in deposition samples over the North Western Mediterranean will be thoroughly examined.

THE WINTER NUTRIENT PROFILE OF OXIC/ANOXIC INTERFACE LAYER IN THE SOUTHEASTERN BLACK SEA WATER COLUMN

Ali Alkan [1]*, Dilek Fidan [2] and Serkan Serdar [2]
[1] Karadeniz Technical University Maçka Vocational School - alialkan@gmail.com
[2] Central Fisheries Research Institute

Abstract
Water column winter nutrient profiles were evaluated of 250 m especially oxic/anoxic interface layer in Southeastern Black Sea. Although nutrient concentrations according to the depth are difference, density profiles are similar. Silicate concentrations were increased depending on depth while maximum phosphate concentration observed with the boundary of the 16,2 density. Ammonium concentrations increased depending on depth below 16.2 density layer. Minimum temperature of the CIL were measured at 100 meter depth of TY, OM and OF statiton while were measured at 75 meter of AA and SB stations. Nitrite maximas were usually observed bottom boundary of oxic layer except for AA station. Nitrate maximas were showed differences on stations according to depth and concentration. Chlorophyll-a maxima, usually at a depth of 30 m and 13.8 sigma-t.

Keywords: Nutrients, Black Sea, Anoxic basin, Redox, Oxygen

Introduction
The Black Sea is the world's largest anoxic water body and H2S gas available below oxic layer which is initial depth depending on the region [1-4]. The Black Sea, due to their characteristic hydrochemical structure, is used as a natural laboratory for studies of actual processes in oxic / anoxic intermediate layer. Winter mixing leads to formation of a cold intermediate layer oxygen-enriched at a depth of approximately 60-100m[3]. Also the Black Sea is serious threat of climate change and intensive anthropogenic pollutants. Various changes were observed in the natural ecosystem of the Black Sea as a results of changes in the composition of nutrients (increase in nitrate, decrease in Si), entry of alien species (mneiopsis, beroa), due to international shipping etc. For this reason, temporal variation of the processes that occur in the Black Sea's the chemical system and the redox boundary is actual and important issues [3]. This study was conducted at least affected areas from two factors are important for the Black Sea hydrodynamic.

Material Method
This study was carried out in February of 2012 in selected 5 stations to represent the Southeastern Black Sea. Stations were 10 nautical miles from the shore (Fig1).

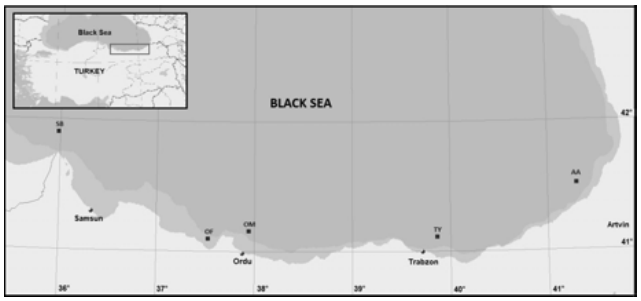

Fig. 1. Map of sampling area

Physicochemical parameters (Temperature, salinity, conductivity, pH, DO, ORP, chlorophyl-a, transmission) of the water column were measured with Sea Bird SBE 25 CTD profiler.Sampling was made at intervals of 5 meters in oxic/anoxic interface layer. DO were measured by winkler method and H2S was measured by titration. Nutrient analyses made with the Seal CFA.

Results and Discussion
SST were measured 8,61-9,69°C at stations. Minimum temperatures were different depths of the cold intermediate layers at the stations and the lowest temperature was measured as 7,23°C in the CIL. Average nutrient concentrations were determined for nitrate, nitrite, phosphate and silicate as 0.48 µM, 0.07 µM, 0.02 µM, 4.16 µM and 0.11 µM, respectively in the first 50-meter oxic layer. Maximum nutrient concentrations were measured for nitrate as 5,54 µM, for nitrite as 0,25 µM, for phosphate as 6,87 µM, for silicate as 161 µM and for ammonium as 22 µM in the water columns. Si concentrations increased depending on depth and phosphate maximas were observed at 16.2 density layer. It was found that hydrogene sulphide starting depth was under 150 meter. Average H2S was determined as 0.18±0.09 mg/L at 175 m, 0.60±0.06 mg/L at 200 m, 0.92±0.18 mg/L at 225 m and 1.52±0.05 mg/L at 250 m. Dissolved oxygen values started to decrease rapidly after 50 meters and drops close to zero at 160-200 meter depth related to stations in this study. It was found that ORP values were started to decrease rapidly after 150-160 m depths all stations. Maximum chl-a concentrations were differ from each stations and chl-a maximas were found about 30 m depth at all stations. Except OM station, nitrite maxima usually was determined at 15.6 sigma-t density layer (Fig 2)

Abstract

The role of phytoplanktonic DOM release is poorly understood. In the framework of a CNR-CNRS cooperation project, strictly linked to MERMEX, we studied the release of extracellular dissolved organic matter (DOM) by viable phytoplankton in a culture of *E. huxleyi* during four months. DOM was mainly released after 41 days even if the highest increase in both DOC and CDOM was observed after 4 months. The fluorescence increased with CDOM content but its relative composition remained constant along the experiment. The DOM release by *E. huxleyi* can be mineralized with high mineralization rates by *heterotrophic bacteria iso*lated from Mediterranean coastal seawater

Keywords: Geochemistry, North-Western Mediterranean, Diatoms

Results Phytoplankton plays a key role in DOM production and release in oceanic water, since it is the most important group capable of producing organic molecules starting from CO_2 and inorganic nutrients. Primary production sets an upper limit to DOM production. It is not clear what is the most important mechanism of DOM release through the food web, however phytoplankton seems to be the main producer of labile DOM, that is the DOM that can be used by heterotrophic prokaryotes on a temporal scale of hours-days. Literature data show that the amount and molecular characteristics of organic molecules released by phytoplankton depends on the specie, growth phase as well as the health of the population [1]. Here we report the results of a 5 month experiment focused on the study of dissolved organic matter released by a 2 liter culture of a non-axenic strain of *E. huxleyi* (Strain CS 57 from CISRO culture collection) . Dissolved organic carbon (DOC), absorption spectra and fluorescence excitation emission matrix (EEM) of CDOM as well as phytoplankton cells (measured by flow cytometry) were measured during time course experiment. This algae is an interesting model since it is cosmopolitan and a major contributor to primary production in the open oceans. The results (Fig. 1) showed an exponential growth of *E. huxleyi* in the first 8 days, while DOC concentration showed just small variations, with a slight increase (30 µM) at day 8. In the following 8 days E. Huxley declined and DOC was characterized by a second pick of 284 µM at day 14s, when the number of cells was at its lowest (at the end of the decline phase). Surprisingly, after the decline, the population started to growth again and entered in stationary phase in which DOC showed a 133 µM increase until the 41 day. EEM showed the occurrence of three groups of fluorophores with characteristics similar to proteins (λex = 280 nm, λem= 350 nm), Fulvic (λex=310 nm, λem=435) and humic (λex=270, 360, λem=480 nm) acid. Surprisingly, after 4 months all the parameters showed an impressive increase. We found that the number of *E. huxleyi* cells was 3-times higher than after 41 days, whereas DOC concentration reached 1031 µM and both absorption and fluorescence increased 3.5 times in the same period.

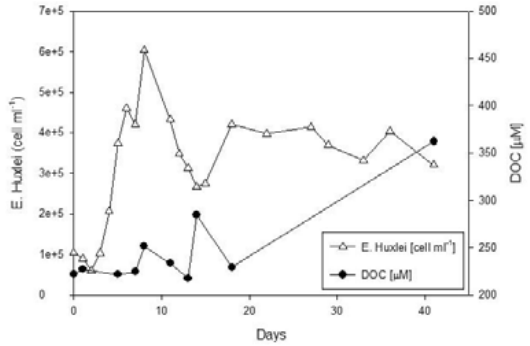

Fig. 1. Cell abundance (by flow cytometry) and DOC content during the growth of *E. huxlei*.

Such dynamic was not observed in previous studies because the experiments were generally stopped after 15-22 days [1, 2]. In order to test the lability of DOM released during the various stages of cell growth, the exudates collected after 14 days (285 µM DOC) and 4 months (1030 µM DOC) were inoculated with coastal seawater from Pisa (filtered at 0.8 µM) and DOC was measured monthly for the following three months, in order to study its removal rates. This second experiment showed an exponential decrease of DOC concentrations with the total removal of 22 and 117 µM in the exudates collected after 15 days and 4 months, respectively indicating the DOM released by *E. huxleyi* is labile and its removal rates are markedly higher for the molecules released in the old culture (4 month), when the highest DOC concentration were observed.

Abstract
Few studies dealing with geochemical properties of the sediment have been done in the abyssal plain. This work aims at assessing the role of physico-chemical conditions and diagenetic processes on trace metals enrichment, and especially on anthropogenic inputs. It is based on samples taken during the CASCADE campaign in the Gulf of Lion (March 2011).

Keywords: Trace elements, Organic matter, Deep sea sediments, Gulf of Lyon, North-Western Mediterranean

Most studies on the geochemical properties of the sedimentation in the western Mediterranean Sea have been performed in slope and margin environments of the Gulf of Lion ([1], [2], [3]). On the contrary few have been done in the abyssal plain ([4], [5]) where sedimentation rates have been modeled and where enrichment of contaminants has been evidenced ([6]).

Geochemical characterization of the deep deposits is of importance in the global study of benthic processes and their modifications through anthropogenic inputs. Discrimination between natural and anthropogenic origins is rather complicated here due to diagenetic transformations that happen in deep sediment and that can cause misinterpretation in trace metals accumulations.

The aim of this work is to assess the role of physico-chemical conditions during the sedimentation and early diagenesis processes in the control of trace metal accumulation in deep environments of the Gulf of Lion.
During the CASCADE cruise (1-31 March 2011) sediment cores were collected using a multi-tube corer at three stations located between 1957 and 2657m in the northwestern mediterranean basin (Fig.1).

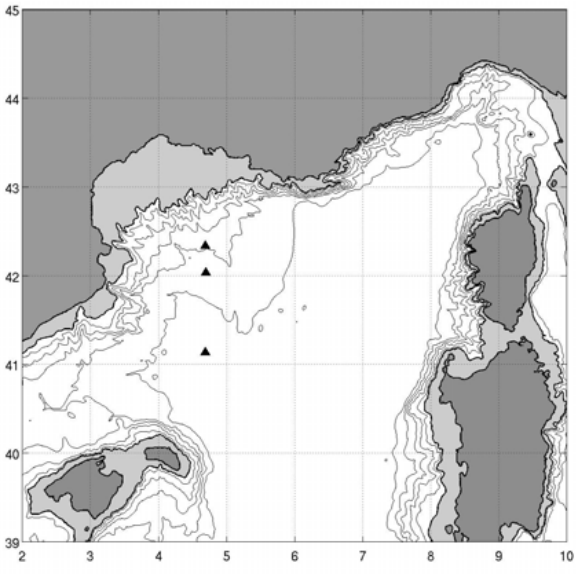

Fig. 1. Location of CASCADE sediment core sampling in the Gulf of Lion

Physico-chemical conditions such as redox potential, pH, porosity and grain-size distribution were considered in order to evaluate changes in relation with environmental and hydrodynamic factors. The first indication for diagenetic processes is given by the thickness of the oxidised mud layer. We find that in these deep-sea deposits the redox discontinuity is located below 25 cm depth. Oxidised layers are hence important and correspond to low sedimentation rates, i.e. a long residence time at the sediment-water interface (SWI). This is supported by the vertical distribution of Mn in the cores which follows a positive gradient from the deepest layers to the surface.
Porosity profiles in sediment cores show a regularly decreasing trend. Grain-size distribution allows to define the sedimentological facies and is hence an important parameter in the interpretation of geochemical data.
The role of carbonates and organic matter is especially important with respect to the enrichment and complexation of metallic elements in sediment. Organic carbon (OC), total nitrogen (TN), C/N ratios, have been measured in order to determine the organic matter origin, abundance and distribution with burial depth. Trace metal concentrations are of the same order of magnitude in each core, with a mean of 42 µg/g of Ni, 33 µg/g of Cu, 76 µg/g of Zn and 26 µg/g of Pb.
The south core (M01) is a classic example where values (OC, trace metals concentrations) are high at the top of the core and then decrease with depth. Nevertheless this core exhibits the highest concentrations of Cu, Zn and Ni (with 230, 160 and 106 µg/g respectively) in a single peak at 2 cm depth.
The north core (M08) shows high values of OC and C/N at 6 cm depth, which is likely the signature of a terrestrial imprint. Trace metals, and Mn concentrations in particular indicate the burial of a redox front at 15cm depth which implies a late turbidite deposition.
The central core (SC2400) shows a classic profile except for a peak in OC at 3cm depth that is characterized by high concentrations of trace metals (Mn, Ni, Cu, Zn).

All these results allow us to draw a first cartography of this abyssal environment in terms of sedimentological properties.

AN UPDATED SILICA BUDGET FOR THE EASTERN MEDITERRANEAN

Michael Krom [1]*, Kent Fanning [2] and Nurit Kress [3]
[1] Charney School of Marine Haifa University - M.D.Krom@leeds.ac.uk
[2] College of Marine Science, University of South Florida
[3] Israel Oceanographic & Limnological Research, National Institute of Oceanography

Abstract
An updated silica budget for the Eastern Mediterranean Sea (EMS) including both silicate and particulate biogenic silica (BSi) showed a net outflow of 27 x 10^9 molesSi/yr. This deficit suggests that the terms in the budget are still as not well defined. The major term in the budget is the exchange at the Straits of Sicily with 137 x 10^9 molesSi/yr flowing into the EMS and 258 x 10^9 molesSi/yr flowing out. Other important terms are the riverine input (34 x 10^9 molesSi/yr) and diagenetic supply of silicate from underlying sediment (54 x 10^9 molesSi/yr). Dust is a minor input (5 x 10^9 molesSi/yr). New focused measurements needed to close the budget should include improved riverine flux, better measurements of diagenetic weathering of clays in the water column and sediment, sediment burial flux and coastal recycling processes.

Keywords: Nutrients, South-Eastern Mediterranean

Nutrient budgets have been used extensively to understand biogeochemical cycling processes in the Eastern Mediterranean[1-2].The most recent silica budget for the EMS [3] found that the net flux of silica out of the basin was far higher (157-250 x 10^9 molesSi/yr) than the best estimates available for the inputs from rivers and other sources. Here we present an improved updated budget that takes into account fluxes of biogenic silica (BSi) which is likely to dissolve in the highly unsaturated waters of the EMS. The silicate flux through the Straits of Sicily was calculated using water flow rates determined in 1997 [4] . Measured silicate from the MTPII-MATER database was used. Crombet et al., [5] found 0.25 µmoles/l of BSi concentration in the upper (inflowing) water column with no BSi in the outflowing water in July 2009 when primary productivity was at a minimum. Here we assumed that dissolved silicate measured in November surface waters (mean value = 3 µmoles/l) was representative of the winter bloom conditions (6 months) and will be taken up as BSi and that total average BSi concentration of 1 µmoles/l during summer stratified conditions The calculated flux of silicate from diagenetic processes in the sediment was 54 x 10^9 MolesSi/yr [6]. We assume that this silicate is all formed from in-situ clay diagenesis since there is no evidence of dissolution of BSi derived silica in the uppermost layers[7]. The estimated average riverine flux between 1963 and 1998 was 23 x 10^9 molesSi/yr [8] but they underestimate the global flux of silica to the ocean because it does not include BSi [9]. We therefore used the global average of 50% for BSi to modify our riverine flux. Finally we determined the atmospheric flux as 5.2 x 10^9 molesSi/yr.

Tab 1 : of calculated fluxes of silicate and BSi into and out of the EMS

Input to the Eastern Mediterranean	**Flux (10^9 Mol/yr)**	**Comment**
Straits of Sicily – dissolved silicate	121	<100m in summer & <200m in winter [4]
Straits of Sicily – BSi	16	See text above for BSi concentrations converted to flux using Astraldi et al., [4] water flow rates.
Riverine input – dissolved silicate	23	Ludwig et al., [8]
Riverine input – BSi	11.5	Assumed value from Conley [9]
Sediment pore water flux	54	Jones [6] assumed to be all fluxing Si is diagenetic based on [7]
Atmospheric input – BSi	5.2	Krom unpublished data
Total input	**203.7**	
Output from the eastern Mediterranean		
Straits of Sicily – dissolved silicate	258	>100m in summer & >200m in winter.[4]
Sediment burial flux	0	Assumes all BSi dissolves
Net export flux	**-27.3**	

With the inclusion of BSi in this budget and maximising all possible external inflow terms, the net deficit of silica, 27.3 x 10^9 MolesSi/yr is much reduced compared to previous estimates of 157-250 MolesSi/yr. We conclude that dissolution of external biogenic silica and diagenetic clay weathering is an important source of silicate to the basin. Another potentially important process not included in this budget is silica cycling processes in coastal areas. To further improve the budget it is necessary to better quantify the annual BSi in the surface inflowing waters at the Straits of Sicily and contribution from rivers and from the sediments both offshore and in coastal regions. SEDIMENTARY POLYCYCLIC AROMATIC HYDROCARBONS IN THE EASTERN MEDITERRANEAN SEA (IONIAN, AEGEAN AND LEVANTINE BASINS):OCCURENCE, SOURCES AND TRANSPORT PATHWAYS

Constantine Parinos [1]*, Alexandra Gogou [1], Ioanna Bouloubassi [2] and Ioannis Hatzianestis [1]
[1] HCMR, Institute of Oceanography, Anavyssos, Attiki, Greece - ksparinos@hcmr.gr
[2] LOCEAN-IPSL, CNRS Université P. et M. Curie, Paris, France

Abstract
Polycyclic aromatic hydrocarbons (PAHs) were investigated in surficial sediments collected from 46 stations in the open Eastern Mediterranean Sea (Aegean, Ionian and NW Levantine basins), in order to assess their distribution, sources and transport pathways. Total PAH concentrations were generally low ranging from 8.76 to 184 ng g^{-1}. Their molecular profiles reveal contributions from both pyrolytic and petrogenic sources, with their relative importance displaying significant regional variability. PAH concentrations are significantly correlated with the total organic carbon (TOC) content of sediments, which indicates that the latter exerts an important control on their transport and ultimate accumulation in sediments. Strong sub-basin variability of water masses also impact the regional patterns of sedimentary PAH accumulation.

Keywords: Pah, Sediments, Pollution, North-Eastern Mediterranean

Polycyclic aromatic hydrocarbons (PAHs) are widespread components in marine systems in which they enter through both atmospheric and aquatic pathways. Therein association with sinking particles is considered as the major mechanism of their downward transport through the water column and subsequent accumulation in sediments. Mostly originating from various anthropogenic activities, PAHs are included in lists of priority pollutants (EU-EEA, US-EPA) since certain homologues are highly carcinogenic/mutagenic to both aquatic and sediment dueling organisms. The Eastern Mediterranean Sea (EMS) is a region under intense anthropogenic pressure resulting in pollutant discharges [1]. Although PAH burden of surficial sediments in the EMS has been thoroughly studied in coastal sites, much less attention has been given to open sea and deep basin settings [2, 3].

In this study, surficial sediments from the open EMS including Aegean, Ionian and NW Levantine basins were analyzed for fourteen PAH compounds (parent and alkyl substituted), in order to assess their distribution, major sources and transport pathways. Samples were collected from 46 stations during various oceanographic cruises between 1998-2012 and PAHs were analyzed by GC-MS [2, 3].

Total PAH concentrations (Figure 1) were generally low ranging from 8.76 to 184 ng g^{-1} comparable to those reported in relatively unpolluted open sea and coastal marine areas. Within the Aegean Sea, higher concentrations were recorded in the northern part (max. 184 ng g^{-1}, aver. 91.1 ng g^{-1}) which likely reflects anthropogenic inputs from major rivers outflowing in the area. The lower concentrations recorded in South Aegean Sea (max. 147 ng g^{-1}, aver. 49.9 ng g^{-1}) are related to the absence of fluvial inputs and the oligotrophic character of the area, which results in lower accumulation of sedimentary organic matter and associated pollutants. In the deep basins of the Ionian Sea and NW Levantine Sea, PAH concentrations averaged 50.4 ng g^{-1} showing an increasing westward trend with maximum concentrations (153 ng g^{-1})found in the central Ionian Sea. TOC contents presented a similar spatial trend.

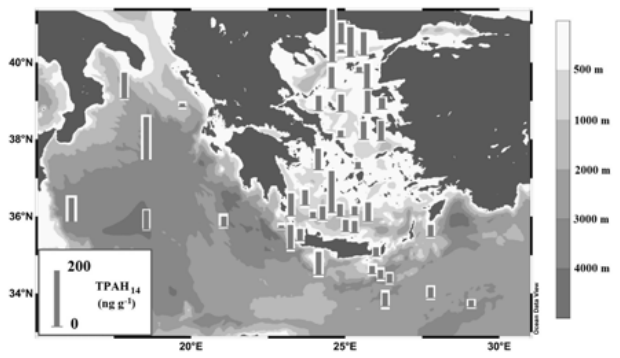

Fig. 1. Concentrations of sedimentary PAHs across the open Eastern Mediterranean Sea

The molecular profile of low- and high- MW PAHs reflects an admixture of both unburned fossil sources and combustion/pyrolysis of fossil fuels. The composition of PAH mixtures displayed significant variability which reflects regional differences in the relative importance of sources. PAH concentrations correlated significantly with the TOC content of sediments, indicating that organic carbon exerts an important control on their transport, fate and ultimate accumulation in the study area, while strong sub-basin variability of water masses also impact their regional characteristics. Our results imply a transport of more soluble, light petrogenic PAHs from the central Aegean Sea towards the EMS through the western Cretan-Antikythera straits canyons, the latter acting as a sink of organic carbon and associated PAHs.

Abstract
Un suivi multiparamétrique de 8 mois sur une station côtière (golfe du Lion, Méditerranée Nord occidentale) permet de décrire la variabilité saisonnière de la matière organique dissoute colorée (CDOM) et de préciser son origine et son devenir. Au cours du cycle saisonnier, la concentration de la CDOM permet de montrer l'importance dominante des apports continentaux par rapport à la production autochtone de matière, même lors du développement d'efflorescences phytoplanctoniques et de montrer l'importance relative de l'exportation vis à vis des consommations par le compartiment bactérien.

Keywords: Organic matter, Gulf of Lyon, North-Western Mediterranean, Nutrients, Phytoplankton

La matière organique dissoute colorée (CDOM) joue un rôle clé dans la régulation de la pénétration de la lumière dans l'océan, en absorbant les ondes électromagnétiques à forte énergie du spectre (visible et rayonnement ultraviolet). D'un côté, cela protège les organismes aquatiques d'une photo-dégradation potentielle, mais d'un autre côté, cette énergie n'est plus disponible pour la photosynthèse (1, 2). Outre des apports continentaux, les principales sources de CDOM en milieu marin sont différents processus physiques et biologiques tels que le photo-blanchiment, la photo-humification, ou la bio-génération, qui agissent autant comme des puits que comme des sources de CDOM. L'objectif de la présenteétude est d'apporter **des informations quant à l'origine et à la dynamique de la CDOM** dans les écosystèmes marins côtiers méditerranéens. La CDOM est dosée par fluorescence de l'échantillon d'eau de mer filtré sur 0.2µm et quantifiée à l'aide d'une gamme d'étalonnage de quinine. L'interprétation est faite en utilisant les valeurs de couples émission/excitation (EM/EX) caractéristiques: 370/460 et 370/450 caractérisent deux types de substances humiques d'origine terrestre et 370/500 caractérise plutôt des substances d'origine marine (3). Cela permet d'avoir des informations sur la composition et l'origine de la CDOM sur la base de fluorophores dominants.

La zone d'étude (station "SOLA" 42°29'300 N – 03°08'700 E) est caractérisée par un cycle saisonnier bien marqué avec le développement d'un bloom phytoplanctonique printanier (avril) qui consomme rapidement les sels nutritifs introduits au cours de l'hiver. Au cours du suivi, les températures sont minimales à la fin de l'hiver (11°C) puis augmentent pour atteindre un maximum (23 °C) en début septembre (Figure 1a). La salinité (proche de 38) est marquée par des épisodes de légère dessalure (mai, juillet août et octobre) traduisant l'influence d'apports continentaux pendant les périodes de précipitations intenses et/ou de crues des rivières locales ou du Rhône. Les concentrations en sels nutritifs sont variables, avec des valeurs minimales en été (limite de détection des méthodes classiques) qui atteignent respectivement 1.06 µM et 0.06 µM en nitrate et en phosphate (Figure 1b). La diminution des sels nutritifs est concomitante à l'apparition d'un bloom printanier prononcé (1.8 µgCHL.L^{-1}; Figure 1c).

Les variations saisonnières et à méso échelles décrites précédemment, sont également bien observées dans le compartiment organique dissous. Les concentrations en carbone organique dissous (DOC) sont marquées par 2 maxima, l'un en fin de printemps en relation avec la fin du bloom printanier et l'autre en fin d'été, suite à l'accumulation de DOC dans les couches superficielles comme déjà discutées pour l'azote (4). Ce processus d'accumulation est accentué par les apports continentaux et par les processus de photo-dégradation.

Au cours du suivi, quelque soit le couple EM/EX considéré, les concentrations en CDOM sont faibles en hiver (<0.2 QSU en février et septembre) et maximales au printemps (<1.4 QSU en avril) au moment des maxima mesurés DOC (Figure 1d). La valeur maximale (1.8 QSU) est mesurée pour le couple 370/500 en mai, c'est-à-dire après le bloom printanier lorsque les nutriments sont faibles et la colonne d'eau stable et stratifiée. Un second maximum en CDOM (1.4 QSU) est mesuré en novembre, de nouveau après le pic de chlorophylle, mais sans augmentation significative du DOC cette fois-ci. D'une façon générale la station SOLA en surface est plutôt influencée par des substances humiques d'origine terrestre. Cela indique notamment le rôle important et dominants des sources continentales allochtones en zone côtière quelques soit le débit des fleuves. Seules 8 (3/03 ; 10/05 ; 25/06 ; 02/07 ; 16/07 ; 29/08 ; 03/09 ; et 22/10) des 23 dates échantillonnées sont caractérisées par une CDOM d'origine plutôt marine, démontrant qu'à l'échelle annuelle, la MOD autochtone est rapidement exportée soit vers la profondeur soit vers les zones plus au large (rôle de source de matière des zones côtières).

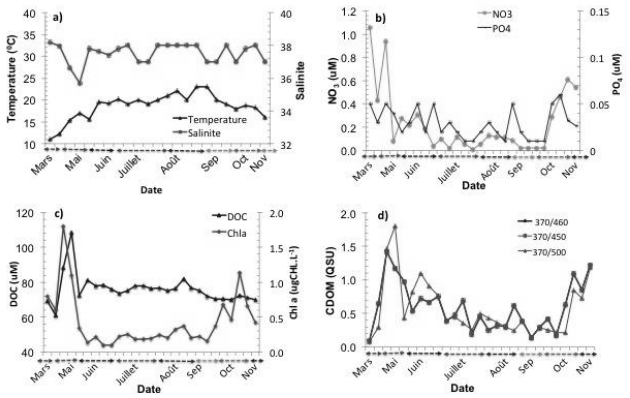

Fig. 1. Suivi à la station SOLA de a) Salinité et Température (°C) et des concentrations en b) nitrate (NO_3) et phosphate (PO_4) en µM, c) en chlorophylle *a* (Chla en µgCHL.L^{-1}) et en carbone organique dissous (DOC, µM), et d) en CDOM (QSU) selon les 3 couples EM/EX (307/460, 370/450 et 370/500).

BENTHIC NUTRIENT FLUXES IN CENTRAL AND SOUTHERN ADRIATIC AND IONIAN SEAS

Abstract
Pore waters were collected and benthic fluxes were calculated at the sediment water interface in 7 stations in Adriatic and Ionian sea to asses the importance of different hydrodynamic and morphological features on early diagenetic processes. Benthic fluxes reflect regional differences due to different quality and quantity of organic matter inputs.

Keywords: Geochemical cycles, Ionian Sea

Establishing the magnitude of benthic fluxes is important for understanding geochemical budgets and for determining the role of early diagenetic processes in sediments. It is known that the burial of organic carbon (OC) in marine sediments is one of the major long-term sinks of reduced carbon on Earth ([1]; [2]) and the long-term sink of particulate OC in marine sediments contribute to moderate atmospheric CO_2 levels on geological time scales [3]. For this reason several efforts have been made to understand early diagenetic zonation and evaluate the associated benthic fluxes. The objectives of the present study are to document the features controlling the early diagenetic processes in areas of different sedimentation in the central Mediterranean Sea (Adriatic and Ionian seas) and to quantify the related reaction rates and fluxes. The study has been carried out in 7 stations characterized by different bathymetry, hydrological setting and trophic conditions. Northern stations, located in the central and southern Adriatic depressions, are characterized by shallow depths, higher sedimentation rates and higher organic matter inputs. Southern stations, located in the Northern and Central Ionian Sea, are characterized by increasing depths, different provenances of terrigenous sediments, lower productivity, lower sedimentation rates and organic matter inputs. In each stations sediment cores were collected to extract pore waters and to calculate diffusive benthic fluxes. Benthic diffusive fluxes highlighted regional differences between the Adriatic and Ionian basins reflecting the early diagenesis processes recorded in the Adriatic and Ionian pore water profiles. Higher inputs of reactive organic matter promote a northern-southern and shallow-deep trend in Adriatic sediments. These sediments are characterized by lowering of remineralization processes in accord with bathymetry, dissolved oxygen fluxes (Fig. 1) into the sediments and Dissolved inorganic Carbon (DIC) fluxes outside the sediments (Fig. 2). Ammonium and nitrate fluxes are complicated by the nitrification/denitrification processes occurring in the oxic zone. In the Ionian basin the remineralization processes takes place mainly by means of oxic reactions-the depth of oxygen penetration is higherthen a lower oxygen uptake and intense NH_4 production occur (Fig. 1, 2), the denitrification processes reach greater depths and produce lower organic matter degradation product. This means that the inputs of reactive organic matter in this area are lower for the lower productivity of this basin, for the greater water column depth and for the higher distance from fluvial inputs. However, an inverse DIC flux occur, Adriatic sediments are a net source of DIC while Ionian sediments show negative fluxes (sink of DIC) suggesting a possible precipitation of carbonate.

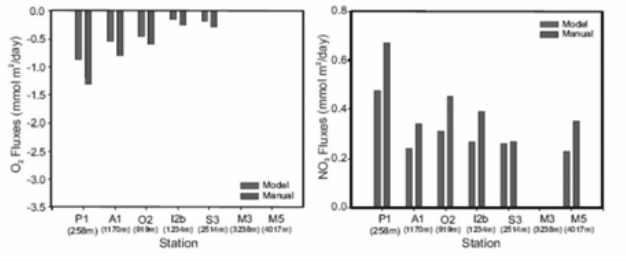

Fig. 1. Oxygen and nitrate fluxes at sediment water interface calculated by Fick's law (black line) and by model (grey line).

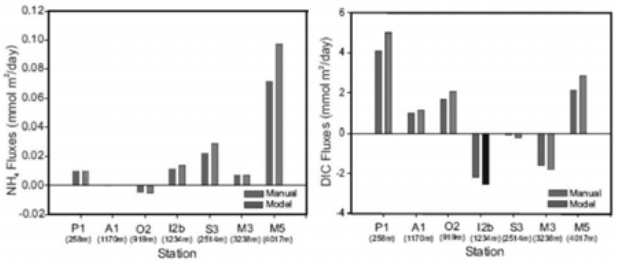

Fig. 2. Ammonium and DIC fluxes at sediment water interface calculated by Fick's law (black line) and by model (gray line).

Abstract

The deep outer margin Gulf of Lions and the adjacent deep basin, in the western Mediterranean Sea, are regularly impacted by open-ocean convection, a major hydrodynamic process responsible for the ventilation of the deep waters. The impact of open-ocean convection on the flux and transport of particulate matter remains uncertain. We present results of 5 mooring lines deployed in the deepest part of the continental margin and the deep basin between September 2007 and April 2009. Our results on temperature, salinity, currents, and near-bottom fluxes suggest that the winter 2008-09 open-ocean deep convection event resulted in significant remobilization of bottom sediment with a subsequent alteration of the seabed likely impacting the functioning of the deep-sea ecosystem.

Keywords: Particle flux, Deep sea sediments, Water convection, Organic matter, North-Western Mediterranean

Introduction

Albeit the deep-sea is the largest ecosystem on Earth, not much is known about how it is affected by changes in environmental conditions controlling the cycling of biogeochemical compounds, the distribution of deep-sea habitats or the functioning of ecosystems. Dense water convection represents, among physical processes influencing circulation in the deep-sea, one of the few linking the surface ocean to the deep ocean and, ultimately, to the seabed. The Gulf of Lions and the adjacent basin, in the western Mediterranean Sea, are regularly impacted by open-ocean deep convection responsible for the ventilation of the deep water in the western Mediterranean Basin. However, the impact of open-ocean convection on the flux and transport of particulate matter remains poorly understood.

Material and method

The variability of water mass properties (i.e., temperature and salinity), currents, and particle fluxes were monitored between September 2007 and April 2009 at five instrumented mooring lines deployed between 2050 and 2350-m depth in the deepest continental margin and adjacent basin of the Gulf of Lions. Four of the lines followed a NW–SE transect, while the fifth one was located on a sediment wave field to the west.

Results

The results of the main, central line SC2350 ("LION") located at 42°02.50 N, 4°410E, at 2350-m depth, show that open-ocean convection reached midwater depth (≈ 1000-m depth) during winter 2007–2008, and reached the seabed (≈ 2350-m depth) during winter 2008–2009. Horizontal currents were unusually strong with speeds up to 39cm.s^{-1} during winter 2008–2009. The measurements at all 5 different locations indicate that mid-depth and near-bottom currents and particle fluxes gave relatively consistent values of similar magnitude across the study area except during winter 2008–2009, when near-bottom fluxes abruptly increased by one to two orders of magnitude. Particulate organic carbon contents, which generally vary between 3 and 5 %, were abnormally low (≤1 %) during winter 2008–2009 and approached those observed in surface sediments (≈ 0.6 %). Turbidity profiles made in the region demonstrated the existence of a bottom nepheloid layer, several hundred meters thick, and related to the resuspension of bottom sediments.

Conclusions

The major outcomes of this study are:

1. Particle fluxes at the different sites between 2050 and 2350-m depth present temporal variations in the 101–104 mg.m^{-2}.d $^{-1}$ range. Near-bottom TMF and POC content show coherent temporal variations with a clear signal of late winter–early spring maxima. The interannual variability was largely dominated by large fluxes in February–March 2009, which relates to deep OOC. This variability confirms similar patterns previously reported in the Gulf of Lions and in the Ligurian Sea for winters with deep OOC. The discrepancy between the fluxes at mid-depth and near the bottom, and the low POC content close to that of the sediment, observed for the highest fluxes in winter 2008–2009 highlight the role of sediment resuspension by strong currents taking place during the deep OOC.
2. Near-bottom fluxes are believed to vary according to the deep-water formation intensity from (1) moderate TMF (< 1000 mg.m^{-2}.d $^{-1}$) from a dominant biological source resulting from the surface production export during the winters of shallow OOC; (2) large TMF (up to 10 000 mg.m^{-2}.d $^{-1}$) from a dominant sedimentary source due to the remobilization of surface sediment of the deep basin during winters with deep OOC and shallow DSWC; and (3) extreme TMF (> 10 000 mg.m^{-2}.d $^{-1}$) from a dominant sedimentary source due to the remobilization of surface sediments from the shelf and slope and mainly from the deep basin during winters with deep OOC and deep DSWC.
3. The observations suggest that the recurrence of deep OOC in the area has a long-term effect on seabed morphology (i.e., by prevention of particle sedimentation) and thus should be considered as a major driving force for deep sedimentary dynamics.
4. Open-ocean deep convection has to be considered, together with dense shelf water cascading, as a major driving force for benthic ecosystems as it occasionally fuels them with labile POC from the surface layer and/or disrupts the benthic habitats by reworking superficial sediment. A better understanding of the composition of the particulate flux (i.e., biogenic and lithogenic contents), and its associated elements (including contaminants) generated by deep OOC events is now required to better assess the impact of such events on benthic ecosystems.

These observations support the view that open-ocean deep convection events in the deep margin of the Gulf of Lions can cause significant remobilization of sediments in the deep outer margin and the basin, with a subsequent alteration of the seabed likely impacting the functioning of the deep-sea ecosystem.

PROKARYOTIC DEGRADATION OF NATURAL DISSOLVED ORGANIC MATTER IN THE DEEP-SEA WATERS OF NW MEDITERRANEAN SEA DURING CONTRASTED HYDROLOGICAL CONDITIONS

M. Boutrif [1], C. Panagiotopoulos [1], R. Sempéré [1], D. Repeta [2], M. Garel [1], B. Charriere [1], D. Nerini [1] and C. Tamburini [1]*

[2] Woods Hole Oceanographic Institution

Abstract
Dissolved organic carbon (DOC) is divided into three reservoirs of different reactivities (labile, semi-labile and non-reactive). The contribution of the semi-labile DOC to the global prokaryotic production has been assessed in very few previous studies. Interestingly enough some experiments show rapid utilization of semi-reactive DOC by prokaryotes, while other experiments show almost no utilization at all (1,2). However, all these studies did not take into account the role of hydrostatic pressure for the degradation of organic matter (3). In this study, we investigate the degradation of HMW-DOM incubated with deep-sea water samples (2000 m-depth, NW Mediterranean Sea) collected under *in situ* pressure conditions with their own prokaryotic assemblages during stratified water conditions (summer) and mixed water conditions (winter).

Keywords: Deep sea processes, Bacteria, Carbon, Geochemical cycles, Ligurian Sea

In the framework of MERMEX (Marine Ecosystems Response in the Mediterranean Experiment, Chantier MISTRALS), we attempt to better understand the role of prokaryotes into the degradation of dissolved organic matter in the deep-sea Mediterranean waters (4). Deep-sea water samples, recovered under *in situ* pressure conditions, were enriched with natural occurring organic matter [high molecular weight dissolved organic matter or HMW-DOM (corresponding to the organic matter > 1000 Da)], and incubated for 10 days under atmospheric (ATM) and *in situ* hydrostatic pressure (HP) conditions. Total organic carbon (TOC), dissolved sugars (DCHO), and bacterial abundance were monitored overtime. Using these parameters we estimated TOC and DCHO decay rates (k) as well as prokaryotic growth rates (μ). Our results indicated that during HP incubations TOC and DCHO exhibited the highest degradation rates ($k_{HP\ TOC}$ = 0.82 d^{-1}; $k_{HP\ DCHO}$ = 0.98 d^{-1}) compared to the ATM conditions were no degradation was observed ($k_{ATM\ TOC}$= 0.007 d^{-1}, $k_{ATM\ DCHO}$= 0.002 d^{-1}). Similarly prokaryotic growth rate was higher in HP than in ATM conditions (μ_{HP} = 0.47 d^{-1} *vs* μ_{ATM} = 0.39 d^{-1}). These results suggest that deep-sea prokaryotic communities are autochthonous to the deep-sea realm and therefore more adapted to degrade HMW-DOC under *in situ* hydrostatic pressure conditions. An opposite trend was observed for the HP incubations from mixed deep water masses (MWM). HP incubation measurements displayed the lowest TOC degradation and prokaryotic growth rates ($k_{HP\ TOC}$=0.031 d^{-1}; $k_{HP\ DCHO}$=0.35 d^{-1}; μ_{HP} = 0.25 d^{-1}) compared to the ATM conditions ($k_{ATM\ TOC}$=0.62 d^{-1}; ($k_{ATM\ DCHO}$=0.60 d^{-1}; μ_{ATM} = 0.46 d^{-1}). These results imply the presence of allochthonous prokaryotic cells in deep-sea samples after a winter water mass convection. Apparently, these prokaryotic communities are more adapted at atmospheric pressure conditions, pointing to a surface origin. This study demonstrates that remineralization rates of semi-labile DOC in deep NW Med. Sea are controlled by the prokaryotic communities, which are influenced by the hydrological conditions of the water column.

NUTRIENT EXHANGES BETWEEN THE MARMARA AND BLACK SEAS TROUGH THE BOSPORUS STRAIT

Suleyman Tugrul [1]*, Ahsen Yuksek [1], Husne Altiok [1] and Erdogan Okus [1]
[1] I.U. Institute of Marine Sciences and Management - tugrul@ims.metu.edu.tr

Abstract
Chemical datacollected systematically by the METU-IMS and IU-IMSM groups between 1987-2010 were compiled to assess temporal changes in the concentrations and fluxes of nutrients (DIN, PO4; TP) and total organic carbon (TOC) exchanged between the adjacent seas of Marmara and Black Sea via the two-layer flow regimes in the Bosporus. Chemicals exported by the Black Sea outflow (0-30 m depth) increased in winter due to changes in both the concentrations and volume fluxes; but no long term trend was seen in this period. The majority of the Black Sea input accumulates in the Marmara lower layer waters entering the Black Sea.

Keywords: Nutrients, Bosphorus Strait

The less saline Black Sea surface waters (S~17) polluted by the major rivers exports nutrients to the Sea of Marmara. The first estimates of the nutrient exchanges between these adjacent seas were carried out in the 1990's [1]. The study evaluates data sets collected seasonally/monthly by the two groups at the Bosporus exits since 1987. The Black Sea inflow is nearly two-fold the more saline Marmara waters (S~38) flowing into the Black Sea annually [1]; the surface N, P fluxes increase in winter-spring periods (Figüre 1). The Marmara lower layer waters flowing into the Black Sea are enriched in nitrate and phosphate concentrations (NO_3: 8-12 µM and PO_4: 0.7-1.2 µM phosphate; N/P: 8-10). No significant long-term trend has been seen in the exchange fluxes during the last two decades. However, the nitrate outflux (6.6 $x10^8$ moles/year) from the Black Sea was about 4- 6 times the summer and autumn outfluxes. Seasonal variations were less pronounced in the TN, (1.2$x10^9$ moles/year), TP (0.24 $x10^7$ mole/year) and TOC (~2.5$x10^{11}$ tons/year). Phosphate constituted about 30% of the Black Sea TP outflux whilst the nitrate outflux was about 10% of the TN export. However, the nutrient exports from the Marmara basin to the Black Sea have been introduced in the forms of nitrate and phosphate ions. Therefore, the Black Sea DIN and DIP exports to the Marmara are much less the inputs from the Marmara lower layer. The Black TOC outflux was about 5 times that of the Marmara export via the Bosporus underflow. However, the Marmara TP export the Black Sea slightly exceeded the TP input from Black Sea via the Bosphorus surface flow, indicating that the TN (biochemically labile) and TP export to the Marmara is nearly compensated by the Bosporus underflow in the forms of phosphate and nitrate with molar ratios of about 8-10.

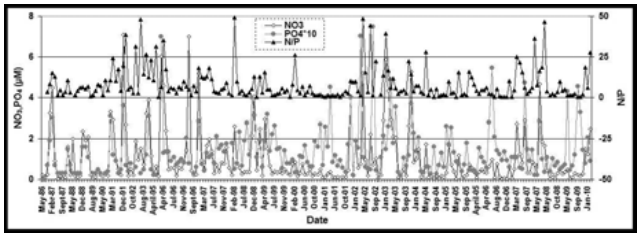

Fig. 1. Variations of nitrate, phosphate and N/P ratio in the Black Sea outflow between 1986-2010

THE ANTHROPOGENIC EUTROPHICATION OF THE BLACK SEA: QUANTITATIVE REGULARITIES AND MECHANISMS

Oleg Yunev [1]*
[1] Institute of Biology of the Southern Seas - yunev@mail.ru

Abstract
The work investigates the main aspects of the Black Sea eutrophication that have never been addressed before. Among the aspects addressed are: 1) the quantitative analysis of the eutrophication made on annual primary production which was calculated for the pre-eutrophication period (1960s) and the period of intensive eutrophication (late 1980s - early 1990s) for all regions; 2) eutrophication mechanisms in the shallow and deep parts of the sea; 3) the main effect of eutrophication on marine ecosystems, namely its impact on the redistribution of incoming organic matter in the pelagic food web.

Keywords: Eutrophication, Black Sea

Materials
This study is based on data mainly pooled from 2 databases created within the framework of the NATO TU Black Sea and MEDAR/MEDATLAS II Projects at the end of the 1990s and beginning of the 2000s [1, 2]. These databases include principal oceanographic data from almost all Black Sea riparian countries. The data are generally on a basin-wide scale and cover the period of most dramatic changes for the Black Sea ecosystem, starting from the "little impact" state in the 1960s [3, 4, 5, 6].

Results
The work shows that in the pre-eutrophication period (1960s) the annual primary production (APP), the factor which is commonly used to evaluate the rate of organic matter income into marine ecosystems, was below 65 g C m^{-2} yr^{-1} in most parts of the Black Sea including its deep regions. We are the first one to show that this low level of APP in the deep regions in that period were determined by the deep nitrates maximum localization and the presence of the highly-stratified zone of upper half of pycnocline which separates the nitrates from a photosynthetic layer and, thus prevents their penetration into a photosynthetic layer. It was shown that in the shelf regions affected by the Danube River nutrient loads, intensive eutrophication resulted in significantly increased levels of APP, up to 250-350 g C m^{-2} yr^{-1}, having reached the eutrophic level. The rest of the regions and the Black Sea on average became mesotrophic with APP of approximately 145 g C m^{-2} yr^{-1} in the late 1980s - early 1990s. It was also shown that the second half of the 1990s - early 2000s was characterized by oligotrophication of all regions of the Black Sea caused by the decreasing rate of input of organic matter into the ecosystem. Moreover, we are the first one to use the international oceanographic databases to comprehensively analyze the long-term changes in related to eutrophication hydrobiological, hydrochemical and hydrooptical parameters in the shallow and deep regions of the Black Sea [3, 4, 5, 6] and to demonstrate that in both regions the eutrophication developed in two phases (from the beginning of the 1970s to the mid of the 1980s and from the mid of the 1980s to the beginning of the 1990s), which differed from each other changes in functionally related eutrophication characteristics (Fig. 1).

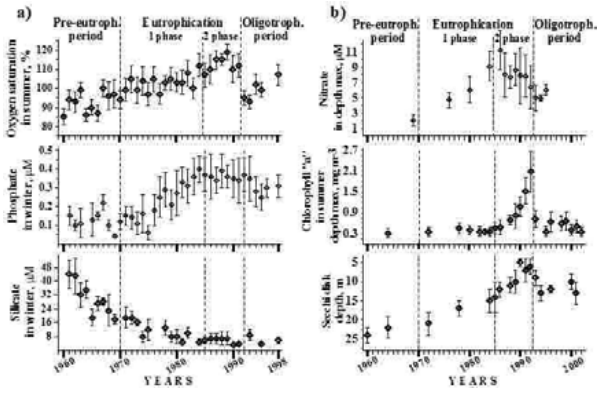

Fig. 1. Long-term changes of eutrophication characteristics in the surface layer of the shelf (a) and in the depth maxima in the open part (b) of the Black Sea.

We further analyzed the role of various natural and anthropogenic factors in the bi-phasic nature of eutrophication of the Black Sea. Finally, the work demonstrated that the eutrophication resulted in significant reduction in the efficiency of transformation of phytoplankton production in the food web in the pelagic zone and in the dominance of a jellyfish-headed trophic chain, that, despite of the high levels of primary production, determined the low energy level of the present Black Sea ecosystem.

Abstract
L'objectif de ce travail est d'évaluer la qualité du lac de Tunis en utilisant des biomarqueurs biochimiques chez la palourde *Ruditapes decussatus*. Les résultats ont montré une augmentation des activités benzo(a)pyrène hydroxylase et glutathion-S-transférase chez les palourdes collectés dans trois sites du lac. Cette augmentation est due à la présence de différentes sources de pollution aux alentours des sites d'étude.

Keywords: Bivalves, Lagoons, Monitoring, Gulf of Tunis

Introduction
Pour la surveillance de la qualité de l'environnement, deux approches biologiques complémentaires sont utilisées de nos jours : la première est basée sur les communautés ou populations. Il s'agit notamment des indices biocénotiques, qui de par la présence ou l'absence de telle ou telle espèce, nous renseignent sur l'état de santé d'un milieu, mais malheureusement à postériori. La seconde approche est plus prédictive sur l'état de santé du milieu, elle se situe au niveau de l'individu et concerne l'utilisation de biomarqueurs [1]. Cette étude a pour but d'utiliser et de suivre mensuellement deux biomarqueurs biochimiques pour évaluer la qualité d'un milieu lagunaire (lac de Tunis).

Matériel et méthodes
Les palourdes *Ruditapes decussatus* ont été récoltées chaque mois dans le lac de Tunis durant la période allant de Novembre 2008 jusqu'à Mai 2009 à partir de trois zones : Z1 (une zone recevant les effluents de plusieurs industries), Z2 (proche du canal de navigation) et Z3 (se localise au voisinage d'un port commerciale qui est le port de Radés). Les palourdes témoins sont des palourdes destinées à la consommation. Les glandes digestives de 18 palourdes/site ont été prélevées et récupérées en pools de trois individus. Dans ce travail on s'est intéressé à deux marqueurs biochimiques qui sont l'activité benzo(a)pyrène hydroxylase (BPH) qui est un biomarqueur de métabolisation des contaminants organiques de phase I et l'activité glutathion-S-transférase (GST), biomarqueur de métabolisation des xénobiotiques organiques de phase II. L'activité BPH a été mesurée selon la méthode fluorométrique décrite par de [2]. L'activité GST a été déterminée selon la méthode de [3].

Résultats et discussion

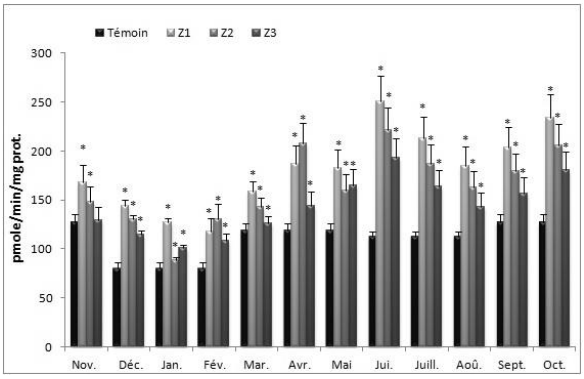

Fig. 1. Variation mensuelle de l'activité Benzo(a)pyrène hydroxylase chez la palourde *Ruditapes decussatus*

Les résultats de l'activité BPH sont présentés dans le fig. 1. L'analyse comparative entre les mois montre que l'activité BPH chez les palourdes provenant des trois sites (Z1, Z2 et Z3) est faible durant les mois de décembre, janvier et février par rapport aux autres mois. L'activité BPH la plus élevée a été enregistrée durant les mois de juin et octobre. On peut souligner que le système CYP chez les bivalves est sujet à des variations saisonnières importantes, ce qui ne facilite pas l'utilisation de ses composants en tant que biomarqueurs pour des études *in situ* [4]. L'analyse comparative entre les sites montre que l'activité BPH chez les palourdes collectées dans Z1, Z2 et Z3 est plus importante par rapport à celle des palourdes témoins. Ces résultats montrent que les sites d'étude choisis sont contaminés par les xénobiotiques. Les résultats de l'activité GST sont rapportés dans la figure 2. L'analyse de cette figure montre que l'activité glutathion-S transférase (GST) a subi une fluctuation temporelle. Comparés aux palourdes témoins les trois sites d'études présentent une activité GST élevée. Ces résultats plaident en faveur d'une contamination des sites d'étude.

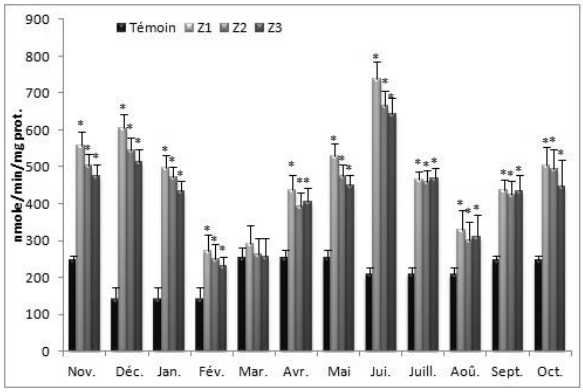

Fig. 2. Variation mensuelle de l'activité glutathion-S-transférase chez la palourde *Ruditapes decussatus*

Conclusion
Les biomarqueurs biochimiques utilisés dans ce travail ont montré la présence d'une contamination dans le lac de Tunis.

HISTORICAL TRACE METAL CONTAMINATION ASSESSMENT OF ORIKUM LAGOON, ALBANIA, BASED ON DATED RECENT SEDIMENTS RECORD

Michèle Forestier [1]*, Neil D Graham [1] and Jean-Luc Loizeau [1]
[1] Institut F.-A. Forel, Université de Genève - forestm7@etu.unige.ch

Abstract
In the present research we reconstructed the time evolution of the metal contamination of Orikum Lagoon on the Albanian coast of the Adriatic Sea. The lagoon is directly connected to the sea on one side and agricultural fields on the other. The lagoon is exposed to several potential contaminant sources. Two dated sedimentary cores allowed for assessing the contamination history of the lagoon in the last century. Metal contents increased by a factor 2 to 4 in the last fifty years, with concentrations of Cr and Ni that could impact the benthic biota.

Keywords: Geochemistry, Lagoons, Sediments, Trace elements, South Adriatic Sea

Sedimentary records are archives of the environmental evolution of a water body and of its watershed. They are especially valuable in region with poor knowledge of environmental contaminations. The present study focused on the Orikum lagoon, a small coastal water body with an area of approximately 1 km2 and a maximum depth of 2.5m (Peja et al. 1996). It is located on the southern end of the gulf of Vlorë on the Albanian Adriatic coast (figure 1). The lagoon is connected to the sea by an artificial channel on its northern margin, and is supplied with freshwater from the south. The lagoon has been potentially contaminated by several sources, including agricultural effluents, municipal and military wastes, or uncontrolled domestic dumping.

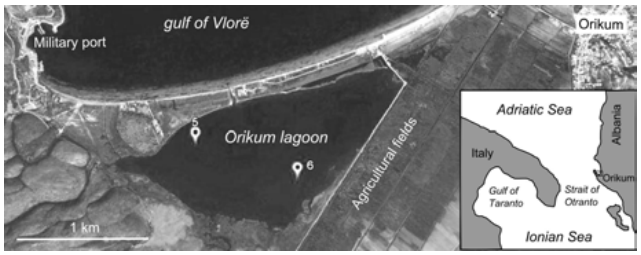

Fig. 1. Location of the sediment cores (#5 and #6) retrieved in the Orikum Lagoon (base image from Google Earth). Inset: situation of the lagoon on the Albanian Adriatic coast

To reconstruct the contamination history of the lagoon, two sediment cores were retrieved, one located on the northern side (#5, figure 1), in the deepest part of the lagoon, whereas the second was collected on the southern side (#6), closed to the freshwater inputs. Dating based on ^{137}Cs and ^{210}Pb methods showed that the sediment were deposited during the last century. Profiles of ^{137}Cs activity, sand, calcite, and metal contents, of the sediment core #6 are presented on figure 2.

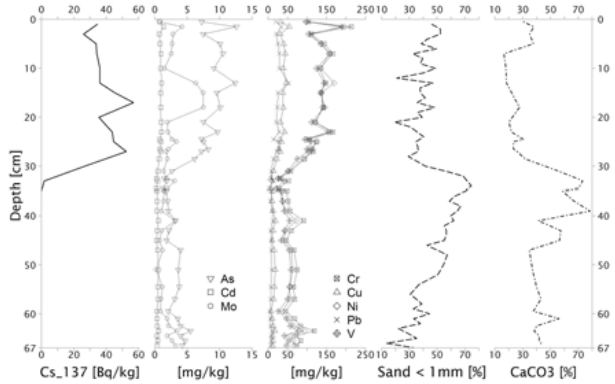

Fig. 2. Depth profiles of ^{137}Cs activity, selected metal concentrations, sand and calcium carbonate percentage in core #6.

The ^{137}Cs activity profile didn't show peaks that could be attributed to Chernobyl (1986) or atmospheric nuclear weapon tests (1964). However no activity has been recorded below 33 cm, indicating that the upper sediment section (0-33 cm) was deposited after the first atmospheric fallouts in 1954-1955, and the lower sediment section was deposited before this date. The profile of sand percentage correlated with the profile of carbonates, indicating that the main source of carbonate probably comes from shell fragments. ICP-MS analysis results showed that the metallic concentrations between 32 and 67 cm corresponded to natural background levels found in the continental crust (Wedephol, 1995), except for As and Cd that were 2 to 4 times more concentrated than natural levels. A significant increase in metal concentrations was observed after 30 cm depth. Concentrations of trace metals ranged in the intervals 1.2-12.6 mg/kg (As), 0.2-1.4 mg/kg (Cd), 27-213.2 mg/kg (Cr), 5.4-53.7 mg/kg (Cu), 1-4 mg/kg (Mo), 36.3-195.0 mg/kg (Ni), 3.1-33.6 mg/kg (Pb) and 20.9-188.7 mg/kg (V). Mean values in the upper section were 2 to 3 times (Cr, Cd and Ni) and 3 to 4 times (Cu, As, Pb and V) more concentrated than in the lower core section. These results showed clearly the beginning of the sediment contamination, corresponding to the mid of the 20th century. The maximum surface values of Cr et Ni (213.2 and 195.0 mg/kg) are above their respective values of Probable Effect Concentration (MacDonald et al, 2000) of 111 mg/kg for Cr et 48,6 mg/kg for Ni. Therefore metal concentrations recorded at the sediment surface may cause adverse effects on benthic organisms.

Abstract
Since 2008, projects supported by french government agencies were dedicated to improve the assessment of chemical contamination of water bodies defined by the Water Framework Directive (2000/60/CE)(Munaron et al, 2012 [1]). Among these studies, the aim of PEPSLAG was to investigate the utility of passive samplers for sampling contaminants present at trace levels in coastal lagoons environments, and to realize a first assessment of the contamination on the French Mediterranean coastal lagoons.

Keywords: Pollution, Coastal waters, Pesticides, Metals, North-Western Mediterranean

The aim of PEPSLAG was to investigate the utility of passive samplers for sampling contaminants present at trace levels in coastal lagoons environments, and to realize a first assessment of the contamination on the French Mediterranean coastal lagoons. 23 transitional lagoons water-bodies were investigated along the French Mediterranean coast, using three passive samplers (DGT, POCIS and SBSE). Passive samplers were exposed in water during one (DGT) or three/four weeks (POCIS), between june and july 2010. A water sample was collected for SBSE extraction at each sample point.

141 contaminants from various chemical families (trace metals, pesticides, pharmaceuticals, alkylphenols, PAHs, PCBs…) were investigated and their concentrations compared to Environmental Quality Standard (EQS) defined until now.

Various analytical methods were used to quantify these contaminants: atomic absorption for metals in DGT, on-line extraction of SBSE and analysis of organochlorinated pesticides, PAHs and PCBs by GC-MS, off-line extraction of others organic contaminants sequestred in POCIS and analysis by HPLC-MS-MS (ESi+ and ESi -) or GC-MS... Several methods developted were previoulsly published (Roy et al, 2005 [2]; Togola and Budzinski, 2007 [3]; Tapie et al, 2011 [4]).

With passive sampling techniques used, concentrations of many dissolved contaminants were detected during analysis and measured.

The study showed the operational assets of these systems, as low quantification limits required by the WFD reached and ensure measurement of metals and organic contaminants at trace levels, which are generally difficult to quantify with classical methods, especially in marine waters. In this study, many usual contaminants that have an EQS did not overstep it except some insecticides and trace metals. In spite of this, many water bodies have been considered in a bad chemical quality according to WFD. These passive samplers represent a sensitive and promising tool for use in marine and coastal monitoring under the EU WFD and the future EU Marine Strategy Framework Directive. Indeed, information is needed about marine contamination and passive samplers could clearly help to better characterize the real exposure of marine organisms to complex mixtures of contaminants present at low concentrations.

DISTRIBUTION OF SOME HEAVY METALS IN SURFACE SEDIMENTS FROM THE HOMA LAGOON (IZMIR BAY, TURKEY).

Elif Çagri Tas [1] and Ugur Sunlu [1]*
[1] Ege University, Fac. of Fisheries, 35100, Bornova- Izmir TURKEY - ugur.sunlu@ege.edu.tr

Abstract
Homa Lagoon is one of the commercially important fishing areas in Izmir Bay (Aegean Sea, Turkey) which is under the influence of heavy metal pollution due to the urbanization, industrial and agricultural activities.The purpose of this study was to determine the levels of some heavy metals such as Cd, Cu, Pb, Zn, Cr, Fe in surface sediment. The sediment samples were collected from 10 stations during autumn 2012. Mean concentrations of heavy metals in sediments are 0.65 ppm for Cd, 18.10 ppm for Cu, 16 ppm for Pb, 68.8 ppm for Zn, 156.6 ppm for Cr and 23900 ppm (d.w.) for Fe in Homa fisheries lagoon. Sediments which was taken from Homa Lagoon were most toxic for Cr due to exceedance of the LEL and SEL values.

Keywords: Sediments, Metals, Pollution, Izmir Bay, Aegean Sea

Introduction
Marine sediments are considered a sink for metals in aquatic environments, especially in estuarine and coastal waters. Generally, sediments contain three or five times higher concentrations of heavy metals than sea water samples. Consequently, sediments usually provide useful information for environmental and geochemical research about marine pollution. The study area, Homa Lagoon is located middle part of the Izmir Bay (Aegean Sea, Turkey) (Fig.1.). It's the only active coastal lagoon located in the Gediz Delta where agricultural drainage water, industrial and domestic wastewater are transported by Gediz River. The Homa Lagoon has approximately 1824 ha of surface area and a depth varies between 0.5-1.0 m. It is added to The Ramsar Convention and preserved by Ministry of Environment in 1998. The main aims of this study are to investigate the present status and distribution of heavy metal concentrations (Cd, Cu, Pb, Zn, Cr, Fe) in the sediments of the Homa Lagoon and compare these sediment results with other study in the same area done previously.

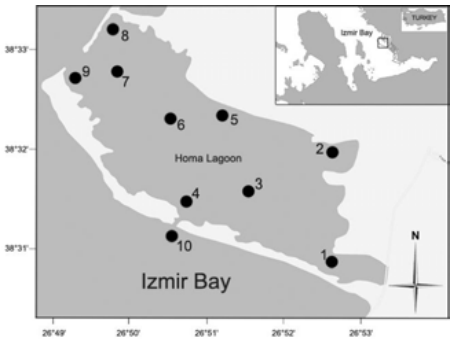

Fig. 1. The locations of sampling stations.

Materials and Methods
This study was carried out 10 stations of the Homa Lagoon. The sediment samples were collected using Van-Veen grap for heavy metals in autumn 2012. Two stages of preparation, consisting of drying and screening, were performed on the sediment samples [1]. The heavy metal analysis in all sub samples was performed using the 4 acid digestion and ultra trace ICP-MS method by the ACME Analy. Lab. Ltd. (Vancouver, Canada). Reference materials (STD DS9 and STD OREAS45EA) were used as a control for analytical methods.

Results and Discussion
The ranges of Cd, Cu, Pb, Zn, Cr and Fe contents of the surface sediments from the Homa Lagoon are 0.5-0.8, 9-24, 6-30, 38-88, 92-220 and 16500-28300 ppm d.w., respectively. Metal concentrations in sediments of this study were compared to other studies performed in Homa Lagoon and Gediz River. As a result of the evaluation between 1990 and 2012, the heavy metal concentrations in sediments of Homa Lagoon were generally similar, except Cr (Tab.1.). Metal distributions show that Cu (24 ppm), Zn (88 ppm) and Fe (28300 ppm) concentrations in sediments of Station 5 were higher than those from the other stations. Sediments from Homa Lagoon were most toxic for Cr due to according to the LEL (26 ppm) and SEL (110 ppm) values [8]. According to the results, high Cr values confirm that the pollution is caused by untreated waste water of espcecially leather industry. The concentrations of Cr were generally higher in the Gediz that the other contaminated rivers worldwide due to the leather tanning plants, which use large quantities of Cr in the tanning procedure [3] (Tab.1.). Sediment characterization was sandy mud in the Homa Lagoon. The percentage of sandy-clay varied between 2%-34%, the percentage of silt-clay 3%-43% and the percentage of silt-sand 34%-93% in the sampling period. The sediment organic carbon content varied from 1.22% to 4.2% with an average of 2.6% throughout the Homa Lagoon [7]. The organic matter is a major factor controlling the distrubition of Hg, Pb, Cr, Cu, Zn, Ni and Fe in the Gediz River [3]. The order of heavy metal concentrations were: Fe>Cr>Zn>Pb>Cu>Cd. In conclusion, the study area Homa Lagoon located in the Gediz Delta is under the effects of Gediz River which is transported industrial and domestic wastewater, agricultural drainage water (Tab.1.).

Abstract

This work aims at assessing the role of plankton in the transfer of PCBs to higher trophic levels in the Gulf of Lions by coupling biogeochemical and hydrodynamical processes and taking into account the physico-chemical properties of PCBs (PCB153 and PCB28). Plankton plays indeed a key role in biogeochemical cycles of PCBs in aquatic environments. Phytoplankton and bacteria sorb persistent organic contaminants by diffusive processes of the planktonic cells and the surrounding waters. On the other hand, for zooplankton, which feeds on them, two contamination pathways must be considered: diffusive transfer and ingestion of contaminated food.

Keywords: Adsorption, Bio-accumulation, Plankton, Pollution, Gulf of Lyon

The environmental occurrence of persistent organic pollutants (POPs), such as polychlorinated biphenyls (PCBs), is a matter of concern for ecosystems. PCBs are mainly characterized by their persistence, long-range transport in the atmosphere and the ocean, bioaccumulation, and toxicity. Thus, understanding and quantifying the dynamics of PCBs are important to assess their environmental impact and final fate. The ocean is considered to be the one of the global PCBs reservoirs. The Mediterranean Sea and the Gulf of Lions are unique marine environments subject to important anthropogenic pressures due to riverine and atmospheric inputs of PCBs.

Plankton plays a key role in the biogeochemical cycles of PCBs in aquatic environments. Since phytoplankton and bacteria are only exposed to the contaminants via water, it seems probable that the bioaccumulation is governed by sorption between the cells and the surrounding water [1,2]. On the other hand, for zooplankton feeding on them, two contamination pathways must be considered: diffusive exchanges and ingestion of contaminated food [1]. There is little information on the transfer of PCBs to zooplankton actually occurring in the field. However such information is crucial to make reliable predictions about PCB transfer to the higher trophic levels.

In the coastal area as Gulf of Lions, the process of PCBs bioaccumulation along the trophic web is ruled by interactions between compounds physico-chemical properties, organisms biological properties and also by hydrodynamical and biogeochemical processes. This work aims at a better understanding of such processes combination in the Gulf of Lions. We developed a coupled three-dimensional model for the assessment of PCB dispersion in space and time and of its transfer to zooplankton via biogeochemical processes. Specifically, the MARS3D hydrodynamical model [3] taking into account the PCB transport was coupled with a biogeochemical model Eco3M [4,5]. The case of two PCBs congeners was studied: PCB153 and PCB28.

Transport of various PCB species were simulated during one year: total dissolved, freely dissolved, particulate, biosorbed on plankton, assimilated by zooplankton. PCB budgets and fluxes into the Gulf of Lions between various species were governed by different processes, such as: adsorption/desorption, bacteria and plankton mortality, zooplankton excretion, grazing, mineralization, volatilization and biodegradation.

In the first step, the simulated PCBs distributions within particulate matter and plankton were compared with several in-situ measurements performed in the Gulf of Lions (COSTAS and Merlumed campaigns) for two size classes of plankton X ($60\mu m<X<200\mu m$ and $200\mu m<X<500\mu m$). The model reproduces quite well the orders of magnitudes. Although the model can not be fully validated for PCBs in terms of transfers in the trophic chain, its application on an annual period can highlight the impact of dominating forcings and the importance of processes necessary to explore in future research. Processes influencing PCB transfer were thereby analysed: (i) physical and chemical processes, such as riverine and atmospheric inflow, volatilization, sorption and resuspension and (ii) biogeochemical processes, namely grazing, mortality, mineralization and excretion. The Rhone River input appears to play a major role in the PCB contamination of the planktonic trophic chain of the Gulf of Lions. The contamination propagation from east to west, from the coast to the sea, from the surface to the bottom and its transfer from water and particules to bacteria and plankton is displayed according to seasonal events. The riverine PCB adsorbed to particulate matter desorbs into the water phase and, then contaminate the lower trophic levels (phytoplankton and bacteria) by sorption process. The higher trophic levels (zooplankton) are contaminated by PCBs mostly by grazing (feeding on the contaminated lower trophic levels) and slightly by sorption.

BIOKINETICS OF RADIOCESIUM IN PRAWN (*PALAEMON ADSPERSUS*): SEA WATER AND FOOD EXPOSURES

N. Sezer [1], Ö. Kiliç [1], M. Belivermis [1]*, S. Topçuoglu [1] and Y. Çotuk [1]
[1] Istanbul University - belmurat@istanbul.edu.tr

Abstract

In the present study, the biokinetics of cesium was investigated in prawn (*Palaemon adspersus*). Prawns were contaminated either from sea water or food exposures under laboratory conditions by using ^{134}CsCl. CF (Concentration Factor) of ^{134}Cs in whole body of prawn was found to be ~15 at steady state. The biological half-lifes were found to be 85.5 and 79.2 days for sea water and food pathways.

Keywords: Biokinetics, Radionuclides, Crustacea, Marmara Sea, Bio-accumulation

INTRODUCTION

Cesium was accumulated in soft tissues of living things. Also cesium is carried to human through the food chain [1]. The aims of this study are: to investigate CF of ^{134}Cs, to determine radiotracer distribution among edible and inedible parts, to examine the uptake and differences the depuration kinetics following sea water and food exposures.

MATERIALS AND METHODS

Approximately 140 samples of prawn (*Palaemon adspersus*) were collected from Marmara Sea coast. Uptake kinetics was followed in 30 l closed circuit spiked sea water (salinity: 24.6‰, temp: 16 ± 1 °C). Activity of ^{134}Cs was arranged to 2582Bq/l. During the experiment, spiked sea water was renewed every other day and animals were fed with *Isochrysis galbana* during 30 minutes in uncontaminated sea water. At the end of the exposure period, 45 prawns were transferred to another aquarium which has running uncontaminated sea water. For the food experiment, 70 mussels were exposed to ^{134}Cs by sea water pathway during 18 days [2] then the prawns were fed with radiolabelled mussels (*Mytilus galloprovincialis*) during 3 hours (pulse-chase feeding method) [3]. Loss experiment was carried out following the feeding.

RESULTS AND DISCUSSION

Uptake experiment continued 27 days and during this period accumulation of Cs was followed in prawns. CF value was found to be~15 at end of the uptake period. CF was found to be 19 and 21 in edible and inedible parts, respectively. After a 27 days exposure, the prawns were maintained for 38 days in uncontaminated sea water to follow depuration kinetics. Biological half-life was found to be 85.5 and 79.2 days following the sea water and food exposure, respectively. Biological half-life of cesium found to be 85.5 days for the slow component which found to be longer for mussel (47 days) [2]and winkle (75 days) in some investigations [4]. On the other hand, under Chernobyl field conditions $Cs_{Tb1/2}$ was determined to be 63 days [5]. CF_{Cs} values found to be lower than previous studies carried out in Turkey which are mussel (*Mytilus galloprovincialis*) and clam (*Ruditapes philippinarum*) respectively [2, 6].

MODELLING THE COUPLING OF BIOGEOCHEMICAL PROCESSES WITH AIR-WATER EXCHANGE AND ITS INFLUENCE ON POP CONCENTRATION IN PHYTOPLANKTON

Jordi Dachs [1]* and Naiara Berrojalbiz [1]
[1] Department of Environmental Chemistry IDAEA-CSIC - jordi.dachs@idaea.csic.es

Abstract
Atmospheric deposition, and particularly diffusive air-water exchange, is the main entrance and driver of the concentrations of many persistent organic pollutants (POPs) in the surface waters of open oceans and Lakes. Once in the water, partitioning processes influence the transport pathways, degradation processes, residence times and the final fate of the compounds. In fact, the occurrence and impact of pollutants in the aquatic environment are the result of the interplay of numerous trophic and physical drivers. The main objective of this estudy is to clarify the interactions of atmospheric inputs of POPs and the biogeochemical processes occurring in the surface ocean mixed layer emphasizing the implications of the biological pump and degradation in such processes.

Keywords: Pollution, Pcb, Models, Atmospheric input, South-Central Mediterranean

Atmospheric deposition, and particularly diffusive air-water exchange, is the main entrance and driver of the concentrations of many persistent organic pollutants (POPs) in the surface waters of open oceans and Lakes. Once in the water, partitioning processes influence the transport pathways, degradation processes, residence times and the final fate of the compounds. In fact, the occurrence and impact of pollutants in the aquatic environment are the result of the interplay of numerous trophic and physical drivers. Nevertheless, there are still major gaps in our knowledge regarding to the relative importance of each of the factors controlling the occurrence of those pollutants in marine waters. The main objective of this estudy is to clarify the interactions of atmospheric inputs of POPs and the biogeochemical processes occurring in the surface marine mixed layer emphasizing the implications of the biological pump and degradation in such processes. An air-water-phytoplankton coupled model to calculate air-water, water-plankton and settling fluxes have been developed modifying the approach developed by the group previously. In addition, we have included the degradation in surface waters in the model. Field measurements of air (C_G), seawater (C_W) and plankton (C_P) POP concentrations have been used in the validation of the model. All samples were obtained on board of RV-Garcia del Cid research vessel during two Mediterranean sampling cruises on June 2006 and May 2007. Both transects from Barcelona to Istanbul and from Barcelona to Alexandria respectively allowed the sampling of many different Mediterranean regions including Marmara Sea and Black Sea. The used sampling strategy has allowed the simultaneous collection of atmospheric and aquatic matrices to enable the parametrization of atmosphere-ocean-plankton interactions. All samples were analyzed for PCBs, PAHs, HCHs and HCB covering a wide range of physical-chemical properties. Concentrations of the more hydrophobic PCBs in phytoplankton decreased at those locations with higher biomass, following the equation:

Log Cp = -b Log Biomass + constant [1]

Conversely, ligther PAHs, which undergo degradation in surface waters, followed the same trend, with lower concentrations in phytoplankton at higher biomass. These results are important because show that the concentrations of a wide range of organic pollutants in the water column depend on the trophic status of the sea, and not on other variables such as distance to coast. The extend of the dependence of concentrations on trophic status, measured as biomass, is given by the term *b* of equation [1]. When *b* is ploted versus the octanol-water partition coefficient (K_{OW}), then HCB, PCBs and high mollecular weight PAH fall in a line (Figure 1), showing a higher value of b, thus major dependence of the concentrations of organic pollutants in phytoplankton with biomass. Conversely, for HCH and low MW PAHs, such as phenanthrene and methylphenanthrene, which are subject to microbial degradation in the water column, the concentrations in phytoplankton decrease to greater extend (higher b) for the les hydrophobic compounds (Figure 1). These trends can be explained using the developed air-water-phytoplankton model and are the result of the relative contribution of the biological pump, the degradative pump, and the dilution effect operating in the surface water column of the Mediterranean Sea. This is the first time that it is shown that concentrations of organic pollutants in open sea phytoplankton depend on the trophic status rather than distance to sources.

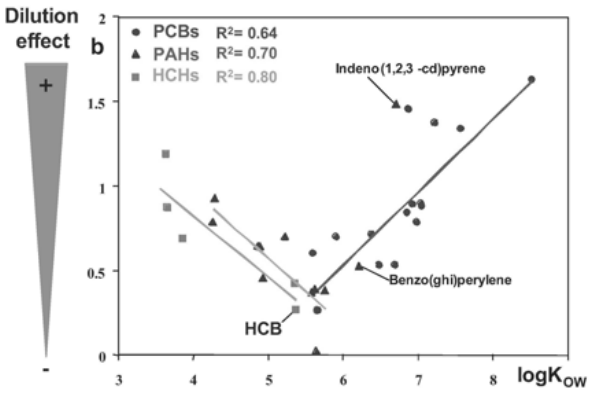

Fig. 1. The concentrations of most PCBs, HCH and PAHs in phytoplankton were higher when lower concentrations of phytoplankton biomass (B) occurred in the water column (following equation 1). However, the intensity of the response varies upon the chemical and their physical chemical properties (K_{OW}).Chemicals with higher values of b (see Equation 1), mean that their concentrations in phytoplankton show a greater dependence on biomass. The high b values for chemicals with low K_{OW} are due to degradaton in the water column, conversely, the high b values at high K_{OW} are due to the biological pump.

Abstract
A three dimensional (3D) ocean biogeochemistry model is used to describe the carbon (C), nitrogen (N) and phosphorus (P) cycles in the Mediterranean Sea in order to estimate the carbon export to the deeper layer (deep water circulation). Combining a high-resolution version of the physical model NEMO and a biogeochemical model with flexible stoichiometry (Eco3M), we investigate the contribution of particulate and dissolved organic matter to the total carbon export.

Keywords: Models, Carbon, North-Western Mediterranean

Introduction
The export of organic carbon into deep waters can be divided into two processes: the sink of large particles and the accumulation followed by vertical transport of dissolved organic carbon. While particulate export is usually considered as the main mechanism in the world ocean ([1]), the dissolved organic carbon export may represent the most part of the total organic carbon export in specific areas like the NW Mediterranean Sea ([2]) characterized by Low P Low Chlorophyll (LPLC) conditions [3].
A 3D physical-biogeochemical model has been developed on an off-line approach in order to investigate dissolved versus particulate organic carbon export to the deep layers of the Mediterranean Sea.

Model
Daily physical parameters are produced by a high-resolution model of the Mediterreanean Sea, NEMO-MED12. This model is a Mediterranean version of the NEMO numerical ocean model here used over the whole Mediterranean basin on a 1/12° horizontal resolution grid with a 50 levels vertical resolution. An exhaustive description of the ocean model can be found in [4].
The atmospheric forcings are derived from ECMWF on a ~50 km grid using the dynamic downscaling tool ARPERA. Ocean physical forcing are available from 1958 to 2010 and they provide realistic representation of deep water formations and extreme events.
The pelagic ecosystem model (figure 1) is a multi-nutrient multi plankton functional types (PFTs) model with a flexible stoichiometry working with 34 variables. It has been implemented in the Eco3M numerical platform [5]. It includes six plankton types (3 phytoplanktons, 2 zooplanktons and bacteria) and represents the cycles of C, N and P. Organisms are also represented through cellular abundances [6]. A constant sinking velocity is applied to the particulate organic matter compartment corresponding to large dead organisms and fecal pellets. Most processes are described with mechanistic formulations (photosynthesis, photoacclimation, exudation,…) and biogeochemical processes including nutrients assimilation and growth are governed by variable intracellular quotas.
In the western boundary of the domain, a nudging to climatic field derived from MEDATLAS for nutrients and in situ measurements for chlorophyll is applied on a buffer zone from 11°W to 6°W.
Rivers inputs are derived from the Ludwig's study [7] and the model includes inputs of dissolved organic carbon, total nitrogen and total phosphorus representing 32 rivers, coastal discharge and the Black Sea.

Results
We obtained a first twenty-year hindcast from 1990 to 2010 validated using in situ biogeochemical parameters and multi-satellite surface chlorophyll measurements. The mean annual total organic carbon export to the deep layer was estimated for the whole Mediterranean Sea and at basin scale, together with the ratio between dissolved and particulate carbon export.

Abstract
The Northwestern Mediterranean Sea (NWMS) is biologically one of the most productive areas of the Mediterranean Sea. The functioning of the NWMS pelagic planktonic ecosystem is strongly influenced by hydrodynamics, in particular deep convection that shows a strong interannual variability and that could be strongly impacted by climate change. We investigated the response of the NWMS pelagic planktonic ecosystem and associated carbon cycle to the interannual variability of oceanic and atmospheric circulations and to climate change. For that we developed and used a dedicated tridimensional coupled physical-biogeochemical model.

Keywords: North-Western Mediterranean, Models, Water convection, Phytoplankton, Carbon

Deep convection is one of the major processes of the NWMS circulation. Winter atmospheric events associated to cold winds (Mistral and Tramontane), high evaporation rates and strong buoyancy losses are at the origin of surface dense water formation. This induces vertical mixing that brings nutrients initially present in the deep layers up to the surface, resulting in spring phytoplanktonic blooms when the water column restratifies. Deep convection shows a strong interannual variability [1] and could severely weaken as a consequence of climate change [2]. Our objective is to understand how this variability and long-term evolution could impact the functionning of the NWMS pelagic planktonic ecoystem and associated carbon cycle. For that, we developed a coupled physical-biological regional model and performed two groups of simulations under respectively the present and future (end of the XXIth century) climate conditions.

Numerical tools and design

The 3D primitive equation ocean model SYMPHONIE [3] is used at 3 km resolution to compute the evolution of the NWMS planktonic pelagic ecosystem due to the hydrodynamics. The biogeochemical model is a multi-nutrient and multi-plankton functional types model that simulates the dynamics of several biogeochemical decoupled cycles of biogenic elements (carbon, nitrogen, phosphorus and silicon) and of non-redfieldian plankton groups. The model structure used in this study is the same as the one used by [4] and [5], with 6 main groups and 33 state variables.

The coupled model was forced by atmospheric and large-scale oceanic fields coming from a basin-scale Mediterranean simulation over the period 1960-2011 under the IPCC A2 scenario assumptions [2]. Due to numerical cost, we could not perform a 140 year simulation with our model. We therefore selected two groups of 7 years for the present (1970-2000) and future (2070-2100) periods and performed the corresponding coupled physical-biogeochemical simulations. [6] presented the results of the simulations concerning the hydrodynamics.

Results

First, our coupled model reproduces correctly and quantitatively the seasonal evolution of the NWMS pelagic planktonic ecosystem in terms of biogeochemical components and processes. It however overestimates the contribution of nanophytoplankton to the total phytoplanktonic biomass and primary production. Our model confirms that the control of phytoplanktonic development and bacteria growth by the phosphorus availability is a marked specificity of the NWMS.

Second, our results show that the seasonal evolution and annual carbon balance of this ecosystem show generally a weak interannual variability, though the strong interannual variability of winter deep convection induces a strong variability of the nutrients availability. The net metabolism and deep carbon export show larger variabilities related respectively to the variability of the euphotic layer temperature and the deep convection intensity. The NWMS however seems to be systematically a sink for the organic and dissolved inorganic carbon.

Finally, our results suggest that the evolution of oceanic and atmospheric circulations during the XXIst century does not significantly influence the functioning of the NWMS pelagic planktonic ecosystem and associated carbon cycle at a first order. However differences mainly induced by the deep convection weakening and the surface layer warming are obtained at a second order. The spring bloom occurs one month earlier. Resulting from the decrease in allochtonous nutrients availability, the bottom up control of phytoplankton development and bacteria growth by the nitrogen and more particularly phosphorus availability strengthens, the microbial loop intensifies and the contribution of regenerated primary production increases.

Abstract
The main scientific goal of COSTAS project is to bring useful knowledge to the understanding of the conditions, which favor the accumulation and transfer of organic and metallic contaminants at the primary trophic levels (autotrophes and hetetrophes), and then within the food web of small pelagic fish (anchovy and sardine) in the Gulf of Lion, Western Mediterranean.

Keywords: Plankton, Bio-accumulation, Trace elements, Pcb, Gulf of Lyon

In the integral scheme of biogeochemical cycles of contaminants in marine ecosystems, the assimilation of anthropic compounds and elements at primary trophic levels, in plankton, is not yet well known [1,2]. However, planktonic populations play a key role in the trophic food webs in marine ecosystems by the mobilizing and transfer of organic matter towards higher trophic levels [3,4]. Thus our study focuses on the whole food web, including water column/ phytoplankton/ zooplankton/ and small pelagic fish.

The main groups of compounds and trace elements were considered: persistent organic contaminants (polychlorobiphenyls PCBs and polybrominated diphenyl ethers PBDEs), mercury (Hg) and methylmercury (CH_3Hg), other trace metals (Pb, Cd, Co, Cu, Ag, Zn), natural radioelements (^{210}Pb, ^{210}Po) and stable lead isotopes (^{204}Pb, ^{206}Pb, ^{207}Pb, ^{208}Pb). The presented approach embraces the ecological and biogeochemical dimensions of the food web. It is also based on the simultaneous use of chemical "tracers" (organic and metallic contaminants) and biological "tracers" (stable isotopes of δ13C and of δ15N and fatty acids).

The presented results show also the mechanisms of the bioaccumulation of toxic substances in the tissues of small pelagic fish (tissue distributions, excretion, metabolization), as well as the influence of ontogenic factors (growth, reproduction, migration) [5]. Finally, the modeling allow us the spatial and dynamic interpretation of data [6], as well as at the first attempt to integrate the biogeochemical, ecological, and physical behavior of contaminants in their transfer at primary trophic levels, including also development and application of the dynamic energy budget model (DEB) of anchovy in the Gulf of Lion [7,8].

The research work was carried out within COSTAS project and calls for competence in marine biology, ecology, biogeochemistry and physics employed together in the scientific tasks of data acquisition during oceanographic cruises, laboratory analysis, and coupled modeling.

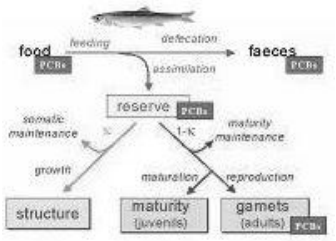

Fig. 1. Conceptual diagram: Dynamic Energy Budget DEB model comprises a good knowledge of physiology of fish controlling vital functions (such as reproduction and growth) and fate of contaminants in fish [9].

Abstract
Polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) were investigated in European anchovy (*Engraulis encrasicolus)* collected in the Gulf of Lions. The contaminants were determined in different organs and tissues of male and female adult fish sampled during the spawning and resting seasons. The influence of sex, age and reproduction on contaminant concentrations was evaluated.

Keywords: Bio-accumulation, Gulf of Lyon, Fishes, Pcb

Small pelagic fish, such as European anchovy (*Engraulis encrasicolus*), stand at intermediate levels in food webs and play an essential role in North-Western Mediterranean ecosystems [1]. Understanding their contamination by persistent toxic contaminants is therefore of importance. The contamination of selected organochlorinated (polychlorinated biphenyls - PCBs) and organobrominated (polybrominated diphenyl ethers -PBDEs) contaminants was investigated in European anchovy collected in the Gulf of Lions (North-Western Mediterranean Sea). The spatial distribution of contamination was assessed at different locations throughout the Gulf of Lions, from the mouth of the Rhône River in the Eastern part of the Gulf, to Port Vendres in the South-Western part. Male and female adult fish of homogeneous size were sampled during the spawning and resting seasons (i.e., July 2010 and March 2011, respectively). Contaminant determination was done on pooled individuals of similar size and sex, and replicate pools were analysed when available. Extensive determination of contaminants in different organs and tissues (muscle, liver, gonad, viscera and carcass) allowed to calculate the whole body's contamination levels and to assess the effects of anchovy's reproductive activity on the distribution and levels of organic chemicals. Fish contamination was examined together with total lipid content. Lipid classes (triacylglycerols, sterols and phospholipids) as well as carbon and nitrogen stable isotopes were also determined in selected tissues in individual anchovies. Finally, contaminants, lipids and stable isotopes were assessed in anchovy main diet (small zooplankton), and BMF and TMF were evaluated. No significant differences in anchovies' contamination levels were observed throughout the Gulf of Lions, revealing a fairly homogeneous population within the study area and no local influence of contaminant inputs on fish contamination. During the spawning season, females exhibited lower contamination levels than males, while no statistically significant difference was found during the resting season. CB-153 (predominant PCB congener) concentrations ranged from 4.1 ng g-1 wet weight (ww) to 9.3 ng g-1 ww in females and males respectively during the reproductive season; they ranged from 9.6 ng g-1 ww to 12.2 ng g-1 ww during the resting season. BDE-47 (predominant PBDE congener) concentrations were 40- to 60-fold lower than those of CB-153. The lower PCB and PBDE levels measured in females during the spawning season could result from a decontamination process that occurred during spawning [2]. Moreover, a modelling approach based on the Dynamic Energy Budget (DEB) theory revealed age differences between fish of given sex and length between the two seasons [3]; this could also explain the differences observed in anchovies' contamination.

Abstract
Distribution of trace metal(oid)s (Zn, Cd, Pb, Cu, Ni, Co and As) along vertically stratified Krka river estuary was studied. The concentrations of trace metals are maintained at low levels across the estuary during winter, because of low input of trace metals by the Krka River and the lack of permanent diffusive sources. Localized anthropogenic influence was identified in the harbor of Šibenik town and in the two nautical marinas. However, due to the intensive nautical traffic during summer periods, a significant increase of metal concentrations (especially of Cu and Zn) in upper brackish layer was evidenced as a consequence of release of metals from the antifouling paints.

Keywords: Trace elements, Estuaries, Vertical profile, Electrochemistry, Central Adriatic Sea

Introduction
Karstic river Krka is situated on the East coast of the Adriatic Sea (Croatia) and is partly located within the National park Krka. Numerous lakes formed by tufa barriers rendered concentration of trace metals in water at very low levels [1]. The Krka river is forming 22 km long estuary which is, due to the low tidal range and sheltered geography, permanently vertically stratified. The three separate layers in a vertical profile exist along the estuary and could be easily spotted: upper brackish layer, freshwater – seawater interface (FSI) with high salinity gradient and bottom seawater layer. Halocline is mostly formed between 1.5 and 2.5 m from the surface with the gradient of more than 20 salinity units within 1 m. Strong salinity gradient is controlled by hydrological conditions (river flow) and weather (precipitation, wind). First measurements of trace metals in a vertical profile of estuary conducted 20 years ago [2] showed their very low levels and the absence of anthropogenic pressure. An increase of nautical tourism and the harbor activities in the last decade refer to the possible anthropogenic influence [3]. Thus, the objectives of this study were to indentify major sources of trace metal inputs to the estuary, as well as to estimate and quantify their influence and distribution in both, horizontal and vertical directions.

Sampling and measurements
Water samples were collect along the estuary transect at total 14 sites in summer 2011 and in winter 2012. Additional freshwater sample was collected in the Krka river, while seawater end-member sample was taken at position far from the estuary. At each estuary sampling site, samples were taken at three depths covering the whole salinity range (upper brackish layer with variable salinity, intermediate layer with salinity ~20 and bottom seawater layer with salinity >37). In order to identify the main sources of trace metals in the Šibenik bay, a high resolution sampling of surface layer at 40 sites was conducted in summer 2012 (Fig. 1).

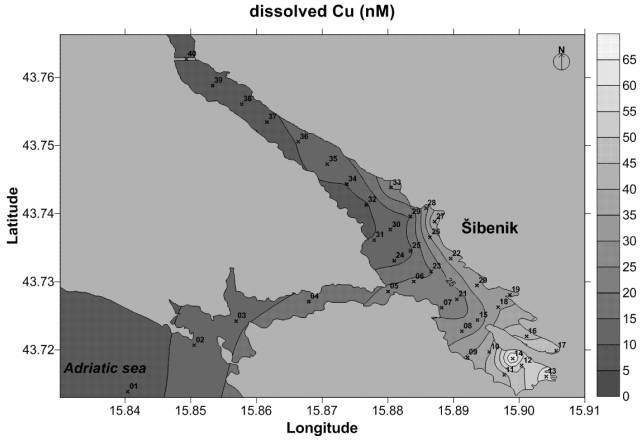

Fig. 1. Locations of sampling sites in the Šibenik bay and diss. Cu distribution

All samples along the vertical profile were sampled by using horizontal water sampler, while surface samples in the Šibenik bay were taken by grab sampling using homemade "swing sampler" (1 L FEP bottle mounted at the end of the long stick). Trace metal concentrations were determined by standard addition method on fully automated auto-sampler. Differential pulse anodic stripping voltammetry (DPASV) was used for measurement of Zn, Cd, Pb and Cu, while adsorptive cathodic stripping voltammetry (DPAdCSV), with Nioxime as a ligand, was used for analysis of Ni and Co. Hydride Generation Atomic Fluorescence Spectroscopy was used for As analysis.

Results and discussion
A non-conservative behavior of metals with salinity was observed because of low content of particulate matter and additional sources of metals within the estuary. Regarding the trace metal distribution along the estuary transect, a significant increase of metals concentration, especially Cu, was found in brackish layer in the summer period (Table 1). Change in concentrations is related to the increase of nautical traffic in touristic period, primarily because of metals leached from the antifouling paints [3]. Due to a progressive enrichment by metals scavenged from the more polluted brackish layer there is an upstream increase in bottom seawater layer. Highest concentrations of all metals were found in the Šibenik bay. Detailed mapping (Fig 1.) has demonstrated that concentrations are highest in nautical marina (Cu diss. ~ 70 nM) and in the Šibenik harbor (Cu diss. ~ 49 nM). Comparing to average concentration of Cd in the bay (0.07 nM), increased concentrations (0.19 nM) were found in part of the harbor where transshipment phosphate ores is located. Zn is significantly correlated to Cu because of the same sources. Difference between unfiltered and filtered metal concentrations (Cu/Zn) is low, indicating that they are mostly added to the ecosystem in a dissolved form and thus are potentially bioavailable/toxic for microorganisms. Taking into account a previous speciation study conducted in this estuary [4], toxic levels of free Cu could be expected in areas of the highest copper concentrations. A survey on a global scale and a study of metal speciation in the coastal zone is needed in order to estimate a potential toxic effect on sensitive organisms such as planktons.

Tab. 1. Ranges of dissolved Cu concentrations (in nM)

Layer	Summer	Winter
Brackish	**1.36** ± 0.46 – **27.6** ± 1.16	**1.76** ± 0.14 – **7.29** ± 0.37
FSI	**3.79** ± 0.36 – **16.01** ± 0.29	**3.07** ± 6.17 – **6.17** ± 0.15
Seawater	**2.57** ± 0.35 – **9.25** ± 0.27	**2.98** ± 0.19 – **5.90** ± 0.20

Abstract

Submarine Groundwater Discharge (SGD) may represent important inputs of water and associated elements to the coastal zone. We evaluated such SGD fluxes on two contrasting environment: the Mar Menor lagoon (Cartagena, Spain) and the Port-Miou karstic springs (Marseille, France). In both cases we used radon and radium mass balances to quantify and/or locate SGD. In the Mar Menor we combined radon and radium surveys with an hydrodynamic modeling of the lagoon.

Keywords: Radionuclides, Lagoons, North-Western Mediterranean, Coastal systems

Coastal areas are vulnerable environments undergoing increasing anthropogenic pressures. Various processes can affect them, and one particularly important is the degradation of water quality in the continent or in the ocean. In this context, the groundwater discharge into the coastal zone has received increased attention in the last years as it is now recognized that this process may represent an important pathway for the delivery of nutrients, and metals to the ocean. SGD have been evidenced as submarine springs (karstic springs) or diffuse seepage across the seafloor. SGD could be freshwater (Submarine Freshwater Groundwater Discharge, SFGD) or recirculated saline groundwater (RSGD), i.e. seawater intrusion into coastal porous sediments, mixed with continental freshwater discharged back to the sea. SGD fluxes are less affected by surface drought than rivers and can occur all the year, in contrast to Mediterranean temporary rivers. Furthermore, because groundwaters can have higher concentrations of dissolved chemicals (nutrients, metals) than most terrestrial surface waters, SGD can make a disproportionately large contribution to the flux of dissolved constituents from continent to ocean. In the Mediterranean Sea, SGD was not studied at the global scale, whereas an estimate from UNESCO (2004) indicates that the karstic areas bordering 65% of the coastline could contribute for 75% of the total freshwater runoff mostly through SGD. However, recent papers underlined the occurrence of SGD in Spain, France or Italy and revealed the different influences they could have on coastal fluxes of elements ([1], [2], [3], [4]).

In the two studied areas we used radon and radium isotopes as tracers of SGD. These elements are enriched in groundwater compared to coastal waters and the estimation of their budget in a coastal area allows locating and quantifying SGD.

^{222}Rn was analysed with a RAD-7 system on 250 mL bottles (groundwater and river water) or in continuous by surface water pumping on-board of small vessel along the coast. 15 L of water were collected for radium isotopes, preconcentrated on Mn-fiber. And analysed using a RaDeCC system designed by Moore and Arnold [5].

In Mar Menor (Spain), we used an approach combining radon (^{222}Rn) and radium (^{223}Ra, ^{224}Ra) surveys together with an hydrodynamic modeling of the lagoon. This allowed to decipher the radionuclide signal issued from surface water, atypically highly enriched in radionuclides and nutrients, than those issued of SGD. Radionuclides mass balances provide SGD fluxes of water of 26-58 (^{222}Rn), 10-20 (^{224}Ra) and 18 m^3/s (^{223}Ra). The budget evidences that sea-level variation is likely to be an important process for this SGD by adding recirculated seawater from the sediment to the water column, while fresh groundwater discharge from the aquifer is about 1% of total SGD. This corresponds to a fresh groundwater input of 0.2 m^3/s that is similar to river flux (0.33 m^3/s) and clearly lower than inter and outer water fluxes exchanged with the Mediterrenean Sea.

The Port-Miou karstic submarine spring (France) is typical of brackish groundwater discharging through karst conduits, and it was investigate in order to validate the mass balance model approach. Combining ^{222}Rn, ^{223}Ra and ^{224}Ra mass balances with water and salt budgets, we obtained a SGD value of 3.6 m^3/s, consistent with the discharge estimated by an hydraulical approach based on pressure sensors. This validation allows the use of ^{222}Rn as a tracer for other important karstic areas in the Mediterranean Sea (Croatia, Greece, ….) where discharges data are not available.

Abstract
A preliminary study of distribution of total trace metal concentrations (Hg, Cd, Pb, Cu, Zn, Ni, Co), nutrients (nitrate, nitrite, ammonium, phosphate & silica) and physico-chemical parameters (water temperature, salinity, conc. of dissolved oxygen - DO), dissolved inorganic/organic carbon (DIC, DOC) in water columns of two anchialine caves (Bjejajka and Živa voda) from eastern Adriatic coast (Croatia) has been performed.

Keywords: Trace elements, Anoxia, Central Adriatic Sea, Organic matter, Nutrients

Introduction
The anchialine environment was defined at the 1984 International Congress of Marine Cave Biology, Bermuda [1] as containing bodies of haline waters, usually with a restricted exposure to open air, and always with more or less extensive subterranean connections to the sea, which show noticeable marine as well as terrestrial influences. Last year, during the 2nd International Symposium on "Anchialine Ecosystems", Croatia, a new definition was proposed: "A type of subterranean estuary containing at least seasonally stratified water body, that may or may not be in direct contact with the atmosphere, and is capable of supporting a characteristic biota" /www.anchialine.com/. Recently, these unique aquatic environments of the Croatian Adriatic coast became the target of interdisciplinary research [1, 2, 3].

Study area & methodology
The anchialine caves presented here are located on the Adriatic islands, and are exposed to a minimal anthropogenic influence. Bjejajka anchialine cave is located on the Island Mljet [1, 2, 3], while Živa voda cave is situated on the the Island of Hvar [1, 4]. Cave waters were sampled by a scuba diver in September 2012. Four samples were taken from each cave (two above and two below the halocline). Differential pulse anodic strippingvoltammetry (DPASV) was used for measurement of Zn, Cd, Pb and Cu, while adsorptive cathodic stripping voltammetry (DPAdCSV), with Nioxime as a ligand, was used for analysis of Ni and Co.Mercury concentrations were analysed by CV-AAS.

Fig. 1. Locations of anchialine cave Bjejajka and Živa voda

Results
Values of total trace metal concentrations, nutrients and physico-chemical parameters (water temperature, salinity & dissolved oxygen), dissolved inorganic /organic carbon (DIC, DOC) are presented in Table 1. Although Živa voda cave is three times deeper than Bjejajka cave, the salinity distributions were similar. Dissolved oxygen concentrations were significantly lower in Bjejaka cave, and hypoxic conditions were registered around the halocline. The nutrient results show that the external nitrogen and phosphorus loading is higher for the Bjejajka Cave. Interesting though, the caves share high similarity with respect to N/P ratio, which is close to the Redfield ratio in deep waters, but substantially higher at the surface. The differences in silica (and inorganic carbon) concentrations between the caves is, as already suggested [3], most likely a result of the compositional differences between the rocks/soils that surround these systems. Mercury and cadmium concentrations were significantly higher in samples taken below the halocline in Bjejajka, and are comparable to those reported earlier [2]. In Bjejajka cave higher copper and zinc concentrations were found, relative to Živa voda cave, while the concentrations of lead, nickel and cobalt were comparable in both caves. Concentrations of DIC and DOC were considerably higher in Bjejaka cave, only DOC amounts were slightly lower than was reported earlier [2]

Abstract
Alien species *Ficopomatus enigmaticus* (Fauvel, 1923) (Annelida, Polychaeta) was registered in the Krka River Estuary for the first time seven years ago. Since *F. enigmaticus* inhabits many polluted areas around the world, it is potential candidate which could be used as a pollution bio-indicator. Thus, the levels of accumulated toxic metals in tubes and in soft tissue of this specieswere monitored at different locations along the estuary.

Keywords: Annelida, Central Adriatic Sea, Alien species, Metals, Estuaries

Introduction
Serpulid species *Ficopomatus enigmaticus* (Fauvel, 1923) builds calcareous tubes on any hard substrate with distinctive collar-like rings at irregular distances. It has been found worldwide inhabiting coastal brackish waters, lagoons, estuaries and anchialine ecosystems of warm temperate areas of both hemispheres. This tubeworm is an efficient suspension-feeder, very tolerant and physiologically well adapted to temperature and salinity variations, eutrophic conditions and low dissolved oxygen content.

Study area and methodology
F. enigmaticus was recently registered at Krka River Estuary [1] and adjacent anchialine caves [2, 3]. Situated in the karst region, the Krka River Estuary is 22 km long with the gradually increasing depth from 2 m to 42 m. It is a typical example of a permanently stratified estuary. Villages Skradin, Raslina and Bilice are located in the upper part of estuary, while Zaton village and the town of Šibenik are located in the lower part of the Estuary.
Around the shores of the Estuary, *F. enigmaticus* occurs as a single tube or in large dense fouling aggregates, mostly on artificial substrates. It exists at depths up to 3 m, but the largest settlements are up to 0.5 m [1]. For analyses on metal contents, *F. enigmaticus* samples were taken by scuba diver at 10 locations along the estuary in two seasons (spring and summer). Carbonate tubes and soft tissues were digested using concentrated nitric acid on a hot plate, and analysed separately by HR-ICP/MS. Mercury concentrations were analysed by CV-AAS.

Results
Concentrations of toxic metals in tubes of *F. enigmaticus* are presented in Table 1. The highest concentrations of Hg, Cu, Zn, Cr, Ni and Co were found in local nautical port Vrnaža situated in the lower part of estuary, while the highest concentration of Pb and As were found in port of Šibenik town.

Regarding the temporal variation, the highest difference at the particular sampling site was found for Pb (four times difference), while at the same site concentration of Hg was three times higher. The highest concentrations of Cd and Ag were found around nautical ports of Zaton village. In general, concentrations of all metals varied on both spatial and temporal scale at least one order of magnitude, reflecting probably variations in a localized anthropogenic pressure at sampling sites. The largest concentration ranges were found for Ag and Pb, following that of Hg, Cu and As. It is interesting to note that for Pb, Hg, As at some sampling points (Table 1) a quite high differences in metal concentrations between samples for two sampling events were observed, while for Cd, Cu, Cr, Ni, Co, Ag concentrations remained at the same level. Fairly good correlations between Cd – Co and Cu – Zn concentrations in tubes of *F. enigmaticus* were found. Concentrations of toxic metals in soft tissue of *F. enigmaticus* are presented in Table 2. Generally, the highest concentrations of metals in tissue were found at locations with likely anthropogenic influence (nautical and city ports). Very high concentrations of Cr and Ni, found at sampling site at nautical pontoon near Skradin village (upper part of the estuary), are probably related to settlements formed on chrome/nickel plated iron surface. Variations of concentrations in soft tissue are smaller comparing to tubes, with the exception of Cr, which varied more than seventy times. Variations in Pb concentrations reflect its levels in water column along the Krka River estuary. Statistically significant correlations were found between Cu-Zn and Co-Pb concentrations in soft tissue of *F. enigmaticus*. Analyses performed in tubes and in soft tissues of *F. enigmaticus* indicated that they respond on the level of toxic metals in the water column, however a more detailed survey should be undertaken in order to define all relevant parameters which have influence on the content of accumulated metals during period of exposure/monitoring.

LITHOGENIC AND BIOGENIC FLUX CHANGES IN DIL CREEK ESTUARINE (THE MARMARA SEA)

H. A. Ergul [1]*, A. Küçük [1], G. Çelebi [1], M. Terzi [1] and S. Aksan [1]
[1] Kocaeli University Department of Biology - halim.ergul@kocaeli.edu.tr

Abstract
This study represents first lithogenic and biogenic particle flux in sediment trap sediments from Dil Creek estuarine in the Izmit Bay (the Marmara Sea). In sediment samples, vertical flux of TOM, C_{org}, $CaCO_3$, BSi and Lithogenic contents were determined between Aug. 2008 and May 2010. Lithogenic matter was dominant component during the sampling period that represents terrigenic input. BSi concentrations in trapped sediment were mainly driven by siliceous organisms. Contrary to common belief, $CaCO_3$ mainly originated from mineralogical sources. TOM and C_{org} concentrations are generally higher than other Mediterranean coasts. It is assumed that elevated TOM and C_{org} levels in Dil Creek estuarine are sourced from untreated discharges.

Keywords: Sediments, Marmara Sea, Particle flux

Introduction: Scientific attention for organic matter (TOM), organic carbon (C_{org}), biogenic silica (BSi) and carbonate ($CaCO_3$) cycle is increasing since recent decades. Studies have shown that marine silica cycle is dominated by phytoplankton and mainly diatomaceous organisms contribute to trophic transfer of organic carbon besides marine biogenic silica [1] and carbonates. Although some studies have been done in Mediterranean Sea coastal ecosystems [2], [3] there was no study related with biogenic components of marine sediment from the Marmara Sea in turn Dil Creek which inflow to the Izmit Bay. The Izmit Bay receives considerable amount domestic and industrial discharges. Dil Creek, is known as the most polluted river of Turkey (Fig 1). Dil Creek carries 200 big factories industrial and more than one million inhabitants (untreated) domestic discharges to the Izmit Bay beside agricultural runoff from its catchment area. Thus, this study represents first lithogenic and biogenic particulate flux results from Dil Creek estuarine in the Izmit Bay.

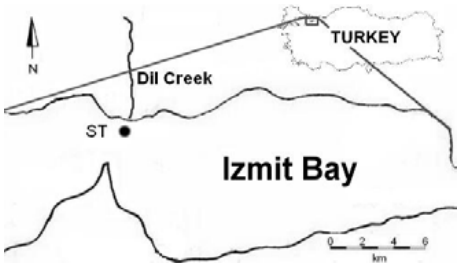

Fig. 1. Sampling station (ST) in the Izmit Bay inshore.

Methods: Sediment trap was deployed Dil Creek estuarine in the Izmit Bay at 15 m depth (Fig. 1) with average 20 days intervals between Aug. 2008 and May 2010. TOM were determined after combustion in 550 ^{o}C, C_{org} were measured using non-dispersive infrared analyzer, 0.5 N HCl were used for $CaCO_3$ determination and wet alkaline digestion method were used for BSi analysis. Also some oceanographic parameters (i.e. Chl-a, Temperature) were determined. All the resuls were statistically tested and Principal Component Analysis (PCA) were used for source identification.

Results: Vertical flux of lithogenic and biogenic material in sediment samples is presented in Fig. 2. Lithogenic matter was generally dominant component that represents terrigenic input. However, correlations between BSi and Chl-*a* (not presented here) (i.e. r=0.5, p<0.01) reveal that BSi in trapped sediment were mainly driven by siliceous organisms (i.e. phytoplankton) in marine water. There were no correlations between $CaCO_3$ and BSi and between $CaCO_3$ and Chl-*a* (p>0.05). Contrary to common belief, PCA results (not presented here) reveals that $CaCO_3$ mainly not related with the lithogenic contents in the bay. Already, It is reported that substantial carbonate mine (i.e. limestone and dolomite) present in the Izmit Bay coasts [4]. Thus it is assumed $CaCO_3$ flux originated from mineralogical sources and inflow to the Izmit Bay via Dil Creek.

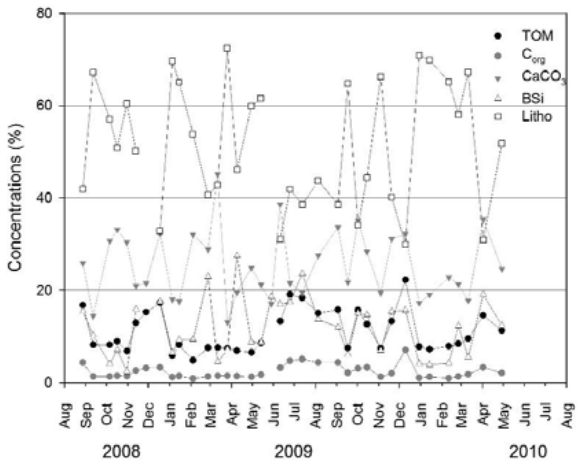

Fig. 2. Lithogenic and biogenic matter concentrations in trap sediments.

Significant correlations were determined between C_{org} and TOM (i.e. r=0.94, p<0.001) and between C_{org} and BSi (i.e. r=0.52, p<0.01). These results indicate that organic material in sediment are strongly related with the biogenic component and Dil Creek is the main source. Data comparison indicates that, except some polluted bays [5], TOM and C_{org} are generally higher than other Mediterranean coastal ecosystem. As is known industrial and domestic effluents discharged to the Dil Creek substantially untreated. Thus, it is assumed that elevated levels of TOM and C_{org} in Dil Creek estuarine are sourced from untreated discharges.

THE MAFRAGH ESTUARY. AN ATYPICAL AND PRISTINE MEDITERRANEAN ESTUARINE SYSTEM

Meriem Khelifi-Touhami [1]*, Meriem Khelifi-Touhami [1] and Makhlouf Ounissi [1]
[1] Département des Sciences de la Mer - meriem_khelifi@yahoo.fr

Abstract
The Mafragh estuary represents a particular Mediterranean wetland area rising northeast Algeria by its diversity of habitats and hydrological functioning. It is a semidiurnal microtidal estuarine system including two river estuaries with their marshlands and three dams. The catchment weakly populated, is exploited for agriculture from the middle estuary to the upper river parts. Distribution of water masses and nutrients has been investigated from 2005 to 2012 at four stations in the lower estuary. The Mafragh appears as an atypical estuary with a hydrologic cycle comprising river, estuarine core and lagoonal phases. The duration of each phase varies with the river input and the extent of dry season. A part from, the low SiO4 levels (Si:N and Si:P ratios are however balanced), the Mafragh may be considered as a rare pristine estuary.

Keywords: Hydrology, Algerian Sea, Nutrients, Salinity

The Mafragh estuary (Fig.1) water flow at the mouth is strongly variable (0 $m^3 s^{-1}$ in dry years and up to 2000 $m^3 s^{-1}$). The estuary mouth might be closed from its tidal connection under extended period of dry years [1]. In dry season, the salt wedge extends up to 20km inland. Following periods of high rainfall and freshwater run-off, the volume of the estuary system (3-4 Millions m^3) was entirely discharged into the sea and the salt wedge was then retreat to the coast in a few days. In winter and in the beginning of spring, tributary rivers discharge high flows to the sea, retreating then the salt wedge up to the sea. From the middle spring to the end of autumn, the estuary was dominated by tidal advection.

Fig. 1. Map of the Mafrag estuarine system. Bold line: limit of the catchment. W: limit of the salt wedge; ?: dam; ¡: position of the studied stations, 2005-2012.

The estuary expands then in a very stratified system, with two layers in which the saltwater layer occupies over 80% of the water column (Fig. 2). Water masses stability remains up to 10 months and very few mixing occurs at the halocline layer thickness (50-150 cm). Surface salinity varied between 0.10-20 and the deep saltwater salinity fluctuated between 28-36. Levels of nitrate in surface water were always 2-3 times higher than those of the bottom. Mean surface levels in all inorganic nutrients were comparable for the studied stations: 11-16 µM for nitrate, 6-10 µM for ammonium, 1-2 µM for phosphate and 50-70 for silicates. Waters were rich in dissolved organic nitrogen (26 µM), indicating then the existence of strong biological activity. This activity is also expressed by the abundance of particulate organic carbon (250 µM).

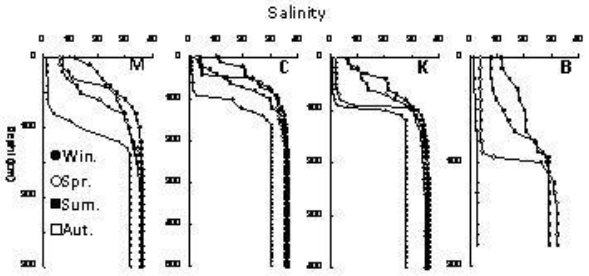

Fig. 2. Seasonal typical profiles of salinity in four stations of the Mafragh estuarine system. M: Mouth; C: confluence; K: Eastern Kebir; B: Bounamoussa.

APPLICATION OF DGT TECHNIQUE IN SPECIATION OF TRACE METALS IN A STRATIFIED ESTUARY

Abstract
An evaluation of Diffusive Gradients in Thin films (DGT) technique for speciation of trace metal(oid)s in relation to their bioavailability was performed in the stratified Krka river estuary (Croatia). Chelex-100 based DGT probes with both open and restrictive pores were used for speciation of Zn, Cd, Pb, Cu, Ni and Co, while iron-hydroxide resin was used for As speciation. The percentage of DGT-labile concentrations varied from >90% for Cd, down to ~20% for Cu. The difference between open- and restrictive-pores was unexpectedly small. An increase of total dissolved and DGT-labile As concentrations was observed with increase of salinity.

Keywords: Brackish water, Coastal waters, Trace elements, Organic matter, Central Adriatic Sea

Introduction
Bioavailability (and toxicity) of trace metals in natural waters depends primarily on the concentration of their reactive species. The speciation of inorganic metal complexes is well known, however the characterization of the interaction between metals and organic matter is still a challenging task, whether due to methodological or analytical limitations. Environmental Quality Standards (EQS) are still mostly based on total dissolved concentrations although it is well recognized that metal speciation should be taken into account for quality criteria. Simple and easy to use speciation methodology is prerequisite for such implementation on a wider scale. The DGT technique is one of the most promising techniques, because it provides a time-weighted average concentration of labile metal (i.e. potentially bioavailable/toxic) obtained directly in the water column (*in-situ*).
In this work, the DGT technique was used for trace metal speciation in the Krka River estuary (Croatia). The estuary is highly stratified with salinity gradient of more than 20 units within only 1 m depth range. Although considered as an unpolluted oligotrophic estuary, it is subjected to periodic anthropogenic pressure in summer seasons due to intensive nautical traffic which makes this site highly interesting to study metal speciation.

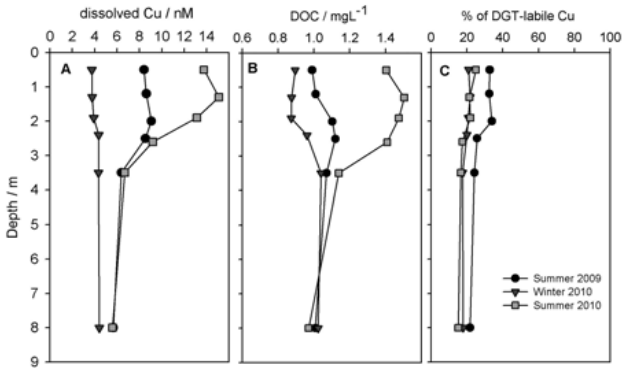

Fig. 1. Dissolved Cu, DOC and percentage of DGT-labile Cu at a "clean" site

Methodology
Several surveys were undertaken between 2008 and 2012 (winter and summer periods). Two contrasting sites were selected, one located in a "clean" area and the other one in a 'polluted" one. DGT devices for metals (open and restrictive pores) and arsenic (iron-hydroxide) were deployed at six depths for ~5 days during 5 separate campaigns. Accumulated metal(loid)s were, analyzed by HR-ICP/MS. Discrete samples were collected once or twice a day at each depth to make up composite samples in which dissolved and total metal concentrations (Zn, Cd, Pb, Cu, Ni, Co, As) were analyzed by voltammetry. Dissolved organic carbon (DOC) was measured as well.

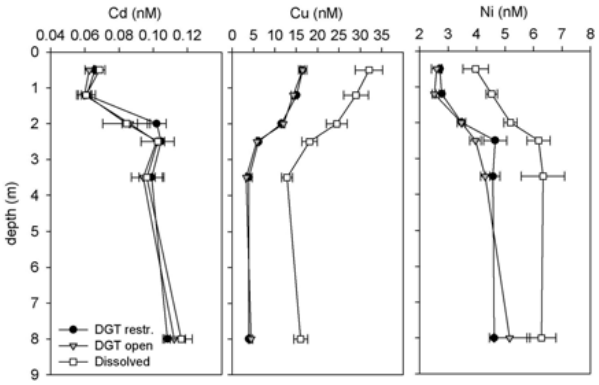

Fig. 2. DGT-labile and diss. Cd, Cu and Ni at "polluted" site (July, 2009)

Results
A typical seasonal variation of vertical concentration profiles of dissolved copper is presented in Fig. 1A. An increase of copper in the upper layer was observed in summer times as a consequence of copper release from anti-fouling paints. However, the extent of this increase is also dependent on the Krka river flow (dilution factor). Although of different origin and behavior, similar vertical concentration profiles were obtained for Cu and DOC (Fig. 1A,B), which in turn resulted in an analogous vertical profiles of DGT-labile copper (Fig. 1C). Vertical distribution of DGT labile metals displayed the same trends with depth as the one observed for total dissolved metals (Fig. 2). The percentage of DGT-labile metal was >90% for Cd, ~60% for Ni, ~50% for Pb and >20% for Cu but varied due to the different affinity of metals to dissolved organic matter (DOM), as well as different metal/DOM ratios [1] (Fig. 2). Surprisingly, DGT-labile metal concentrations measured using restrictive pore devices were almost the same or only slightly lower (<10 %) than those obtained using open pore probes (Fig. 2). In addition, a performance of DGT devices for measurement of Mn, Mo, V and U in estuary conditions was also examined. Voltammetricaly-labile (reactive) concentrations of Cu determined at natural pH were similar to those found by DGT technique, despite different characteristic timescale regarding the lability criteria of the two techniques [2]. The same increasing trends of both, DGT-labile and total dissolved concentrations of arsenic with salinity were observed in estuary water column. The absolute difference between these two concentration profiles suggests that As is to some extent organically complexed.

Abstract
We studied the relations between the estuarine Alexander River (eastern Mediterranean) and the adjacent aquifer. In this river, salinity and stratification are controlled by the sandbar at the river mouth. Highest salinities (27, 4 km from the sea) were observed following storm events, when the sand bar was breached, while during the dry season salinities dropped (<15) and stratification weakened. Electrical resistivity surveys (ERT and TDEM) and observations in shallow boreholes reveal that seawater intrusion is limited to the close proximity of the river. However, while at 300 m from the sea high salinities were restricted to several meters, at 1,800 m from the sea salinization reaches 100 m from the river. At both sites, salinization is limited to the superficial aquifer (<10 m), while the underlying aquifer retains its fresh water.

Keywords: Coastal processes, Levantine Basin, Estuaries, Salinity, River input

Introduction
Surface water-groundwater interaction, in particular seawater intrusion, occurs both along the coastline and along estuarine rivers. Seawater intrusion and its impact on coastal aquifer was widely investigated [1]. However, seawater intrusion via estuarine rivers was hardly studied in the field. The riverbed of the Alexander River (eastern Mediterranean, Israel) is partly below sea level, therefore it is permanently subjected to seawater encroachment, which reaches 4-5 km upstream. The estuarine part of the river cuts through a Quaternary granular aquifer, which is the main aquifer along the Mediterranean coast of Israel. The lithological sequence varies along the river due to temporal and spatial variability in sedimentatary environments.

Results and Discussion
The river mouth is usually blocked by a sandbar. Due to sandbar dynamics, major sea encroachments occur as short events (few days), mostly during or shortly after flood events (2-3 times a year), when high discharge flows and high sea conditions combine to breach the bar. Shortly after flood cessation (a few days), seawater intrudes through the entire length of the estuarine river. In such events, salinity may reach 27 at a distance of 4 km upstream. Shortly after the flood (<week), the sandbar is re-built, and seawater is no longer entering the river. Consequently, salinity of the bottom layer starts decreasing, usually within two weeks after the flood. Dry season salinities remain relatively high, with surface layer salinity ranging between 2-8 and bottom layer salinity usually does not exceed 15 and 7 (500 and 3900 m from the coastline, respectively). The applicability of the electrical resistivity method to the characterization of the salinity field was studied at the sea-aquifer system [2] but was never tested in the saline river-aquifer systems. We studied the extent of aquifer salinization along the estuarine part of the Alexander River, using both the electrical resistivity ERT and TDEM methods and salinity profiles in shallow boreholes. It was found that aquifer salinization is pretty limited but variable along the river. At 1,800 m from the sea, high salinities (<12) were observed in boreholes up to 45 m from the river and the ERT transect further extends the high salinity zone (low resistivity values) up to 100 (Fig. 1). On the other hand, at 300 m from the sea, high salinities were limited to a few m from the river. Both methods agree that salinization is limited to the superficial aquifer, and that the regional aquifer, at depths greater than 15 m (both sites), retained its fresh water (high resisitivity, Fig. 1). The variability in the extent of aquifer salinization is explained by differences in the aquifer-river hydraulic gradients (significantly lower at the eastern site), though it could also be related to heterogeneity in the near-river conductivities due to sediment variability. In other studies, salinization was observed to much larger distances from the river (e.g. 500 m) [3]. This is probably due to different hydrogeological settings and should be further studied.

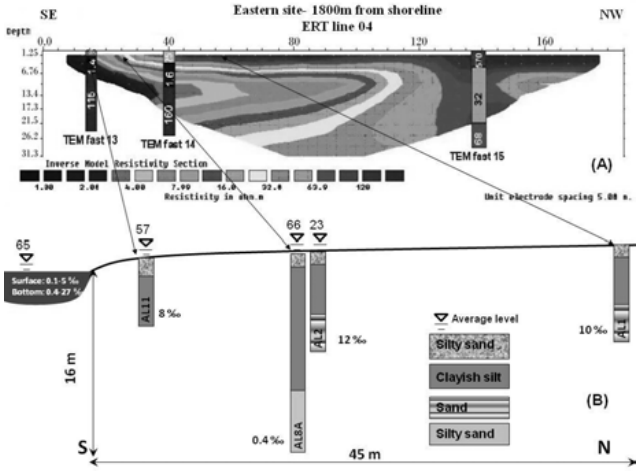

Fig. 1. (A) Integrated ERT-TDEM transect north of the river, 1,800 m from the sea; (B) borehole lithology, salinities (during drilling) and average water level at the same site. Black area (on the left side) in the ERT profile represents low resistivity, which is interpreted as high salinity water, while dark area (from right end to below) is of low salinity water. The gray area (in between) is of mixed water. Arrows indicate the boreholes location on the ERT line.

Abstract

A growing concern for environmental issues is observed in the development of marine paints and coatings. This study is part of ECOPAINT PACA project and is focused on the comparison of the activity of several natural compounds to those of commercial biocides on the adhesion of marine bacteria and macroorganisms. *In vitro* and *in situ* tests were carried out on the selected compounds and on coatings containing them.

Keywords: Fouling, North-Western Mediterranean, Bacteria

Introduction

Any object immersed in seawater will rapidly attract the attention of marine fouling, causing severe problems on dynamic or static structures such as vessels, platforms, buoys or fishnets. Antifouling coatings generally comprise biocides or active compounds which could inhibit the settlement of marine micro- and macro-organisms [1]. In the past decade, the antifouling paint industry has been totally disrupted with the ban of tributyltin oxide or tributyltin-based compounds by the International Maritime Organization. The ECOPAINT PACA project aims at developing innovative antifouling paint technologies with long-time efficiency and limiting toxic products. In accordance with the European Biocidal Products Directive, the selected active compounds have to inhibit the adhesion of target marine organisms on immersed structures without toxicity and to exhibit no ecotoxicity against non-target organisms.

Materials & methods

3 wt. % of commercial active compounds [SeaNine^{TM} 211N (SN), Preventol® A4S (Dichlofluanid), copper oxide (Cu_2O), copper sulfate ($CuSO_4$), and bis(tri-*n*-butyltin)-oxide (TBTO)] were dispersed separately in a polymer matrix (Metamare^{TM} B175). Eleganediol previously extracted from the brown alga *Bifurcaria bifurcata* [2] and two commercial natural compounds (e.g. farnesol and capsaïcin) were used. TBTO was used as a toxic reference. Panels coated with paints together with a reference panel coated with the matrix only were immersed in duplicates. The immersion was performed for 6 months in Toulon bay. Macrofouling development was followed every month and a score, called N factor, was given. The N factor depends on the intensity and the type of species settled on the surface. An anti-adhesion test was performed for assessing the EC_{50} of each substance on three pioneer marine bacteria [3]. Two *Pseudoalteromonas* spp. and one *Polaribacter* sp. were used. The ecotoxicity of each substance was also assayed on five species (i.e. *Phaedactylum tricornutum, Acartia tonsa, Crassostrea gigas, Paracentrotus lividus, Psetta maxima).*

Results & discussions

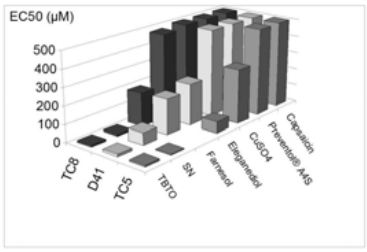

Fig. 1. Adhesion response (EC_{50}) for the three bacterial strains with all the assayed compounds.

Figure 1 shows the ability of each substance to inhibit the adhesion of three marine bacterial strains. TBTO was found unsurprisingly to be the most efficient compound against all the strains but SN exhibited also a high activity. Natural compounds such as eleganediol displayed interesting results with quite good anti-adhesion activities against two of the three strains associated with no toxic effects. Preventol® A4S showed no activity as it is classified as a fungicide. Figure 2 shows that four coatings exhibit a good antifouling activity over 6 months of immersion. Coatings containing SN, Cu_2O and Preventol® A4S were efficient against macrofouling. Farnesol, eleganediol and capsaicin did not show any effective enhancement of the antifouling activity of the coating. Finally, a correlation was established between the N/N_{ref} ratio and the adhesion response (EC_{50}) from bioassays. Ecotoxicity tests showed that TBTO, SN and $CuSO_4$ are highly toxic towards phytoplankton, crustacea, bivalve molluscs, echinoderms and fish juveniles. Eleganediol and Preventol® A4S exhibited moderate toxicity whereas capsaicin was not toxic towards all species. Therefore, promising results were shown for Preventol® A4S-based coatings considering its activity/ecotoxicity ratio.

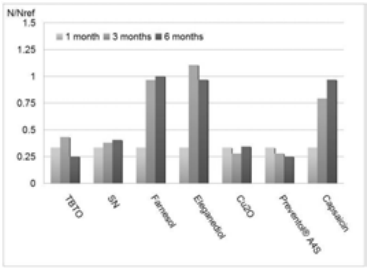

Fig. 2. *In situ* activity of coated panels through the assessment of the N factor (*Adapted from the French standard NFT-34-552 (September 1996)).* N = antifouling efficiency of the active compound-based coatings. N_{ref} = antifouling efficiency of the polymer matrix-based reference coating.

Conclusion

This study highlighted the difficulties encountered to found and to assess the antifouling efficiency of new eco-friendly antifoulants. To replace TBTO or copper-based compounds in antifouling coatings, the active compounds have to inhibit the adhesion of foulers on immersed structures without toxicity and to exhibit no ecotoxicity on non-target marine organisms.

Abstract

Biofouling is a natural process of colonization of submerged surfaces, involving a wide range of organisms, from bacteria to invertebrates. This study aims to assess the spatio-temporal variation of microbial communities that colonize different antifouling coatings for ship hull in two contrasted immersion sites.

Keywords: Fouling, North-Western Mediterranean, Bacteria, Coastal waters, Diatoms

Introduction

When immersed in sea water, any substrate would be rapidly colonized by micro and then macroorganisms. This complex natural process called biofouling induces economic and ecological prejudices, especially talking about ship hulls or aquaculture nets. Antifouling (AF) coatings are required to prevent the coloniation of ship hulls. Increasing attention is paid to biofilms that develop on coatings [eg 1], firstly because their presence directly increases frictional resistance and consequently fuel consumption, and secondly, because biofilms have been shown to influence the secondary settlement of invertebrate larvae and/or algal spores [2]. Biocidal coatings include several biocides without clear idea of the effect of each one. Previous studies in the Toulon bay with commercial AF paints showed that specific effects could be observed on biofilm communities for each coating [3]. In this study, we intend to characterize the specific effect of three commercial biocides on biofilm communities.

Material & methods

The commercial biocides (Copper pyrithione, Zinc pyrithione and Zineb®) were dispersed separately in one polymer matrix (Neocryl B725®). Panels coated with the polymer matrix alone together with a Poly(vinyl chloride) (PVC) reference surface were also immersed in triplicates as negative controls. The immersions were performed for one month at each season, in two temperate French coastal sites, Toulon bay (North-Western Mediterranean Sea) and Lorient bay (Atlantic Ocean). Water quality (temperature, salinity, oxygen, pH, dissolved organic/inorganic carbon, dissolved trace metals) was monitored during the immersion periods. Microbial communities were analysed using complementary tools: PCR-DGGE, pyrosequencing and flow cytometry (FCM) for prokaryotes, pico- and nano-eukaryotes, inverted microscopy for microphytobentic populations.

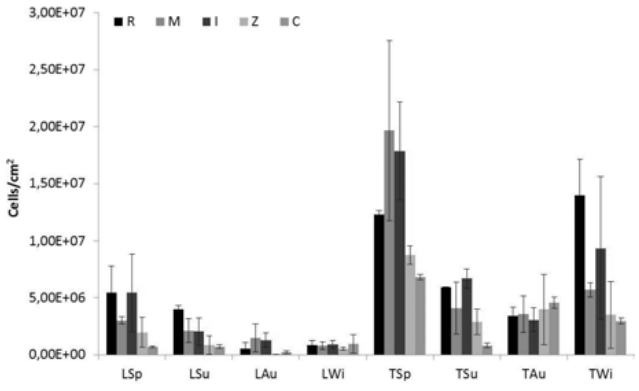

Fig. 1. Seasonal variations of the density of bacteria on the five coatings (R=PVC, M=B725, I=Zineb, C=CuPyr, Z=ZnPyr) assessed using flow cytometry (L=Lorient, T=Toulon / Sp=spring, Su=summer, Au=autumn, Wi=winter)

Results & discussion

FCM shows that copper pyrithione was the most efficient biocide whatever the location. Bacterial density was divided until 8 times compared to R, although no effect was also be observed in one case at each location (Fig.1). On the contrary, I displayed no significant difference in terms of abundance compared to R. Higher densities were observed at Toulon without a clear seasonal effect whereas the latter was clear at Lorient with the highest densities in spring. Similar clustering was obtained using DGGE analysis at both locations (Fig.2): Season was preponderant but coatings also impact clearly the prokaryotic communities. M (closely related to I) did not show a significant effect compared to R in terms of bacterial abundance (Fig.1) but clearly in terms of structure of bacterial communities (Fig.2). C and Z also displayed closed communities whatever the season and the location although densities appeared different in most cases. The current analysis of the whole data will allow us to get a general vue and to precise the effect of each parameter (biocide, season, geographical location) on biofilm communities on AF coatings.

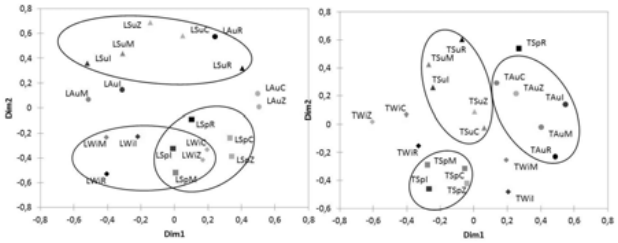

Fig. 2. MDS graph showing Jaccard similarity index of bacterial diversity of the five coatings analysed by 16S rDNA DGGE

FRC/SPC HYBRID ANTIFOULING COATINGS: A NEW CONCEPT OF ENVIRONMENTALLY FRIENDLY ANTIFOULING TECHNOLOGY.

Marlène Lejars [1]*, André Margaillan [1] and Christine Bressy [1]
[1] Université de Toulon, MAPIEM, EA 4323 - marlene.lejars@univ-tln.fr

Abstract
Environmentally friendly FRC/SPC hybrid antifouling coatings were developed with the aim of improving the antifouling efficiency of FRCs during idle periods and at low ship speed and reducing the impact of biocides into the marine environment. Well-defined graft copolymers based on hydrolyzable *tert*-butyldimethylsilyl methacrylate (SPC-type) and hydrophobic poly(dimethylsiloxane) methacrylate (FRC-type) were synthesized by the RAFT process. The polymers exhibited a low surface energy similar to FRCs and erosion properties like SPCs. They were used as binders in the formulation of FRC/SPC hybrid antifouling coatings containing no biocides (or low amounts). The coatings were immersed in the Toulon bay (France), and good antifouling properties were observed after several months of immersion, combined with a fouling release behavior.

Keywords: North-Western Mediterranean, Fouling

Any surface immersed in seawater is rapidly colonized by fouling organisms. This colonization has serious impacts on ship navigation (e.g. increased roughness, increased fuel consumption) and is responsible for the transfer of invasive species from an eco-system to another. Two main antifouling coatings can be applied on ship hulls to limit fouling colonization:
- Self-Polishing Coatings (SPC) [1]: These coatings release toxic biocides into the marine environment by controlled erosion of the surface.
- Fouling Release Coatings (FRC) [2]: These coatings based on a poly (dimethylsiloxane) (PDMS) matrix, without biocides, limit the fouling adhesion strength owing to their low surface energy, resulting in the easy removal of fouling organisms at ship speed higher than 10 knots.
The aim of our work is the development of an environmentally friendly FRC/SPC hybrid coating, without biocides, with both the hydrophobic properties of PDMS and a controlled erosion of the coating. Thus, the antifouling efficiency of FRCs during idle periods and at low speed could be improved and the impact of biocides into the marine environment reduced.

Tri-alkylsilyl methacrylate monomers can be used for the synthesis of binders for SPCs. Indeed, they can be hydrolyzed in seawater which influences the hydrophilic character of the synthesized polymers and consequently its erosion upon time. Hybrid FRC/SPC polymer binders, based on *tert*-butyldimethylsilyl methacrylate (TBDMSiMA, SPC-type) and PDMS methacrylate (FRC-type) have been synthesized by the RAFT process (Radical Addition-Fragmentation chain Transfer) (Figure 1).This controlled polymerization process enables the synthesis of well-defined graft copolymers (diblock, blocky, gradient) with controlled molecular weights (M_n = 20,000 and 50,000 g.mol^{-1}) and narrow distributions (PDI < 1.2).[3]

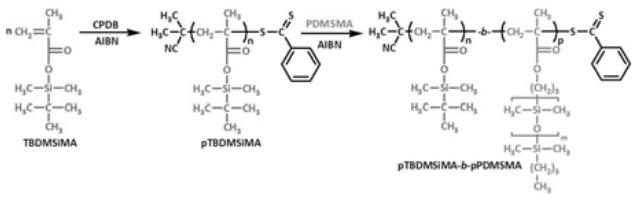

Fig. 1. Synthesis of pTBDMSiMA-*b*-pPDMSMA diblock graft copolymers by the RAFT process in the presence of 2-cyanoprop-2-yl dithiobenzoate (CPDB) as chain transfer agent, azobisisobutyronitrile (AIBN) as initiator, at 70°C, in xylene.

The PDMS side chains distribution and length (1,000 or 5,000 g.mol^{-1}) were shown to be significant parameters influencing the thermal behavior of the copolymers, their low surface energy and their erosion properties in artificial seawater. The graft copolymers exhibited surface energies as low as 21 mJ.m^{-2}, similar to commercial FRCs. They were used as binders for the formulation of antifouling coatings with no biocides (or low amounts). The coatings were applied on PVC panels and immersed in the Mediterranean sea (Toulon bay). Coatings showed good antifouling properties after 7 months of static immersion, combined with fouling release properties (Figure 2). Indeed, coatings containing 20wt.% of Cu_2O + 2wt.% of Seanine 211 were free from fouling organisms, like the commercial SPC reference which contains higher amounts of biocides. Coatings without biocides were colonised by only 15% of spirorbus and 10% of bryozoans compared with the PVC panel without coating which was fully covered by spirorbus, barnacles, bryozoans, ascidies, tubeworms, etc. Moreover, it showed good fouling release properties when slightly washed with a wet sponge on the top of the panel.

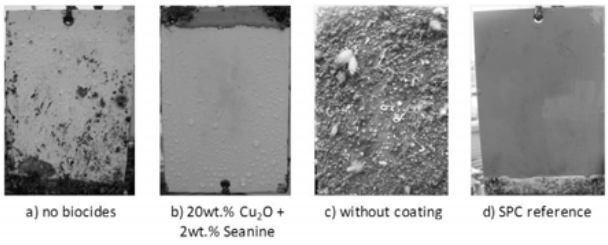

Fig. 2. Pictures of panels coated a) with a FRC/SPC hybrid coating containing no biocides, b) with a FRC/SPC hybrid coating containing 20wt.% of Cu_2O and 2wt.% of Seanine 211, c) panel without coating and d) panel coated with a commercial SPC reference, after 7 months of static immersion in the Toulon bay. Fouling organisms were easy removed using a wet sponge at the top of the panel a).

INTERACTIONS BETWEEN MACRO-ALGAE AND ASSOCIATED BACTERIA: BIOFILM CONTROL BY SURFACE SECONDARY METABOLITES IN THE MEDITERRANEAN BROWN SEAWEED *TAONIA ATOMARIA*

A. Othmani [1]*, M. Molmeret [1], Y. Blache [1], J. F. Briand [1] and G. Culioli [1]
[1] Université du Sud Toulon-Var, ISITV Laboratoire MAPIEM - ahlem.othmani@univ-tln.fr

Abstract
Marine biofouling concerns all submerged surfaces. However, some marine organisms, namely macroalgae, such as the Mediterranean brown species *Taonia atomaria*, appeared to be relatively free from macro-colonizers. The production of secondary metabolites at the surface of this alga could be strongly linked to its antifouling defence capability.

Keywords: Algae, Bacteria, North-Western Mediterranean

Introdcution
In the marine environment, biofouling can be observed on all immersed surfaces including natural substrata. However, some marine organisms, such as macroalgae, appeared to be relatively free of epibionts. Many studies have shown that various algal taxa release substances with inhibitory effects to colonizers [1, 2, 3]. In order to understand the defence strategies of marine organisms against foulers, the analysis of the surface metabolome and the study of its involvement in the regulation of bacterial biofilm were undertaken in the case of the Mediterranean Phaeophyta *Taonia atomaria*, which appeared to be somewhat colonized.

Materials and methods
Specimens of *T. atomaria* were collected on the French Mediterranean coast (Carqueiranne, Var). In a first step, the total and the surface chemical composition of this alga were characterized. A specific extraction protocol of surface compounds was developped using the dipping technique in organic solvents [4]. This included the choice of organic solvents and exposure time, which were selected in order to preserve the integrity of the algal surface. The resulting surface extracts were analyzed by chromatographic techniques (GC-MS and LC-DAD/ELSD/MS^n) and the identification of their major compounds was achieved by comparison of these data with those of the pure metabolites isolated from the whole-cell extracts and characterized by spectral techniques (MS, 1D & 2D NMR). The next step was to isolate bacterial strains associated onto the surface of *T. atomaria*. Two methods were used: (i) sonication of rinsed thalli in artificial sea water and (ii) scraping with cotton swab. These strains were inoculated on VNSS agar meduim. The main objective, following the identification of surface secondary metabolites and the isolation of bacterial strains, was to understand the chemical mediation between this alga and associated biofilms by the assessment of the deterrent effects of those metabolites against some associated bacterial strains and several marine strains isolated from artificial substrata (Reference bacteria).

Results and Discussion
Spectral analyses allowed the characterization of several phytoconstituants of this alga as sesquiterpenes and fatty acids. Some of them were identified as new compounds. After the development of a specific extraction protocol of surface-associated metabolites. MeOH and mixture of CH_2Cl_2/MeOH seemed to be the suitable solvent systems for the extraction of surface metabolome. The corresponding surface extracts showed the occurrence of a major compound after GC-MS analysis, which was identified as (1) by comparison of its spectral data with those of the resulting pure substances obtained from the whole-thallus extract. Cell lysis was assessed by staining the treated algal pieces with a solution of DAPI (60 µM). Using an epifluorescence microscope, damaged cells were counted and the appropriate time exposure without disrupting cells was determined (less than 30s). The anti-adhesion effectiveness of selected surface compounds was tested against ten marine bacterial strains including five out of 33 cultivable bacterial strains isolated from the surface of *T. atomaria*, and five reference strains isolated from artificial surfaces. The obtained results showed that commercial biocides (TBTO and Zineb®) and other compounds from the whole-extract of *T. atomaria* exhibited a similar effect on all bacterial strains. Interestingly, the main surface metabolite (1) showed no effect against surface-associated bacteria while it seemed to inhibit significantly the settlement of reference strains. Further experimentations are in progress to test the effectiveness of these surface-associated metabolites against a large panel of fouling colonizers (spores of macro-algae, larvae of invertebrates,...) and to explore if chemical cues from associated bacterial strains are implicated in the biofilm regulation?

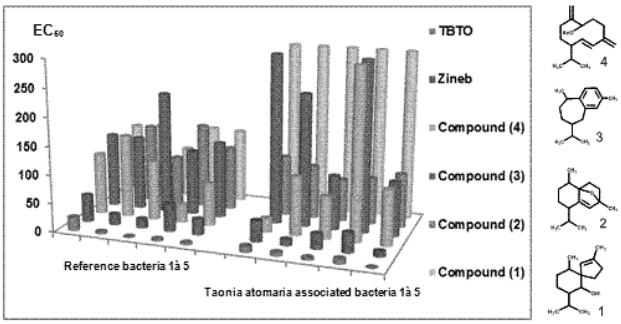

Fig. 1. Anti-adhesion activity (EC_{50}) of commercial biocides and compounds isolated from *Taonia atomaria* against several marine bacterial strains.

Abstract
Crambe crambe (Porifera - Poecilosclerida) is known to possess an array of highly bioactive metabolites strongly bioactive in general bioassays. Crude extracts from *Crambe crambe* (Schimdt, 1862) collected in Paraggi Bay (Ligurian Sea) have been investigated for their antifouling activities using larvae of the barnacle *Amphibalanus amphitrite*.

Keywords: Fouling, Ligurian Sea

Introduction

Many marine sponges, as well as other benthic organisms, are relatively free of settlement by fouling organisms (1) due to the production of biogenic compounds that possess many chemical defense agents.
The common encrusting sponge *Crambe crambe* (Schmidt, 1862) is widely distributed in the Mediterranean Sea and this species is known to possess an array of potentially active metabolites with lots of activities, including antifouling properties (2).
The present study investigated the antifouling activity of a series of crude extracts from the sponge *Crambe crambe* against *Amphibalanus amphitrite*, one of the main constituents of sea biofouling.

Materials and Methods

Six specimens of *C. crambe* was collected by SCUBA diving at Paraggi Bay (44°18'38.81"N 9°12'47.48"E), Ligurian Sea. After collection the samples were rinsed with filtered sea water and debrids and surface microflora was removed. The clean material was freeze and then freeze-dried. The dry material was pulverize and then extracted three times at room temperature with MeOH. The extract was then concentrated under vacuum.
The antifouling activities was detected in CNR-ISMAR's laboratory where the crude extracts were tested with cypris larvae of *A. amphitrite* in the settlement inhibition bioassay and with nauplii of *A. amphitrite* in the mortality bioassay. Settlement inhibition (EC50) at 72h and mortality (LC50) values at 48h were calculated using Trimmed Spearman–Karber analysis. The extracts were tested in three replicates at 10, 5, 2.5, 1 and 0.1 µg of extract per ml.
The Therapeutic Ratio (TR) is defined as LC50/EC50. It was calculated in order to estimate whether settlement inhibition is due to a toxic or non-toxic mechanism (3).

Results

The results of settlement inhibition and mortality bioassays summarized in Table 1.

Tab. 1. EC50 (cyp) and LC50 (cyp) derived from settlement inhibition test with cypris larvae after 72h and LC50(nauplii) from mortality test with nauplii of *A. amphitrite* (with 95% confidence limits).
The values are express in µg/ml.

Sample	EC50 (cyp)	LC50 (nauplii)	LC50 (cyp)
1	0.67(0.31-1.47)	1.33(1.20-1.48)	>10
2	1.71(1.41-2.06)	1.11(1-1.23)	>10
3	2.53(2.31-2.77)	0.92(0.79-1.06)	>10
4	1.64(1.47-1.84)	1.50(1.35-1.68)	>10
5	1.73(1.54-1.94)	1.33(1.19-1.49)	>10
6	0.70(0.63-0.78)	1.10(0.98-1.23)	>10

In table 2 it is reported the TR values. High TR values indicates low toxicity of the tested compounds.

Tab. 2. TRn values

Sample	TR (nauplii)
1	1.98
2	0.65
3	0.36
4	0.91
5	0.77
6	1.57

Conclusions

Complying with the guidelines of the U.S. Navy Program that require an EC50 <25 µg/ml for a compound to be considered a promising natural antifoulant products (NAPs), all the samples evaluated in this study meet this requirement. Settlement inhibition levels of the tested extracts are similar to some of the most significant ones found in literature for natural products (3). Looking at TR, compounds with TR>15 could be considered as non toxic antifouling: the results suggest that settlement inhibition of all the texted samples can be associated to a toxic mechanism. This study confirms that Crambe crambe is a highly successful Mediterranean sponges in chemical defence (4) and it points out the well performing antisettlement activity against barnacle, which is due to a toxic mechanism. Ecotoxicological characterization with non-target organisms will be needed in the future to assess the potential environmental impact and to validate the passage to the second stage of screening as a potential biocide of natural origin.

Abstract
The development of macrofouling settled on the VLCC Haven wreck was followed after sinking from 13 years to 18 years in relation to oil removal operations. The main components of the fouling assemblage are algae, serpulids, bryozoans , sponges, madreporians, hydroids, molluscs. The bivalve *Neopycnodonte cochlear* (Poli, 1795) and the jewel sea anemone *Corynactis viridis* Allman, 1846 are the dominant species of fouling after 18 years.

Keywords: Artificial reefs, Fouling, Ligurian Sea

On April 11th 1991 the VLCC Haven, carrying 144,000 tons of "heavy Iranian crude oil", exploded off the Genoa oil terminal. In the first explosion the ship lost the deck, the burning wreck broke into two parts: the main part (220 m of length) sank to a depth of 75-78 meters, 1,5 nm off the coast of Arenzano. The amount of burned petroleum hydrocarbons was estimated in the range 95,500-103,500 tons while 3,000 tons remained trapped inside the wreck. The paint of the hull was also burned.

Many years later, in 1999 money was made available to carry out a study and, mainly, for restoration work. Moreover, it was decided to remove liquid oil residues still contained inside the wreck and to monitor the environment before, during and after the removal operations. The study of fouling was considered a valid tool, along with others, to assess the potential impact of reclamation activities on the marine environment.

To our knowledge, there are no studies on fouling of shipwrecks in the Mediterranean sea except for photos and films produced by scuba divers, but identification of organisms is lacking.

The macrofouling of the NW Mediterranean basin is quite well known [1] and some data also deal with colonization of offshore structures [2]. The main aim of this paper is to describe the macrofouling monitored on the largest wreck in the Mediterranean Sea during the 18-year period from 1991 to 2009.

The study of Haven fouling was performed on the main part of the wreck sunk at 75-78 m depth off the coast of Arenzano (Lat. 44°16'24''N, Long. 008° 41'23'' E) by scuba divers expert in marine biology and ecology. A first survey, visual and photographic, was carried out in December 1991 but only many years later it was decided to organize and support a detailed programme of investigation on the fouling of the wreck from February 2004 to November 2009. Two complementary methods were used: scraping of the benthos settled on the wreck and photographic monitoring. Five stations were chosen at about 39 m depth on the main deck and the funnel. The samples were collected on a vertical surface of 310 cm^2 in three replicates per station. Before scraping all sampled areas were photographed by a Nikon with 28 mm lens on a surface of 310 cm^2.

Biomass was assessed by wet weight of entire samples than transformed in g/dm^2; the main difficulty was the separation of ferrous and burned material scraped with biological material. Organisms are identified at the lowest possible taxonomic level. Six surveys were carried out three before (on 12-13/02/2004; 01/04/2004; 9-17/11/2004), one during (15-19/05/2008) and two after (17-27/11/2008; 19-24/11/2009) reclamations activities. In the present paper only organisms present in the samples of five stations are described. Fish and megabenthos observed by scuba divers are not taken into consideration.

In December 1991, eight months after the Haven sinking, some organisms were settled on the wreck in spite of the presence of burnt materials on the surface. About 25% of the surface was settled, the main foulers were serpulids *Serpula concharum* (Lagerhans 1880), *Pomatoceros triqueter* (Linnaeus 1758), *Spirobranchus polytrema* (Philippi 1844) and the bivalve *Neopycnodonte cochlear*.

During the six surveys (February 2004-November 2009) in total 217 taxa were identified, 161 at species level in the five sampled stations. The most numerous taxon is Annelida (N=50) followed by Algae (N=47) and Mollusca (N=27), this ranking occurred in almost all surveys. Among cirripedes only *Verruca spengleri* Darwin, 1854 was found in a single sample. The number of taxa increased from February 2004 (N=42) to May 2008 (N=126) then decreased to 102 in November 2008 and 83 in November 2009 (Table 1).

Tab. 1. Number of taxa monitored during the six surveys.

	Survey							
	1	2	3	4	5	6	*Total Number*	
Taxa	Feb-04	Apr-04	Nov-04	May-08	Nov-08	Nov-09	*Taxa*	*Species*
ANNELIDA	11	12	12	28	30	24	*50*	*43*
ALGAE	2	2	2	29	19	20	*47*	*45*
MOLLUSCA	7	8	4	22	17	12	*27*	*18*
BRYOZOA	6	6	8	15	9	8	*24*	*15*
PORIFERA	3	4	3	9	9	8	*21*	*13*
CRUSTACEA	3	3	4	10	8	5	*18*	*13*
CNIDARIA	8	7	5	8	7	5	*15*	*11*

PROTOZOA	1	2	1	2	1	1	*4*	*1*
PYCNOGONIDA	1	1	2	0	0	0	*2*	*0*
TUNICATA	0	1	1	0	0	0	*2*	*0*
SIPUNCULIDA	0	1	1	1	0	0	*1*	*0*
PLATYHELMINTHES	0	1	0	0	0	0	*1*	*0*
Tot.	42	49	45	126	102	83	*217*	*161*

The higher reduction occurred for molluscs, algae and bryozoans. The main components of the fouling assemblage are algae, serpulids, bryozoans , sponges, madreporians, hydroids, molluscs. *N. cochlear* and the jewel sea anemone *Corynactis viridi*s are the dominant species of the final community in 2009. Their role changed from the first survey (13 years after sinking) to the sixth, carried out five years later (18 years after sinking).

The biomass (wet weight - g/dm^2) of fouling increased with time from the first survey to the last two: there is a huge difference between the first two samplings (an average of about 30.6 g/dm^2) and the final two with an average of 168.0 g/dm^2. The value of the 6th survey is a little lower than that of 5th survey. This trend is confirmed in almost all stations. The highest values generally were in relation to the amount of the oyster *N. cochlear*.

The highest number of taxa occurred during the 4th survey where a large number of shells of the oyster *N. cochlear* were found empty and no more individuals settled in the following years, probably because of competition with sponges and *C. viridis*. These taxa not only take up a lot of space but can produce antifouling substances (antibiotic/allelopatic competition) and so be the main cause of reduction of the fouling community. An additional cause could be the increased silting in the last year due to beach nourishment along the nearby coast. There is no evidence that the restoration (cleaning) operation of the wreck carried out in May-June 2008 has influenced the fouling community of the wreck.

The Haven wreck is of great interest for scuba diver tourism and behaves as an artifical reef, like that described by Hiscock et al. [3].

PROJECT TO RAISE SOCIETY AWARENESS TO THE IMPACT OF MARINE DEBRIS ON THE SEABED: PILOT PLAN IN THE MEDITERRANEAN SEA

M. Demestre [1]*, E. Vallejo [1], M. Masó [1], S. De Juan [1], R. Sáez [1], A. Muntadas [1], A. Gárcia-De-Vinuesa [1], P. Sánchez [1], P. Martín [1] and J. Fortuño [1]
[1] Institut de Ciencies del Mar - CSIC - montse@icm.csic.es

Abstract
This Pilot Plan was designed with the aim to report the impact of marine litter and to heave public awareness of the necessity to protect marine ecosystems. The project consisted on a socio-scientific work developed by students who analysed the marine debris collected from bottoms off Palamós coast (NW Mediterranean). It aimed to raise awareness of the importance of management actions to favour drastic reduction of the litter dumped at sea.

Keywords: Plastics, North-Western Mediterranean, Continental shelf

AIM AND OBJECTIVES
The Pilot Plan was the outreach objective of the scientific Project "Evaluation of the state of benthic communities subjected to impact of trawling and marine debris as a tool for the ecosystem management", COMSOM (CTM2008-04617/MAR) (http://comsom.cmima.csic.es). The final aim of the Pilot Plan was to alert the society about the necessity to protect marine ecosystems from the accumulation of bottom marine debris and about the urgent need to eliminate this source of impact on the seabed. The Pilot Plan was designed to be an education tool aiming to change the attitudes of the society, that need to be involved if the problem of recycling the marine debris is to be solved. The project was a pioneer experience that coordinated both social and scientific work and, most importantly, it simultaneously involved different stakeholders: fishermen, students, managers, disseminators and scientists.

WORKING PLAN
A spatiotemporal work plan was designed in the Palamós fishing grounds (fig. 1), to collect the benthic marine debris obtained during a week:
• at each season of the year, and
• at 5 different depths: <50m, 50-100m, 100-200m, 200-400m and 400-900m

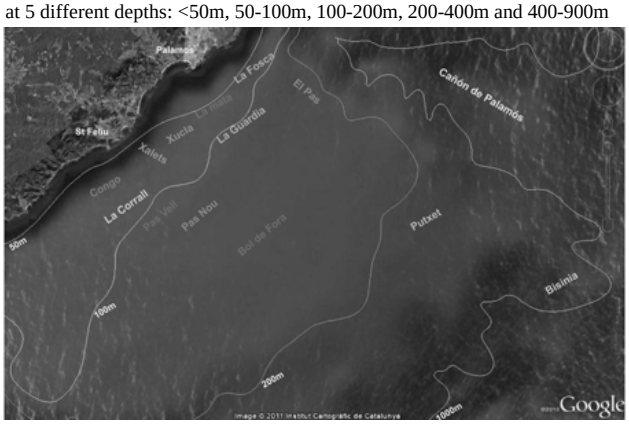

Fig. 1. Palamós fishing grounds where the benthic marine debris was collected

Therefore, 4 outreach activities, each with 5 samples of benthic debris, were developed. The fishermen were responsible to "fish" the benthic debris with 5 fishing boats, 1 trammel net (<50m) and 4 trawlers (50-900m), during the proposed plan. The students were the "scientists" that worked during each of the four activities with the debris "fished", and followed a research protocol, sampling, process of samples, analysis of data, discussion of results and conclusions, always supervised by the scientific team from ICM-CSIC. The work of communicating with the society and contacting with schools was conducted by the Museum of the Fishing of Palamós, and the recycling was done by the Environment Area of the city hall of Palamós.

ACHIEVEMENTS AND STATEMENT
The participation of 191 students from three schools during the four activities was the greatest achievement of the Pilot Plan. At the end of the experience each School presented their results and discussion in a joint meeting (Fig. 2).

Fig. 2. Images during the activities of the schools: a) sampling of debris at the vessels; b) presentation of the Pilot Plan to the students; c) preparing samples; d) separation and classification of the debris; e) weighing plastics; f) identification of colonizing organisms; g) analyzing data; h) closing meeting, presentation of results by students

The students' work provided basic information to convincingly inform the society of the need to advance towards a correct management for the recycling of marine debris. The main conclusion presented by the students were: i) plastics are the most abundant marine litter accounting to 63% of the total litter, being bags the most abundant typology (29%), ii) the abundance of marine litter diminishes with depth, being plastics and general litter most abundant at depths between 50-100 m, iii) there is no clear seasonal pattern in litter collection, and iv) the majority of the plastics had a great level of degradation and were colonized by organisms that evidenced a long permanence on the seabed. In addition, two high school research works were developed with those data. The major conclusion that students deduced from the Pilot Plan was that the presence of litter, particularly plastics, on the seabed could modify the natural benthic ecosystem equilibrium. The statements presented by the students were in accordance with published scientific papers ([1], [2], [3]).

Acknowledgements. Thanks to Gloria Ñaco and colleagues of the Museu de la Pesca de Palamós for their help on the dissemination works. We are grateful to skippers and crew of the vessels used for the sampling, and the Fishermen's Association of Palamós port. We acknowledge the enthusiastic participation of the IES Puig Cargol, Vedruna and Palamós.

Abstract
This protocol aims to the standardization of the data collection procedure for litter deposited on the sea floor that is collected mainly during the International Bottom Trawl Surveys in the Mediterranean (MEDITS). Thirty four different typologies were identified including 9 main categories related to litter material and 25 sub-categories related to source and main litter findings. Information on litter composition is recorded in terms of total weight and number and weight by litter categories, in a specific form to be integrated with haul information. This procedure will enable the estimation of total and by categories litter abundance per km^2, by depth and geographic area, aiming to future recommendation depending on litter sources.

Keywords: Trawl surveys, Monitoring, North-Central Mediterranean, North-Eastern Mediterranean, North-Western Mediterranean

The manufactured litter lost or deliberately discarded into the sea is variable and represents a growing threat to marine ecosystems, fisheries and public safety [1]. The availability of Litter Monitoring Data and harmonized monitoring methodologies are considered of prime importance to assess marine litter spatio-temporal abundance, to identify its origin and achieve an equal level of Good Environmental Status (GES) across all European Seas through the implementation of Marine Strategy Framework Directive (MSFD) concerning Descriptor 10 : «Properties and quantities of marine litter do not cause harm to the coastal and marine environment». The MSFD GES Technical Subgroup on Marine Litter, established following to the Commission Decision 2010/477/EU, proposed the inclusion of litter monitoring during the coordinated MEDITS trawl surveys, which are conducted for demersal fish stock assessments on the continental shelf and upper slope in 20 Geographical Sub-Areas (GSA), as the best option to gather information on the amount and composition of litter on the Mediterranean Sea bottom [2]. The protocol prepared by the MEDITS Working Group for Litter is mainly based on the IFREMER protocol for the observation of macro-litter during Fisheries Surveys [3] but also on the suggestions of Marine Litter Technical Recommendations for the Implementation of MSFD Requirement [2], CEFAS protocol for benthic litter recording [2], as well as the results of a relevant study in the Tyrrhenian Sea [4]. The proposed procedure concerns observations of macro-litter collected from the sea floor by fishing gears (trawl nets, drags, hand lines, e.t.c.) used during fisheries surveys, but not those of floating litter or non-fisheries surveys.

Definition of marine litter:
In the framework of the MSFD for the GES of the sea, marine litter consists of items that have been deliberately discarded, unintentionally lost, or transported by winds and rivers, into the sea and on beaches. It mainly consists of plastics, wood, metals, glass, rubber, clothing and paper. Land-based sources account for up to 80% of marine litter – these include tourism, sewage and illegal or poorly managed landfills. The main sea-based sources are shipping and fishing [5].

Procedure to collect litter data:
On board the vessel, the litter collected is weighted as total and split into the categories and sub-categories shown in Table 1. It is mandatory to record or estimate total weight, regardless the categories and subcategories, as well as number of items for each main category: It is facultative to register weight by categories and number of items by sub-category. Qualitative and quantitative data on the litter must be reported in a specific form on litter and be connected to data regarding the general characteristics of the haul (haul code, date, geographic coordinates, depth zone, e.t.c.) and the gear performance, allowing the estimation of the trawled surface for each haul and standardized indices of total and by categories litter abundance per km^2. A photograph of total litter separated from fish catch, labelled with main haul data, is recommended as it might be used to future analysis of litter composition by Image Analysis Tools. Organisms attached on litter might be also noted.

WAVEGLIDING FOR MARINE LITTER

Francois Galgani [1]*, Gilles Hervé [1] and Ryan Carlon [2]
[1] IFREMER - francois.galgani@ifremer.fr
[2] Liquid Robotics, Sunnyvale, CA 94089, USA

Abstract

A video-camera was mounted on a Wave Glider, an unmanned autonomous marine robot using wave energy for propulsion, to observe and count marine litter. A gopro2 type camera was fixed on the submersed winged ballast of the glider and programmed for 10.5 hours videos during a 24 hours survey. The system enabled to count floating debris in the subsurface layer (0-4.5 m), providing consistent data along a distance of 17.75 km. Densities were found at 40.5 items/km2. The system may be used for monitoring surface debris and large passive organisms from plankton such as jellyfishes.

Keywords: Surface waters, Pollution, North-Western Mediterranean, Monitoring

The Wave Glider is the first autonomous marine robot to use only wave energy for propulsion (http://liquidr.com/index.html). Because of its energy independence, its long persistence and its cost-effective operation, the Wave Glider platform is able to collect and transmit data over distances of thousands of miles across wide geographic areas and specific areas of interest and operation, with a strong potential to replace ships, satellites or buoys when considering surface of the sea. Many applications have been recently described including (i) the Tracking of ocean salinity, temperature, primary production and ocean CO2, (2) the continuous acoustic monitoring of fish, micro nekton populations and tagged mammals or sharks, (3) the Monitoring of Hurricanes and earthquakes, and (iv) the environmental monitoring of oil fields or radioactivity (review in http://liquidr.com/resources/downloads.html).

To date, the use of video has not been tested for regular and distance surveys. Here we report a first application of video-camera to monitor surface/subsurface marine litter at sea. After tests of various camera/positions, a HD Gopro2 Long-Play camera, with 13 hours of autonomy in Full HD, 1080p, 30 images per second, mounted in resistant tube (60cm length) was fixed on ballast (Figure 1a), front side and sea surface oriented with a 45° angle to enable observation in the 0-4.5 meters subsurface layer. After tests, the system was launched at sea for a 24 hours transect offshore south of Toulon (starting position at 43.05980 N / 5.96595 E), along 2 regular routes of 7.40 + 2.5 nautical miles (13,70 + 4,05 km), enabling line transect evaluation (figure 1b). The video was programmed for 45min per hour to avoid warming, at day light, with 10.5 hours of videos on 24h used for analysis. Many approaches have been used for the evaluation of floating marine litter, including ferry boxes, trawling, aerial surveys and direct counting (review in Galgani et al., 2012). The use of subsurface video has been restricted because of sea movements and cavitation at speeds above 5-6 knots. Moreover, evaluation of surface covered is difficult and results are given as items per m or km observations. In our study, we demonstrated that what may be a problem and restrict the use of video imaging becomes an advantage. A speed never above 1.5 Knots and the immersion of the camera at 4,5 meters, provided consistent and stable images along straights routes. The orientation of the camera (45°) and the angle of the video lens (90°) enabled counts along a transect of 12.7m width at the surface.

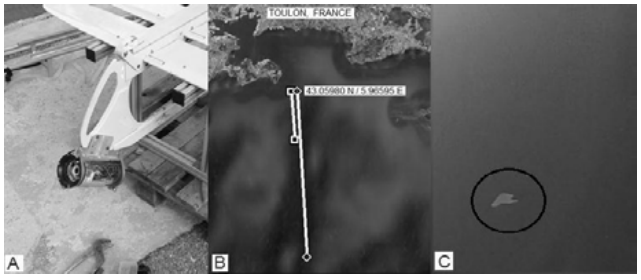

Fig. 1. Video camera system for marine litter quantification. (1) video system on Wave Glider's ballast, (2) map of sampling routes (13.70 + 4.05 km), and (3) Sample of litter observed during transects.

Video analysis revealed the possible counts of marine litter (figure 1c). 9 litter (100% Plastic) were observed giving a density of 40.5 items/ km2, above known densities in the basin (Aliani et al., 2003), indicating a possible underestimation of classical approaches. Optimisation is still necessary, including the evaluation of best capes in relation to the sun orientation and/or the use programmed cameras with large memories which will allow regular shots during more than 20 days surveys. One *Cestus veneris* and two *Pelagia noctiluca* were also observed indicating the possible observation and quantification of large passive organisms from plankton. Finally, we think a rotating camera system (Pelletier et al., 2012), as developed for necto-benthic species, may also be used as a controlled Fish Aggregating Devices (FAD) for evaluation of fish populations at selected and chosen areas.

Abstract

This study presents the main findings from the review of the methodological approaches used by EU countries to assess Marine Litter in the Mediterranean and Black Seas, according to the Marine Strategy Framework Directive requirements (MSFD). The analysis provided information on main methodologies and gaps identified in the Initial Assessment (IA) draft reports for articles 8, 9 and 10 of the MSFD. Outcomes suggest that there is still an important need to harmonize methodologies and to establish coherent monitoring programs, and underline the general lack of data and knowledge constraining the assessment of the current status of Marine Litter.

Keywords: Pollution, Monitoring, Black Sea, North-Eastern Mediterranean, North-Western Mediterranean

The aim of the research project PERSEUS (Policy-orientated marine Environmental Research for the Southern European Seas) is to assess the impact of pressures on marine ecosystems in the Mediterranean and Black Seas in order to design a research governance framework based on solid scientific knowledge. One focal point of the project is to identify, develop and promote tools and methods to ensure consistency in the assessment of marine environmental status across EU and non-EU countries, in accordance with the Marine Strategy Framework Directive (MSFD, 2008/56/EC). Information included in this study refers to the MSFD Descriptor 10, "Properties and quantities of marine litter do not cause harm to the coastal and marine environment". Criteria and indicators for the achievement of Good Environmental Status are defined by Commission Decision 2010/477/EU (Tab 1). Within PERSEUS, the analysis of methodological approaches has been based on information compiled in the review of the available Initial Assessment (IAs) draft reports (MSFD - Articles 8, 9 and 10), including the following Mediterranean and Black Seas EU countries: Cyprus, France, Greece, Romania and Spain.

Tab. 1. Criteria and indicators for Descriptor 10 (Commission Decision 2010/477/EU)

Criteria	Indicators
10.1. Characteristics of litter in the marine and coastal environment	**10.1.1.** Trends in the amount of litter washed ashore and/or deposited on coastlines, including analysis of its composition, spatial distribution and, where possible, source.
	10.1.2. Trends in the amount of litter in the water column (including floating at the surface) and deposited on the seafloor, including analysis of its composition, spatial distribution and, where possible, source
	10.1.3. Trends in the amount, distribution and, where possible, composition of micro-particles (in particular micro- plastics)
10.2. Impacts of litter on marine life	**10.2.1.** Trends in the amount and composition of litter ingested by marine animals (e.g. stomach analysis)

Figure 1 and 2 include relevant findings from the analysis: main methodologies used in the IA and main gaps mentioned by EU countries in their reports. Marine litter was not considered in the IA by Cyprus and Romania, due to lack of pertinent data and knowledge, while the other three countries adopted a qualitative approach. In the overall analysis, references to methodological elements were limited. Only Spain and France included international methodological frameworks in their approaches. Both cited the use of methodologies recommended by the MSFD Good Environmental Status Technical Subgroup on Marine Litter and OSPAR. Furthermore, France included also other valuable methodological sources such as scientific programs, monitoring programs and reports at different geographical scales (Figure 1). The analysis showed that, in general, there is an important lack of data and knowledge for all countries. Regarding specific information for Criterion 10.1 (Tab 1), although data was almost inexistent for Romania, its document referred that characteristics of marine litter (amount, sources and the composition) should be included. Greece based the assessment on Criterion 10.1, but no information at indicator level was provided. For indicator 10.1.1, Spain reported that no adequate information was available. France referred to an OSPAR protocol and to MED-POL recommendations, but sampling methodologies needed further development. For indicator 10.1.2, Spain reported partial lack of information. Only bottom litter in the shelf area was characterized (trawling surveys). France mentioned that protocols were under development for the water column. For the seafloor, France included trawling surveys and diving observations. Regarding indicator 10.1.3, Spain asserted lack of knowledge, while France highlighted that inter-calibration and harmonized protocols were necessary. France reported that methodologies were under development for sandy beaches and already available for surface sampling. Criterion 10.2 (Tab1) was only considered by France and Spain. For indicator 10.2.1, Spain stated a lack of information to assess litter impacts: only scarce data on fish stomach content (from trawling surveys); and marine birds stomach content and plastic entanglements. In France, data were available on turtle stomach content, however, the data collection network needed improvement.

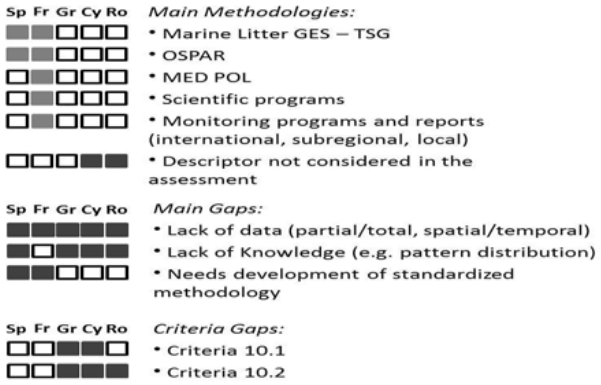

Fig. 1. Main methodologies and gaps reported in Descriptor 10 (Marine Litter): Spain (Sp), France (Fr), Greece (Gr), Cyprus (Cy) and Romania (Ro).

In conclusion, the implementation of the MSFD Descriptor 10 will require further development of harmonized methodologies and support to the establishment of appropriate and coherent monitoring programs at EU level. Due to the cross-border nature of the marine litter problem, the methodologies should also be harmonized with the neighbouring Regional Sea Conventions. In particular this is important within the Southern European Seas as they constitute marine areas in which the majority of bordering countries are not in the EU.

Abstract
Une campagne de prélèvements de microplastiques en surface a été opérée dans les masses d'eau littorales méditerranéennes françaises, de la frontière espagnole à la frontière italienne et sur le pourtour de la Corse. Les microplastiques sont présents dans tous les échantillons récoltés, avec des concentrations variant de 20 à 5 656 particules à l'hectare.

Keywords: Plastics, Pollution, Surface waters, North-Western Mediterranean

Introduction Le plastique n'est pas biodégradable et à ce titre a été longtemps considéré comme un matériau inerte. Sous l'action combinée des forces mécaniques, des UV et de la température, il se fragmente en particules de plus en plus fines, les microparticules (Thompson, 2009). En se fractionnant, le plastique développe une surface de contact considérable avec le milieu environnant qui permet l'adsorption sur ces particules, de contaminants organiques hydrophobes tels que PCB, hydrocarbures et pesticides et leur transport en mer. Afin de définir les modalités scientifiques et techniques d'une surveillance des micro-particules dans le contexte de la Directive Cadre Stratégie pour le Milieu Marin, 30 prélèvements ont été réalisés sur trente masses d'eau littorales méditerranéennes de la frontière espagnole à la frontière italienne et sur le pourtour de la Corse en mars et avril 2012 à bord du N/O l'Europe (IFREMER). Ces prélèvements ont été effectués dans le cadre d'un programme de surveillance de la qualité des eaux méditerranéennes françaises afin d'étudier la densité des microplastiques en surface, leur distribution en mer, leur composition et leur évolution dans le temps.

Méthode Les 30 prélèvements sont réalisés dans chaque masse d'eau côtière avec un filet « Manta » de 90 cm d'ouverture, 15 cm de hauteur et une maille de 0,3 mm. La durée de chaque chalutage est de 20 min pour une vitesse moyenne de 2 nœuds, permettant un échantillon composite sur une distance parcourue d'environ 1 mille, ce qui correspond à une surface d'environ 1000 m2. Les microplastiques sont collectés, séparés par taille supérieure ou inférieure à 5mm, comptés et pesés (poids sec).
Le nombre de microplastiques (< 5mm) et de particules plastiques (> 5 mm) et leur poids est rapporté à la surface échantillonnée et exprimé en nombre et poids par hectare.

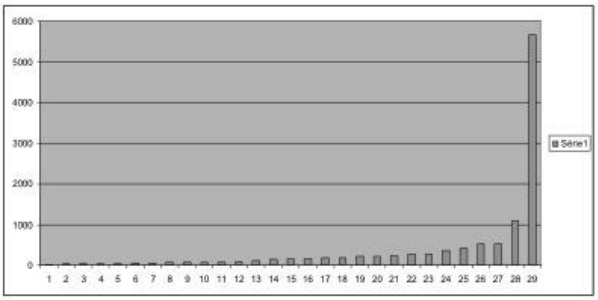

Fig. 1. Nombre de particules (<5mm) à l'hectare sur chaque masse d'eau échantillonnée

Résultats et discussion Les microplastiques sont observés dans tous les prélèvements, confirmant une présence généralisée. Le nombre de microplastiques (de taille inférieure à 5mm) est en moyenne de 393 par hectare (minimum 20 ; maximum 5 656). Un total de 1 454 particules a été compté dans les 29 échantillons pour un poids sec total de 0.749 g, soit un poids moyen par particule de 0.515 mg. Le poids moyen à l'hectare des microplastiques est égal à 0.204g (minimum 0.003g ; maximum 3.168g). La variabilité est identique à celle observée pour l'expression en nombre. Pour les particules plastiques supérieures à 5mm, leur nombre moyen est de 38 par hectare, avec également une grande variabilité (minimum 0 ; maximum 366). Le poids moyen à l'hectare des particules plastiques supérieures à 5mm est égal à 0.197g (minimum 0 g ; maximum 3.216 g) et à 0.089g.

Si les prélèvements effectués sur la majorité des masses d'eau génèrent des valeurs largement inférieures à 1000 microplastiques à l'hectare, ls deux zones de Figari Bruzzi (5656 particules ha) et Saint Tropez (1103 particules /ha) présentent des valeur élevées. L'analyse retro active de courants pendant la période de prélèvement (www.Previmer.org) permet d 'expliquer les niveaux dans ces zones par l'existence d'un courant de surface d'Est en Ouest dans les bouches de Bonifacio qui remonte sur la zone Figari Bruzzi, ainsi que la formation d'un gyre au large de Saint Tropez.

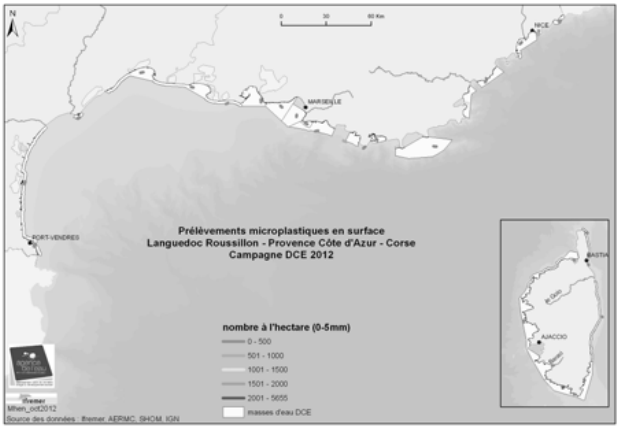

Fig. 2. Distribution du nombre de microplastiques (<5mm)

Les premiers résultats de cette campagne confirment que les microplastiques sont présents dans tous les échantillons récoltés, confortant les résultats des campagnes précédemment effectuées en Méditerranée (Collignon et al., 2011) . Les quantités sont cependant significativement inférieures en raison d'un échantillonnage en dehors de la période estivale et sur une emprise spatiale plus large. L'ensemble des travaux permet de disposer des bases scientifiques et techniques en vue d'une intégration dans les programmes de surveillance dès 2014.

Abstract
The objective of this study is to investigate the density, distribution and composition of marine litter on the seafloor of selected marine areas in the Eastern Mediterranean basin. This is the first large-scale study related to benthic marine litter in Saronikos Gulf in Greece and Limassol Gulf in Cyprus, whereas in Patraikos Gulf it is one of the few attempts towards the creation of time series datasets (2002, 2003, 2013, 2014).

Keywords: Pollution, Plastics, Aegean Sea, Ionian Islands, Levantine Basin

For centuries, the oceans have been a convenient and cost effective dumping site ([3]). Nowadays, marine litter is one of the most serious, rapidly developing and worsening global environmental problems ([5]). Especially for the Mediterranean Sea, marine litter has been an issue of concern since the early 1970?s ([6]). There are various studies ([4], [1], [2]) related to the assessment of benthic marine litter in the Mediterranean Basin.

In Greece, marine litter was investigated in two semi-enclosed Gulfs, Saronikos Gulf (SR) in the Aegean sea and Patraikos Gulf (PT) in the Ionian sea, while in Cyprus the Limassol Gulf (LM) was selected. Litter items, were collected by professional trawling fisheries during the fishing period; Jan-Mar 2013. Marine litter, from each trawling was stored in separate bags together with their corresponding trawling characteristics. In total, 47 trawl cruises have been sampled (SR:19, PT:24, LM:4). The collected litter items were sorted according to their material type and size following the TSG ML Monitoring Protocol.

A total of 3,238 marine litter items were collected during the twenty-seven trawling cruises (SR:1,664; PT:1,561; LM:13). In Saronikos Gulf the items collected per trawl ranged from 22 items/trawl to 176items/trawl; in Patraikos Gulf from 6 to 202 items/trawl; while in Cyprus the collected items were considerably fewer ranging from 1 to 12 items/trawl. Moreover, two trawl surveys in Limassol Gulf were completely litter free. The total weight of the collected marine litter items reached up to 589 kg (SR:162kg; PT:425kg; LM:2kg). In terms of densities (items/m^2), the mean concentration of marine litter on the seafloor was $11x10^{-4}$ items/m^2 in Saronikos Gulf and $5.9x10^{-4}$ items/m^2 in Patraikos Gulf, while in Limassol Gulf it was $0.3x10^{-4}$ items/m^2. Our preliminary data show that there is a difference among the semi-enclosed gulfs (SR, PT) and the open gulf (LM) with the open gulf giving significantly lower benthic marine litter densities. Plastics consisted the major component of marine litter, significantly higher than the other types of material (SR: 94.8%; PT: 60.0%; LM: 61.5%).

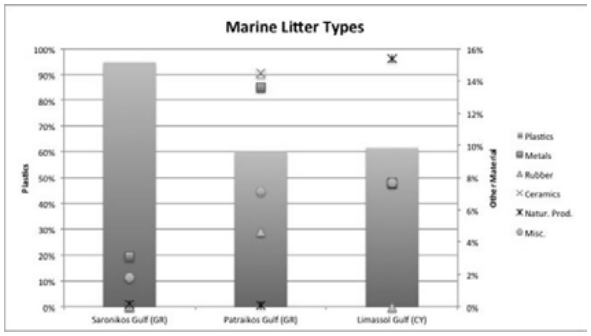

Fig. 1. Different benthic marine litter types

The second most abundant type was metals for SR (3.1%), ceramics for PT, (14.5%) and natural products for LM (15.4%). Regarding the size of the benthic marine litter, six size categories were recorded referring to surface area. The majority of the items belonged to the following three categories: i) <100cm^2, ii) <400cm^2, iii) <2,500cm^2.

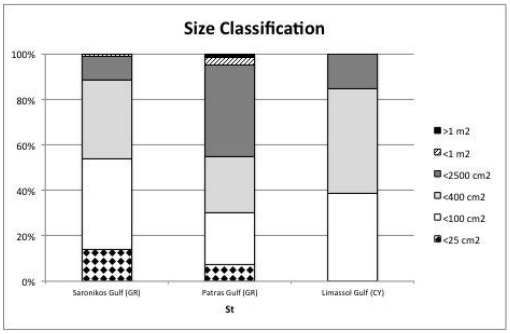

Fig. 2. Different size categories of the recorded marine litter items

Lastly, the recorded marine litter items were separated according to their origin, whether they originated from fishing activities or not. The majority of the items in the three study areas were not related to fishing activities (SR: 87.9%; PT: 90.5%; LM: 100.0%), while the fishing related items were much less (SR: 12.1%; PT: 9.5%; LM: 0.0%).

Aknowledgments This work was supported and funded by PERSEUS FP7 Program.

Abstract

Abundance and composition of beach litter was assessed for 161 beaches in Greece, with the participation of volunteers in 2010, 2011 and 2012. This study showed that plastic is the dominant litter material (43-51%) while plastic lids from water/beverage bottles are the most affluent (8-12%) litter item regarding former use. Recreational activities seem to account for more than 20% of the beach litter load in the Greek coasts.

Keywords: Pollution, South-Eastern Mediterranean, Beach, Coastal management

Introduction

Marine litter is identified as a global environmental issue that poses a threat to marine ecosystems and negatively affects marine-based human activities. In this work we present the results of recordings made by volunteers of beach stranded litter in 161 coasts from all over Greece. The aim of this study is to evaluate the beach litter composition and origination on the Greek coastline, with the participation of volunteers [2], to promote public environmental awareness and to provide a baseline study for the development of future beach litter management plans.

Methods

For the purposes of the present study, data were collected on May 2010, 2011 and 2012 from 161 beaches, with the participation of thousands of volunteers (2010 in 16,495; 2011 in 21,020; 2012 in 17,238) of the "Clean up the Med" nationwide campaign of voluntary beach clean – ups, coordinated by the environmental N.G.O. Mediterranean S.O.S Network. The campaign takes place once a year, each May in Greece, where thousands of volunteers remove manmade debris from local beaches while recording them in a questionnaire, the "Beach Observation Questionnaire" (B.O.Q). With guidance provided by the B.O.Qs, and the research working group, the volunteers counted and classified all items of litter they find in the beaches in terms of former use (e.g. plastic bags, plastic bottles of water, detergents, aluminium beverage containers, fishing lines etc.). All data were statistically processed and re-classified by material in the following 12 categories: plastic, paper, nylon, Styrofoam, fabric, metal, glass, wood, rubber, foam, building materials, leather.

Results and Discussion

According to the acquired data all litter items that were recorded and removed from the surveyed beaches account for 89,652, 83,039 and 27,074 in 65, 53 and 43 Greek beaches in 2010, 2011 and 2012 respectively. Plastic was the dominant litter material (Table 1) in the studied beaches, accounting for 43-51% of the total litter items, in accordance with the global tendencies [1,2,3]. Plastic dominance was followed in all years by paper (14-18%) and metal (12-14%; Table 1) showing the same tendency as in previous studies in Greece [2]. High paper litter abundance compared to global levels probably indicates recent pollution due to its low pervasiveness [1,2].

Tab. 1. Percentages of the top five litter material categories.Other materials include all material categories with low contributions.

Litter Material Categories	2010 (%)	2011 (%)	2012 (%)
Plastic	51	44	43
Paper	14	19	18
Metal	14	14	12
Wood	7	7	6
Glass	6	6	5
Other Materials	9	10	16

Plastic lids from former water/beverage containing bottles (8-12%) appear to be the most abundant litter in the Greek beaches (Table 2). Plastic bottles (6-7%), plastic pieces (5-7%), straws (5-7%), cardboard (6%) and paper pieces (7%) are some of the dominant litter in the majority of the beaches (Table 2).

Consequently, more than 20% of litter found in the studied beaches are related to the consumption of water and beverages near or on the beach, suggesting recreational activities as a major contributor to the beach litter load [2, 3].

Tab. 2. Percentages of the top five former use categories. Other include categories with contribution >5%.

Year	Use	%
2010	Plastic Lids (water/ beverage containing bottles)	12
	Straws	7
	Plastic bottles (water/beverage)	6
	Plastic Bags	5
	Plastic Pieces <50cm	5
	Other (each category participation < 5%)	65
2011	Plastic Lids (water/ beverage containing bottles)	8
	Plastic bottles (water/beverage)	7
	Cardboard	6
	Plastic Bags	5
	Straws	5
	Other (each category participation < 5%)	69
2012	Plastic Lids (water/ beverage containing bottles)	8
	Paper Pieces	7
	Plastic bottles (water/beverage)	7
	Plastic Pieces <50cm	7
	Straws	5
	Other (each category participation < 5%)	66

Former use categories that individually include relatively low amounts of litter (<5%) but when grouped they total significant contributions, suggest that apart from recreation, the studied Greek beaches are also affected by urban/domestic activities, with litter related to domestic use (detergents, sanitary paper etc.) reaching levels of at least 8% and fishery, with related litter items accounting for more than 5%. The present study was made possible with the participation of volunteers of different age groups, whose direct involvement in coastal management issues lead to the promotion of environmental awareness and to the achievement of a large-scale survey.

Abstract
Microplastic pollution is of growing concern worldwide and hence the assessment of its extent in the Greek marine environment is of uppermost importance due to the vast, albeit fragile biodiversity it possesses. In 2009, the first research phase assessed 114 beaches of the Greek islands and mainland producing evidence of microplastic contamination at all sites, leading to further study of an extra 49 sites in 2011. In order to evaluate the impact of this contamination at the lowest level of the trophic chain, the 2012 investigation focused on deposit feeder microplastic ingestion of *Holothuria* spp. from the NE Aegean, finding an average of 4.68 fibres ingested per individual.

Keywords: Plastics, Aegean Sea, Pollution

Introduction
A newly defined threat, microplastic fibres and particles (≤ 5mm), have become a major constituent of debris in the marine environment [1]. The small size of microplastic particles make them easily accessible to many marine biota and, feeding unselectively, filter feeders and deposit feeders ingest these plastic particles in the place of their natural food source, giving them the potential to accumulate throughout the food chain [2]. In order to collectively assess the level of microplastic pollution in the Greek environment, this study investigates microplastic contamination of beach sediments on a wide scale, in addition to quantifying the uptake of microplastics by deposit feeding Holothurians.

Materials and methods
Beach sediments were sampled from the shore line at 3, 25 metre intervals in 114 sites during phase 1 of research in 2009 and in 49 sites during phase 2 in 2011. 50 ml of each sediment sample was mixed with 100ml saturated salt solution and shaken vigorously. Solution was left for 30 minutes to allow microplastic particles to float to the surface, where they are removed with a syringe and processed using Whatman™ GF/F filters and a vacuum filtration apparatus, microplastic fibers were then visually identified. During phase 3 of research (2012), 18 *H.forskali* and 4 *H. tubulosa* individuals were stored in tanks of filtered sea water for 24 hours. The sample containing Holothuria faeces was shaken and left for sedimentation, water was then removed and filtered through Whatman™ GF/F filters, microplastics were then visually identified.

Results
All 114 sites sampled in 2009 were contaminated with microplastic fibres. Overall, in 2009 the most contaminated locations were the Attika peninsula and Ikaria Island, at a mean microplastic level of 20.13 ± 16.03 (SD) and 19.79 ± 10.74 (SD) fibres per 50 ml of sediment, respectively (Fig. 1). All 49 locations sampled in 2011 exhibited microplastic fibre contamination. Sifnos Island displayed the highest microplastic contamination, at 112.08 ± 67.54 (SD) fibres per 50 ml of beach sediment. Locations sampled in both 2009 and 2011, Rhodes and Ikaria, showed an increased mean microplastic level per 50ml of sediment (Fig. 1). 100 % of the Holothurians examined were found to have ingested microplastic fibres, at an average of 4.68 microplastic fibres per individual. One exceptionally high result measured 32 fibres for *H.forskali* individual. As well as confirming that microplastic particles are ingested by deposit feeding organisms at the lower level of the food chain, the results indicate that all Greek beaches are potentially polluted with microplastic fibres, showing a trend of increasing microplastic contamination over time. This provides strong evidence that enhanced efforts to reduce plastic debris in marine ecosystems are an immediate priority, whilst further and more extensive research is also required in order to provide a better understanding of the extent of microplastic fibre contamination at different levels of the food chain, as well as in marine sediment and water.

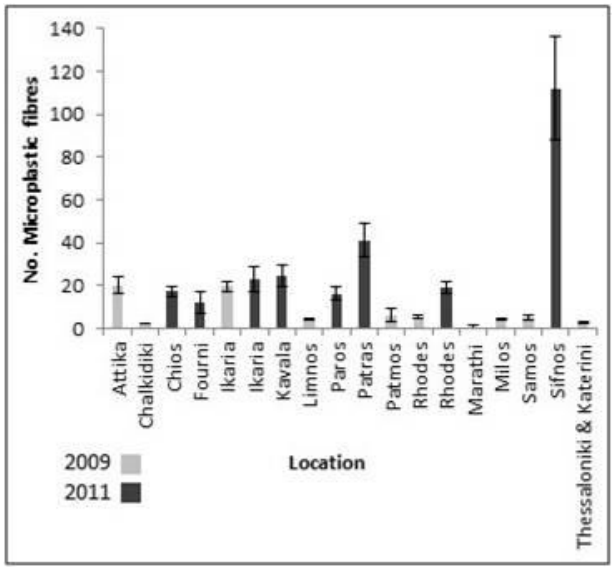

Fig. 1. Mean frequency of microplastic fibres per 50 ml of beach sediment ± standard error (SE) per location sampled in 2009 and 2011.

DEGRADATION OF BIOPLASTIC IN MARINE ENVIRONMENT

V. Turk [1]*, T. Tinta [1], N. Glavaš [1], O. Bajt [1] and N. Kovac [1]
[1] National Institute of Biology Marine Biology Station Piran - Valentina.Turk@mbss.org

Abstract
Because of their positive characteristics and benefits, bioplastic or biodegradable polymers are considered to be a viable alternative to conventional plastics. The biodegradation of bioplastic in the presence of different microbes was evaluated under diverse conditions in laboratory and marine environment.

Keywords: Plastics, Bacteria, Pollution, North Adriatic Sea

Marine bacteria have been recognized as playing the key role in the mineralization of organic matter including pollutants of man-made origin in marine ecosystems (1). Plastics are one of the major contaminants in the world's oceans (2). The huge production of plastics and their omnipresence/persistence represent many social and economical benefits. At the same time there is a need for assessing the negative, hazardous effects of plastics on the marine environment (3). An alternative way to reduce the environmental impact is to reduce the amount of synthetic plastic, or to replace it with new biodegradable materials on the basis of renewable resources such as polysaccharides, proteins and cellulose nano-fibrils. The general use of such new materials needs additional testing. Abiotic and biotic parameters influence the disintegration of macroplastic into small fragments, and compounds with lower molecular mass microbes tend to degrade only partway.

The biodegradation of polyethylene compounds in the presence of different microbes (bacteria, fungi) has been extensively studied in landfills (4), but there are only a few studies of complete degradation to CO_2. There are some studies performed *in situ* in the marine environment. Photochemical processes, proceeding in the seawater under sunlight, lead to the degradation of many organic compounds. Quite commonly, they are connected to microbial degradation, since photochemical degradation usually transforms large molecules into smaller ones, which are a better substrate for microbial degradation.

In our project, a series of laboratory and *in situ* experiments was set up to follow the changes in the taxonomic structure of the microbial community, the changes in chemical composition and oxygen as well as CO2 concentrations. Three different settings were performed to follow bio fouling and degradation processes of bioplastic material: marine microbial population enclosed in bottle in controlled laboratory conditions, in an aquarium filled with different organisms and *in situ, under* natural conditions in seawater (above the bottom, at 3m depth). The microbial dynamics was followed using microscopic, molecular and radiolabel techniques to determine the succession rates and species composition of microorganisms, and possible differences according to different types/sizes of plastic. The degradation was followed using different chromatographic and spectroscopic techniques (HPLC, GC-MS, FTIR). In order to determine the microbial community composition changes during the degradation process, the bacterial community DNA was extracted and 16S rRNA gene clone libraries were constructed. Experiments, using artificial UV-light sources with the wavelengths characteristic of natural sunlight, were performed first in the laboratory and afterwards under natural conditions.
Our preliminary results show that the degradation process was on the time scale from weeks to months. According to FTIR and elemental analyses, the intense degradation of studied substrate was indicated by decreasing absorption intensities of aliphatic CH_3 and CH_2 stretching (2800-3000 cm^{-1}) and ester C=O stretching (1755 cm^{-1}). The analysis of 16S rRNA gene clone libraries from unfiltered seawater treatment in laboratory experiment showed that most of the clones (app. 33%) are related to *Alphaproteobacteria* (mainly *Rhodobacteraceae*, *Rhodospirillaceae* and *Hyphomonadaceae*), followed by otherwise rare community members *Firmicutes* (*Clostridiaceae*), which represented up to 24% of total bacterial community. *Deltaproetobacteria* represented around 12% and *Gammaproteobacteria* only up to 3%. A large percentage of clones (app. 27%) did not affiliate with any of the sequences deposited in the GeneBank (NCBI). Our first genetic and microscope observations suggests a fast biofouling and importance of complex living communities of bacteria and eukaryotes. Furthermore, these preliminary results suggest a large possible impact of bio-plastic on the ambient bacterial community structure and consequently on the ecosystem functioning. The experiment was conducted within the Eco Innovation project MarineClean (Grant Agreement ECO/10/277396/SI2.601543).

THE ACCUMULATION OF MARINE LITTER ON THE SEABED OF THE MARMARA SEA

Ahsen Yuksek [1]* and Çolpan P. Beken [2]
[1] Istanbul University Institute of Marine Sciences and Management - ayuksek@istanbul.edu.tr
[2] Environment Institute, Marmara Research Center-TUBITAK

Abstract

Abstract: Distribution of seabed marine litter has been studied in the Sea of Marmara during few demersal biodiversity studies made in the last two decades. The spatial coverage of data was good to make an arial distribution analysis in 2000, hence the accumulation spots were identified and a comparison with earlier findings was made. The major component of litter was found as packing material having plastics in higher percentage. The study has to be evaluated with up-to-date data to assess the trends

Keywords: Biodiversity, Marmara Sea, Pollution

Introduction: It has been accepted that marine litter is a global pollution problem. A number of regional assessments has been made within the UNEP's global inititive including the Mediterranean and the Black Sea. It has also been reserved in the MSFD (2008/56/EC) as one of the descriptors (#10) to define and achieve good environmental status (GES). Considering the importance and current advances in research and monitoring needs of the topic as well as the lack of data and information on the distribution, trends and the impacts on ecosystems, Ministry of Environment of Turkey has started to support a number of studies. In the frames of a national integrated Project (DeKoS), a preliminary assessment on the capacity and extend of the information available around the country for the shore, sea surface and the seabed is being prepared and almost all data sets were gained. The data and information on the sea floor litter distribution is very limited for the Turkish Seas since monitoring activities have not been performed up to now. Only few published studies exist as part of fisheries studies (Topçu et al. 2008, 2010; Bingel et al. 1987). One of the rare data sets –being gathered for DeKoS- of the similar works is presented here for the Sea of Marmara. This study is on the litter accumulation on the seabed as number of items, content and weight of them. A broad comparison of the collected material is presented for two years; 1994 and 2000, and a relationship seen between the solid material ditribution and the biodiversity has been cited. **Material and methods :** The soft bottom substratum was sampled between 20-200 m depth interval at 34 trawl stations. The litter and the biological material caught in 30 min samplings were analyzed according to their types, weight and biomass. **Results :** The results obtained for different periods have shown that about 90-97% of the trowled items is composed of packing material and a small amount of the wastes are related to fishing, sea vehicles and accidents. About 50% of the pollution caused by packing material is plastics and other petroleum derivatives and 30% is cans and other alliminium material. The wastes intensively distributed mainly around Istanbul metropolitan area, coastal shelf between Büyükçekmece-Yenikapi (northern coastal strip), Tuzla shipyards area (southern coastal strip) and Izmit Bay. This is illustrated in Fig.1 and Fig.2, respectively showing the distribution of number of items and the weight of solid wastes in August 2000. In general, 406 kg/m2 solid waste was calculated for unit area which makes 1925 tonnes of litter for the whole seabed. This value is about 16% of the weight of demersal fish caught during the same survey. In 1994, the amount of litter was about 318 tonnes in the same trowling areas showing a ~6 times increase until the year 2000. More reliable trends can be obtained with the analysis of similar data sets after 2000. **Discussion:** The investigations have shown that the species diversity and the biomass of demersal fish was less in areas where quantity of litter was higher. The increasing trend of litter has been causing greater problems for fisheries too. The activities in the river basins as much as in the coastal and marine areas may fairly effect the intense seabed accumulation of marine litter. The problem causing activities in the region are: un-properly managed waste storage sites at the coastal areas and up-stream, intense maritime activities along the Turkish Straits System and lack of enough port reception facilities. The waste collection by fishermen might be encouraged within ongoing fishing activities applying a payment system for the return of wastes. ThIs has to be supported with enough number of waste reception facilities at ports and sea. Nevertheless, the trends and effects of litter at seabed and water column have to be systematically investigated, as being required by the criteria and standards on GES, in order to better understand the present status and the extend of resulting damage.

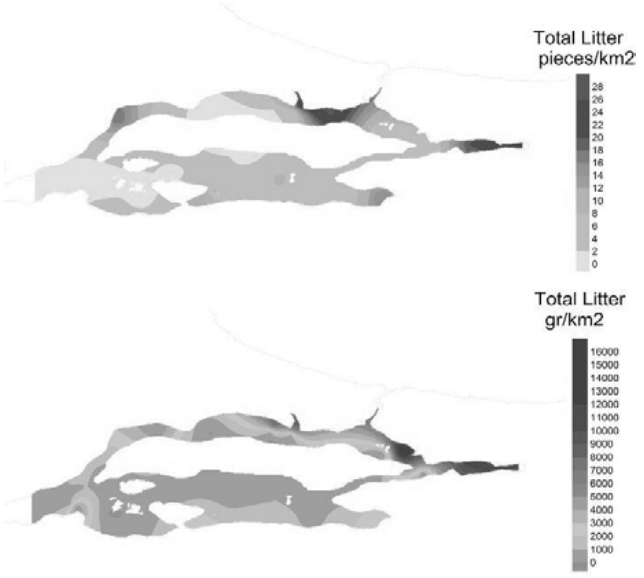

Fig. 1. Distribution of weight (a) and number of items (b) of solid wastes (kg/m2) at the seabed of Marmara Sea in 2000

The activities in the rivers basins as much as in the coastal and marine areas may fairly effect the intense seabed accumulation of marine litter.

EFFECTS OF ABANDONED KALECIK MERCURY MINE ON THE MARINE SEDIMENT (KARABURUN, IZMIR, TURKEY)

Hasan Baha Buyukisik [1]*, Ebru Yesim Okan [1], Ugur Sunlu [1] and Mert Turkdogan [1]
[1] Ege University, Fisheries Faculty, Turkey - h.baha.buyukisik@ege.edu.tr

Abstract
Hg and other heavy metals with some sediment parameters were investigated by statistical methods.14C age determinations were also used for explaining vertical variations in Hg.

Keywords: Mercury, Izmir Bay

Kalecik mercury mine exists in 4 km southeast of Karaburun Peninsula. Apart from Kalecik mercury mine, Karareis and Küçükbahçe mercury mines exist in western part of the peninsula. These mines were abandoned gradually since beginning of 1990s. The aim of this study are to investigate the pathways of Hg accumulation in the sediments and to determine the first contamination date and the changes of sediment properties during the historical times. This study was carried out 8 stations in the NorthEastern part of Karaburun coastal zone (Fig.1). Sediment core samples were taken by gravity core sampler in 20.09.2012 (KB01) and 23.05.2012 (KB02). Subsamples taken were dried at < 60°C and then homogenized.

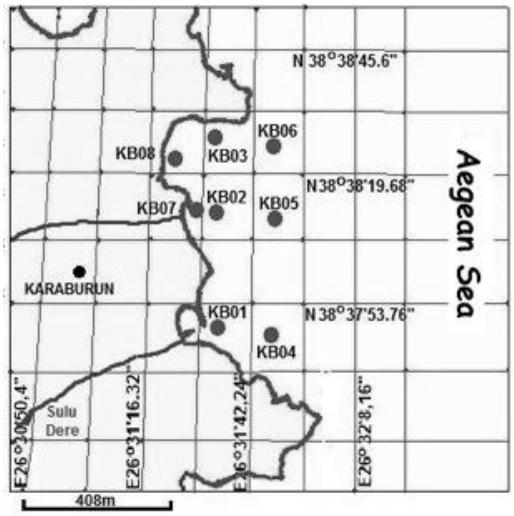

Fig. 1. Sampling stations in coastal area of Karaburun

The heavy metal analysis in all sub samples was performed using the four acid digestion and ultra trace ICP-MS method by ACME Anal. Lab. Ltd. (Vancouver, Canada). Reference materials (STD OREA S45E, STD OREA S24P,…) were used as a control for analytical methods. A contamination factor (Cf) was described the contamination of a given toxic substance in a basin by Hakanson (1980). Contamination factor is ratio of the concentration of the element in samples to preindustrial reference value for the element. The degree of contamination (Cd) in a depocentre is defined as the sum of all contaminants factor various heavy metals (Aksu et al.,1998). The contamination factor calculated from background values determined for the region corresponds to very high contamination level for Hg. Cd, Zr have serious level of contamination, Cu, Pb, Ni, Co, Mn, Fe, Ca, Mg, Ti,Sn, As, Y have medium level of contamination, Sb, Mo, Zn have low-medium level of contamination and Cr have low level of contamination. It was determined that Hg is carried to the sea by increasing rainfall at Holocene maximum and medieval warm period and that it decreased due to decreasing rainfall in small ice ages. In last two thousand years, ca (Fig. 2). 300 significant earth quake occured in Izmir Bay region , so that core samples were not reached to present times. The correlations of metals and Al and their linear relations show that clay minerals are one of the primary carrier phases. 6 factors were distinguished by the factor analysis applied on Al normalized elements. The factor 5 is *Detrital mafic rock* factor. It exposes the unity of Ni,Co and Hg. The mafic rocks surrounding Karaburun are carried to the sea as detrital material by wave erosion and rainfall. OrgC- normalized elements decreasing hyperbolically with orgC emphasizes that a balance with marine organic carbon is established. As a matter of fact the plotting of particulate Hg with dissolved Hg in the water column in the research field shows a hyperbolical decrease. This situation was explained by participating to dissolved phase by colloidal pumping on the surface and by the precipitation of the particulate material at the bottom. (Wen et al.,2008) It was understood at the research field that the particulate Hg input source is the sea water entering the Izmir bay after following the Karaburun shore rather than the river coming from mercury mine. It was emphasized that CDOM, POM and Hg relations has to be examined in detail.

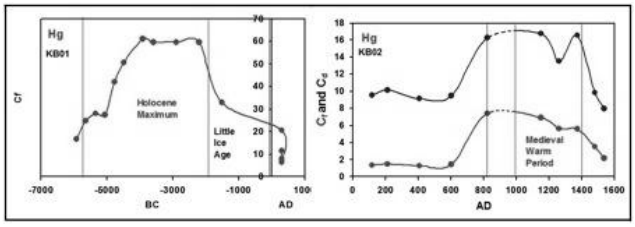

Fig. 2. In Core KB01 change of Hg C_f values in time (in left side), in Core KB02 change of Hg C_f and C_d values in time in (the right side).

MERCURY AND ITS SPECIES IN THE ADRIATIC SEA

J. Kotnik [1]*, M. Horvat [1], N. Ogrinc [1], V. Fajon [1], D. Žagar [2], D. Cossa [3], F. Sprovieri [4] and N. Pirrone [4]

[2] Faculty of Civil and Geodetic Engineering, University of Ljubljana
[3] Ifremer, Centre for the Mediterranean Sea
[4] CNR - Institute of Atmospheric Pollution Research, Rende, Italy

Abstract
Mercury and its speciation were studied in surface and deep water of the Adriatic Sea during two oceanographic cruises onboard the research vessel Urania. Several mercury species together with some other water parameters were measured in coastal and open sea deep water profiles. Spatial and seasonal variations of measured Hg species concentrations in different identified water masses were observed. THg concentrations in the water column, as well as in sediments and pore waters, were the highest in the northern, most polluted part of the Adriatic Sea as the consequence of Hg mining in Idrija and the heavy industry of northern Italy. Furthermore, a Hg mass balance for the Adriatic Sea was calculated based on these measurements and literature data.

Keywords: Mercury, Central Adriatic Sea

The Adriatic Sea receives the inflow of heavily polluted rivers and other direct or indirect natural or anthropogenic Hg loads, especially in its northern and central parts. Elevated Hg levels were found on both the western and eastern coast of the N Adriatic. Water concentrations are reflected in THg concentrations in the sediments and pore waters of the area. It is evident that Hg enrichment in coastal N Adriatic waters and sediments is limited to the near shore zone and continental shelf. The spatial distribution of THg in water and sediment strongly depends on the water circulation of the sea, but there are several biological and/or geological factors affecting its speciation. N Adriatic water columns exhibit strong temperature and salinity stratification. The vertical distribution of Hg species reflects well mixed water with low deviations from the average for each location. Some correlations between maximum DGM and RHg peaks and the low oxygen zone were observed, which was not the case at the most polluted locations of the Gulf of Trieste and near Venice. Such an association is more evident in locations in the Central and Southern Adriatic where DGM at the surface is relatively low, reflecting the importance of evasion and photochemical oxidation due to the strong UV radiation and the presence of chlorine and bromine [1] and hydroxyl radicals [2, 3] at the surface. In deeper water layers the DGM distribution shows correlation with the oxygen concentration and indicates the importance of redox processes due to microorganism activity, and another, usually sharp increase towards the bottom. This indicates microorganism production and diffusion from sediment and/or tectonic activity, especially at locations in the S Adriatic Pit, which is tectonically very active. RHg vertical profiles are mostly opposite to those of DGM as Hg(II) is a substrate for DGM production. MeHg profiles are mostly related to Chl-a and oxygen concentrations. This underlines the role of planktonic production and regeneration in the methylation/demethylation processes. The low MeHg concentrations found in shelf edge or coastal sediments and water over the sediment indicate that coastal or shelf sediments are not a significant MeHg source for adjacent open sea waters. At some exceptional deep sea locations the increase of MeHg over the bottom suggest some bottom source (i.e. resuspension or diffusion from sediment), further supported by the estimated diffusive fluxes from sediments ranging from 0.150 to 16.6 pmol m^{-2} day^{-1}. Mass balance calculations showed that deposition and inflow from the Strait of Otranto are the most important sources of Hg, while evaporation and outflow to the Mediterranean are the most important sinks.

DISSOLVED GASEOUS MERCURY MEASUREMENTS IN SURFACE AND DEEP WATERS IN THE MEDITERRANEAN SEA

Jože Kotnik [1]* and Milena Horvat [1]
[1] Jožef Stefan Institute Department of Environmental Sciences - joze.kotnik@ijs.si

Abstract
Dissolved gaseous mercury (DGM) was studied in surface and deep waters of the Mediterranean Sea for last 12 years during several oceanographic cruises on board the Italian research vessel Urania. The cruises were part of several EU and national research projects (MEDOCEANEOR, MERCYMS, GMOS, etc.), covering regions from Strait of Gibraltar on the west and Levantine Sea on the east as well as Adriatic Sea with the Gulf of Trieste as Mediterranean most northern part. DGM was measured together with some other mercury species (RHg - reactive Hg, THg - total Hg, MeHg - monomethyl Hg and DMeHg - dimethylmercury), and with some water quality parameters in coastal and open sea deep water profiles.

Keywords: Mercury, North-Western Mediterranean

DGM in water profiles was measured manually by purging 0.5 L of sample for 10 min, followed by double gold amalgamation and CV AFS detection (Tekran 2500) [1, 2]. During 2011 cruise, continous method [3, 4] was applied and compared to manual. Hg free ambient air was equilibrated with the seawater in a plexiglass purging bottle with opposite air and water flow. The flow of Hg free ambient air was introduced through a glass frit positioned at the bottom of the bottle. Released DGM was then detected by Lumex RA 915+ AAS detector. The DGM concentration of the water was calculated assuming Henry's law equilibrium between the mercury concentration in the equilibrated air and the water [3, 4]. Special attention was also given to quality control steps by comparing data on board the ship by different laboratories (IJS Slovenia, IVL Sweden, UGOT Sweden, CNR-IIa Italy, IFREMER France) using different analytical protocols on samples collected on board. Dissolved gaseous Hg measured in water is composed of dissolved gaseous elemental Hg (Hg0) and dimetyl Hg (DMeHg), which is present in very small fraction (< 5 %) and is measurable mostly in deep waters [1, 2]. Typically DGM is low at the surface, depeer in oxygen minimum zone it increase to its maximum levels. At most locations DGM sharply increase again in bottom water layer. DGM generally increases with depth, suggesting the presence of a source of volatile Hg in deeper waters. The average DGM concentration was the highest in deep water masses (WMDW and EMDW). Such distribution reflect the importance of evasion and photochemical oxidation/reduction processes due to strong UV radiation and presence of chlorine and bromine [1] and hydroxyl radicals [5, 6] at the surface. In deeper water layers DGM distribution indicate the importance of reduction/oxidation processes due to microorganisms activity, and towards the bottom microorganisms production and diffusion from sediment and/or tectonic activity, which may be the main source of DGM in deep waters where higher concentrations and portions of DGM near the bottom at locations with strong tectonic activity (Alboran Sea, Strait of Sicily, Tyrrhenian Sea, Strait of Otranto) were found. It is well known that emissions from tectonic activity and geological anomalies could represent an important source of mercury. Rajar et al. [7] calculated total natural underwater emission of Hg in the Mediterranean Sea to be 11 to 20 tons y-1 with mean estimate of 15 tons per year. The spatial distribution of DGM in the Mediterranean Sea is generally connected to water circulation in the basin, however there could be several other chemical, biological and/or geological factors affecting the DGM distribution. DGM in bottom and deep waters increase from east toward west. The concentrations of DGM were highest in severely polluted N Adriatic, while S Adriatic waters were within the range reported for the Mediterranean Sea.

Abstract
Two different models released by US-EPA, SERAFM, a steady state model, and WASP, a dynamic model, have been used to describe major dynamics in the mercury cycle in the Marano-Grado lagoon, (Northern Adriatic Sea, Italy). The lagoon shows high mercury concentration in the water column, sediments and biota due to natural and anthorpogenic sources. The model applications aim at: 1) computing mercury budgets within the lagoon and fluxes between the lagoon and the surrounding systems (watershed, Adriatic Sea, atmosphere); 2) improving the understanding of the importance of different loading sources and transformation processes on methylmercury concentration and bioavailability. Moreover, the models allow to identify major knowledge gaps and suggestions for further modeling development.

Keywords: Lagoons, Mercury, Models, North Adriatic Sea

The Marano-Grado Lagoon (Northern Adriatic Sea, Italy), covers an area of approximately 160 km2. It is one of the most important and best conserved wetland environments in the Mediterranean area, also identified as a Site of Community Importance (SCIs – IT3320037) and it provides important ecosystem services which sustain several economic activities. The lagoon is also a sink for anthropogenic contaminants, and, in particular, for mercury compounds released via natural and anthropogenic sources. Smelting activity at the Idrija mine in western Slovenia has released 39000 tons of mercury over 500 years, and a chlor-alkali plant has released around 186 tons of mercury directly into the lagoon during the 45 years of operation. Elevated Hg concentrations in sediments, ranging from 0.61 to 14.01 µg g-1, have been found related to both historical and more recent anthropogenic activities. Mercury (Hg) is a ubiquitous environmental pollutant of great concern because of the toxicity of its methylated form (MeHg) and bioaccumulative and biomagnifying properties. Mercury occurs in the marine environment in three chemical forms: elemental Hg (Hg(0)); divalent ionic Hg (Hg(II)), present in a variety of both inorganic and organic complexes; and methylated forms that include monomethylmercury (MeHg) and dimethylmercury (DMHg). All these species are linked intricately through the Hg(II) pool [1]. Within the Marano Grado Lagoon, several studies have been developed addressing the state of the mercury contamination in different media, including sediment, water column and biota, ([2, 3, 4] but the implementation of a biogeochemical model could add insight into the mercury fluxes and support the risk management [5]. Data characterising the biogeochemical cycle of mercury in the Marano-Grado Lagoon have been assembled and two models released by US EPA, publicly available, have been implemented to complement the experimental knowledge and to highlight knowledge gaps. A scenario analysis have been performed in order to highlight the relevance of different processes in the mercury fluxes in the lagoon. The two model applications enabled to focus on different aspects of the mercury biogeochemistry. Model parameters have been derived from site specific data, when available, or from parameters related to similar environments, as reported in literature. The Marano Grado lagoon have been represented as a 6 box system, interacting with the surrounding systems (Adriatic Sea, atmosphere, deepest sediments and watershed), following the classification given by [6]. The SERAFM model has been implemented describing the lagoon as indipendent six-box systems at steady state. The model calculates the concentration of the mercury species (HgII, MeHg, Hg0) in the water column, in sediment and in biota, driven by hydrological characteristics, external forcing influence, initial concentration and mercury process parameterization. The SERAFM model calculates also wildlife and human exposure risks related to methylmercury bioaccumulation. The analysis have been made under different scenarios of contamination, decontamination and exchanges with the surrounding systems. The WASP model implementation allows to reproduce the temporal evolution of the mercury in the lagoon. In this application, the Lagoon is represented as a 6 connected box system. Time variable water fluxes between the six boxes and with the Adriatic Sea have been introduced based on hydrodynamic model results. Variable river discharge, and precipitation have also been included as well as mercury and water quality concentration at the boundary systems. The WASP model allows to represent the seasonal evolution of the three from of mercury concentration in the lagoon environment, giving preliminary indications on the temporal and spatial evolution of mercury the mercury species (HgII, MeHg, Hg0) in water (total, particulate, dissolved, Fig. 1) and in sediment. The results have been compared with the available data and used to assess the relative value of different mercury sources on the availability of methylmercury to biota.

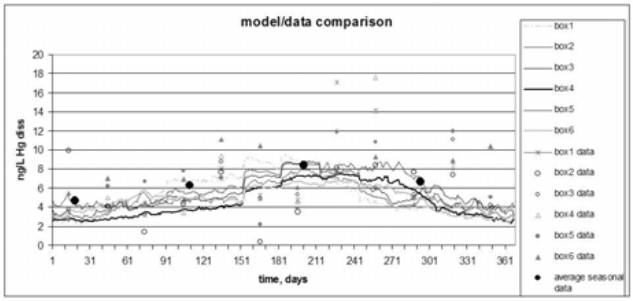

Fig. 1. WASP model predicted concentrations compared with observations and with seasonal averaged data of dissolved mercury.

Abstract

This research examines the level of metals in various tissues of wild caught Muraena Helena from Adriatic sea in the year 2010 by the atomic absorption spectrometry (Perkin-Elmer Analyst 600 Zeeman equipped with a THGA-600 graphite furnac). The analysis shows that Hg and As had highest levels in muscle, gills and especially liver while Pb and Cd had highest levels in skin.

Keywords: Bio-accumulation, Fishes, Metals, South Adriatic Sea

Introduction: the trophic level of Moray eels makes them a model organism for the local studies of bioaccumulation or biomagnifications of metals [1].

Material and Methods: morays (N=18) were caught in East Adriatic near Dubrovnik (in 2010). Bioaccumulation of Pb, Cd, As and Hg in various tissues were analyzed by the atomic absorption spectrometry (Perkin-Elmer Analyst 600 Zeeman equipped with THGA-600 graphite furnac) [2].

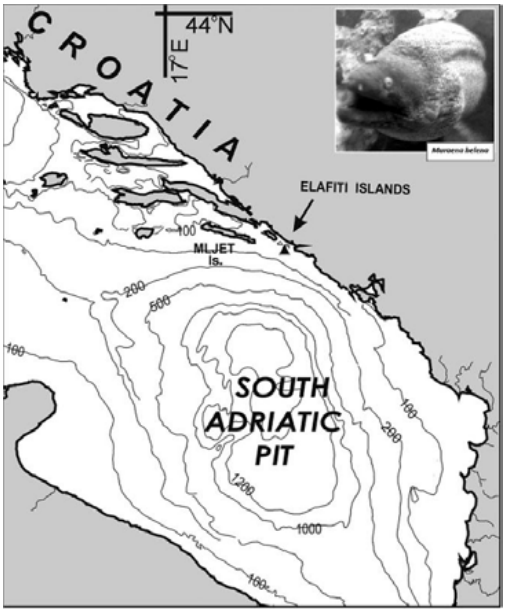

Fig. 1. The sampling location in eastern Adriatic.

Results: all analyzed metals (Table 1) were present in skin, bone, muscle, liver, gills and heart and results were expressed per kg of wet weight (ww). Liver was the tissue with highest and heart with lowest levels of bioaccumulated metals. Hg and As had highest levels in muscle, while Pb was highest in the liver and with Cd had highest levels in skin.

Discussion and Conclusion: in analyzed morays, liver was the organ with highest bioaccumulation potential as similar in other marine fish of similar trophic status and kin eel species. Interestingly, bioaccumulation of As was highest in gills of moray eels although it is known that As accumulation potential in fish muscle tissue is greater than liver [3]. Regardless of the detection and presence of analyzed metals none of them were above allowed safe levels [4]. The levels of detected metals were lower than previously measured in other species from different locations in Adriatic sea.

Abstract
The contents of four heavy metals (Mercury, Lead, Cadmium, Chromium) were assessed in four mollusk species (*Gibbula ardens, Patella caerulea, Pinctada radiata* and *Pinna nobilis*), collected from twelve coastal stations in the gulf of Gabes. High concentrations of heavy metals were recorded in the central area of the gulf, nearer to Gabes city; however the low concentrations were found at the gulf edges, which is probably due to the chemical pollution generated from the huge industry of phosphoric acid in Gabes city. The highest heavy metals' concentrations, noted during this study, are comparable to the findings of other authors in other areas, but they are considerably beyond the standards.

Keywords: Pollution, Bio-accumulation, Bio-indicators, Mollusca, Gulf of Gabes

The gulf of Gabes was reported to be highly exposed to pollution through the huge industrial activity based in this area, in particular in Gabes city. In fact, large quantities of phosphogypsum from the phosphoric acid and chemical products industry of Gabes are released into the Gulf of Gabes [1; 2]. Although phosphogypsum is known to contain quantities of heavy metals, only few studies were done before about the distribution of these pollutants in this area. In this work, we assessed the heavy metal pollution in the gulf of Gabes, using four mollusk species: *Gibbula ardens*, *Patella cearula*, *Pinctada radiata*, and *Pinna nobilis*. The contents of four heavy metals (Mercury, Lead, Cadmium, Chromium) were analyzed in the tissues of these species collected from twelve sites (from the north to the south: Chebba, Louata, Sfax, Kerkennah Island, Mahres, Gabes, Zarrat, Elgrine, Djerba Island, Boughrara, Zarzis, and El Biban lagoon), and the level of pollution was compared between the sampling sites. Average concentrations of the four analyzed heavy metals in the four mollusk species are summarized in table 1.

Tab. 1. Minimal and maximal average concentrations of heavy metals recorded with the four mollusk species in the sampling sites of Gabes gulf. CH, Chebba; LO, Louata; SF, Sfax; KI, Kerkennah Island; MA, Mahres; GA, Gabes; ZA, Zarrat; EG, Elgrine; DI, Djerba Island; BG, Boughrara; ZZ, Zarzis; EB, El Biban lagoon.

	Chromium	0.192±0.009 (EB)	0.604±0.077 (DI)
P. nobilis (hepatopancreas)	Mercury	0.033±0.010 (EB)	0.285±0.051 (LO)
	Lead	0.645±0.133 (EB)	1.209±0.200 (DI)
	Cadmium	0.674±0.157 (EB)	1.121±0.090 (CH)
	Chromium	0.386±0.056 (EB)	1.687±0.302 (DI)

The distribution of these pollutants in the gulf of Gabes appeared to follow almost a similar pattern between the four mollusk species. The highest concentrations were found in the area between Gabes and Zarzis sites (central and southern parts of the gulf). The analysis of variance showed highly significant differences between localities of study. The species *P. nobilis* and *P. radiata* were found to accumulate heavy metals less than the two other gastropod species, probably due to their lower trophic level. The hierarchical classification of the sampling localities allowed separating between 6 clusters at a distance of 2.6: cluster 1 consisted of Chebba, Louata, Kerkennah Island, and El Biban lagoon; cluster 2 was formed by Djerba Island; Cluster 3 by Sfax and Mahres; cluster 4 by Gabes and Zarzis; cluster 5 by Zarrat; while cluster 6 was represented by Elgrine and Boughrara (Fig. 1). Heavy metal pollution is certain in the gulf of Gabes and it seems that it has reached a critical level since the highest pollutants' concentrations exceeded the standards fixed as well by the World Health Organization (WHO) as by the Food and Agriculture Organization (FAO). A remediation action is necessarily needed to protect the marine life in the gulf of Gabes.

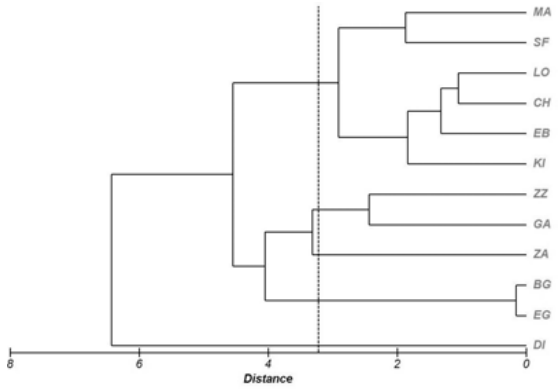

Fig. 1. Hierarchic classification of the sampling sites, done based on Euclidean distance. EB: El Biban lagoon, DI: Djerba Island, CH: Chebba, GA: Gabes, LO: Louata, ZZ: Zarzis, MA: Mahres, KI: Kerkennah Island.

COMPARISON OF AMINO ACID ANALYSIS METHODS IN SEAWATER

Hakan Alyuruk [1]* and Aynur Kontas [1]
[1] Dokuz Eylül University Institute of Marine Sciences and Technology - hakan.alyuruk@deu.edu.tr

Abstract
Dissolved organic matter is one of the largest reservoirs for organic carbon in seawater. It contains molecules from simple to complex structures as by-products of metabolism or degradation products. Determination methods of amino acids in seawater were discussed in the present study.

Keywords: Organic matter, Izmir Bay, Analytical methods, Coastal waters

Introduction:
Dissolved organic matter (DOM) is an important component of aquatic biogeochemical cycles. It can be classified as autochthonous (marine origin) and allochthonous (terrestrial origin) according to its source. It is composed of different types of micro- and macro-molecules that are difficult to characterize and separate from each other. Most abundant biomolecules in DOM are amino acids, carbohydrates, lipids, fatty acids, sterols, humic acids, fulvic acids, and lignins. Among other organic molecules, amino acids are descriptive of the origin and transformation rate of DOM [1]. For example, D-amino acids are found in the cell walls of marine bacteria. Therefore, determination of enantiomeric amino acid abundance in seawater gives important information about the origin of DOM [1,2]. Also, enantiomeric amino acid abundance is used in geochronology for estimation of age in fossil samples [1,3]. In the literature, amino acid content found in DOM was fractionated as dissolved free amino acids (DFAA), dissolved combined amino acids (DCAA) and total hydrolyzible amino acids (THAA) [4]. On the other hand, carbon and nitrogen contents in DOM can be measured as bulk quantities; however, amino acid content can only be obtained by advanced analytical techniques such as gas chromatography (GC) and high performance liquid chromatography (HPLC).

Comparison of Methods:
Prior to analysis of amino acids by GC method, high volume seawater sample (about 50 L or more) is filtered from GF/F membrane filters, concentrated via ultrafiltration and diafiltrated to remove salts. Samples can be analyzed without hydrolysis to determine DFAA or it could be subjected to acid hydrolysis to determine THAA. For derivatization, samples are first esterified with 2-propanol and esterified amino acids are acylated with trifluoroacetic anhydride to form trifluoroacetyl-isopropyl esters of amino acids. Then, amino acids in derivatized samples are determined by GC or gas chromatography-mass spectrometer [5-7]. Detectable amino acids by using GC method are alanine, valine, glycine, leucine, isoleucine, proline, serine, threonine, phenylalanine, tyrosine, lysine, asparagine + aspartic acid and glutamine + glutamic acid. Total analysis time for GC method is changed between 80-100 min. On the other hand, HPLC methods can be separated into two categories as simple method and enantiomeric method. In both HPLC methods, concentration step for samples is not required; therefore, just about 100 or 1000 mL of seawater can be directly analyzed after hydrolysis step. In the simple method, amino acids are analyzed via fluorescence detector of HPLC after derivatization with o-phtaldialdehyde (OPA) and mercaptoethanol [4]. Analysis time for this method is about 60 min. Methanol and acetate buffer are used as mobile phases. In the enantiomeric method, derivatization is performed by using OPA and chiral reagents, N-isobutyryl-L or D-cysteine before analysis [4]. Since derivatization reaction is sensitive to reaction time and reactants, an HPLC autosampler is required in this step for reproducibility of the results. Separation of amino acids is achieved by two successive analyses with both chiral reagents on reversed-phase HPLC column. Analysis time per analysis is about 2 hours and it takes about 4 hours in total. In addition to amino acids in L- form listed in GC method, D/L-arginine and D-enantiomers of listed amino acids can be determined.

Conclusion:
HPLC methods are more sensitive and their detection limits are lower than GC methods. Also, D-/L- amino acid speciation can be obtained by using enantiomeric HPLC method. It can be concluded that HPLC methods are much faster and sensitive to apply compared to GC methods for amino acid analysis in seawater. Seasonal variation of DOM in Izmir Bay will be investigated within the PhD thesis of Hakan Alyuruk.

LESSONS LEARNED FROM PROFICIENCY TESTS ORGANISED BY IAEA/MESL AND UNEP/MAP - MED POL FOR TRACE ELEMENT ANALYSIS IN THE MEDITERRANEAN

Michael Angelidis [1]*, Emilia Vassileva [1] and Sabine Azemard [1]
[1] IAEA Marine Environmental Studies Laboratory - M.Angelidis@iaea.org

Abstract
More accurate analytical results for trace elements in marine samples are generally provided by Mediterranean monitoring laboratories which are regularly participating in Proficiency Tests organised by IAEA/MESL and UNEP/MAP-MED POL. Sample contamination and inappropriate pre-treatment/analytical methods applied also affect the quality of analytical results.

Keywords: Monitoring, Metals, Pollution, Mediterranean Ridge

Marine pollution monitoring is a legal obligation of the Contracting Parties of the Barcelona Convention and much effort has been made to generate marine pollution data through national monitoring programmes implemented in the framework of the MED POL Programme of UNEP/Mediterranean Action Plan. Monitoring data is needed to assess the level and trends of pollution in the Mediterranean in order to decide on action plans, programmes and measures to be established for the protection of the marine environment and for the sustainable development of the coastal zone. It is therefore of primary importance that the generated monitoring data is accurate and representative of the environmental status, i.e. that it is "quality assured". In order to strengthen the data quality assurance of Mediterranean laboratories involved in national marine monitoring programmes, IAEA's Marine Environmental Studies Laboratory (MESL) in collaborating with UNEP/MAP – MED POL, is organising since many years Proficiency Test (PTs) to assess the analytical performance of laboratories through the analysis of a test sample with known reference values for different trace elements. The performance of the participating laboratories is assessed through the evaluation of Z score in accordance with ISO 13528 [1] and the International Harmonised Protocol for the Proficiency Testing of Analytical Chemistry Laboratories [2]. This score effectively express the difference between results reported by participating laboratories and the assigned value for the respective analyte in the PT test sample. The performance is considered acceptable if $|z| \leq 2$, the result is regarded as questionable when $2 < |z| < 3$ and the result is regarded as unsatisfactory if $|z| \geq 3$.

In the last 6 PTs organized by IAEA/MESL since 2005 on the analysis of trace elements in sediment and biota, the participation of the designated Mediterranean laboratories ranged from 53 to 76% (average 61%). Most laboratories did not participated regularly in the PTs, since only 8 out of 44 participating laboratories reported 4 or more times their results in the last 6 PTs. No-participation and low frequency of participation in PTs is a major problem, because it does not allow for a meaningful assessment of the quality of data generated by laboratories. Although no-participation does not necessarily mean that the data of a particular laboratory is "unsatisfactory", it indicates low understanding of the necessary activities to establish and maintain a good level of data Quality Assurance / Quality Control. The laboratories that are regularly participating in PTs have in general better z-scores that those participating less frequently to these exercises (Figure 1).

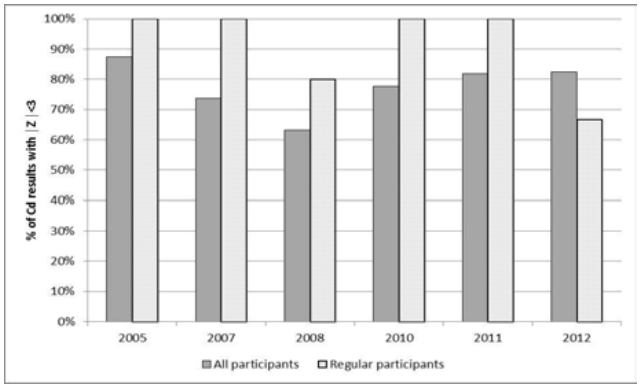

Fig. 1. Percentage of results (Z-score <3) reported for Cd in MED POL PTs: regular participants are laboratories that reported at least 4 times Cd values over 6 PTs

Available PTs results indicate that the number of unacceptable results tend to increase when the concentrations of the element to be detected are low. The measurement results for some elements at low concentrations are seriously biased by sample contamination, as well as when the methods applied for pretreatment and instrumental analyses are not under control (Figure 2). The implementation of principles for good laboratory practice in Mediterranean laboratories is an important point for the further improvement of their measurement capabilities.

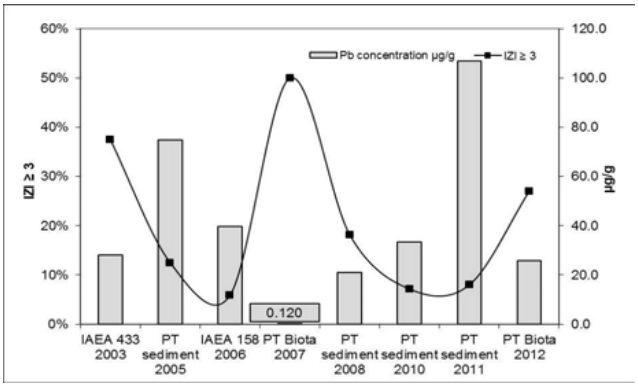

Fig. 2. Comparison between the percentages of unacceptable results ($Z \geq 3$) reported for Pb in PTs and the concentrations of Pb in the sample

Conclusions

Proficiency Tests organized since many years by IAEA/MESL and UNEP/MAP-MED POL indicate that a part of the marine pollution data generated by Mediterranean laboratories in the framework of national monitoring programmes is not quality controlled. Mediterranean monitoring laboratories should improve their data Quality Assurance / Quality Control.

Abstract

Des analyses chimiques, des tests *in-vitro*, des examens des anomalies morphologiques et histologiques ainsi que des dosages des biomarqueurs biochimiques ont été réalisés chez des gobies, appartenant à l'espèce *Zosterisessor ophiocephalus*, collectés dans la lagune de Bizerte. Les résultats obtenus ont montré la pertinence de *Z. ophiocephalus* comme espèce bio-indicatrice.

Keywords: Bio-indicators, Fishes, Ecotoxicology, Lagoons, Tunisian Plateau

Introduction: L'environnement aquatique est affecté par différents types de polluants chimiques d'origine anthropique. Toutefois, la complexité des interactions rend les observations in situ plus difficiles à interpréter que les données issues d'expériences contrôlées en laboratoire. L'utilisation d'une approche multiparamétrique, à savoir le poisson gobiidé *Z. ophiocephalus*, est basé sur certaines de ses caractéristiques (mode de vie benthique sédentaire, abondance dans le milieu d'étude) qui lui confèrent un intérêt en écotoxicologie. L'objectif de cette étude est d'évaluer le potentiel de cette espèce comme bio-indicateur modèle pour la biosurveillance de l'environnement aquatique.de biomarqueurs permet de pallier à ce problème. Le choix du modèle biologique,

Matériel et méthodes : Des collectes mensuelles de gobies ont été effectuées d'août 2005 à juillet 2006. Cinq stations de la lagune de Bizerte ont été prospectées (NJ: Njila, MB: Menzel Bourguiba, MR: Maghrawa, MJ: Menzel Jemil et ML: Menzel Abderrahmen). Une station située au niveau de la communication entre la lagune de Ghar El Melh et la mer a été choisie comme station de référence, GH (Fig. 1), en raison de sa salubrité. Les prévalences des malformations vertébrales (Def%) et des altérations histologiques des testicules (Syn%) ont été notées. En outre, le rapport gonado-somatique (RGS), le facteur de condition (IC), le rapport hépato-somatique (RHS) et les biomarqueurs biochimiques, tels que l'activité EROD, la GST, la GSHtot, la teneur en TBARS, ont été déterminées. La présence de composés dioxine mimétiques dans les extraits organiques de sédiments a été évaluée au moyen de tests *in-vitro* et les facteurs d'équivalence toxique (BEQs) ont été estimés. L'ensemble des données obtenues ont été soumises à une analyse multivariée en composantes principales (ACP) afin d'apprécier les relations entre les réponses biologiques et les contaminants chimiques tels que les HAPs que nous avons, nous mêmes, dosés [1] et le DDT, les PCBs et les composés organométalliques CorM dont le dosage a été effectué par d'autres auteurs au cours d'une période très proche de celle de nos prospections [2], [3], [4].

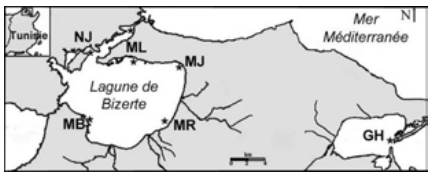

Fig. 1. Localisation des stations d'échantillonnage.

Résultats et discussion: La superposition des stations sur le plan factoriel (F1-F2) a permis une très bonne ségrégation. La composante F2 s'avère être la plus discriminante. Elle sépare, sur son côté négatif, les stations les plus impactées qui sont intimement liées à : (i) une induction des activités GST et GSH, (ii) une prévalence élevée des anomalies vertébrales (Def), (iii) de fortes valeurs des facteurs d'équivalence toxique (BEQs) et (iv) la contamination du sédiment par les PCBs, les HAPs et les CorM. Les stations sont disposées dans l'ordre croissant de perturbation, et ce, en allant de la partie positive à la partie négative de cette composante. Les gobies, provenant de la station (MB), paraissent les plus touchés par les rejets polluants permanents de la zone industrielle (industrie lourde) située à proximité de cette station. En revanche, les gobies capturés au niveau de la station de référence (GH) sont les moins affectés. Ces résultats confirment l'importance de l'utilisation d'une batterie de biomarqueurs pour apprécier l'état de perturbation d'un écosystème aquatique.

Conclusion: Ce travail a montré la pertinence de *Z. ophiocephalus* comme espèce bio-indicatrice et a affirmé l'intérêt de l'utilisation d'une approche multiparamétrique dans un programme de biosurveillance du milieu.

Abstract
The low sedimentation rate and the high water residence time of Toulon bay (NW Mediterranean Sea) associated to numerous anthropogenic inputs have led to a high multi-contamination of its sediments. Lab experiments aiming at simulating resuspension events (e.g. dredging), affecting such sediments (suboxic and anoxic layers), were demonstrated to significantly remobilize inorganic pollutants toward seawater and therefore deteriorate the considered ecosystem.

Keywords: Sediments, Interfaces, Trace elements, North-Western Mediterranean

Introduction
Through the impact of numerous anthropogenic activities, coastal environments are highly contaminated, and mainly the sediments which are the final receptacle of particles. In order to preserve the hydrodynamics features and to maintain harbour and touristic activities, sediment dredging is a frequent practice. Previous studies have proven a high risk of contaminant remobilization from river sediments [1, 2]. Toulon bay (NW Mediterranean Sea), a semi-closed area with a low sedimentation rate (0.2 cm yr^{-1}), is presenting a high sedimentary contamination [3]. This study aims at apprehending the risk of dredging operation upon seawater quality through batch simulations on surface/suboxic and deep/anoxic polluted sediment. Furthermore, the obtained results will allow a better understanding of the processes controlling the contaminant remobilization, mainly governed by the change from anoxic marine sediments to oxic seawater.

Materials and methods
Core sediments, sampled in a site where dredging is intended, was sliced every 2 cm under inert atmosphere. Porewaters and solid fractions were recovered and characterized for their physical-chemical parameters, total concentration of major, minor, trace elements, as well as dissolved/particulate organic matter content and quality (UV and 3D fluorescence). Surface (0-2 cm) and deep (20-22 cm) sediments were stored under inert atmosphere until their mixing with seawater (sampled at the same site, filtered through 0.45 µm filter) at different solid/liquid ratios in Teflon bottles. The mixture was shaken head-over-head at 15 rpm, and exposed at least daily to ambient air to maintain the oxic conditions. Aliquots were collected at 10 contact times, ranging from 5 min to 2 weeks. Physical-chemical parameters (pH, Eh, O_2...) were recorded and different analyses were performed (major, minor, trace elements, dissolved organic/inorganic carbon and organic matter quality).

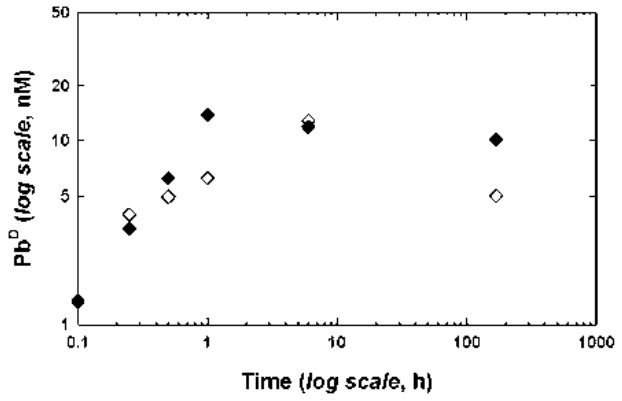

Fig. 1. Pb^D variation as a function of time in dredging simulation of surface sediments at solid/liquid of 0.1 and 1 g L^{-1} (*open and filled diamonds*, respectively).

Results and discussion
The sediments were highly contaminated in inorganic contaminants (0-10 cm: 11 $\mu g_{Hg}\ g^{-1}$, 270 $\mu g_{Cu}\ g^{-1}$, 220 $\mu g_{Pb}\ g^{-1}$, 370 $\mu g_{Zn}\ g^{-1}$...). The batch simulation results showed a continuous acidification of seawater (up to 1 unity of pH over 2 weeks of contact time) whose amplitude was mainly dependent on the solid/liquid ratio but less on the initial redox status of the sediment. A significant increase of active silicate was also demonstrated: signature of bacterial mineralization, while inorganic/organic carbon remained almost stable. Concerning trace elements, As was characterized by a rapid mobilization, right away followed by a readsorption. A similar, but even more pronounced, behaviour was demonstrated for Pb (Fig. 1) and Cd whereas Cu showed an inverse trend. For all cases, the trace element concentrations reached at the maximum of remobilization exceeded the toxicity levels for microorganisms (e.g. plankton). The changes of environmental conditions have then impacted the mobility of the studied contaminants and dredging operation could have a significant impact on the coastal ecosystem.

Conclusion
These labs experiments, simulating sediments resuspension events, demonstrated that such processes could significantly alter the seawater quality. The impacts on the ecosystem of such operations must be deeply surveyed and reconsidered in further Environment Impact Estimation reports.

CADMIUM ACCUMULATION AND PROTEIN OVEREXPRESSION IN BIVALVES EXPOSED TO CADMIUM CONTAMINATED SEAWATER

Manos Dassenakis [1]*, Olga Chalkiadaki [1] and Nikos Lydakis-Simantiris [2]
[1] University of Athens - edasenak@chem.uoa.gr
[2] Technological Education Institution of Crete

Abstract
Three bivalve species, (*Mytilus galloprovincialis*, *Callista chione* and *Venus verrucosa)* were exposed to Cd concentrations (0.5 - 20 ppm) for 20 days. The tolerance to Cd pollution, the Cd accumulation and the protein over-expression in gills, mantle and the remaining body were measured after 5, 10, 15 and 20 days of exposure and a depuration period of 10 days. The effects of Cd accumulation on the levels of biologically related metals were also examined. The studied species showed different behavior for both Cd accumulation/distribution and protein overexpression in the examined tissues.

Keywords: Cadmium, Bio-accumulation, Bio-indicators, Aegean Sea

It is known that various bivalves accumulate heavy metals from seawater *Mytilus galloprovincialis*, *Callicta chione* and *Venus verrucosa* are common species and seafood in the Mediterranean area. Many studies have been published regarding the behavior of *Mytilus galloprovincialis* in heavy metal polluted environments, whereas only a few studies exist in the literature for the effects of heavy metals on *Callicta chione and Venus verrucosa*. This study aims to cover this gap. To compare these three species and to examine the potential use of these organisms as Cd pollution bioindicators. A significant number of animals of all three species were adapted to laboratory conditions and then exposed to 0.5, 1.0, 2.5 and 20 ppm Cd for 20 days, followed by a 10 days depuration period in fresh seawater. Gills, mantle, and the remaining body were separated from animals collected every 5 days of exposure. The concentration of Cd in all tissue samples was measured by AAS [1], and of metallothionein as described in [2]. Differences regarding the tolerance of the three bivalves to Cd were observed. The survival of *Venus verrucosa* was 15 days at the highest exposure level, while *Callista chione* 10 and *Mytilus galloprovincialis* 5 days. Cd accumulation and distribution in the three tissues was species-dependent and tissue-dependent, (gills appeared to have the highest concentrations of Cd, but the accumulation and the distribution levels varied greatly between the same kind of tissue of different species). Indicatively, Figure 1 presents data on Cd accumulation in *M. galloprovincialis* (a) and *C. chione* (b) gills, where the above mentioned differences are apparent. Depuration of Cd from various tissues of the three organisms occurs slowly and it is species-dependent, since considerable amounts of Cd are still present in the tissues after the depuration period, but different in each bivalve.

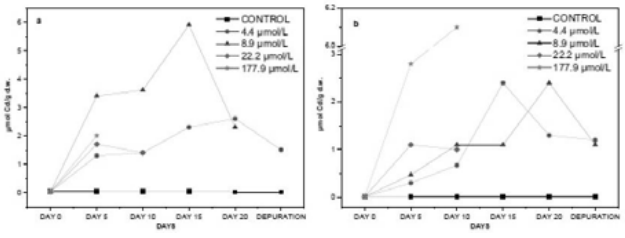

Fig. 1. Cd accumulation in gills of *M. galloprovincialis* (a) and *C. chione* (b) exposed to various contamination levels.

Statistically significant correlations (negative for most of the conditions and tissues under examination), were found between the accumulated Cd and thelevels of the biologically important metals Zn and Fe (especially for M.galloprovincialis). The levels of Cd, Zn and Fe in the tissues of bivalves unexposed to any Cd pollution, were also completely different. A statistically significant positive trend of Cd accumulation in the three tissues of the animals was observed over the exposure period. Significant similarities and differences between the three bivalves in the metallothionein induction and expression were observed. Our research indicate that there are strong interspecies differences in Cd accumulation, elimination and protein overexpression.

Abstract
The fan mussel *Pinna nobilis* L. is the largest endemic bivalve in the Mediterranean Sea under strict protection. The aim was to determine the effects of anthropogenic activity on antioxidant and oxidative stress biomarkers in digestive gland of *P. nobilis*. Antioxidant enzyme activities and protein oxidation were significantly increased in mussels sampled in the impacted area. The anthropogenic activities induced a situation of oxidative stress in *P. nobilis*, resulting in an antioxidant response and in an increased protein oxidation.

Keywords: Ecotoxicology, Bio-accumulation, Bio-indicators, Endemism, Balearic Islands

Aquatic organisms are exposed to anthropogenic contaminants that may strongly affect their performance and survival. The exposure of bivalves to pollutants results in oxidative stress throughout the formation of reactive oxygen species (ROS), which can produce deleterious effects on biomolecules and cell damage [1]. The measurement of the antioxidant response and/or the presence of oxidative damage are potential biomarkers to evidence the effects associated to contaminants and also to eutrophication in marine organisms. The fan mussel *Pinna nobilis* L. is the largest endemic bivalve in the Mediterranean Sea under strict protection. The population of *P. nobilis* has been greatly reduced during the last decades as a result of recreational and commercial fishing for food, the use of its shell for decorative purposes, and incidental killing by trawling and anchoring. Moreover, in a previous study we reported that the presence of *Lophocladia lallemandii* colonising *P. nobilis* induces a biological stress and oxidative damage to the fan mussel [2]. Nowadays, *P. nobilis* is under strict protection and all forms of deliberate capture or killing them are prohibited (Council directive 92/43/EEC). The aim of the present work was to determine the antioxidant enzyme response and markers of oxidative damage in digestive gland of *P. nobilis* growing under anthropogenic pressure. *P. nobilis* (20 individuals) were collected from two locations along Mallorca waters during May-June 2011 attending to different degree of human impact. The first station was located in a marine protected area off Cabrera Archipelago National Park (Western Mediterranean), located 9 km southeast of Mallorca Island and was considered as a clean non-polluted area. The second set of stations because of the low *P. nobilis* densities, the difficulties to find large specimens and in order to minimize the impact in their populations were collected in two sites (Magalluf and Port d'Andratx) with similar characteristics and individuals were considered as human impacted. Digestive glands from each specimen were immediately dissected out on board and frozen with liquid nitrogen. Enzymatic activities of catalase, glutathione peroxidase and glutathione reductase were significantly increased in the impacted area ($p<0.05$), whereas no differences were reported in superoxide dismutase activity (Figure 1). Catalase protein levels determined by western blot were significantly higher in the exposed group ($p<0.05$). Malondialdehyde as marker of lipid peroxidation reported no significant differences, whereas a significant increase in protein oxidation was evidenced in the impacted area ($p<0.05$). In conclusion, the anthropogenic activities induce an oxidative stress situation in digestive gland of *P. nobilis* evidenced by an increased antioxidant enzyme activities and protein oxidation.

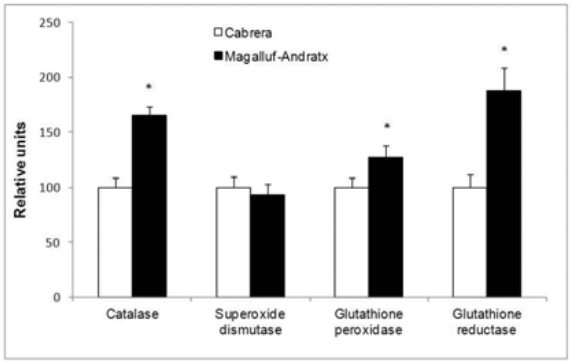

Fig. 1. Antioxidant enzyme activities in digestive gland of *Pinna nobilis* from a clean area (Cabrera) and a polluted area (Magalluf-Andratx). (*) Significant differences analysed with one-way ANOVA. $P<0.05$ was considered statistically significant. Values are expressed as mean ± S.E.M.

Abstract
The aim of the study was to characterize marine sediments for following studies of microbial biodiversity, gene mining and bioprospecting. Further, data on the sediment quality in the Eastern Adriatic regarding heavy metals, PAHs and PCBs concentrations are urgently needed, because the environmental authorities have to define limits for contaminants in sediments for different use of marine resources. We collected sediment at 5 locations in Rovinj costal area according human activities. Sediment chemical analyses and leachates toxicity sort our sites S5 and S4 as pristine areas, and ranked sites regarding degrees of contamination (S5<S4<S3<S2<S1) and decreasing phytotoxic effects (S5›S4›S1›S2›S3).

Keywords: Sediments, Chemical analysis, Ecotoxicology, North Adriatic Sea

Mediterranean coastal sediments are particularly contaminated with metals and organic compounds such as organotins, polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyl (PCB) congeners [1]. Croatia doesn't have defined limits of contaminants in sediments for different use of marine resources: e.g. bays, beaches, villages, ports, marina service areas and others [2]. The French regulatory management of contaminated sediments is based on two levels (N1 and N2) of contaminant concentrations in the whole sediment (Table 1) [1].
We collected sediment at 5 locations in Rovinj costal area taking into account degrees of pollution and applied French regulations. Open sea site (S5) was used as a reference point, while other locations are under different influence as industrial and urban runoff waste: local harbour (S1), Marina (S2), traffic; Lim out (S3), and mariculture; Lim middle (S4) (Figure 1).

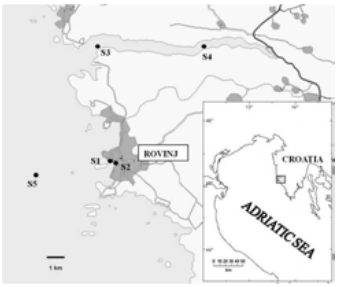

Fig. 1. Location of the sampling sites in the Rovinj costal area

PAH analyses: The PAHs were identified and quantified using HPLC system HP 1050 by a modification of the method previously described [3].
PCB analyses: The procedure used for PCB analyses was under standard protocols [3].
Heavy metals analyses: Heavy metals were quantified using atomic-adsorption spectrometer Perkin Elmer 200 analyst 600 [3].
Genotoxicity: The genotoxic effect of sediment was estimated by umu-test according to standard ISO procedure with slight modification [1]. Serial dilutions (7) of leachates were used in triplicates, with maximal sediment equivalent dose 33.33 g/L [4].
Phytotoxicity test: Germination test was conducted at 25ºC over 72 h test period using seeds of Flax (*Linum usitatissimum*) [1].
Results
Physico-chemical data in whole sediments and reference levels (N1 and N2) are displayed in Table 1. Several pollutants are present at higher concentrations than N1 level (Cu, Ni and PAHs) and few have values close to N1 (As, Pb and PCBs). Chemical pollution decreases according QN1, sum of ratios between contaminant concentration and legal N1 level in investigated sediments as follows: S1>S2>S3>S4>S5. Phytotoxicity assay using Flax seeds showed inhibition of germination, root length reduction and root biomass production with 5 ml of leachates samples ranged sediments by decreasing effect: S5›S4›S1›S2›S3 (Table 1).

Tab. 1. Physicochemical and ecotoxicological evaluation of marine sediments.

Parameters	Units	Locations					N1	N2
		S1	S2	S3	S4	S5	Legal level	Legal level

QN1 = Σ (sum) ratios between contaminant concentration / legal level(N1)
Values close to level N1
Values higher than level N1
Emg5 - IR = induction rations of Equivalent mg of Sediment (IR>1.5 mean positive result)
GI(%) = Germination index (sum of seed germination inhibition, root lenght and biomas production)
Site No. 5 presents control pristine marine sediment of Rovinj costal area

For genotoxicity determination serial dilutions of leachates were used, with maximal sediment equivalent dose 33.33 g/L. The results of umu-test without metabolic activation of analyzed samples were all negative (IR < 1.5), i.e. leachates (metal contamination) did not resulted with genotoxic activity/effects on used test bacteria (Table 1).

Conclusions
In general sediment chemical analyses and leachates toxicity results sort sites S5 and S4 as pristine areas, and ranked sites regarding degrees of contamination (S5<S4<S3<S2<S1) and decreasing phytotoxic effects (S5›S4›S1›S2›S3). According French marine sediment quality guidelines, sediments from Rovinj area even the "hot spot" as local harbour doesn't contain contaminants higher than N2 threshold, what's mean there is no potential ecological impacts on the aquatic environment.

Abstract
In the present work we have highlighted the neurotoxicity of the permethrin, a pyrethroid insecticide by measuring the acetylcholinestrase activity in the brain and muscle of the thick- lipped mullet *Chelon labrosus*. In vivo permethrin's exposure (5µg/l and 10µg/l) after 24 h, 7 days and 30 days revealed a maximal decrease of the acetylcholinesterase activity in both brain and muscle after a week of exposure.

Keywords: Pesticides, Monitoring, Mediterranean Ridge

In Tunisia, mullet species as *Chelon labrosus* (thick-lipped mullet) are very exploited in inland aquaculture. Specimens coming from hatcheries are growing in lake dams freshwater. These ecosystems are submitted to the impact of anthropogenic activities. In fact, pesticides are very used by farmers around the lake dams. These synthetic compounds could have negative effects on the physiological performances of the reared fish species. For this fact, we will point out the effect of the permethrin a very used pyrethroid insecticide on the acetylcholinesterase activity in the brain and muscle of the mullet. The acetylcholinesterase is an enzyme responsible to the nervous transmission in the fish.

Juveniles of the thick-lipped mullet (10-12 cm) obtained from a fish hatchery and acclimated in freshwater were transferred in aquariums and exposed to 5 and 10 µg/l of permethrin for a maximal period of a month. Sacrifices were carried out after 24h, 7 days and 30 days. After each sampling, fish were dissected; the brain and a fragment of muscle were removed and kept frozen in liquid nitrogen until the acetylcholinesterase analyses. The activity of acetylcholinesterase expressed as nmoles/min/mg proteins was determined according to the Ellman et al. [1]

Basal levels of the acetylcholinesterase activity in the brain and muscle of the mullet were 165 and 306 nmoles/min/mg proteins respectively. According to the literature no data are yet available about the acetylcholinesterase activity in the brain of Chelon labrosus species. However, the level of brain acetylcholinesterase activity in the wild mullet species, *Mugil cephalus* was about 126 nmoles/min/mg proteins [2]. The permethrin was observed to cause dose dependant decrease of the acetylcholiesterase activity in both brain and muscle of the mullet. The Results shown in figure 1 and 2 indicated that the permethrin treatment at 5 and 10 µg/l caused an inhibition of the AChE activity in both brain and muscle of the mullet compared with control fish reared in clean water. In fact, after 24 h of exposure, a significant decrease of the enzyme activity by 42 - 69 % in brain and 51 - 48 % in muscle was observed for the both doses: 95 and 150 nmoles/min/mg proteins at 5 µg/l and 50 and 158 at 10 µg/l respectively. According to the USEPA a significant inhibition of the acetylcholinesterase by 20 % is caused by a neurotoxic effect [3]. This decrease was more accented after 7 days; in fact the inhibition rate reaches 83 % in the brain enzymatic activity (26 nmoles/min/mg proteins) at a dose of 10µg/l. In the other hand, we have registered an enhancement in the AChE activity in both brain and muscle after a month of permethrin exposure: 111 and 187 nmoles/min/mg proteins respectively. It seems that the toxic effect of the permethrin in the mullet species is maximal after a week of exposure. Our results highlighted the neurotoxicity of the permethrin in the mullet species. This disruption could have an impact in the physiological performances of this species exploited in aquaculture.

Abstract
Despite of an increasing number of surveys describing adverse effects in marine organisms, few previous studies have addressed protists. In this study the free-crawling marine ciliate *Euplotes crassus* was first validated as novel biological model and then utilized both as test organism for the screening of sediment toxicity using sediments from both coastal and estuarine areas and to study the changes of temperature-related pollutant toxicity in a thermal based toxicological study with oxytetracycline and copper. Further investigations were carried on evaluating the biological and ecological effects of ocean acidification on protozoa by exposing the organism to artificial seawater pH increments in an open flow system.

Keywords: Ecotoxicology, Sediments, Zoobenthos, Thermal pollution, North-Central Mediterranean

In recent decades, the levels of contaminants in the marine environment have increased as a consequence of anthropogenic activities, leading to serious ecological and human health problems. In aquatic systems, partition and bioavailability of these chemicals strongly depend on biological processes, redox potential, ionic strength, pH, activities of organic and inorganic chelators and scavenging processes [1]. Studies on the interactions between ciliates and environmental pollutants are scarce compared with other microorganisms despite the fact that ciliates are easy to culture and considered to be reliable biological models and hence good candidates for use in bioassays [2]. As single cells, directly exposed to the external environment, protozoa may be more sensitive to environmental alterations than the cells of higher organisms that are part of differentiated and complex biological structures. Hence, the potential of protists as both biological model and a predictive tool for hazard and risk assessment in the water and sediments quality criteria as well as in the evaluation of biological effects of climate change and ocean acidification has been evaluated. *E. crassus* were isolated from samples collected in the Tyrrhenian Sea (Italy). Ciliated protozoa were grown in ISO standardized artificial seawater (34 ‰, pH= 8.0) [3] and kept at 24±1°C under oxygen saturation. Organisms were fed with *D. salina*, kept in dark conditions and analyzed during their logarithmic growth phase. Toxicity tests were performed under strictly controlled laboratory conditions; afterwards the organism was validated as bioassay by both a pilot biomonitoring study in the Venice Lagoon and several toxicological studies combining thermal, pollutants and pH changes treatments. Two endpoints of high ecological value, mortality (Mry) and replication rate (RpR), were set up and evaluated in combination with two sublethal biomarkers of stress, endocytotic rate (Ecy) and lysosomal membrane stability (NRRT, [4] Gomiero *et al.*, 2012). The sensitivity of *E. crassus* bioassay has been evaluated by exposing the organisms to lethal and sub lethal concentrations of widely occurring inorganic pollutants, such as essential (Cu^{2+}) and non-essential (Hg^{2+}) heavy metals, as well as to the organic pollutant toxicant model benzo[a]pyrene (BaP) and mixtures of them. The results of validation test showed a significant direct dose/response relationship for all investigated stress index underlying that such pollutants can severely alter physiological and ecological processes of the protozoa such as reduction in food uptake and inhibition of growth, hence influencing survival and replication rate [5,6,7]. Several mechanisms have been proposed to explain metal-induced cellular toxicity. One of the most accepted is the tendency of free metals ions to participate, by Fenton reaction, in the ROS formation. With regard to cellular targets for metals toxicity, lysosomes might be the main sources of ROS generation [8]. Furthermore a pilot biomonitoring program was developed in the Venice Lagoon by collecting sediments from four sites according to their different pollutant's abundance and distribution. The results of the biomonitoring program showed a significant inhibition of RpR, Ecy and NRRT, paralleled by a small and slightly increased Mry of exposed specimen. Interestingly, these outcomes demonstrated that only a combination of mortality and sublethal biomarkers was able to characterize an exposure-related stress syndrome [9]. This research was also oriented towards the study of climate changes effects on environmental pollutants toxicity thus the single cell biological model was also exposed to sub lethal levels of single compounds and binary mixtures of Cu and the oxytetracycline (OTC), an antibiotic commonly used in aquaculture, under five increasing temperatures from 25 up to 31 °C. The outcomes of temperature-related toxicity test showed that the selected toxicants presented opposite behaviors as both protozoa's Mry, RpR, Ecy and NRRT rates increased following increasing thermal gradient in OTC related treatments. On the contrary a decline of tolerance to Cu related treatments were observed in targeted organisms. Furthermore, results of tests combining binary mixtures of toxicants showed a complex pattern of responses. According to the results of a recent ocean acidification model developed under EU-EPOCA project [7,8], the effects of acidification on marine organisms were studied under two combinations of temperature and pH (28,0°C, $7{,}8_{pH}$; 32°C, $7{,}5_{pH}$) simulating changes of seawater chemical and physical conditions expected within 50-100 years from now on in the Tyrrhenian Sea. The preliminary outcomes will be reported. Overall, biological responses indicate a high potential for using protozoa both as biological model and as bioassays to assess environmental risk in marine coastal systems.

Abstract
The polychaetes occupy a prominent place in the food chain. They are used as bioindicators of pollution of the marine environment. This work was carried out in order to assess the variations in activity of glutathione-S-transferase (GST) as an enzyme involved in the detoxification process and compare the diversity of polychaetes species between different study sites. The establishment of an inventory of Polychaeta allowed the identification of several annelid species. The estimated GST activity shows a low activity level at ElKala site and induction at the site of Skikda.

Keywords: Biodiversity, Annelida, Polychaeta, Pollution, Algerian Sea

Introduction
Les annélides polychètes sont les taxons les plus abondants en termes de biodiversité [1], et l'un des groupes de macroinvertébrés les plus utilisés dans les études à caractère écotoxicologique [2]. L'annélide polychète *Perinereis cultrifera* (Grube, 1840) appartenant à la famille des Nereididae. Elle est considérée comme une espèce sentinelle de la pollution. Notre travail a permis l'identification de plusieurs espèces d'annélides polychètes et d'un dosage de l'activité de la GST au niveau de 3 sites : El-Kala, Annaba et Skikda.

Matériels et Méthodes
La récolte a été effectuée du mois de février au mois de juillet de l'année en cours. L'identification des espèces a été réalisée selon la classification taxonomique de Fauvel [3]. La mesure de l'activité GST a été réalisé selon la méthode de HABIG et al.[4].qui consiste à homogénéiser à 4°C dans du tampon phosphate 0,1 M, pH 6. Les homogénats ainsi obtenus ont été centrifugés pendant 30 mn à 15 000 trs/mn.et le surnageant a servi comme source d'enzyme.

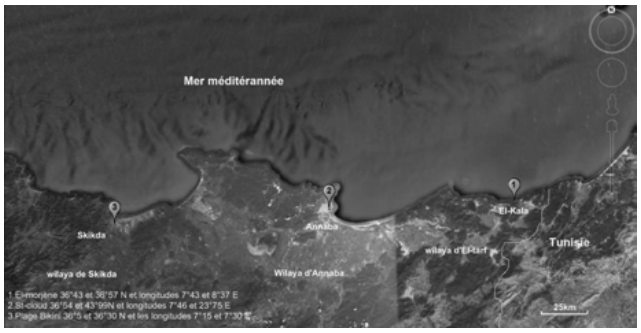

Fig. 1. Sites d'étude du littoral algérien

Résultats et Discussion
Nos résultats montrent une diversité au niveau des sites d'étude : *Nereis falsa, Platyneries dumerillii, Perineries marionii, Lepidonotus clava, Nereis diversicolor*, au niveau des différents sites d'étude.Le graphe montre une augmentation dans le site de Skikda et Annaba qui est dû à la présence du complexe pétrochimique et des activités industrielles.Il a été démontré que l'activité de la GST du néréidien *Laeonereis acuta* peut être induite suite à une exposition à des métaux lourds) [5] et [6] ou à un bloom de cyanobactéries [7].

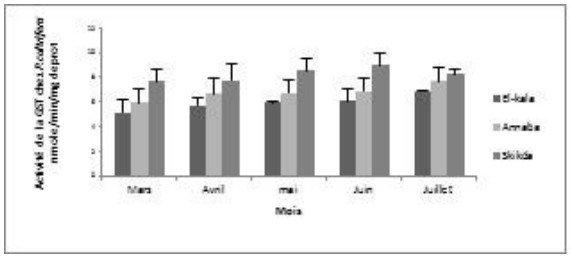

Fig. 2. Variations mensuelles de l'activité de la GST (nm/min/mg de protéines; m ± s; n =4) chez les individus de *P. cultrifera* récoltés au niveau des trois sites d'étude

Abstract
This study was aimed at determining the levels of defense (antioxidative enzyme activities and MXR protein density) and damage (lipid peroxidation) biomarkers in *Hediste succinea*, living in polluted areas of the Berre lagoon. All oxidative balance endpoints and the MXR membrane density were increased in a PAH predominantly polluted area. In a metallic predominantly contaminated site, where significant PAH levels were also found, only membrane MXR density was increased. The increase of lipid peroxidation suggests that these organisms are submitted to pro-oxidative living conditions. These damages can result from reactive oxygen species produced during PAH biotransformation. The MXR protein induction is explained by their role in PAH cell expulsion. These biomarkers enlighten the survival of *H. succinea* in Berre lagoon.

Keywords: Polychaeta, Pollution, Pah, Metals, Gulf of Lyon

In the « BERTOX » program (INSU/EC2CO/AP–AO 2011), which aimed at improving the knowledge in the relationships between pollutants, biogeochemical dynamics of sediments and their impacts on the macro- and micro-fauna, we have determined the levels of some "defense" and "damage (lipid peroxidation) " biomarkers in *Hediste succinea*, living in polluted areas of the Berre lagoon. Some of our questions were: do the contaminants limit the diversity of the macrofauna living in the lagoon? What are the biological mechanisms allowing the species present today to survive in this ecosystem? For this purpose, endpoints of the oxidative balance (enzymatic activities of the superoxide dismutase- SOD, of catalase- CAT, glutathione peroxidase- GPx and lipid peroxidation- Tbars) and the membrane density of MultiXenobiotic Resistance (MXR) proteins, proteins belonging to the first line of cellular defense, were studied. We have collected the specimens of *H. succinea* in the sediments from an area especially contaminated with polycyclic hydrocarbons (PAH) located in the north of the Vaïne part of the lagoon (Vn), from a central area of the Vaïne part of the lagoon (Vc) where trace metallic elements are predominant and from a presumably non polluted one (B9). Results show that all endpoints of the oxidative balance as well as the membrane density of MXR were increased in the PAH predominantly polluted area, as compared with organism collected in B9 site. In the metallic predominantly contaminated site, Vc, where significant PAH levels were also found, only the membrane density of MXR was increased as compared with the one of specimens from B9 site. The increased values of lipid peroxidation in *H. succinea* collected in the PAH contaminated area suggest that these organisms are submitted to pro-oxidative living conditions that can cause membrane degradation. These damage can result from an over production of Reactive Oxygen Species (ROS) by cytochrome P_{450}, an enzymatic complex involved in PAH biotransformation. However, the organisms are able to survive in these polluted sites probably by inducing the synthesis of membrane MXR proteins that are involved in the expulsion of PAH compounds (as we have previously shown in other aquatic invertebrates – Saez et al., 2008). In addition to this induction of MXR proteins, the increase in the enzymatic activities reflects the ability of the organisms to detoxify hazardous ROS and thus maintain their homeostasis to evolve in this contaminated environment. It can be hypothesised from these results that *H. succinea* not only possess but also are able to induce the biological mechanisms which allow a resistance to the pollution (essentially HAP pollution), mechanisms that were probably not induced in other organisms living by the past in the Berre lagoon and that have disappeared from the ecosystem.

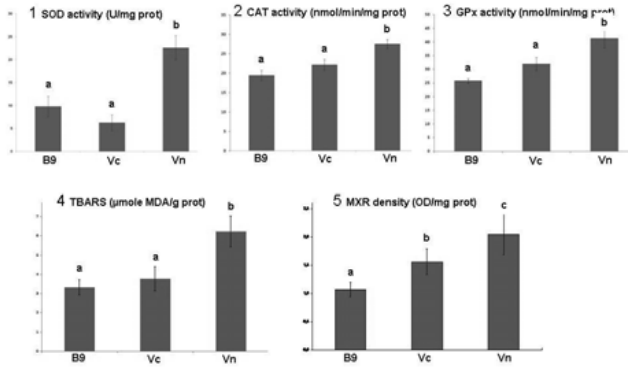

Fig. 1. Enzymatic activities of SOD (1), CAT (2), GPx (3) and lipid peroxidation (Tbars) (4) and MXR membrane density (5) measured in *Hediste succinea* collected in an unpolluted area (B9), in a PAH and metallic (MTE > PAH) polluted area (Vc) and in a PAH polluted area (Vn) of the Berre lagoon (France). Two different letters mean a significant difference between groups (ANOVA, Tukey test, $p < 0.05$).

Abstract

The purpose of this study was to evaluate the role of sunscreen as source of chemicals to the coastal marine system. Concentrations of UV filters included in the formulation of sunscreens, such as benzophehone-3 (BZ-3), 4-methylbenzylidene camphor (4-MBC), TiO_2 and ZnO, are detected in nearshore waters. Concentrations varied along the day and were highest in the surface microlayer. We experimentally demonstrate growth rate of populations of the marine diatom *Chaetoceros gracilis* declines in response to sunscreen products. Dissolution of sunscreens in seawater also releases inorganic nutrients (N, P and Si forms) that can fuel algal growth. Our results show that sunscreen products are a significant source of organic and inorganic chemicals that reach the sea with potential ecological consequences on the coastal marine ecosystem.

Keywords: Trace elements, Coastal systems, Balearic Islands

1. Introduction

A growing awareness of the risks associated with skin exposure to ultraviolet (UV) radiation over the past decades has led to increased use of sunscreen cosmetic products leading the introduction of new chemical compounds in the marine environment. Despite of coastal tourism and recreation are the largest and most rapidly growing activities in the world, the evaluation of sunscreen as source of chemicals to the coastal marine system has not been addressed.

In this study we estimate the potential effect of commercial sunscreen released in nearshore waters by beachgoers. We conduct field and laboratories studies to evaluate the presence of chemicals products released from sunscreens in coastal seawater and its effect on the marine phytoplankton. Particularly, (1) we present the results for UV chemical filters levels in different fractions of surface marine waters of three Majorca areas; (2) we evaluate the contribution of sunscreen products to the total dissolved P in nearshore waters of a populated beach in Majorca island; and (3) we test the effect of sunscreens on the growth rate of a marine diatom (i.e. *Chaetoceros gracilis*).

2. Results

Chemical analysis of the surface nearshore waters of three areas around Majorca Island showed that four of the main chemicals used in commercial sunscreens were detected in the surface waters, with the highest concentrations measured in the unfiltered fraction of the surface microlayer (SML) (i.e. BZ-3: 580 ± 50 ng L^{-1}; 4-MBC: 113 ± 7 ng L^{-1}; and TiO_2: 38 ± 7 µg L^{-1}; ZnO: 10.8 µg L^{-1}). Levels of these chemicals co-varied throughout the day reaching the highest concentrations between 14:00 and 18:00 h (Figure 1), suggesting a common source for these products.

Our results also show the release of some inorganic nutrients from sunscreens (i.e. PO_4^{3-}, NO_3^-, and NH_4^+). A total of 13 commercial sunscreens tested provided final concentrations in water of 2 ± 5 µmol g^{-1} of PO_4^{3-}, 0.2 ± 0.4 µmol g^{-1} of NO_3^-, 0.001 ± 0.002 µmol g^{-1} of NO_2^-, 2 ± 2 µmol g^{-1} of SiO_2 and 0.02 ± 0.01 µmol g^{-1} of NH_4^+. It is particularly notable that on the average the release of PO_4^{3-} occurs in relatively high molar ratios compared to nitrogen forms.

We tested the effect of sunscreens on the growth rate of the marine phytoplankton *Chaetoceros gracilis*. The acute toxicity was measured by calculating half maximal effective concentration (EC_{50}) after 72h incubation in presence of different amounts of sunscreen, resulting in an average of 125 ± 71 mg L^{-1}. Our results demonstrate the toxicity of the commercial sunscreen for marine phytoplankton, and confirm previous studies of toxicity carried out with individual organic and inorganic UV filters on marine organisms [1, 2].

The present work includes a culture study "in vitro" of the marine angiosperm *Posidonia oceanica* in presence of growing amounts of sunscreen. Our preliminary results confirm that *P. oceanica* absorbs components derived from sunscreens in its tissues, such is TiO_2, which effects remains to be explored.

3. Conclusions

More than half of today's world population live in coastal areas, and estimates for the future suggest that in three decades from now nearly 75 percent of the world's population will live along coasts. This fact, combined with data showing that sun protection products are one of the fastest growing products globally, points to sunscreens as a potential pollutant with implications for the coastal marine ecosystem. The results presented here suggest that sunscreens in coastal waters may produce deleterious effects in the coastal ecosystem, either, by inhibiting growth of some marine phytoplankton species or by adding essential micronutrients which may stimulate the growth of others.

Abstract
Climate change, population increase, industrialization and agricultural activities are effecting eutrophication in estuaries and coastal waters. The Mediterranean Sea, as a semi-enclosed sea must be very sensitive to global change and is impacted by human activities. Coastal cities has been identified as hot spots for several pollution types. Along the Algerian coast we present the evolution of nutrients and oxygen in two bays : Algiers and Bou-Ismail. We also present the distribution of pH and CO_2 air-sea exchange in these areas. This work is part of the international "MerMex, MISTRALS" program which aims at studying the viability of the Mediterranean Sea for the next century.

Keywords: Coastal waters, Eutrophication, Oxygen, Algerian Sea, Air-sea interactions

Introduction

The world's climate has changed, and human activities are continuously contributing to greenhouse gases emission and water pollution. The drivers causing coastal eutrophication are set within a large framework of multiple human-induced stressors, including overfishing, chemical contaminants, coastal habitat degradation and invasive species [1]. Eutrophication is a global phenomenon with significant effects on food webs, water quality, and biogeochemical cycles [1]. The Mediterranean Sea showing short-term response to anthropogenic forcing can be considered as an ocean model. In this context, acidification, eutrophication status, sea water warming and change in biodiversity are the key topics in assessing the viability of the Mediterranean Sea for the next century. The Algerian coastal areas characterized by high biodiversity are very sensitive to human activities. For instance, every year, millions of cubic meters of untreated wastewater pour into the bay of Algiers, the latter being also influenced by the fresh water input from 2 rivers. The Bou Ismail bay extends on about 50 kms in the west of Algiers, and presents an accelerating process of degradation following the development of anthropogenic activities since the last 10 years. Few data are actually available concerning the distribution of pCO_2 in surface waters for the Algerian basin of the Mediterranean sea. In this work, we present sea water nutrient content and dissolved oxygen and how these parameters have evolved over 20 and 10 years respectively for Algiers and Bou Ismail bays, taking advantage of historical data collected in the same zones [2] and present day cruises. We also present the role of these areas as source or sink for atmospheric CO_2 in spring 2012.

Material and method

More than 20 stations were sampled in the two bays between 3 and 100 m depth. The dissolved O_2 was measured using the Winkler method [3]. The mean and standard deviation on the replicate is 2±0.2 µmol/kg. The nutrients (nitrogen, phosphorus) were measured with the auto analyzer SAN PLUS (Skalar, 1996). The mean and standard deviation on the replicate was 0.03±0.0001 µmol/kg. The pH and Total alkalinity (TA) were measured according to Dickson recommendation [4]. TCO_2 and pCO_2 were calculated using Mehrbach dissociation constants for carbonate system in sea water [4]. Accuracies are, 0.002 for pH, 4µmol/kg for TA, 5 µmol/kg for TCO_2 and 6 µatm for pCO_2.

Results and discussion

Averaged phosphorus concentration has increased in the two bays over time. That explains a decrease in N/P ratio. The N/P ratio decreases from 1.6 in 1989 to 0.79 in 2012 in the Algiers bay and from 4 in 1996 to 0.4 in 2011 for the Eastern part of the Bou Ismail bay. Boulahdid et al [5] have shown a difference in N/P distribution between the western part (N/P=16) and the Eastern part (N/P=2) of Bou Ismail bay in 1996, probably caused by higher demography on the eastern coast of the bay. Recent observations do not show this difference as the demography and urbanization have gained the western part of the bay as well. Therefore, we suppose that N/P ratio decrease is a consequence of an increasing trend in the volumes of untreated domestic waters that reach the bay, as well as a change in river inputs following some rainfall changes over the years.

Tab. 1. Data for Algiers and Bou-Ismail bay: mean and (standard deviation) for nitrogen, phosphorus and dissolved oxygen. Air-sea CO_2 fluxes (FCO_2), the negative value indicate sink for atmospheric CO_2, positive value indicate source of CO_2 for the atmosphere.

	Bou-Ismail bay		Algiers bay		
	Mai-2002	April-2012	1989	April-2011	April-2012
Nitrogen (µmol/l)	0.83 (1.2)	0.26 (0.14)	0.63 (0.3)	0.17 (0.08)	0.82 (0.4)
Phosphorus (µmol/l)	0.13 (0.02)	0.52 (0.54)	0.39 (0.25)	0.39 (0.05)	0.48 (0.02)
O_2 (mg/l)	8.62 (0.28)	6.22 (0.65)	No data	6.98 (0.63)	6.99 (0.88)
FCO_2 mmol/m²/day	No data	-15.79	No data	+ 0.37	- 0.27

Dissolved O_2 is of about 8 mg/l on average for Bou Ismail bay in 2002 and around 6 mg/l for 2012 in the two bays. The dissolved oxygen is a good indicator of eutrophication for coastal waters. According to IFREMER [6], an oxygen decreasing trend is an indicator for eutrophication risk. However, the Bou Ismail bay is also under a strong influence of the Algerian current hydrodynamics which may contribute to the ventilation of these waters. Concerning the sea surface pCO_2, the distribution is controlled by the temperature, and river inputs. In spring 2012, the eastern part of Bou Ismail bay acts as a sink for atmospheric CO_2 (-15.8 mmol/m^2/day on average). In the Algiers bay, the pCO_2 distribution shows a clear contrast: near-shore waters are influenced by river input with low pH and low TA and therefore act as a source of CO_2 for the atmosphere (+4.35 mmol/m^2/day on average), while the waters off the coast, more influenced by the Algerian current, act as a sink with a mean flux of -2.75 mmol/m^2/day.

HYPOXIA IN THE BLACK SEA NORTH WESTERN SHELF : FROM EUTROPHICATION TO CLIMATIC STRESSORS

Arthur Capet [1]*, Jean-Marie Beckers [1] and Marilaure Grégoire [2]
[1] GHER - Université de Liège - arthurcapet@gmail.com
[2] Laboratoire d'Océanologie - Université de Liège

Abstract
The dynamics of seasonal hypoxia, which affects the Black Sea north-western shelf since the mid 1970's until present days, is investigated by means of a 3D biogeochemical model. Comparison of the model results with in-situ data reveals that the phenomenon may have been underestimated after the mid 1990's due to the distribution of observations. We investigate the mechanism of hypoxia at seasonal scale, and identify the main drivers of its interannual variability. While high nutrients discharge caused severe hypoxia in the 1980's, it was sustained in the 1990's by the pool of organic matter accumulated during the previous years in the sediments layer. With an increasing intensity, climatic stressors intensifies the response of hypoxia to nutrient discharge, and affect the seasonal dynamics of hypoxia by extending its temporal scale.

Keywords: Black Sea, Oxygen, Models, Benthic-pelagic coupling, Continental shelf

As many other stratified continental shelves exposed to eutrophication (Diaz and Rrosenberg, 2008), the Black Sea North-western shelf (NWS) is affected by seasonal hypoxia : the summer stratification isolates bottom waters from the atmosphere and prevents ventilation to compensate for the large consumption of oxygen due to respiration in the bottom waters and in the sediments.

We used a 3D coupled physical biogeochemical model to investigate the dynamics of bottom hypoxia in the Black Sea NWS at seasonal and interannual scales (1981-2009). The model integrates the biological model presented in Grégoire et al.,2008, within the hydrodynamical 3D model GHER (Capet et al., 2012) and includes a dynamical representation of organic matter in the sediment layer (i.e. resuspension and benthic diagenesis) (Stanev et al., 2012 ; Soetart et al. 2000). Model skills are evaluated with 14500 in-situ oxygen measurements available in the NOAA World Ocean Database and the Black Sea Commission data. Specific validation procedures prove the model's ability to resolve the seasonal cycle and interannual variability of oxygen concentration as well as the spatial location of the oxygen depleted waters and the resolution of the specific threshold of hypoxia ($[O_2]< 62$ mmolO/m³). Spatial variability and seasonal fluctuations complicate the monitoring of hypoxia leading to contradictory conclusions when different sets of data are considered. Noteworthy, the recovery process was overestimated after 1995 due to the concentration of observations in areas and months not typically affected by hypoxia. This stresses the urging need of a dedicated monitoring effort in the NWS of the Black Sea focused on the areas and the period of the year concerned by recurrent hypoxic events.

The severity of hypoxia for a given year is quantified by an index H which combines the aspects of spatial and temporal extension of hypoxia, and is equivalent to the maximal spatial extension if the duration is equal to the average. In order to explain the interannual variability of H and to identify and disentangle its main drivers, a multilinear stepwise regression analysis ($p < 0.01$) is applied on the long time series provided by the model. This statistical model gives a general relationship (Fig. 1.) that links the intensity of hypoxia to eutrophication and climate related predictors. It is known that hypoxia is caused by an enrichment of river waters in nutrients (e.g. Diaz and Rosenberg, 2008). Here we show that the accumulation of organic matter in the sediments, during the years of high nutrient discharge, continues to cause an important benthic oxygen demand, even after the reduction of discharge (in the early 1990's for the Black Sea NWS), with a typical inertia timescale of 9.3 years.

This introduces an important aspect in the dynamics of recovery from eutrophication by riverine discharge management. The major climate-related driver of hypoxia is the sea surface temperature (SST) in March, which fixes the solubility of Oxygen in sea water, hence the pool of oxygen content in the bottom watermass, before it is locked by the summer stratification. Also, high SST in the late summer extends the duration of the stratification period, which increases the damages caused by hypoxia since the last days of the stratification is when the bottom waters bear the lowest oxygenation levels, eventually reaching anoxia and causing the release of hydrosulphide from the sediments. Higher summer temperature observed in the Black Sea for the last decade thus adds a new challenge in the management of eutrophication as it intensify the sensitivity to the nutrient discharge.

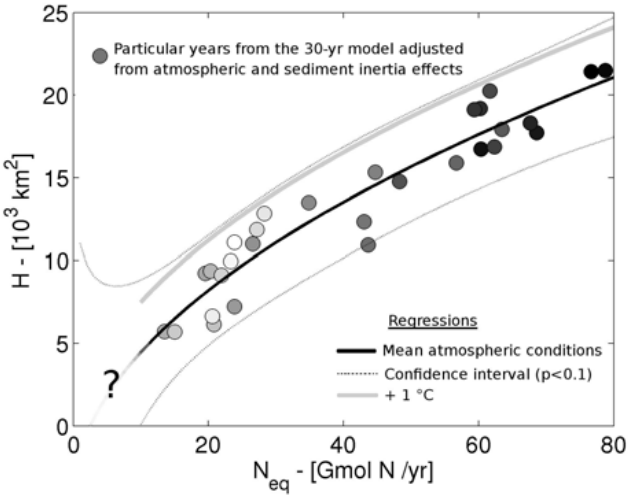

Fig. 1. The role of atmospheric drivers and sediment inertia on the intensity of hypoxia, as revealed by the stepwise regression, allows to redraw the distribution between H, the intensity of hypoxia, and N, the riverine nitrogen discharge, for mean atmospheric conditions and equilibrated sediment pool of organic matter. The effect of warming (+1°C) on the H(N) relationship is indicated by the gray line. This statistical relationship is not validated for the low level of nitrogen discharge that were not experienced during the period of the modeling experiment (1981-2009).

EVENTS OF HYPOXIA IN RELATION TO CIRCULATION PATTERNS IN THE NORTHERN ADRIATIC SEA

Tamara Djakovac [1]*, Nastjenjka Supic [1] and Robert Precali [1]
[1] Rudjer Boskovic Institute - djakovac@cim.irb.hr

Abstract
Marked hypoxia has been often observed in the northern Adriatic (NA) bottom layers during autumn. Assuming that the frequency of these events is significantly affected by the circulation regime in the NA, and not exclusively due to eutrophic pressure, datasets of bottom dissolved oxygen volume ratio at two stations in the area are compared to the velocity of geostrophic currents for the period 1972-2010. Significant correlations were obtained pointing the importance in circulation patterns.

Keywords: Oxygen, Currents, North Adriatic Sea

Introduction Marked hypoxia in the bottom layer frequently develops progressively from August to November in the northern Adriatic. The region is under the impact of the Po River, one of the largest in the Mediterranean (Fig. 1) which nutrient richer waters can spread over the entire northern Adriatic region, remaining in a large portion entrapped within gyres, which usually extend from the surface to 10-20 m, or even more (Supic N., pers.comm.). An anticyclonic gyre often forms in the north-eastern Adriatic and is marked by the southward Istrian Coastal Countercurrent (ICCC; [1]). Alternatively, river waters do not spread significantly across the northern Adriatic and the region largely belongs to the Adriatic-wide cyclonic gyre. Thus, events of hypoxia/anoxia resulted from a combined effect of excess primary production and reduced lateral advection due to gyre formations [2]. To verify the importance of lateral advection, datasets of dissolved oxygen volume ratio of bottom layers of some northern Adriatic areas during the period 1972-2010 were correlated to the velocity of geostrophic currents of different direction. **Material and Methods** Dissolved oxygen volume ratio in bottom layers of two stations (SJ107 and SJ108), located along the transect Po River Delta-Rovinj (Fig. 1) was determined by the Winkler titration technique described in Strickland and Parsons (1972).

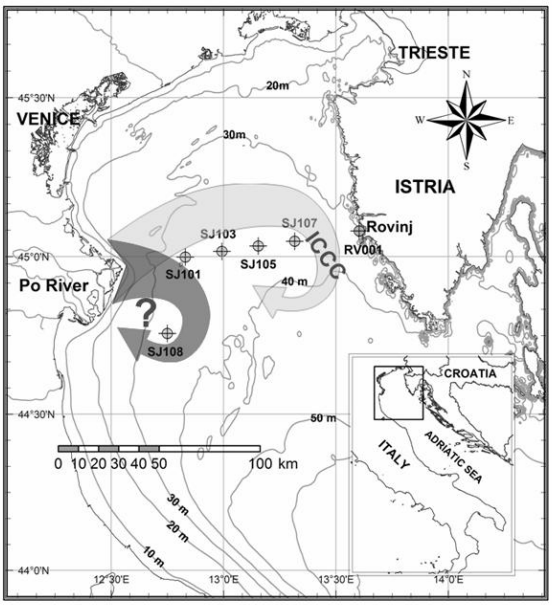

Fig. 1. Northern Adriatic map with station locations and geostrophic currents.

Geostrophic surface currents relative to 30 dbar between stations were computed as described in [1]. **Results and Discussion** The correlations between current velocities and hypoxia events were statistically significant (Fig. 2a, b). At the eastern, more oligotrophic station SJ107, southward geostrophic current (ICCC), which indicates the presence of an anticyclonic gyre (Fig. 1), appeared along with hypoxia events (Fig. 2a).

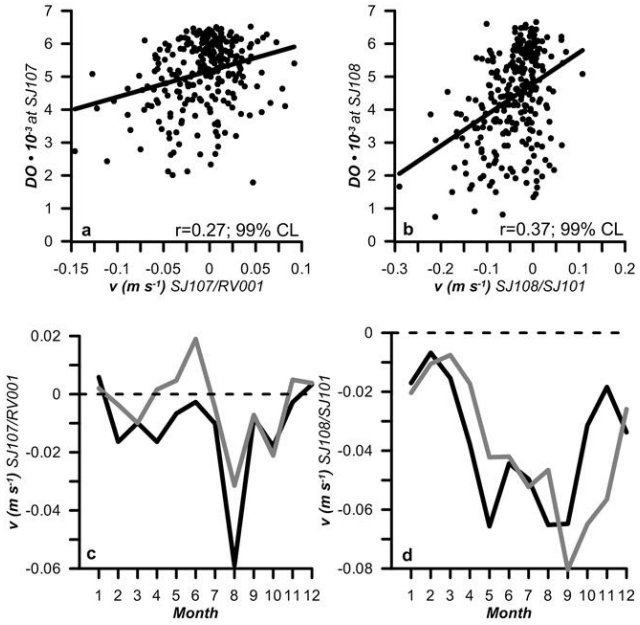

Fig. 2. A) Bottom dissolved oxygen volume ratio (DO) at station SJ107 in relation to the component of surface geostrophic current relative to 30 m between stations SJ107 and RV001; b) Same as a) but for stations SJ108 and SJ101; c) Seasonally cycle of geostrophic currents component between stations SJ107 and RV001 in years with (black) or without (gray) hypoxia event; d) Same as c) but for stations SJ108 and SJ101. Positive currents indicate inflow into the NA.

This gyre seems to form by the end of winter and persists throughout spring and summer, increasing the advection of low-salinity waters (enriched in nutrients) eastward, consequently with oxygen consumption in bottom layers in autumn (Fig. 2c). But, in years when hypoxia event does not occur, the gyre forms much later, in summer (Fig. 2c). Unexpectedly, in the western, more eutrophic part of the region (station SJ108), which is more directly influenced by nutrient inputs, low bottom oxygen concentrations coincided with intense surface southward current between stations SJ108 and SJ101 (Fig. 2b). This current seems to be present throughout the year (Fig. 2d), concurrently with hypoxia in bottom layers from August to September, that points to a presence of another anticyclonic gyre near SJ108 (Fig. 1). **Conclusion** The results indicate that particular circulation patterns, especially when gyres form, are an important cause of hypoxia in the northern Adriatic.

Abstract
A long term time series at the ANTARES MOOSE fixed moored site is on going since 2008 to monitor hydrological parameters. A special focus has been carried out in situ oxgen concentration evolution and its associated dynamics. Results over 3 yeras exhibit a annual decrease of 2.5 µM O2 with a variability assiciated to hydrological and biological events at the basin scale.

Keywords: Oxygen, North-Western Mediterranean, Time series, Pelagic

The role of the ocean and the biological pump is the CO_2 system regulation in relation with global warming is now recognised (IPCC 2007). This climate change will induce some evolution in oceanic circulation, impaction surface oceanic stratification, decrease in cascading or convection events (Bopp et al. 2002); major process in deep water ventilation. Some extreme events have already been observed in the Mediterranean Sea Méditerranée (Schröder et al., 2006, Font et al. 2007, Fuda et al. 2007, Canals et al. 2006, Bourin et al. 2008, Schröder et al. 2012). The long term study of in situ oxygen concentration and its associated dynamics is a key index of the ecosystem evolution (Keeling and Garcia, 2002). The surface production fluxes are also controlled by the mixed layer depth and associated temperature. Almost 50% of surface production, proxy of the biological pump functioning, is exported as organic matter to the deep sea (Ducklow & Carlson, 1992) as dissolved of particulate organic material. These exports are the main conveyor of carbon and energy to the mesopelagic and bathypelagic zone which is then buried in the sediment. The export flux intensity and the organic material quality (dissolved semi labile or refractory, or particulate organic material) will set the marine micro-organism activity in the deep ocean and will impact the in situ oxygen concentration. This study presents a unique time series of in situ oxygen concentration and its associated dynamics at the fixed moored station MOOSE-ANTARES on going since 2008. The oxygen time series exhibits an annual decrease of 2.8 µM O_2 (figure 1). The trend is comparable at 2300 m and 2000 m depth.

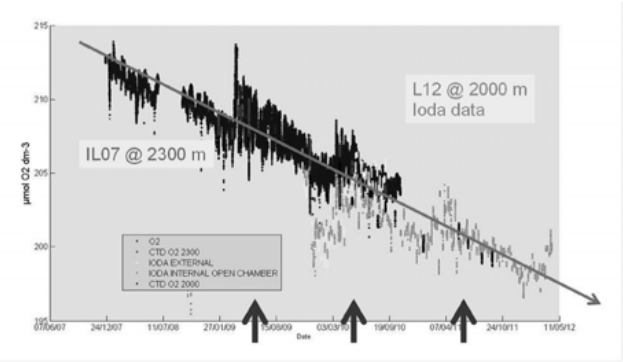

Fig. 1. *In situ* Oxygen concentration time series since 2007 at the ANTARES site observed at 2300m and 2000m. Black and grey coloured points are respectively from 2300 m and 2000 m. Arrows are related to hydrological events observed at the ANTARES site. The observed drift for the 2007-2012 period correspond to a decrease of 2.8 µM a-1. Oxygen measurements are measured with an Aanderaa optode 3830. The calibration was performed using CTD-O2 profiles in the vicinity of the mooring site.

Some annual variations are observed during the February-March period, most likely associated with hydrological events occurring in the Gulf of Lions. Indeed, deep water convection occurs with more or less intensity every year and in some occasion this mixing occurs on the whole water column. Cascading events also occur in the Gulf of Lions in winter under wind and temperature forcing. This has a direct effect on mesopelagic and bathypelagic water ventilation as well as redistributing nutrients and organic carbon along the water column. Alongside a time series of oxygen dynamics has been monitored at 2000 m depth using the innovative instrumentation $IODA_{6000}$. In situ incubation was performed over 5 days cycles since 2009. The background oxygen consumption rate is 0.12 µM O_2 d^{-1} and some seasonal variation are observed which may be related to the main hydrological events and primary production events at the basin scale At different scale, the hydrodynamic and surface primary production, carry the role of fertilising the deep ocean and may trigger some unexpected intense biological activity (Tamburini et al. 2013). These two on going and unique time series offers insight in the bathypelagic ecosystem functioning with higher oxygen consumption rates than expected.

TOXICITY OF POLYCYCLIC AROMATIC HYDROCARBONS TOWARDS NATURAL PHYTOPLANKTON FROM COASTAL MEDITERRANEAN LAGOONS

Hiba Ben Othman [1]*, Elodie Lanouguère [2], Asma Sakka Hlaili [1] and Christophe Leboulanger [2]
[1] Laboratoire de Cytologie Végétale et Phytoplanctonologie, Faculté des Sciences de Bizerte, Université de Carthage, Zarzouna 7021, Bizerte, Tunisia - benothmanhiba@yahoo.fr
[2] UMR 5119 ECOSYM, CNRS-IRD-Université Montpellier II-Ifremer-Université Montpellier I, SMEL 2 rue des Chantiers, F-34200 Sète, France

Abstract

Toxicity of PAH mixture against natural phytoplankton was evaluated on two coastal Mediterranean lagoons: Thau (France) and Bizerte (Tunisia), exposed to increasing concentrations of synthetic PAHs in mixture (up to 441 µg L^{-1}). Toxicity endpoints used were both structural (taxonomic composition) and functional (photosynthetic potential). At short term, a dose–response relationship was observed in the two experiments, with significant changes in photosynthetic potential and phytoplankton community structure. The Fv/Fm-based EC50s showed that Thau phytoplankton community was more sensitive to PAH mixture than the Bizerte one. Similarity analysis enlightened the difference in taxonomic composition between the two systems, and the strong structuring pressure exerted by the PAHS; toxicity of the mixtures was dose- and species-dependent.

Keywords: Lagoons, Phytoplankton, Ecotoxicology, North-Western Mediterranean, South-Western Mediterranean

Introduction

Widely distributed in the marine environment, PAHs are of great concern because of their toxic and carcinogenic properties [1]. They are common constituents of complex pollution. An estimated total input of 230,000 metric tons of PAHs is released annually to the aquatic environment [2] and may accumulate in the sediments especially in coastal Mediterranean lagoons. A number of changes mediated by chemical or microbial activities, meteorological events or dredging, can release PAHs from the sediment into the water column. The aim of this study was to assess the impact of PAH mixture on the photosynthetic efficiency of PSII and phytoplankton community structuring in microcosms inoculated from Thau and Bizerte lagoons.

Materials and Methods

Fifteen 5 L microcosms were inoculated with phytoplankton assemblages collected from coastal stations in Bizerte (Tunisia) or Thau (France) lagoons. Replicate of controls (T) and four-level of contaminated microcosms were prepared, with increasing concentrations of PAHs mixture from 1.5 to 441 µg/L. PAHs concentrations were analytically controlled.

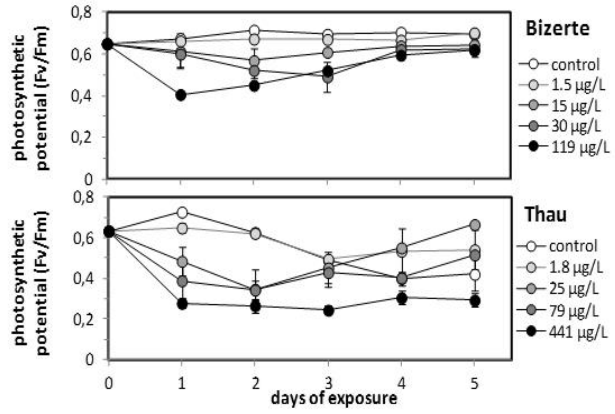

Fig. 1. Toxicity of PAHs mixture on photosynthetic efficiency of PSII (Fv/Fm) of phytoplankton communities.

The microcosms were incubated *in situ* and samples collected from each bottle after 24, 48, 72, 96 and 120h to measure the relative photosynthetic efficiency of PSII (Fv/Fm) using PAM fluorometry (AquaPen-C, PSI, Czech Republic). Fv/Fm parameter after dark adaptation was selected as functional endpoint to detect the toxic effects [4]. Lugol-preserved samples of phytoplankton were counted and identified using an inverted microscope. Data were processed using PAST freeware (Bray-Curtis similarity indices for taxonomic composition), and the EC50 was estimated according to the Hill dose-response model.

Results and discussion

After 24h exposure, PAHs were toxic to photosynthetic parameters. Thau and Bizerte community EC50 were 297µg L^{-1} and 75µg L^{-1} respectively. Photosynthetic efficiency (Fv/Fm) decreased at the highest PAH concentration for Thau and Bizerte lagoon relative to the control (from 0.65 to 0.27 and 0.4, respectively). This significant inhibition remained unchanged throughout the exposure in Thau, suggesting a persistent degradation of PSII efficiency. For Bizerte phytoplankton community, the highest concentration was not lethal, and Fv/Fm parameter fully recovered after 120h (Fig.1).

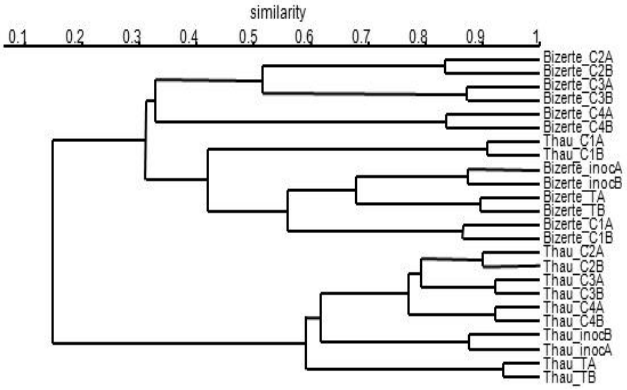

Fig. 2. Effect of PAHs mixture on community structure after 24h exposure. Composition similarity is expressed by Bray-Curtis distance. Sample name indicates origin (Thau, Bizerte) and contamination level (T for control, Cx for levels of PAHs) for duplicate analysis (A,B).

For Thau, a significant increase of Fv/Fm was observed for the three lower concentration compare to control after 120h. Tolerance acquisition towards PAHs mixture appears greater for Thau than for Bizerte phytoplankton community. The similarity analysis enlightened the difference in taxonomic composition for two lagoon ecosystems, and for each one, the species diversity was strongly driven by the contamination level (Fig.2).

VARIABILITÉ INTERANNUELLE DE LA TRANSPARENCE DES EAUX D'UN CANAL RELIANT DEUX LAGUNES MÉDITERRANÉENNES (TUNISIE SEPTENTRIONALE)

Besma Chaouachi [1]*, Abdessalem Shili [2], Domia Menif [3] and Oum Kalthoum Ben Hassine [1]
[1] Faculté des Sciences de Tunis, Université Tunis El Manar. Tunisie. - Besma.Chaouachi@fsb.rnu.tn

Abstract
La transparence des eaux du canal Tinja dépend du vent mais aussi du sens et de la durée du courant lequel est tributaire du niveau de l'eau dans la lagune Ichkeul. Les transparences mensuelles moyennes calculées à partir des mesures quotidiennes (1992-96) montrent des maximums (73 à 107 cm) pendant l'été ou l'automne par courant continu vers la lagune Ichkeul et des minimums (12 à 30 cm) en hiver ou au printemps par courant circulant vers Bizerte. Les transparences moyennes relativement faibles (<30 cm) coïncident avec des vents forts. Durant les périodes de transition séparant les courants continus et lorsque les vents sont calmes, un mélange s'effectue entre les eaux claires provenant de la lagune de Bizerte et les eaux turbides de l'Ichkeul.

Keywords: Hydrology, South-Central Mediterranean, Lagoons, Monitoring

Le canal Tinja long de 5 km et profond d'environ 1 m relie la lagune Ichkeul (1 m de profondeur moy) à la lagune de Bizerte (7 m de profondeur moyenne). Celle-ci s'ouvre en permanence sur la mer Méditerranée par le goulet de Bizerte (long de 7 km et profond de 12 m). L'écosystème Ichkeul-Bizerte a connu de grandes modifications suite aux variations des conditions du milieu et à l'édification des barrages de retenue d'eau douce sur le bassin versant de l'Ichkeul. Pour ces raisons, une écluse sur le canal Tinja a été mise en service pour mieux gérer les réserves en eaux douces de l'Ichkeul et préserver l'originalité de cet écosystème (Fig. 1).

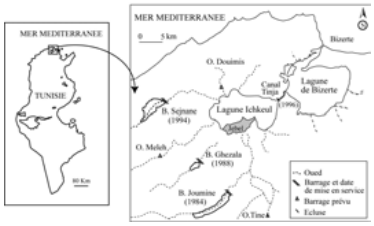

Fig. 1. Situation du complexe lagunaire Ichkeul-Bizerte (Nord de la Tunisie)

La transparence des eaux du canal Tinja a été évaluée tous les matins (mars 1992-septembre 1996) à l'aide d'un disque de Secchi (DS). Parallèlement, le sens du courant du canal Tinja, entrant ou sortant par rapport à la lagune Ichkeul a été régulièrement relevé. La transparence mensuelle moyenne des eaux (Fig. 2) a fluctué entre un minimum de 12 cm (mars, courant sortant) et un maximum de 107 cm (août, courant entrant) et les vitesses mensuelles moyennes du vent ont varié de 1,7 à 5,6 m/s. Durant les années hydrologiques 1991 à 1996, les transparences mensuelles les plus élevées ont été observées pendant les saisons estivales et automnales (août à novembre) par courant entrant dans la lagune Ichkeul. Les moyennes mensuelles maximales ont varié entre 73 et 107 cm. Les transparences mensuelles les plus faibles ont été enregistrées en périodes hivernales et printanières (février et mars) lorsque le courant est dans le sens Ichkeul-Bizerte et les valeurs calculées pour chaque année, ont été comprises entre 12 et 30 cm. Les transparences mensuelles relativement faibles, inférieures à 30 cm ont été observées essentiellement par courant continu vers Bizerte et correspondent à des vitesses moyennes du vent relativement élevées et allant jusqu'à 5,6 m/s. En effet, le vent fort remet les particules en suspension, augmente, de ce fait, la turbidité des eaux et limite l'énergie lumineuse disponible pour le phytoplancton [1]. Le début et la durée des courants continus vers Bizerte ou Ichkeul, variables d'une année à l'autre, dépendent des apports en eaux douces lesquels ont été réduit par la mise en eau des barrages. En considérant l'ensemble des courants continus répartis sur toute la période d'étude, les DS moyens calculés ont été compris entre 13 et 34 cm pour les courants sortants continus de l'Ichkeul qui ont duré 2 à 5 mois. Pendant ces derniers, les transparences évaluées dans le canal sont celles de la lagune Ichkeul. Celle-ci a une faible profondeur, par conséquent, le vent remue les particules argileuses du fond et celles provenant du bassin versant. Pour les périodes des courants entrants continus dans l'Ichkeul qui ont été de 3 à 7 mois, les DS moyens relevés dans le canal et proches de ceux du bassin de Bizerte ont varié entre 42 et 93 cm. Les fonds de la lagune de Bizerte, plus profonde, sont moins susceptibles d'être remis en suspension par le vent.

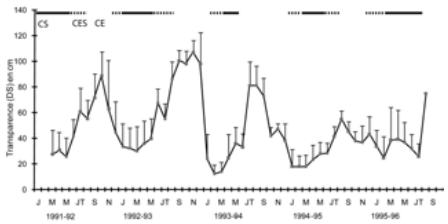

Fig. 2. Evolution des transparences (cm) moyennes des eaux en relation avec le sens du courant du canal Tinja. Les barres verticales représentent l'écart-type. CE. : courant entrant continu dans l'Ichkeul ; CS : courant sortant continu de l'Ichkeul ; CES. : courant entrant-sortant.

Au cours des périodes de transition (quelques jours à 3 mois) séparant les courants continus et lorsque les vents sont calmes, un mélange s'effectue entre les eaux claires provenant de la lagune de Bizerte et les eaux turbides de l'Ichkeul et les transparences mesurées au niveau du canal sont intermédiaires entre celles des deux plans d'eau. Bien que les échanges entre la lagune Ichkeul et celle de Bizerte soient régis par l'écluse, le canal Tinja continu à jouer son rôle capital dans le transfert hydrobiologique entre les deux milieux lagunaires. Certains travaux se sont intéressés à la transparence du canal et ont estimé les débits sur la base de relevés quotidiens ([2], [3]) ou mensuels [4] d'une année hydrologique. Nos mesures quotidiennes, sur environ cinq ans nous permettrons d'accéder à une bonne estimation des débits solides, de définir le rôle du canal Tinja dans leur transport et d'évaluer l'effet des aménagements hydrauliques (barrages et écluse) sur ces débits.

Abstract
Le suivi quotidien sur environ cinq ans des échanges entre la lagune Ichkeul et celle de Bizerte *via* le canal Tinja a permis d'analyser certaines variations hydrobiologiques de l'écosystème. La lagune de Bizerte s'est déversée dans la lagune Ichkeul pendant 5 à 9 mois selon la pluviométrie de chaque année. La salinité mensuelle moyenne du canal Tinja a varié de 7,9 à 46,3. Durant les années pluvieuses ou normales, les salinités minimales mesurées dans le canal reflètent celles de la lagune Ichkeul et les salinités les plus élevées sont proches de celles de la lagune de Bizerte. Cependant, au cours des périodes très sèches, les salinités maximales, dépassant celles de l'eau de mer, peuvent résulter des eaux en provenance de l'Ichkeul. Ces salinités exceptionnelles engendrent la disparition des espèces à affinité dulçaquicole.

Keywords: South-Central Mediterranean, Hydrology, Monitoring, Lagoons

La lagune de Bizerte d'environ 150 km^2 de surface, communique avec la lagune Ichkeul par le canal Tinja. Largement ouverte à la mer, la lagune de Bizerte présente des salinités peu fluctuantes et proches des salinités marines. La lagune Ichkeul, de position continentale, est alimentée par les apports d'eau douce en période hivernale et d'eau marine en période estivale. Elle possède une surface variable entre l'été et l'hiver (78 km^2 à 110 km^2) et des salinités qui fluctuent en fonction du bilan hydrique. Les trois barrages construits au niveau du bassin versant de l'Ichkeul ont diminué les apports d'eau douce alimentant l'écosystème lagunaire et ont perturbé ses caractéristiques hydrologiques. Depuis 1996, les échanges entre les deux lagunes sont contrôlés par l'écluse de Tinja. Au cours de la présente étude qui s'étend de mars 1992 à août 1996, des prélèvements journaliers ont été effectués le matin au niveau des eaux de surface de la station Tinja. La salinité de l'eau (psu) a été déterminée à l'aide d'un conductimètre et le sens du courant a été noté au moment de chaque relevé. Les données de précipitations (mm) ont été fournies par l'Institut National de la Météorologie. La période d'étude étalée sur environ 5 ans comprend des années à pluviométrie normale (proche de 600 mm/an) et d'autres exceptionnelles par défaut ou par excès (Fig. 1).

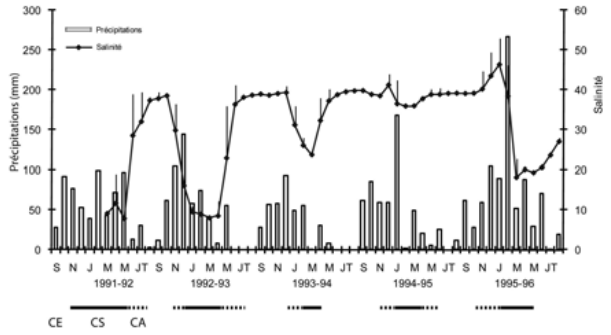

Fig. 1. Relation entre les précipitations, le sens du courant et les salinités des eaux du canal Tinja. Les barres verticales en haut de la courbe représentent l'écart-type. CE: courant entrant dans l'Ichkeul; CS: courant sortant de l'Ichkeul; CA: courant alternant.

De plus, au cours de ces années d'étude ont été mis en service le troisième barrage (Sejnane, fin 1994) et l'écluse de Tinja (avril 1996). La salinité suit de près les variations du niveau de l'eau de l'Ichkeul lequel est influencé par la pluviométrie. Les salinités mensuelles moyennes calculées à partir des données quotidiennes ont été comprises entre 7,9 (mai 1992) et 46,3 (janvier 1996). Pendant les cinq années hydrologiques 1991-1996, la lagune de Bizerte s'est déversée dans la lagune Ichkeul durant 5 à 9 mois suivant les précipitations annuelles. Suite à des années normales ou pluvieuses successives, les salinités mensuelles minimales sont relevées dans le canal Tinja par courant sortant de la lagune Ichkeul. C'est le cas des années 1991-92 et 1992-93 dont les salinités (environ 8), représentent celles de l'Ichkeul. Les salinités mensuelles maximales enregistrées (37,3 et 38,6) par un courant émanant du plan d'eau de Bizerte reflètent les salinités de ce dernier. En moyenne, durant une année pluvieuse ou normale, les eaux circulent dans le sens Bizerte-Ichkeul ou dans le sens inverse pendant 6 mois. Au cours de l'année 1993-1994 particulièrement sèche, la salinité annuelle moyenne des eaux du canal Tinja a été relativement importante (35,3). La lagune Ichkeul s'est déversée dans la lagune de Bizerte pendant seulement 3 mois. La salinité mensuelle minimale, enregistrée aussi par courant sortant de l'Ichkeul a été relativement élevée (23,7 en mars) du fait d'une pluviométrie très déficitaire (375 mm). La salinité maximale, relevée par courant entrant continu dans la lagune Ichkeul correspond encore aux salinités des eaux de la lagune de Bizerte (39,7 en août) influencées par le faible apport en eaux douces et la forte évaporation. Pour les années 1994-95 (normale) et 1995-96 (très pluvieuse), consécutives à 1993-1994 très déficitaire, les salinités mensuelles maximales (41,2 en 1994 et 46,3 en 1996) correspondent aux périodes d'alternance entre courant sortant et entrant, mais montrent l'influence majoritaire du plan d'eau de l'Ichkeul et non pas de Bizerte. Toutefois, malgré les précipitations abondantes enregistrées la seconde année (1995-1996) et par conséquent, le niveau élevé des eaux dans la lagune Ichkeul et la durée relativement longue du courant vers la lagune de Bizerte (7 mois), la salinité minimale mesurée dans le canal par courant sortant est restée relativement élevée (18,2 en mars) du fait des salinités encore fortes du plan d'eau de l'Ichkeul. De plus, la mise en service du barrage Sejnane a contribué à la restriction des apports en eau douce alimentant la lagune et donc à l'augmentation des salinités. Celles-ci, très élevées, ont engendré la disparition des espèces d'eau douce particulièrement, le poisson *Barbus callensis* et la Magnoliophyte *Potamogeton pectinatus*, principale source trophique des oiseaux aquatiques hivernant à l'Ichkeul. Il en découle que suite à une succession d'années sèches et surtout après la mise en service du barrage Sejnane, il est possible d'enregistrer dans le canal Tinja, des salinités maximales, dépassant largement les salinités marines, par courant sortant de l'Ichkeul. Or, l'écluse de Tinja, destinée à contrôler les échanges entre les deux lagunes devait maintenir dans l'Ichkeul une réserve d'eau à faible salinité. L'analyse des fluctuations dans le canal Tinja donne des informations importantes sur l'évolution intersaisonnière et interannuelle des conditions du milieu dans l'écosystème lagunaire. Celles-ci régissent la distribution des peuplements floristiques [1] et faunistiques ([2], [3]) notamment les espèces dulcicoles et les espèces marines migratrices.

Abstract
The potential impact of the ctenophore *Mnemiopsis leidyi* on the zooplankton community of the Berre Lagoon was studied. *Mnemiopsis* did not reach any satiety level when fed with *Artemia salina* nauplii, even for concentration as high as 700 nauplii L^{-1}. *Mnemiopsis* displayed also a very narrow selection for its prey type, feeding particularly upon nauplii of copepods and rotifers when offered natural zooplankton assemblage. This species can then control the copepods community through a top-down control, which in turn can have a negative impact on the control of the eutrophication. The fish recruitment could be also impacted by food competition and occasional predation of *M. leidyi* on eggs and larvae.

Keywords: Alien species, Biodiversity, North-Western Mediterranean, Food webs

Introduction Observed in the mid 1980's for the first time in the Black Sea, the ctenophore *Mnemiopsis leidyi* has been extended its invasive range both through the Baltic and North Seas and the Mediterranean Sea. Large bloom of this species was first reported in the Berre Lagoon (south east of France) in 2005. An impact of this invasive species on the zooplankton community has been already reported in several regions, feeding particularly on copepod populations [1]. This study aims to evaluate the effect of prey concentration on the ingestion rate of *M. leidyi* and the potential selectivity of preys among natural zooplankton assemblage of the Berre Lagoon.

Material and Method Response of the ingestion rates of *Mnemiopsis leidyi* when fed *Artemia salina* nauplii was studied over a large range of concentration (1-700 ind L^{-1}). Ctenophores were individually placed in 13.2 L containers placed over a rotating table, and remaining prey items were estimated after 15h at 20 °C in the dark. Selectivity ability of *M. leidyi* was studied according to the same protocols with natural zooplankton assemblages of the Berre Lagoon. The electivity indices were calculated according to [2].

Results and Discussion The functional response of *M. leidyi* to prey concentration on *A. salina* showed a linear increase from $0.4 \pm 0.2 \times 10^{-2}$ µgC µgC^{-1} j^{-1} (1.7 ± 0.1 mgC m^{-3}) to $722.1 \pm 58.5 \times 10^{-2}$ µgC µgC^{-1} j^{-1} (559.4 ± 7.4 mgC m^{-3}) (Figure 1).

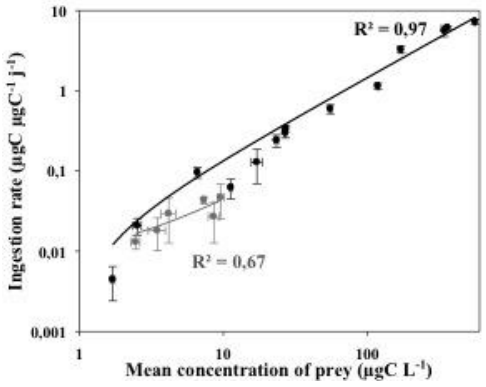

Fig. 1. Ingestion rate of *Mnemiopsis leidyi* (µgC µgC^{-1} j^{-1}) as a function of mean concentration of prey (µgC L^{-1}) (A. salina in black and natural zooplankton in grey).

Ingestion rates on natural assemblage present a similar increase from $1.3 \pm 0.2 \times 10^{-2}$ µgC µgC^{-1} j^{-1} (2.5 ± 0.2 mgC m^{-3}) to $4.7 \pm 2.2 \times 10^{-2}$ µgC µgC^{-1} j^{-1} (9.6 ± 0.5 mgC m^{-3}). The lack in reaching a satiety level suggests a superfluous feeding, preys captured are therefore often partially digested, then regurgitated by the ctenophore [3].

Moreover, an active selection of copepod nauplii and rotifers was observed with mean electivity indices of 0.23 ± 0.13 and 0.14 ± 0.18 respectively (Figure 2).

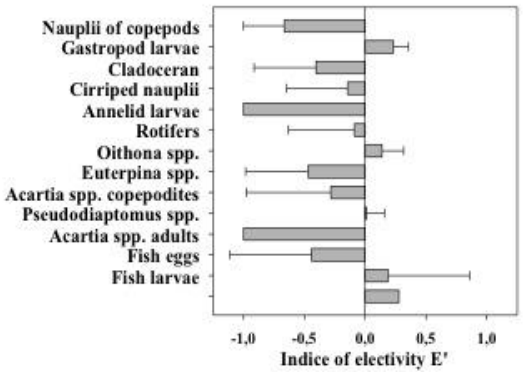

Fig. 2. Indices of electivity E' for each taxa present on the natural zooplankton assemblage.

Indeed, small size organisms are preferentially consumed by the ctenophore [4]. Zooplankton community used during this series of experiments was dominated by copepod nauplii (62.4 ± 14.7 %). In accordance with the optimal foraging theory, *M. leidyi* has a feeding strategy concentrating its effort of capture upon the more abundant preys. This behavior has been already observed for cyddipid larvae of this species [5]. The lack of a satiety level and the active selectivity of preys can largely explain the drop in copepod abundance following *M. leidyi* proliferations observed during the in situ survey conducted since 2010 in the Berre Lagoon. Moreover, the occasional selectivity of fish eggs and larvae (Figure 2), associated to a food competition on zooplankton, could also affect the fish recruitment.

Abstract

Since the 1960s, the Mediterranean lagoons have accumulated high quantities of the elements N and P in their sediments, which may induce a restoration delay of the lagoons. The present study aims to quantify the sedimentary stocks and benthic fluxes of N and P in order to asses the internal N and P loadings to the pelagos and to estimate the time needed for restoration of an acceptable eutrophication status of Mediterranean lagoons. Nitrogen and phosphorus benthic fluxes were estimated using undisturbed cores in 6 stations distributed along an eutrophied gradient in French Mediterranean lagoons. The preliminary results obtained in spring highlighted a clear efflux of nitrogen in higher eutrophied sediments.

Keywords: Lagoons, Nutrients, Eutrophication, Sediments, North-Western Mediterranean

Since the 1960s, Mediterranean lagoons have been particularly affected by large nitrogen and phosphorus watersheds inputs leading to significant changes in ecosystem structure, functioning and services [1]. In the context of Water Framework Directive (WFD), most public policies and management of Mediterranean lagoons have been focused on reducing the external nutrient loadings (N and P) to achieve ecological restoration. Nevertheless, these Mediterranean lagoons have accumulated high quantities of N and P and stocked them internally, particularly in their sediments. These stocks may represent a risk for retarding the restoration of the lagoons. The present study aims to quantify the sedimentary stocks and benthic fluxes of N and P in order (1) to asses the internal N and P loadings to the pelagos and (2) to estimate the time needed for restoration of an acceptable eutrophication status of Mediterranean lagoons. In spring, summer and autumn, nitrogen and phosphorus benthic fluxes were estimated using undisturbed cores in 6 stations distributed along an eutrophied gradient in French Mediterranean lagoons. The cores were incubated in laboratory over a 20h dark/light cycle in *in situ* temperature conditions to measure benthic fluxes. The total nitrogen and phosphorus concentration in sediment was also quantify in the top 5 cm of each core to link stocks and benthic fluxes.

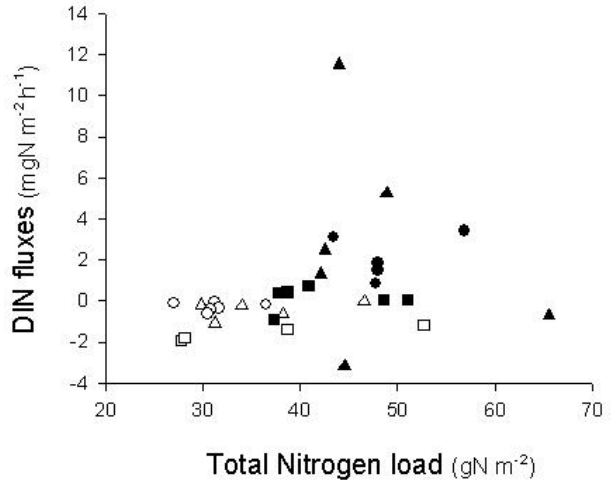

Fig. 1. Benthic fluxes (dissolved inorganic nitrogen) during light along eutrophied Mediterranean lagoons in spring. Shapes and colours (open or close) of symbol correspond to each sampling station

Our preliminary results obtained in spring highlighted a clear efflux of nitrogen for the most eutrophied sediments (close symbol in Fig. 1 and 2), but we also showed that the benthic N and P fluxes are linked to the O_2-DIC community metabolism (uptake of DIN and DIP by marine Magnoliophyta, net release in net heterotrophic systems).

Abstract
The early diagenesis of Fe, Mn, trace elements and nutrients and their exchange at the sediment water/interface were studied in the Berre Lagoon, a polluted Mediterranean lagoon in France. This process was studied at one site under contrasting oxygenation conditions and on two other sites. The concentration profiles were combined with one-dimensional steady-state transport-reaction modelling and thermodynamic speciation calculations to define and calculate diagenetic reactions controlling the mobility of the elements. The results show that fluxes at the sediment-water interface are essentially dependent on the localisation of their remobilisation and immobilisation reactions under the interface, which is governed by the benthic water oxygenation conditions and kinetic competition among those reaction and diffusion processes.

Keywords: Geochemistry, Pollution, Trace elements, Interfaces, Gulf of Lyon

The early diagenesis of the major carrier phases (Fe and Mn minerals), trace elements (As, Co, Cr, Hg, MeHg, Ni) and nutrients (ΣNO_3, NH_4^+, ΣPO_4) and their exchange at the sediment water/interface were studied in the Berre Lagoon, a polluted Mediterranean lagoon in France. This process was studied at one site under two contrasting oxygenation conditions (strictly anoxic and slightly oxic) and on two adjacent sites with perennially well-oxygenated water. From the concentration profiles of the primary biogeochemical constituents and trace elements of the pore and bottom waters, as well as the total and reactive particulate phases, we were able to locate and identify the diagenetic reactions controlling the mobility of trace elements in the sediments and quantify their rates by coupling one-dimensional steady-state transport-reaction modelling and thermodynamic speciation calculations (PHREEQ and PROFILE models).

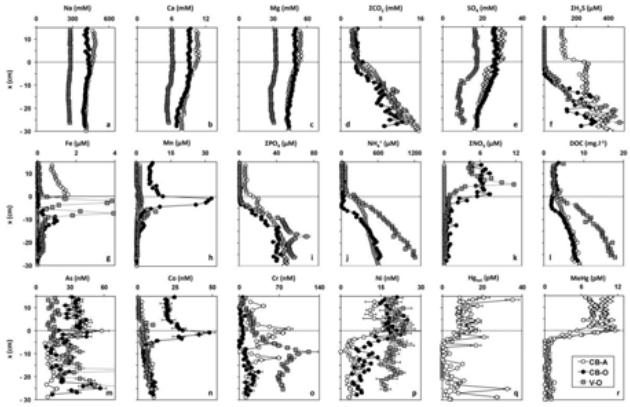

Fig. 1. Concentration profiles of major species (a–l) and trace elements (m–r) in pore and overlying waters on two diferents sites CB and V of the Berre lagoon. CB-A and CB-O correspond to anoxic and slight oxic conditions. The horizontal dashed line represents the sediment/water interface.

Under oxic conditions and in the absence of benthic organisms, the main redox reactions were identified vertically in the surface sediments and followed the theoretical sequence of oxidant consumption: $O_2 > SNO_3/MnO_2 > Fe(OH)_3 > SO_4^{2-}$. However, under anoxic conditions, only MnO_2, $Fe(OH)_3$ and SO_4^{2-} reduction were present, and they all occurred at the interface. We identified the main biogeochemical controls on the mobility of As, Cr, Hg, MeHg and Ni in the surface sediments as the adsorption/desorption and/or coprecipitation/codissolution with Fe oxy-hydroxides. In contrast, Co mobility was primarily controlled by its reactivity towards Mn oxy-hydroxides. In sulphidic sediments, As, Hg and MeHg were sequestered along with Fe sulphides, whereas Co and Ni precipitated directly as metallic sulphides and Cr mobility was enhanced by complexation with dissolved organic ligands. The fluxes of trace elements at the sediment-water interface are essentially dependent on the localisation of their remobilisation and immobilisation reactions under the interface, which in turn is governed by the benthic water oxygenation conditions and kinetic competition among those reaction and diffusion processes. Under oxic conditions, the precipitation of Fe or Mn oxy-hydroxides in the surface sediments constitutes the most efficient mechanism to sequester most of the trace elements studied, thus preventing their diffusion to the water column. Under anoxic conditions the export of trace elements to the water column is dependent on the kinetic competition among the remobilisation during the reductive dissolution of Fe and/or Mn oxy-hydroxides, diffusion and immobilisation with sulphides. We also show that benthic organisms in the perennially oxygenated site have a clear impact on this general pattern. Based on our extensive dataset and geochemical modelling, we predict that the planned reoxygenation of the entire lagoon basin, if complete, will most likely limit or reduce the export of the trace elements from the sediments to the water column and therefore limit the impact of the contaminated sediment. This work was performed with the financial help of two French INSU-EC2CO programs: BERTOX and BIOMIN, and is related to the WP3 of the MERMEX-Chantier Mistrals program.

INVESTIGATION OF NUTRIENT FLUXES IN THE SEDIMENTS OF HOMA LAGOON (IZMIR BAY, THE AEGEAN SEA)

Abstract
Nutrient flux experiments in Homa Lagoon (Izmir Bay, The Aegean Sea) were first performed between January 2006 and December 2006 monthly. At the beginning and of the autumn it fluxes from sediment to water, whereas it binds from water to sediment in the middle of the autumn. Nitrification and denitrification processes are of great importance for Homa Lagoon. The size of the grains is variable and is thought to lead to spatial variation in fluxes. <\/div>

Keywords: Nutrients, Lagoons, Sediments, Izmir Bay, North-Central Mediterranean

Introduction
The nutrient transition between the water column and sediment is performed with pore water. This transition is determined with various factors such as the type (NH_4^+, NO_2^-, NO_3^-) and speed of the nutrient, the amount and distribution rate of the organic matter, temperature, available nutrients in the sediment and bottom water, porosity, and physical and biological reactions occurring on the sediment surface [1,2]. Due to these features, lagoonal areas are special ecosystems which have a critical importance in biogeochemical cycles [3]. This study was carried out to determine the sediment structure of Homa Lagoon (Izmir Bay) and the contribution of sediment to the water column.

Materials and Methods
Grain-size distributions of the region were determined with the sediment samples collected from 17 stations in the research area. Sediment samples were collected with a Gravity corer 4.7 cm in diameter. Sediment parameter calculations were based on [6] parameters. Nutrient and Nutrient Flux calculations were based on [4] calculations while Nutrient Flux calculations were based on [5] calculations.

Results
While the increase in organic matter is compatible with the amount of fine material the increase in organic carbon is compatible with the clay / silt percentage. Significant reductions observed in the concentration of dissolved oxygen in June, August, and September indicate the presence of heterotrophic activity in the lagoon. Significant increases in salinity were observed in August and November. Silicate fluxed from sediment to water during the summer months most. Nitrate fluxed both from sediment to water and from water to sediment in the summer and winter months. Nitrite fluxed from water to sediment. Reactive phosphor fluxed from sediment to water in the summer months and bound to sediment in the middle of the winter and in the fall. Ammonia fluxed both from sediment to water and from water to sediment in the winter months, and from water to sediment in the summer months.

Discussion
That NO_2^- fluxes occur from water to the sediment all year-round indicates the effectiveness of the nitrification process in the lagoon. Negative values in the NH_4^+ and the nitrification of NH_4^+ at top layer of the sediment show the presence of an important process in the lagoon. Since the organic carbon binds to the fine material, it is evident that mineralization and accumulation of the organic carbon in the sediment will increase. Coarse material (like sand) can allow more RP to flow into the environment from the sediment. The flux of RS from the sediment into the water occurs mostly during the summer months while NO_3^- flux occurs both to the sediment and to the water in the winter and summer months.NO_2^- flows to the sediment significantly except in the summer months. Both due to nitrification and due to denitrification, RP flows from the sediment to the water in the summer while it binds to the sediment in the middle of the winter and in the autumn. Here, the limitation of RP can be mentioned especially in winter and autumn months. Changes occur in NH_4^+ throughout the year. During the winter months, there is a flux both from the sediment to the water and from the water to the sediment. However, the flux in the summer months is only from the water to the sediment. Therefore, it has been revealed how important the process of nitrification and denitrification in the area is and that the lagoon sediment is a good phosphate trap. In addition, it has been determined that the lagoon is becoming rich in nutrient due to waters flowing from non-point sources, and especially from the Gulf of Izmir.

Blue biotechnology

Balbina Nogales Fernández, Universitat de les Illes Balears, 07122 Palma de Mallorca , Spain

Résumé

This session included presentations on relevant topics for marine biotechnology such as the production of biofuel using algal biomass, production of antioxidants by algae and sponge symbionts, optimization production of bioactive molecules, development of antifouling agents and improvement of hydrocarbon biodegradation. There was a very active discussion with the speakers and the audience, in relation to aspects that are of concern for marine biotechnologists. The issues discussed were: (1) importance of conservation of biodiversity in relation to the exploitation of marine invertebrates, particularly endangered species, for the discovery of novel compounds; (2) bottlenecks in the development of biotechnology applications down to the final user, such as in the production cost of biofuel from algae or the characterization and production of bioactive molecules; (3) need for consortia with multidisciplinary expertise for the development of marine biotechnology solutions that are useful and safe for people and the environment; (4) need for cooperation with industry and the importance in developing new professional figures for knowledge- and technology-transfer, serving as a bridge between researchers and industry.

Extremophiles

Josefa Antón, Univ. Alicante, Spain

Résumé

The total duration of the session was around 50 minutes, half of which was dedicated to the debate. The debate, very vivid in a relaxed and friendly atmosphere, focused mainly on two issues:

i/ The difficulty of working with samples from extreme environments, more specifically in high salt and high pressure samples. Particularly active was the discussion about the Dead Sea sediment presentation, since this is likely one of the most difficult samples we could think of. Several attendants gave their opinion and advice on this issue.

ii/ The ecological meaning of antimicrobial peptides and antibiotics. It was argued that these molecules could be acting as chemical messengers between microbial cells in nature rather than just ways of killing ?enemies?. Several examples and opinions were provided. In addition, there was a discussion on our lack of knowledge about how microbes ?behave? in nature, away from laboratory cultures.

HAB (Harmful Algal Bloom)

Antonella Penna, University of Urbino, Italy

Résumé

The HAB session included ten contributions about the ecology, molecular biology and taxonomy of HAB species in the Mediterranean basin. The session discussed recent advances on HABs, with interesting exchanges regarding the role of human impact via eutrophication on the toxic bloom development in Mediterranean coastal sites such as enclosed bays or lagoons. This has negative effects on marine ecosystems and services, since many Mediterranean coastal areas are exploited for aquaculture activities. Often the algal blooms caused massive mussel kills. It was highlighted that the development of operational tools for rapid detection of microalgal species and timely prediction is a high priority for such important Mediterranean farming areas. In south Mediterranean lagoons, harmful blooms were also triggered by environmental factors that were studied in models for forecasting future HAB events.

The speakers described the temporal distribution of several toxic species, among them a new toxic diatom, Nitzschia bizertensis, a new domoic acid-producing diatom. The specific role of dinoflagellate cysts that represent the reservoir for bloom events was also discussed. It was demonstrated that resting stages accumulate in surface sediments of coastal areas subjected to human eutrophication; the dinoflagellate cyst assemblages are proposed as bioindicator of eutrophication.

Further, different molecular approaches, mostly based on qPCR techniques, have been illustrated for various purposes, as the molecular phylogeny and statistical parsimony distribution of harmful Pseudo-nitzschia species, or the quantification of ribosomal genes per cell as molecular markers for taxonomic and physiological studies. Recent advances on the the qPCR based assay proved useful to estimate the abundance of toxic Ostreopsis cf. ovata cells in the marine aerosol implicated in the human respiratory syndromes in the Mediterranean Sea.

The debate continued on the toxic blooms of Ostreopsis cf. ovata that produce palytoxin-like compounds harmful for the marine biota and humans. In a in vitro assay under controlled conditions, O. cf. ovata produced mucilage with toxic effects. Mucilaginous filaments are associated with toxicity on Artemia salina bioassay. This is an important finding on the key-role of mucilage in growth strategy and micropredation process of Ostreopsis sp. in the benthic ecosystem.

Interactions Prokaryotes-Eukaryotes

Gulsen Altug, Istanbul University, Turkey

Résumé

A brief presentation of the subject was given by the moderator. emphasizing the global importance of these interactions. For example, relationships between bioactivity and occurrence of proteobacteria in sponges have medical and environmental significance. The general comments were converging: to provide future drugs against diseases, such as antibiotic-resistant infections, cancer and malaria, there may be possible resources.

The five presentations contributed to clarify: host associated bacterial diversity, toxicity of cyanobacterial strains on some host organisms, algal-bacterial interactions, bacteria and environmental changes on the coral surface, changes in primary productivity and chlorophyll content. The communications and debates were focused. Future studies will likely reveal environmental changes on the coral surface, and the role of coral mucus and beneficial microbes in coral health.

Marine - Omics / ABS

Frank Oliver Glöckner, MPI-Bremen & Jacobs University Bremen, Germany

Résumé

The introduction emphasized that the advent of the new Omics techniques has revolutionized how marine biodiversity and function can be addressed. Especially mass-spectrometry and proteomics have shown to be effective methods to investigate the active workhorses ? the enzymes ? in single organisms as well as in whole communities. Applications include all three domains of life, from marine Bacteria and Archaea to small and large Eukaryotes. The broader application of Omics only contributes to our knowledge and understanding of the marine ecosystem, but provides prime targets for new biotechnological applications. This raises the issue of equitable access and benefit sharing (ABS) between provider states and users of biodiversity, which is of special interest for the Mediterranean Sea.

Seven communications were presented and followed by an intense discussion. Starting with two talks focusing on the investigation of aromatic compounds degradation pathways as well as the lifestyle of the Roseobacter clade, the follow up speakers expanded the application of proteomics to the Dinoflagellate Catanella under metallic stress conditions and Chrysophsins in farmed sea Bass mucus. Before moving on to the important question of intellectual property management and access and benefit sharing, the EU project Micro B3 with its Ocean Sampling (OSD) day on 21 June 2014 was presented. The cumulative OSD samples, related in time, space and environmental parameters, will provide insights into fundamental rules describing microbial diversity and function. They will also be a perfect use case for model contracts on ABS as well as data and material transfer agreements of samples under national jurisdiction. To facilitate the use of Marine Genetic Resources in the Basin, a pool of genetic resources for the Mediterranean was proposed in the last talk as a simple and fair mechanism to enable access and avoid conflicts of interests between Mediterranean States.

The discussion started with very practical issues on the exchange of data between different researchers. Still a huge heterogeneity of tools and exchange formats exists, hampering to easily synthesise and analyse data across studies. Bioinformatic skills are often a bottleneck at the marine biological labs and research sites to support the workflow from data acquisition to submission. It became clear that Omics technologies need to be applied complementarily and data need to be combined to get a more ?complete? view on marine ecosystems functioning. The technological progress has also opened the road for new applications for all colours of biotechnology. To fully unfold this potential for the bioeconomy in the Med, a commonly accepted stable legal framework for marine genetic resources is of utmost importance.

Microbial diversity

Monia El Bour, INSTM, Tunisie

Résumé

The introduction emphasized that marine microbial diversity investigations have progressed in scale from optic microscopic counting to the newest gene sequencing generations and modern molecular ?omics tools (metagenomics, metaproteomics, etc), which have greatly contributed to the rapid advancement of our understanding of microbial diversity and its functions in the world oceans. Much remains to be found since deep exploration of marine microbial diversity has just begun.

Eleven communications were presented and followed by an intense discussion. The speakers described several aspects of marine microbial diversity for several zones of the Mediterranean Sea and Black Sea, considering their metabolic active forms, xenobiotic pollutant tolerance, trophic levels and pathogen influence mainly for bacterial communities and virulent forms present in water columns or sediments. For several pathogens the effect of sediment characteristics on their survival was highlighted by in vitro assays. Further, epiphytic microbial communities were described for species of sponges or seaweeds with hypotheses about these marine host-microorganisms interactions or symbiosis.

The debate made clear that deep investigations on fonctionality and metabolic processes for marine microbiota are still needed for a large number of marine organisms and sites in the Mediterranean Sea basin. Therefore monitoring surveys for microbial diversity should be intensified to determine their metabolic pathways and interactions with macro-organisms and substrates under different conditions. Besides, a clear need was expressed to intensify in vitro assays under controlled conditions to assess the specific influence of biotic or abiotic parameters in different metabolic marine processes

Microbial pathways

Gian Marco Luna, CNR - ISMAR, Venice, Italy

Résumé

This session, attended by some 100 researchers, began with a brief introduction about recent discoveries, and some future perspectives of research, on microbial processes in the surface and deep waters of the Mediterranean and the Black Sea. The following flash talks did cover a very broad range of topics, ranging from nitrogen fixation in the photic and aphotic zones to bacterial bioluminescence, from the effect of temperature on microbial activities to how dense water transiting can modify processes in deep waters. Other interesting contributions concerned microbial food webs in Mediterranean coastal areas, and the role of eukaryotic predation.

Following the brief communications, the scientific debate arose. Overall, this led to an intense discussion, and a vivid participation by a large percentage of the audience. A number of potential future research priorities emerged from the debate: the need to understand relationships between processes and climate variability, the necessity to study fast-emerging, yet poorly known microbial processes (e.g. dark CO2 fixation and heterotrophic N2 fixation in deep waters), the requirement for a better identification of the controlling factors and drivers (including some geological drivers, such as the seafloor morphology). An interesting discussion was about the role of high pressure devices to measure microbial rates at in situ pressure, an important issue deserving future investigations. The combination of metagenomics, molecular ecology, remote sensing of microorganisms and modeling will undoubtedly help to decipher the role of marine microbes in the functioning of the Mediterranean and Black Sea.

Phytoplankton

Asma Sakka Hlaili, Faculté des Sciences de Bizerte, Tunisie

Résumé

The communications presented dealt mainly with (1) temporal and spatial dynamics of phytoplankton; (2) size structure and diversity of phytoplankton (3) algal succession and controlling physical-chemical factors and (4) fast shift of phytoplankton structure including algal blooms.

The presentations were followed by a general discussion concerning mainly two points: (1) the identification of species bio-indicators of local or global changes (eutrophication and acidification of seawater, climatic warm, chemical contaminations?); and (2) novel approaches and methods for in situ monitoring of phytoplankton. In particular, the combination of automated flow cytometry and remote sensing achieved optimal in situ observations of phytoplankton and provided relevant data sets that are needed to understand the role of phytoplankton in biogeochemical cycles and the impact of environmental changes on the community of primary producers.

ETUDE *IN VITRO* DE L'ACTIVITÉ ANTIOXYDANTE DE QUELQUES ESPÈCES ALGALES AU NIVEAU DES CÔTES DE LA CHEBBA

Rihab Ben Abdallah [1]*, Hamadi Fetoui [2], Imed Jribi [3] and Karima Belghith [4]
[1] Faculté des Sciences de Sfax - rihab_b86@hotmail.com
[2] Unité de recherche UR11ES72 : Toxicologie-Microbiologie Environnementale & Santé
[3] Unité de recherche UR11ES72 : Biodiversité et écosystèmes aquatiques
[4] Laboratoire des Biotechnologies Végétales Appliquées à l'Amélioration des Cultures (LBVAAC)

Abstract
Quatre espèces algales ont été récoltées de la région de la Chebba : deux algues brunes (*Dictyota dichotoma* (*Dd*) et *Cystoseira crinita (Cc)*) et deux algues vertes (*Anadyomene stellata (As)* et *Flabellia petiolata (Fp)*) pour étudier leurs teneurs en phénols totaux, flavonoïdes, tannins condensées et statut antioxydant. L'analyse de ces extraits algaux a montré une richesse en polyphénols, flavonoïdes et en tannins condensés, possédant un statut antioxydant puissant. Ce qui confirme l'intérêt applicatif de ces algues comme source de nouveaux composés antioxydants qui pourraient être utilisés dans différents domaines

Keywords: Algae, Tunisian Plateau

I. Introduction : Les algues présentent un intérêt nutritionnel connu et exploité depuis de nombreuses années, notamment par les populations du Sud-Est asiatique. Récemment, et vue leur richesse en produits naturels, la recherche tunisienne s'est orientée vers l'identification de nouvelles molécules qui suscitent un intérêt croissant en vue de leur application en cosmétique, en pharmacologie et en médecine. Dans ce contexte, nous nous sommes intéressés à l'étude de quatre espèces algales prélevées de la zone de Chebba afin d'identifier leurs caractéristiques physicochimique et antioxydante.

II. Matériel et méthodes :

II.1. Extraction par macération : On met la substance végétale émincée et pilée dans un récipient en contact prolongé avec des solvants organiques de polarité croissante (Hexane ; Acétate d'éthyle; Méthanol) pendant 24h d'agitation à température ambiante afin de calculer les rendements.

II.2. Détermination des teneurs en composés bioactives Le dosage des composés phénoliques est déterminé par la méthode colorimétrique par le réactif de Folin Ciocalteu (1). Le dosage des flavonoïdes est déterminé par la méthode colorimétrique par le tri chlorure d'aluminium (AlCl3) (2).Les teneurs en tanins condensés dans les échantillons ont été déterminées par le Vanilline en milieu acide (3).La capacité antioxydante totale est basée sur la réduction du Mo(VI) en Mo(V) et la formation du complexe molybdo-phosphate qui présente une coloration verte (4).

III. Résultat et discussion :

III.1. Extraction des composés actifs algaux : Les résultats présentés dans le tableau 1 montrent que le méthanol présente le meilleur rendement pour les quatre espèces algales. Ces algues sont plus riches en composés polaires qu'en composés apolaires.

Tab. 1. Rendement des différents extraits algaux.

	Extrait à l'Hexane	Extrait à l'acétate d'éthyle	Extrait au méthanol
Dd	0,66%	1,60%	3,01%
Cc	0,30%	0,64%	2,88%
As	1,47%	0,91%	10,39%
Fp	8,00%	5,80%	15,70%

III.2.Détermination des teneurs en composés bioactives: L'analyse des extraits en composés phénoliques a montré que l'extrait méthanolique à partir de l'algue verte *Anadyomene setellata* est la plus riche en ces composés (37 méq AG / g extrait) (Tableau 2). Bien que, l'éthanol et le méthanol fussent les meilleurs solvants que d'autres en extrayant les composés phénoliques, en raison de leur polarité et de leur bonne solubilité pour ces composés, nos résultats ont prouvé que le méthanol et l'acétate d'éthyle étaient les meilleurs solvants pour extraire les composés phénoliques, suivi de l'hexane.

Tab. 2. Les teneurs en composés bioactives des différents extraits algaux.

	Dd	*Cc*	*As*	*Fp*
	Teneur en phénols totaux (méq Acide gallique/g extrait)			
E.H	9.55	8.82	19.37	13.801
E. AE	14.41	13.49	26.80	20.55
E.M	10.80	11.69	37.94	26.80
	Teneur en flavonoïdes (méq quercétine/g extrait)			
E.H	7.5	62.38	49.70	19.22
E. AE	11.65	9.96	3.75	52.16
E.M	3.19	3.198	5.22	1.80
	Teneur en tanins condensés (méq Catechine/g extrait)			
E.H	7,5	6,23	4,97	1,92
E.AE	11,654	9,96	3,75	5,21
E.M	3,198	3,198	5,22	1,801
	Statut antioxydant (méq acide ascorbique/g extrait)			
E.H	3,99	6,28	5,43	6,05
E.AE	42,65	57,02	43,25	16,07
E.M	55,90	16,55	6,81	22,34

E.H : Extrait hexanique, E.AE : Extrait à l'Acétate d'éthyle, E. M : Extrait méthanolique

De plus, la détermination quantitative des flavonoïdes totaux par la méthode du trichlorure d'aluminium révèle que l'extrait à l'hexane et à l'acétate d'éthyle est la plus riche en flavonoïdes avec des teneurs qui peuvent atteindre 63 méq QE au niveau de l'extrait hexanique chez *Cc* et 50 méq QE au niveau de l'extrait à l'acétate d'éthyle chez *Fp* (Tableau 2). L'examen de ces résultats permet de mettre en évidence une corrélation linéaire significative (r^2 =0,59, $p \leq 0.05$) entre la teneur des extraits en flavonoïdes et en composés phénoliques. Ceci est logique étant donné que les flavonoïdes représentent les composés majoritaires des polyphénols. Dans le même contexte, l'analyse des extraits algaux en tannins condensés révèle que l'extrait à l'acétate d'éthyle présente les teneurs les plus importants en tannins avec des taux qui peuvent atteindre 11,65 méq catéchine / g extrait chez *Dd* et 9 ,96 méq catéchine / g extrait chez *Cc*. D'autre part, l'analyse du statut antioxydant des espèces algales a montré que les extraits à l'acétate d'éthyle présentent les capacités les plus élevées qui peuvent atteindre 57 méq AA d'extrait chez *Cc*. L'extrait methanolique chez Dd présente également des capacités antioxydantes importantes (55 méq AA) par apport aux autres espèces (Tableau 2). Ces résultats sont en accordance avec ceux de Kumaran et al (2007) qui ont montré que l'activité antioxydante potentielle qui peut atteindre 245 à 376 mg AA /g extrait chez des fractions algales méthanoliques.

ARTIFICIAL NEURAL NETWORK MODELLING FOR SELF-POLISHING COATINGS IN MARINE APPLICATIONS

Levent Cavas [1]*, Zeynelabidin Karabay [1], Gurbuz Comak [1] and Cagin Kandemir-Cavas [2]
[1] Dokuz Eylül University, Faculty of Science Department of Chemistry - levent.cavas@deu.edu.tr
[2] Dokuz Eylül University, Faculty of Science, Department of Computer Science, Izmir-Turkey

Abstract
An artificial neural network (ANN) modelling was developed to estimate the effect of the fibre addition on self-polishing percentages of a lanolin-based material used to prevent biofouling formation.

Keywords: Biotechnologies, Fouling, Chemical analysis, Aegean Sea

Introduction
Analysing complex data and predicting relationship between components [1] or reactants [2] are usually difficult as the entire system is dependent upon more than a few variables, which indicates the number of dimensions of the system. ANN could provide invaluable information in such complex cases as it would be able to create a function for these kinds of non-linear systems where complexity is enormous [3]. Lanolin is commercially obtained from sheep wool. It has so far been widely used in many biotechnological applications [4-5]. Fibre-reinforced lanolin-based material is recommended for propeller protection as an eco-friendly solution for preventing biofouling organisms. Biofouling has a lot of negative effects not only for propellers and ships' hull but also for bridges [6]. Self-polishing percentage (SP %) of lanolin-based material depends on a number of parameters such as fiber type and content (%), temperature and rotary rate.

Materials and Methods
The lanolin based material (LBM) was provided by the Henleys Propellers & Marine LTD, New Zealand. The commercial fibres, Rockforce® MS730-Roxul®1000 and Rockforce® MS675-Roxul®1000, were kindly provided by Lapinus Fibres, the Netherlands. In order to study the self-polishing percentages of the LBM, LBM was applied into the glass surfaces (26x76 mm) and then exposed to rotary test by a rotary rate controlled magnetic stirrer (Heidolph MR Hei-standard). Function approximation by the means of MATLAB® 2012b ANN Toolbox used in this study is basically error-based learning, which is based on Levenberg-Marquardt backpropagation. First, an ANN network, a function was developed with existence data, inputs and outputs (SP %). The network was subsequently tested with a number of randomly selected inputs.

Results and Discussion
Fibre type, fibre content (%), rotation time and rate were used as input rates and the self-polishing percentage as an output and calculated as;

$SP\% = ((w_i - w_f)/w_i))*100$

where SP%, wi and wf are expressed as self-polishing percentage, initial weight of plate and final weight of plate, respectively. Figure 1 shows the comparison of experimental and ANN Network modelling results. The correlation created using ANN network gives reasonable accuracy as the regression is 0.9154.

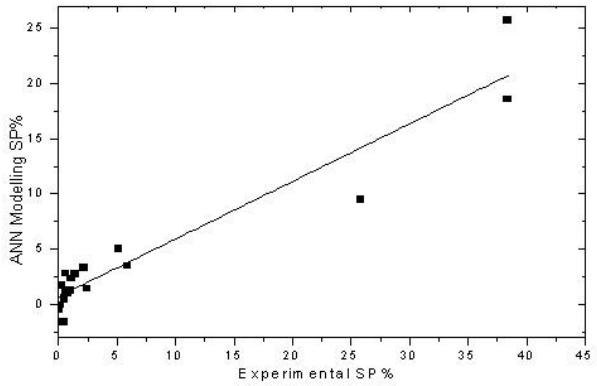

Fig. 1. A comparison of SP% results of ANN Modelling and experimental studies. 20 samples out of 210 were arbitrarily selected for comparison study.

A total number of 190 data were used to form the ANN network where 90%, 5% and 5% were used training, validation and test, respectively. In the present study, the plates coated by LBM remarkably prevented biofouling. However, the control plates were covered by micro- and macro-fouling organisms such as *Bugula* sp., *Balanus* sp., *Hydroides* sp., *Navicula* sp. and *Achnanthes* sp. It is suggested that the addition of particular fibres into LBM significantly increase the mechanical durability of the material, thereby increasing antifouling activity. ANN modelling tool brings new approach to analyse complex data and estimate better eco-friendly antifouling formulations for marine applications.

AIR-LIFT PHOTOBIOREACTOR PRODUCTIONS OF *CYLINDROTHECA CLOSTERIUM* AND *NITZCHIA* SP.

Zeliha Demirel [1]*, Esra Imamoglu [1], Ender Cimen [1] and Meltem Conk Dalay [1]
[1] Ege University, Faculty of Engineering, Department of Bioengineering, Izmir, 35100, Turkey - zelihademirel@gmail.com

Abstract
Diatoma species, which are widely distribute in marine coastal waters, were collected "Exploring Marine Resources For Bioactive Compounds: From Discovery to Sustainable Production and Industrial Applications (MAREX)". *Cylindrotheca closterium* and *Nitzchia* sp. were isolated from Aegean Sea in Izmir, Turkey. The aim of this study was to determine the effect of nitrogen on the growth rates, lipid yields and fatty acid compositions of C.closterium and Nitzchia sp. in the air lift photobioreactor. Lipid concentrations were determined gravimetrically and fatty acids were analyzed by GC-MS. Biomass concentration and doubling time were also measured. Both of the diatoms were showed the same tendency. As a result of, the existence of nitrogen has a positive effect on the biomass and the lipid content for both diatoms at the same light intensity.

Keywords: Diatoms, Izmir Bay, Biomass, Chemical analysis

Introduction
Diatoms are an important group of phytoplankton's that are widely distributed in the oceans, but are also found in fresh and brackish water, which are taking the attention with their siliceous in cell walls [1]. The aim of this study was to determine the effect of nitrogen in the culture medium on the growth rate, lipid yields and fatty acid composition of two species of diatoms, *C.closterium* and *Nitzchia* sp.

Material and Methods
C. closterium (JQ886456) and *Nitzchia* sp. (JQ886457) were isolated from Aegean Sea in Izmir, Turkey. The cultures were grown under 20±2 ºC in N and N-free F/2 media at 56 µmol photons m^{-2} s^{-1} with 12:12 light and dark period in air lift PBRs for 13 days. The determinations of the biomass were carried out by the measuring the absorbance values using a spectrometer and by counting the cells in a Neubauer chamber using a microscope. The specific growth rate (µ) of the cells was calculated from the initial log phase of growth for at least 48 h, as $\mu = lnX2 - lnX1/dt$, where X_2 is the final cell concentration, X_1 is the initial cell concentration and dt=X_2-X_1.
Photobioreactor cultivations were harvested by centrifugation and washed with distilleted water. They were stored at −20 °C until lyophilization. Oil was extracted from dried algal biomass by a modified method of Bligh and Dyer [2]. The lipid concentration was determined gravimetrically. Fatty acids were analyzed by GC-MS [3].

Result and Discussion
Microalgal production of triglycerides and fatty acids plays an important role in some energy, aquaculture, nutraceuticals and pharmacological applications [4, 5]. F/2 media were prepared both with and without nitrogen to determine the effect of nitrogen availability in the medium for *C. closterium* and *Nitzchia* sp in air-lift PBRs (Fig 1, 2). At the end of the period, nitrogen cultures reached the maximum biomass, although nitrogen-free cultures were not shown significant rise. The fatty acids compositions determined by the GC-MS during the stationary phases of growth were shown in Table 3.

Abstract
The objective of this study, which is supported by an EU Project called ***MAREX***, was to investigate the growth and bioactive molecule yields of native green seaweed species, *Ulva rigida*, which distributed along the coast of Turkey and has high potential for industrial applications. Results of the study indicated that *Ulva* growth and extract yield percentages were significantly different among the treatment groups of different nitrogen-enriched F/2 medium, temperature, salinity, aeration, illumination, etc. and it was concluded that *U. rigida* may be produced via biotechnological processes or optimized culture conditions in a sustainable medicinal chemistry program with the aim of developing *Ulva*-based agents to the stage where they are available for various industrial applications.

Keywords: Biotechnologies, Aegean Sea, Algae

Material and Methods :

- **Seaweed Collection:** *Ulva rigida* samples were collected from the coast of Inciralti (38°24' 42 N, 27°02' 29 E), Izmir Bay, Izmir, Turkey.
- **Seaweed Optimization Studies:** Collected *Ulva* individuals were placed in the growing vessels where a total of 17 treatment groups were applied. Growth rates of *Ulva* were measured daily and presented as percentage. Experimental treatment groups were included: Group 1 (200% nitrogen), Group 2 (100% nitrogen), Group 3 (0% nitrogen), Group 4 (with $\%_0$ 25 salinity), Group 5 (with $\%_0$ 50 salinity), Group 6 (with $\%_0$ 100 salinity), Group 7 (no aeration), Group 8 (low aeration), Group 9 (high aeration), Group 10 (no light-dark treatment), Group 11 (low light), Group 12 (high light), Group 13 (20 ^{0}C), Group 14 (30 ^{0}C), Group 15 (low *Ulva* density), Group 16 (moderate *Ulva* density), and Group 17 (high *Ulva* density).
- **Crude extracts from the seaweeds:** The lyophilised *Ulva* samples were extracted with 80% ethanol using Soxhlet apparatus and the extract yields were measured volumetrically and presented as percentage.
- **Statistical Analysis:** All data with three replicates were analyzed using SPSS statistic program ($P \leq 0.05$) and represented as mean ± sd.

Results and discussion :

Overall, biomass and extract yields of *Ulva* were experiment treatment group-depended (Figure 1). *Ulva* growth was found to be quite manageable for production. The highest biomass yield was recorded as 2.80 %.day^{-1} in Group 4 (with $\%_0$ 25 salinity) , followed by 1.89 %.day^{-1} in Group 9 (high aeration) and 1.45 %.day^{-1} in Group 13 (20 ^{0}C).

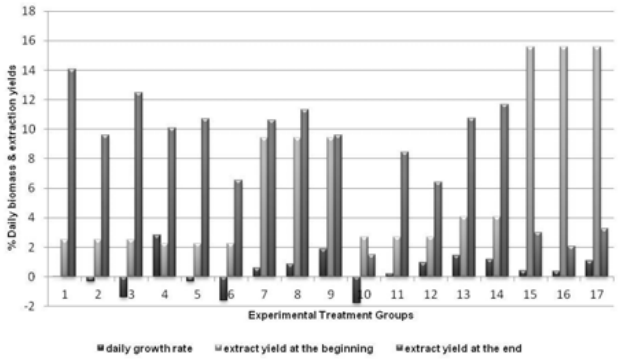

Fig. 1. Ulva Biomass as daily growth rate (%0. day-1) and extraction yields as percent dry weight (% dry weight) results among the seventeen experimental treatment groups.

Ulva has a significant increase in extract, such as 14 % of its dry weight in Group 1 (200% nitrogen), followed by 12% in Group 3 (0% nitrogen), 11 % in Group 8 (low aeration) and Group 14 (30 ^{0}C) and 10 % extract yield in Group 5 (with $\%_0$ 50 salinity), Group 7 (no aeration), and Group13 (20 ^{0}C).

Abstract
Hydrocarbonoclastic bacteria exhibit genetic and phisiological features to use hydrocarbons as sole source of carbon and to compete for the uptake of nutrients. As an example the iron uptake system includes the production of siderophores, small high-affinity iron chelating compounds. We identified the siderophore produced by *Alcanivorax borkumensis*, which behaves as a shuttle transferring iron from marine environment within the cell. Such siderophore belongs to the hydroxamates group and it is one of the few isoxazolidine found in nature which mimics the antibiotic action of the β-lactams. The alternance of dominant members of microbial communities in oil polluted marine samples and in pure cultures, revealed that the siderophores produced by Alcanivorax sp act as inhibitor factors during the competition for substrates.

Keywords: Pollution, Petroleum, Biotechnologies, Messina Strait

Bioremediation in marine environment is a promising cheap biotechnology which proposes the recovery of hydrocarbons-polluted sites exploiting the self-cleaning capacity of the sea. A special group of hydrocarbons-degrading marine bacteria (HCB), namely *Alcanivorax* sp., *Cycloclasticus* sp., *Thalassolituus* sp., *Oleispira* sp., *Oleiphilus* sp., exhibit both genetic and phisiological features to use hydrocarbons as sole source of carbon and energy and to compete for the uptake of nutrients. Among these, iron is one of the essential nutrients for the success of in situ biodegradation by microrganisms. In fact, for in situ biocatalysis, the iron is one of the limiting factors because of its very low availability in marine environment. To bypass this matter, bacteria have developed the capability to produce siderophores, small high-affinity iron chelating compounds which behave as a shuttle taking iron from marine environment and transferring it within the cell. Bacterial siderophores have been associated to many biotechnological application: drug delivery, bacterial communication, antibiotic function, iron chelator in iron metabolism diseases, inducers of bacterial growth, quorum sensing, but up to day there are very few study on the role of siderophore within natural occurring biodegradation processes.

The aim of the present study was to study the role of siderophores produced by *Alcanivorax borkumensis* during the processes of bioremediation.

We have performed a first screening on the production of siderophores both in solid and liquid CAS-assay using HCB as samples. *Alcanivorax*, *Thalassolituus* and *Oleispira* were positive to the test, on the contrary, *Cycloclasticus* didn't show siderophore activity, data confirmed by the the lack of genes involved in siderophore production in *Cycloclasticus* genome.

After the first screening we decided to proceed with the isolation and characterization of the siderophore produced by the most known hydrocarbonoclastic strain, *Alcanivorax borkumensis*. *Alcanivorax* produces a siderophore which belongs to the hydroxamates group and is one of the few isoxazolidine found in nature, very similar to pesudomonine produced by *Pseudomonas fluorescens*, it seems to mimic the antibiotic action of the β-lactams and show a high affinity for iron. Experiments carried out in pure culture of *Alcanivorax borkumensis* showed that when the growth was in the medium containing optimal concentration of iron we were not able to detect siderophores production. On the contrary, in iron limiting conditions we have registered the highest siderophore activity during the esponential phase of growth. Moreover, at the same phase we didn't registered significant differences in the rate of tetradecane degradation between optimal and iron limiting conditions, suggesting that siderophores play a pivotal role in natural environment during biodegradation processes.

One of the interesting feature of microbial siderophores is that some of the microbial community members (helpers) are usually the most active in the production of siderophores, such siderophore–iron complexes can be used by the no-siderophore-producer (cheaters). In the present study we observed whether such crossfeeding occurs among the HCB strains during bioremediation processes. We monitored the growth of *Cycloclasticus* (no siderophores-producers) in a medium amended with siderophore produced by *Alcanivorax*. We observed that the addition of siderophore didn't facilitate *Cycloclasticus* growth in iron-limiting conditions. On the contrary, siderophores seemed to have an inhibitor effect on the growth of *Cycloclasticus* during the first 10 days.

At the moment we are not able to explain this behaviour. On the basis of our previous studies, we know that during treatment of bioremediation of oil-polluted marine sediments, an alternance of *Alcanivorax* and *Cycloclasticus* as active dominant members occurred. Further studies are suggested to verify if *Alcanivorax* is able to modulate, by the use of siderophores, interspecific interaction during the processes of bioremediation for the competition of substrates.

Abstract
The characterization of lactic acid bacteria of *Leuconostoc* genus, isolated from different organs of Nile Tilapia, was carried out in order to assess their antibacterial activities against different pathogen species of bacteria. Universal primers p8FPL / p806R was used to molecular identification of isolates. Thus, twelve LAB with important antibacterial activities were identified as members of *Lc. Mesenteroides* (8 strains), *Lc. Pseudomesenteroides* (3 strains) and *Lc. Citreum* (1 strain). These antimicrobial activities were sensitive to proteinase K and revealed the eventual proteinaceous nature of these substances. These results highlighted the first report on bioactive *Leuconostoc* strains isolated from freshwater fish in Tunisia with local potential for their further probiotic use experiments.

Keywords: Aquaculture, Fishes, Tunisian Plateau

Introduction

The genus *Leuconostoc* includes Gram-positive lactic acid bacteria hetero-fermentative, aero-anaerobes and catalase free. They are present most often in association with plants, meat or milk and dairy products. The antimicrobial effect due to bacteriocins produced by*Leuconostoc sp.* was observed for the first time in 90's years [1] including *Leuconostoc mesenteroides* Y105 from goat's milk [2]. The present data highlighted for the first time the isolation of *Leuconostoc* from different organs of freshwater fish *Oreochromis niloticus* (Tilapia) with large antibacterial activities against several food borne pathogens for human or in aquaculture.

Material and Methods
LAB were isolated from samples of skin, gills and intestine of tilapia *Oreochromis niloticus* collected from a northern dam in Tunisia used to farming activities. First isolation of the strains studied was realized in MRS (Liofilchem, Italy) agar medium with incubation at 20ºC for 48h. Antimicrobial activity was assessed for the isolates using well diffusion agar technique [3] in addition to test of sensitivity to proteinase K. Their molecular identification was performed using universal primers set p8FPL/p806R.

Results and discussion
Cultural methods were applied for the isolation of twelve lactic acid bacteria that were identified by morphological and molecular methods as members of *Lc. mesenteroides, Lc. pseudomesenteroides* and *Lc. citreum* (Figure 1). The results of their bioactivities showed that these strains display large antibacterial activities against several pathogen species of bacteria (Figure 2). Previous data signalled *Lc. citreum* and *Lc. mesenteroides* both from fermented fish [4]. The present study revealed *Leuconostoc* genus related to freshwater Tilapia *Oreochromis niloticus* environment with mainly isolated species of *Lc. Mesenteroides, Lc. Pseudomesenteroides* and *Lc. Citreum*. The Proteinase K test indicated probably proteinaceous nature of the bioactive coumpound(s) of the identified *Leuconostoc* species [5]. Nevertheless, further tests continue to be done to suitable characterization of eventual antibacterial peptides using proteomic approach in order to finalize bacteriocin compounds related to*leuconostoc* species identified.

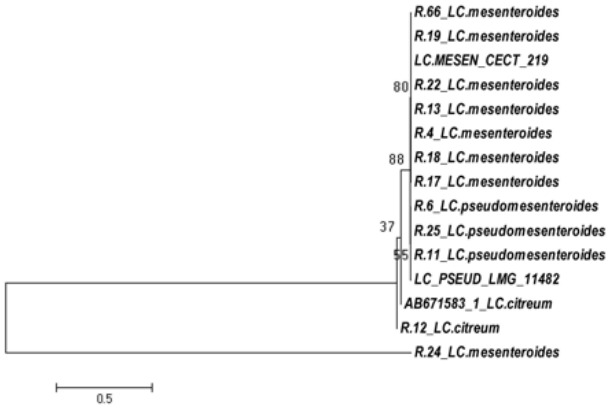

Fig. 1. Phylogenetic analysis of the nucleotide sequences of the 16S rRNA gene of *Leuconostoc* by means of the neighbor-joining method. Numbers above and below branches indicate bootstrap values from neighbor-joining analysis.

Abstract

Study of increasing lipid production from fresh water microalgae (*pleurochloris pyrenoidosa*) was conducted by subjecting it to chemical stress, including some factors such as the effect of NaCl, $NaNO_3$ with different concentrations and environmental stress such as pH. A significant increase in lipid content from 19% to 35% was detected when increasing NaCl concentrations from 5 to 17 g/L and on addition of 8 g/L $NaNO_3$. The growth measurement showed a positive correlation and maximum lipid content was recorded at pH 4. The extracted lipid from (*pleurochloris pyrenoidosa*) indicates that oleic acid the most common fatty acid content in biodiesel represents 57.94%.

Keywords: Algae, Salinity, Growth, Nile Delta

Introduction: Microalgal lipids are the oils of the future for sustainable biodiesel production. Microalgae offer a very promising source of biomass due to very high productivity comparing to other oil crop plants in addition to its potential of being incorporated with CO_2 mitigation (1). High lipid productivity of fast growing algae is a major prerequisite for commercial production of biodiesel which can be considered a biodegradable, renewable and non-toxic biofuel. However under optimal growth conditions, large amounts of algal biomass are produced but with relatively low lipid while species with high lipid content are typically slow gowing. Under nufavorable environmental stress chemically or physically conditions microalgae alter their lipid biosynthesis toward the formation and accumulation of neutral lipid from 20 to 50% mainly in the form of triatheyl glycerol (TAG) (2). **Material and Methods :** The microalgae (*pleurochloris pyrenoidosa*) was isolated from local fresh water collected from El-Mahmoudea canal in Alexandria. It was preserved and grown in BG11 medium, tested for lipid productivity by cultivating it in a cylindrical glass photo bioreactor with four liter of working at 26°C ± 1. The culture was grown under light intensity of 3000 lux using fluorescent tubes and aerated with compressed air. The isolate was studied under different pH values (4-11), different NaCl concentrations (5-17g/l) and $NaNO_3$ (5-20g/l) and incubated for 21 days. The total lipids were extracted by mixing chloroform –methanol in proportion in 1 to1 according to (Bligh and Dyer's method) (3). All statistical analysis were performed according to the T-test one-way ANOVA test.

Results & discussion : *Pleurochloris pyrenoidosa* isolated from fresh water canal (Mahmoudia canal) in Alexandria has a high lipid content reached (19%) with good growing rate which can considered suitable as a raw material for biodiesel production. A significant increase in lipid content was recorded on addition of $NaNo_3$ concentration 8 g/l while the growth is not affected (4). The desired salt concentration were added at early stationary phase, the culture were withdrawn after 21 days of incubation, although the growth of microalgae was decreased by increasing NaCl concentration from 5 to 17 g/L, lipid content with enhanced at the same time by 73% (5). pH was the important environmental factor affecting cells growth and products formation. Status of external pH can determine complex physicochemical parameters such as membrane permeability and cell morphology (6). pH value was varied from 4 to 11, max lipid content of pleuchlochris pyrenoidasa was recorded at pH 4.

EFFECT OF LIGHT INTENSITIES ON THE GROWTH OF *PICOCHLORUM* SP.

Esra Imamoglu [1]*, Zeliha Demirel [1] and Meltem C. Dalay [1]
[1] Ege University, Faculty of Engineering, Department of Bioengineering, Izmir, 35100, Turkey - esraimamoglu@yahoo.com

Abstract
The aim of this study was to compare three different light intensities (30, 55 and 80 µmol photons m^{-2} s^{-1}) on the growth of *Picochlorum* sp. for batch cultivations. Experiments were carried out in 250 ml Erlenmeyer flasks containing 150 ml of F/2 medium at the shaking frequency of 150 rpm under the temperature of 25 °C for 12 days. After 12 days of cultivation period, the maximum specific growth rate of 0.141 day^{-1}, which correspond to the doubling time of 4.93 day was obtained for *Picochlorum sp*. with the agitation rate of 150 rpm at 25 °C under the light intensity of 55 µmol photons m^{-2} s^{-1}. When the light intensity was increased from 55 to 80 µmol photons m^{-2} s^{-1}, the biomass production was negatively affected due to the light saturation level of the cells.

Keywords: Algae, Biomass, Aegean Sea

Introduction
Microalgae constitute a diverse group of photosynthetic microorganisms which are distributed in a huge range of ecosystems and account for about 50% of global organic carbon fixation. Microalgal biomass is mainly used for aquaculture, animal feeding and for the extraction of high-added value compounds, used as nutraceuticals or dietetic complements in human nutrition [1]. *Picochlorum* sp. is a unicellular halotolerant green algae due to its growth rate under adverse conditions is a good candidate for outdoor culture. The characteristics of its lipid profile make *Picochlorum* sp. a promising candidate for biodiesel production and the high content in the carotenoids (lutein and zeaxanthin) indicates that the microalgae could also be a good source for natural eye vitamin supplement, which could be obtained as co-products [2]. This study on the determination of the light intensity was carried out to maximize the growth of *Picochlorum* sp. for batch cultivations.

Material and Methods
Microalgae Growth Conditions; *Picochlorum* sp. was isolated from Aegean Sea in Izmir, Turkey and deduced from the analysis of 18S rRNA encoding gene with the accession number of JQ981946. *Picochlorum* sp. was cultured under three different continuous light intensities (30, 55 and 80 µmol photons m^{-2} s^{-1}) in 250 ml Erlenmeyer flasks containing 150 ml of F/2 medium at the shaking frequency of 150 rpm under the temperature of 25 °C for 12 days. Illumination was provided by LED downlight lamp (Cata 10 W CT-5254) from the top of the orbital shaking incubator. Irradiance was measured in the center of the flask with a quantum meter (Lambda L1-185).
Analytical procedures; these investigations were carried out by the measurements of the absorbance value (556 nm). The number of cells was determined by counting in a Neubauer chamber using an Olympus phase-contrast microscope. Chlorophyll-a in the cells was extracted with 100 % (v/v) methanol solution. The Chlorophyll-a amount was determined spectrophotometrically by measuring the light absorption at different wavelengths (665 and 750 nm). The amount of protein was also determined using Bradford method with Brilliant Blue G 250 dye. The specific growth rate (µ) of the cells was calculated from the initial logarithmic phase of growth for at least 48 h, as $\mu = \ln X_2 - \ln X_1/dt$, where X_2 is the final cell concentration, X_1 is the initial cell concentration and dt is the time required for the increase in concentration from X_1 to X_2. Doubling time was also calculated as $DT = \ln 2/\mu$. Statistical analysis was made by analysis of variance (ANOVA). Results are expressed as mean ± standard deviation from duplicate samples.

Result and Discussion
The effects of 3 different light conditions on the growth of *Picochlorum* sp. were simultaneously investigated for 12 days of cultivation period. The experiments were performed under the same growth conditions. As shown in Fig. 1a, the similar absorbance values of 1.097±0.05 and 1.095±0.02 were obtained on the 12^{th} day at the light intensity of 80 µmol photons m^{-2} $s^{-1}$and at the light intensity of 30 µmol photons m^{-2} s^{-1}, respectively. The cell concentration reached the maximum value (4.16 x 10^7 cells ml^{-1}) at the light intensity of 55 µmol photons m^{-2} s^{-1} on the 12^{th} day of cultivation period (Fig. 1b). On the other hand, Chlorophyll-a concentration reached the maximum level of 8.72±0.05 mg/mL at the light intensity of 55 µmol photons m^{-2} s^{-1}, which was about 35% higher than the other light intensities at the end of the period (Fig.1c). No protein production was determined at the first 4 days of cultivation period under the light intensity of 80 µmol photons m^{-2} s^{-1}.

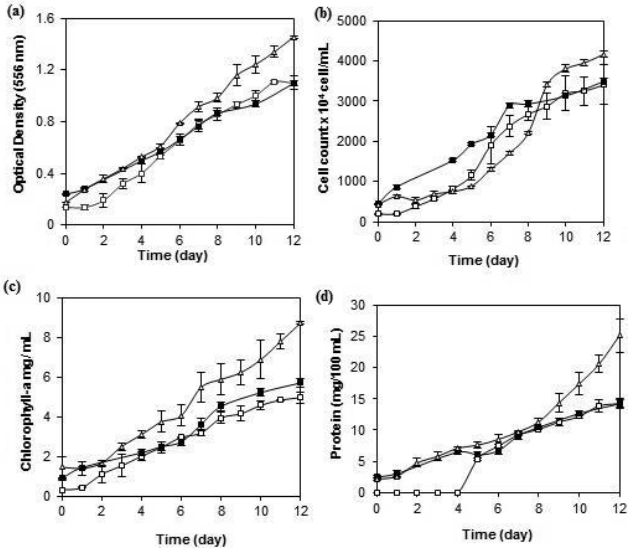

Fig. 1. Effect of different light intensities on the growth of *Picochlorum* sp.: (a) absorbance value, (b) cell count, (c) chlorophyll-a concentration and (d) protein concentration. close square: 30 µmol photons m^{-2} s^{-1}, open triangle: 55 µmol photons m^{-2} s^{-1}, open square: 80 µmol photons m^{-2} s^{-1}.

As reported by Vega et al. [2], the maximum biomass and cell density reached at the stationary phase by *Picochlorum* sp HM1 in batch cultures was 1.8 g DW L^{-1} and 4.4 x 10^7 cells mL^{-1}, respectively at 25 °C and under a continuous photon irradiance of 100 µE m^{-2} s^{-1}. In this study, the temperature degree was selected based on the reported paper by Vega et al. [2].
As shown in Table 1, the maximum specific growth rate of 0.141 day^{-1}, which correspond to the doubling time of 4.93 day was obtained for *Picochlorum sp*. with the agitation rate of 150 rpm at 25 °C under the light intensity of 55 µmol photons m^{-2} s^{-1} after 12 days of cultivation period.

Abstract
We evaluated the antioxidant potentialities of 55 bacteria strains associated with two Mediterranean sponge species. This evaluation was carried out by their ability to interact with the stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH). Three of them showed a % of DPPH reduction of more than 40%.

Keywords: Biotechnologies, Mediterranean Ridge

Introduction
Since sponges are simple and sessile organisms; during evolution they have developed potent chemical defensive mechanism to protect themselves from competitors and predators as well as infectious microorganisms. These natural products have interesting biomedical potential, pharmaceutical relevance and diverse biotechnological applications. Furthermore, more sponge-derived compounds are in clinical and preclinical trials (*e.g.*, as anticancer or anti-inflammatory agents) than compounds from any other marine phylum [1]. Since chemical synthesis of natural products can be problematic and expensive due to their structural complexity. Sponges are known to host a large community of microorganisms, which can represent a significant percentage (up to 50–60%) of the sponge biomass [2-3]. Current data suggest that at least some of the compounds are of bacterial origin [4], and several reviews discussed the role of symbionts in sponge chemistry and the pharmacological, ecological implications. In this study we performed a screening of antioxidant activities of sponge associated bacteria from the two common Mediterranean sponges: *Crambe crambe* and *Sarcotragus spinosulus*. Both sponges are known to possess an array of bioactive compound.

Material and methods
We collected by SCUBA *C. crambe* in Lugurian Sea (NW Mediterranean Sea, Italy) and *S. spinosulus* in Sardianian Sea (NW Mediterranean Sea, Italy). After collection the sponges were rinsed for remove the non-associated bacteria and the bacteria was collected and isolated. The bacteria obtained were then selected and then grown for obtain biomass. The biomass achieve after the washed-out of the broth was then freeze-dry and extracted with DCM:MeOH 1:1. The antioxidant potential of the crude extracts was evaluated *in vitro* by their ability to interact with the stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH).

Results and Discussion
We tested 55 sponge associated bacteria strains and three of them showed more than 40% of DPPH reduction (Fig. 1).

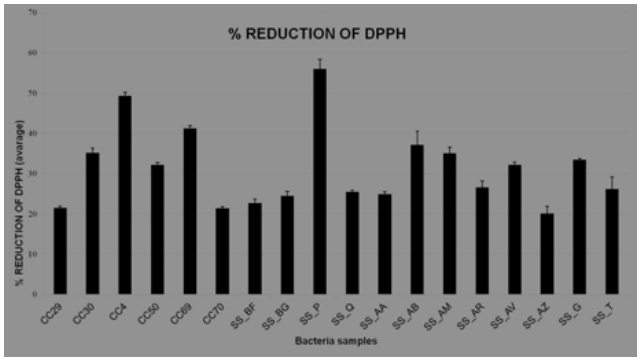

Fig. 1. Sponge associated bacteria that have had more than 20% of DPPH reduction. (CC – Bacteria from *Crambe crambe* specimens, SS – bacteria from *Sarcotragus spinosulus* specimens.

The lower IC_{50} (the concentration of an inhibitor where the response is reduced by half) obtained from one *S. spinosulus* bacteria extract were: 0,851 mg/ml (0,732-0,988). These results on experimental antioxidant activities in sponge associated bacteria crude extracts are certainly positive, although further analysis will be needed to assess 1) the stress factors that can improve the antioxidant activities and 2) the molecules involved in the antioxidant capacity.

Abstract
We have analyzed the potential of high resolution ion cyclotron resonance Fourier transform mass spectrometry (ICR-FT/MS) as a tool to unveil microdiversity within the species *Salinibacter ruber*. This extremely halophilic bacterium thrives in hypersaline environments close to saturation, such a crystallizer ponds from solar salterns, which are very frequent in the Mediterranean coast. Previous studies indicated that the species is very homogeneous according to the 16S rRNA gene sequences of the isolated strains although they displays a high genomic microdiversity. Here, we show that this high microdiversity is mirrored by a amazingly high diversity of its metabolomic potential.

Keywords: Corsica Trough, Bacteria, Salinity, Balearic Islands

In a previous work (Rosselló-mora et al., 2008)), ICR-FT/MS proved very useful to discriminate among 28 S. ruber strains isolated from three different geographical areas (Mediterranean, Atlantic and Peruvian, indicating that the metabolites responsible for the differences among geographical groups were generally associated with cell membranes, such as fatty acids and terpenoids. In a further study (Peña et al., 2010), this technique was useful to unveil phenotypic differences among two extremely closely related strains coexisting in the same saltern pond. These two strains (M8 and M31) shared around 90% of their genomes but presented differences in the abundance of genes coding for sulfotransferases and glycosyltransferases. Accordingly, the metabolomic analysis indicated differences in sulfonated and glycosylated metabolites among the two strains, which were considerably higher in the extracellular fraction of the cultures. These differences were remarkable considering the high similarities between the two strains.

In order to investigate the extent of metabolomic diversity within the species S. ruber, we have undertaken an ICR-FT/MS study (Antón et al., 2013) of a collection of 57 strains isolated from two Mediterranean solar salterns: 22 from the Salinas de Campos in Mallorca and 35 from Bras del port in Alicante, both in the Western Mediterranean region. Each set of strains were simultaneously isolated from a water samples and were thus coexisting in the same environment. MAldi-TOf and 16S rRNA gene analysis indicated that all the strains were very closely related and were not resolutive enough to unveil differences among them. On the other hand, pulsed field gel electrophoresis analysis of the genomes digested with restriction enzymes indicated a very high heterogeneity in the strain collection since in no single instance were the genomic patterns repeated. In addition, none of the strains displayed the same patterns of the old strains originally used in 2000 for the description of the species, in spite of the fact that they had been isolated from the same ponds analyzed in this study.

For each of the 57 strains, three fractions were analyzed: extracellular, cellular soluble (cytoplasm) and cellular insoluble (membrane and envelopes). Each set of strains was analyzed independently. In each case, a collection of 5 "old" strains was also analyzed for comparative purposes. The metabolomic diversity displayed by the analyzed strains was amazingly high, with thousands of metabolites, only a few hundreds of which could be annotated by comparison with available databases. This high diversity was specially remarkable in the extracellular fraction. Indeed, this extracellular diversity was so high that almost every strain behaved in a different way, which hampered any clustering or comparison among them. The intracellular soluble and insoluble fractions, however, were amenable to comparison. According to the composition of these fractions, strains could be grouped into metabolomic OTUS (m-OTUS) that were delineated according to their discriminiative metabolites. With the species metabolome, the metabolic classes including the highest number of metabolites were, in this order, lipid metabolism, metabolism of other amino acids, biosynthesis of other secondary metabolites and metabolism of terpenoids and polyketides. Lipid metabolism seemed to be the most versatile metabolic network in S. ruber, as also indicated by the wide diversity of lipids found among the discriminative metabolites in other metabolic classes. In addition, it was also remarkable the high number of metabolites related to antibiotic and bioactive compounds that were responsible for the differences among m-OTUs. Finally, metabolomic differences were found between old and new strains isolated from the same ponds that could be not be explained based only in the genomic differences among old and new strains and could thus be related to extended exposure to laboratory conditions.

Overall, these results point to a microniche diversification of the species in nature wider than previously though and have implications for the search of compounds of biotechnological interest.

EFFECT OF DIFFERENT BIOREMEDIATION TECHNIQUES ON PETROLEUM BIOMARKERS AND ASPHALTENE FRACTION IN OIL POLLUTED SEA WATER

N. S. El-Gendy [1]*, H. R. Ali [1], M. M. El-Nady [1], S. F. Deriase [1], Y. M. Moustafa [1] and M. I. Roushdy [1]
[1] Egyptian Petroleum Research Institute - nourepri@yahoo.com

Abstract
Treatment of petroleum hydrocarbon polluted sea water with *Pseudomonas aeruginosa* Asph2 and corn steep liquor CSL significantly enhanced the progress of biodegradation BD, with statistically highly significant difference between natural weathering NW and both bioaugmentation BA (P = 2.92e-14) and biostimulation BS (P = 3.56e-13) at 95% confidence interval (α = 0.05). BA significantly improved BD of total petroleum hydrocarbon TPH and asphaltene by ≈ 23% and 17% compared to BS (P = 2.0693e-5 and P = 1.4e-3, respectively). BD of biomarkers; pristane Pr, phytane Ph, diasteranes, hopanes, steranes and terpanes were very apparent, while Oleanane was more recalcitrant.

Keywords: Nutrients, Biotechnologies, Bacteria, Pollution, Suez Canal

Introduction
The incidence and threat of aquatic pollution by petroleum hydrocarbons in Egypt has resulted in extensive research [1]. Although, mechanical and chemical techniques are the commonly applied methods in Egypt for getting rid of oil spills, the Egyptian oil industry views bioremediation of oil polluted sites as a top priority research field [2]. The present study was carried out to assess the capability of treatment of oil polluted sea water with special emphasis on BD of recalcitrant asphaltene and petroleum biomarkers through different bioremediation processes.

Experimental work
Batch bioremediation processes were carried out over a period of one month at room temperature and 150 rpm. NW; natural ability to degrade the contaminant, BS; through acceleration of bioremediation capacity of the naturally occurring microorganisms by addition of CSL and BA; by adding CSL and augmenting indigenous community with halotolerant *Pseudomonas aeruginosa* Asph2 previously isolated from the oil polluted sea water under study, for its ability to degrade asphaltenes [3]. Gravimetric analysis and liquid column chromatography were applied to follow up BD of different petroleum hydrocarbons fractions. Gel Permeation Chromatography GPC and Gas Chromatography with mass-selective spectrometry GC-MS were used to follow up BD of asphaltene and biomarkers, respectively.

Results and discussion
Generally efficiencies of bio-treatments for BD of TPH and different petroleum fractions were ranked in the following decreasing order BA>BS>NW. BD of petroleum fractions ranked in the following decreasing order saturates>aromatics>asphaltene. Recording ≈ 14%, 69% and 84% for saturates, ≈ 6%, 55% and 82% for aromatics and ≈ 7%, 38% and 55% for asphaltene in NA, BS and BA, respectively. The resin fraction showed nearly no biodegradation in all biotreatments except for BA, recorded ≈ 87%. It was noticed that; there were obvious correlations between some of the studied parameters and represented by eq.1 and 2.

Z=-0.375+17.3e^(-((X-52.3)/32.8)^2)+3.608Y^0.4 (1)

where Z is microbial growth ln(TCFU/mL), while X and Y are the percentage decrease in surface tension and TPH, respectively.

f(x)=ax^b (2)

where, x is % BD of asphaltene, f(x) is % decrease in asphaltene molecular weight, a and b are constants = 1.002 and 0.9796, respectively. GC-MS analysis revealed that, although there was no significant effect on biomarkers in NW flasks. There was a remarkable degradation of Pr, Ph, steranes, hopanes, diasteranes and terpanes in BS and BA flasks, with the superiority of BA flasks. This indicates the good synergetic activity of *P. aeruginosa* Asph2 with indigenous microbial population.

Conclusions: The encouraging results from this study, would present CSL as a powerful, cheap, readily available and effective source of nutrients for BD of petroleum contaminants in the aquatic environment. The recorded high BD percentage of recalcitrant resin, asphaltene and biomarkers in BA flasks encourage the superiority of using the BA technique with previously isolated strains over BS.

THE USE OF AN OPTICAL METHOD TO EVALUATE PROKARYOTIC OXYGEN CONSUMPTION UNDER HIGH PRESSURE CONDITION

Marc Garel [1]*, Séverine Martini [1], Dominique Lefèvre [1] and Christian Tamburini [1]
[1] Aix-Marseille University, Mediterranean Institute of Oceanography (MIO), 13288, Marseille, Cedex 9, France Université du Sud Toulon-Var, 83957, La Garde Cedex, France CNRS-INSU/IRD UM 110 - marc.garel@univ-amu.fr

Abstract

Planar-optode-oxygen sensors are emerging as a new method to measure prokaryotic oxygen consumption. We propose to adapt this methodology to high-pressure bottles with the aim of measuring oxygen consumption (1) from high-pressure bacterial cultivation and (2) from natural microbial assemblages under *in situ* pressure conditions.

Keywords: Deep waters, Oxygen, Bacteria, Bathyal, Gulf of Lyon

The heterotrophic prokaryotes are the main contributor to organic matter degradation in the ocean and particularly in the deep ocean. Nowadays, a classical way to evaluate the prokaryotic carbon demand needs the estimation of both prokaryotic heterotrophic production (PHP) and prokaryotic respiration (PR). PHP measurements in deep-sea waters are relatively well documented and the importance of maintaining the in situ pressure conditions to avoid bias of the real deep-sea activities have been highlighted [1]. However, nowadays no accurate methodology is available to measure directly, under in situ pressure conditions PR throughout the water column from the surface to the deep ocean. PR is usually derived from bacterial production and prokaryotic growth efficiency (PGE) measurements. For the latter only few estimates are available for surface waters [2] and none for deep-sea waters under in situ conditions. This study is challenging to measure PR under in situ pressure conditions. We have adapted to high-pressure bottles a non invasive method to measure prokaryotic oxygen consumption activities [3–5] (Fig 1).

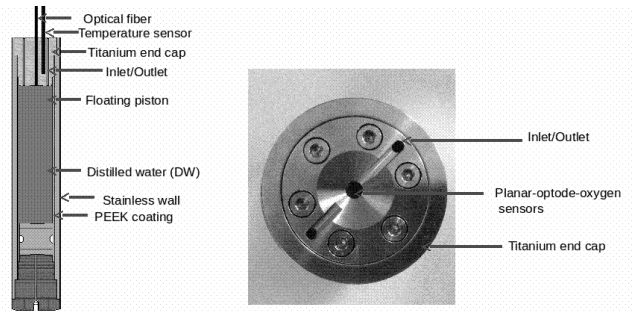

Fig. 1. At left schematic diagram of high pressure bottle with titanium top end cap. At right view of below of Titanium end cap with Planar-optode-oxygen sensors mounted on saphir window.

This methodology is based on fluorescence quenching where molecular oxygen quenches the luminescence of planar-optode-oxygen sensor. We first investigated the accuracy, detection limit, precision and response time of oxygen concentration measurements in relation to an increase of hydrostatic pressure within the incubation chamber. The results show that the use of sensor under in situ pressure conditions needs preconditioning at in situ pressure and temperature prior to perform any measurements. Secondly, a model strain (Photobacterium phosphoreum ANT-2200) has been used to estimate biological oxygen consumption. Finally, theexperimental setup will be used for natural prokaryotic assemblages oxygen consumption rates measurements from surface to deep-sea waters.

Results and Discussion

Pressure affects the physiology and metabolic activities from heterotrophic prokaryotes (see review of Tamburini et al. [1]). However to our knowledge, few study deal with pressure effect on oxygen consumption byheterotrophics prokaryotes [6]. The first main result show that the sensor need 24h preconditioning at working pressure and temperature to prevent disturbance of dissolved oxygen signal. The disturbance time is ranged between 0.5 and 14 h. After preconditioning pressure influence on sensor is predictable and reversible (about 4% lower response per 10 MPa of pressure) [4]. Preliminary experiments have been performed usinga pure culture of the strain P. phosphoreum ANT-2200 to measure biological oxygen consumption at 0.1 and 22 MPa (13°C). The result shows an oxygen consumption 1.5-fold higher than at atmospheric pressure during the log phase.

Abstract
L'étude des interactions antagonistes entre 36 isolats d'archées halophiles extrêmes de la saline de Sfax, nous ont permis de détecter 12 souches productrices d'antimicrobiens. Ces substances antimicrobiennes sont stables à une température atteint jusqu'au 90°C et supporte une large variation de pH allant de 1 à 10. Trois biomolécules dont le principe actif est de nature peptidique/protéique, nommées Hal ETD5, Hal ETD8 et Hal SS1R12, ont été sélectionnées suite au traitement protéolytique par la protéase halophile.

Keywords: Bacteria, Tunisian Plateau

Introduction
Les archées halophiles extrêmes sont des microorganismes extrêmophiles qui exigent des concentrations de sel très élevés pour croitre dans des environnements hypersalins (3-5M), lacs salés, marais salants, les sebkhas, la mer morte et les salines. De nombreuses études ont montré que les archées, de la famille des Halobacteriaceae dominent ces écosystèmes [1]. La production de peptides antimicrobiens, appelés halocines est l'un des mécanismes de défense utilisés par les archées halophiles pour dominer leurs concurrents. La production des halocines est une caractéristique quasi-universelle des halobacteriales.

Matériel et méthodes

Souches utilisées, milieu et conditions de culture
Une collection de 36 souches halophiles a été criblée pour la détection de souches productrices d'antimicrobiens. Ces souches ont été isolées de la Saline de Sfax au niveau de deux stations TS18 et M1 de salinité respective 39 et 20%. Les isolats testés ont été cultivés dans le milieu SW 25 %. Le pH du milieu a été ajusté à 7,2 par KOH 2M. Les cultures ont été réalisées dans des erlenmeyers de 250ml contenant 50ml du milieu liquide SW 25%.

Test de l'activité antimicrobienne
L'activité antimicrobienne a été détectée dans le surnageant de la culture productrice par la méthode de diffusion en puits [1, 2].

Effet de la dénaturation thermique, pH et enzymes protéolytiques
Dans le but d'étudier la stabilité des antimicrobiens à la dénaturation thermique, le surnageant de la culture productrice a été exposé à différentes températures (37 à 100°C), dans un bain-marie pendant 15min. La stabilité du surnageant à la variation du pH a été déterminé par l'ajustement du surnageant a différents valeurs de pH comprises entre 1 à 10. Après 2h d'exposition à 37°C, l'activité résiduelle a été déterminée [2]. Pour identifier la nature peptidique/protéique des antimicrobiens produites par les souches testées, le surnageant a été exposé 15 min à 50, 100, et 200µl de surnageant de protéase halophile.

Résultats et discussion
Nos résultats sur la production des antimicrobiens par les archées halophiles nous ont permis de révéler, parmi la collection de 36 isolats, 12 souches productrices d'activités antimicrobiennes a l'encontre d'une ou plusieurs souches cibles. Les zones d'inhibition observées s'étendent de 6 à 35 mm. Le dendrogramme présenté par la figure 1 montre que les 12 souches productrices se répartissent au moins en 3 sous groupes (groupes I, II III). Ceci suggère l'existence de différentes halocines produites par ces souches d'archées. L'étude de la stabilité des biomolécules actives au traitement thermique montre que les produits de la souche SS1R14 reste stable à une température atteint jusqu'au 90°C, alors que les substances des autres souches résistent à une température qui ne dépasse pas 80°C. De plus, ces substances antimicrobiennes ont marquées une grande stabilité aux variations de pH. Le traitement par la protéase montre que seule l'activité antimicrobienne des trois souches ETD5, ETD8 et SS1R12 diminue ou disparait complètement après un traitement pendant 2h à 45°C. Leurs principes actifs, de nature peptidique/protéique ont été respectivement nommés HalETD5, HalETD8 et HalSS1R12. L'identification moléculaire de ces souches sur la base du gène codant pour l'ARNr 16S montre que ETD5 et ETD8 sont apparentées à l'espèce *Halobacterium salinarum* alors que SS1R12 est une *Haloterrigena thermotolerans*.Ces résultats sont en accord avec les travaux de Kavitha et al. (2011) qui suggèrent que la production de l'halocine KPS1 par la souche d'archée halophile Haloferax volcanii est maximale à une température de 40°C, pH 7 et thermolabile à partir d'une température de 80°C. Nos études sont actuellement en cours pour purifier ces 3 halocines, déterminer leurs tailles, leurs spectres d'activité ainsi que leurs modes d'action.

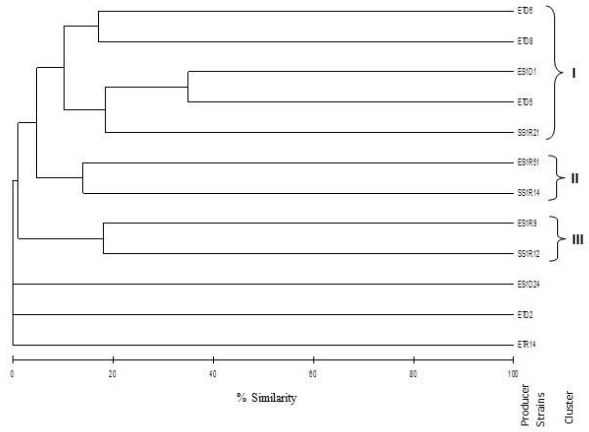

Fig. 1. Dendrogramme présentant le regroupement des souches d'archées halophiles, en fonction de leurs production des antimicrobiens, par l'utilisation d'un logiciel statistique Primer5.

Abstract
La diversité des communautés de procaryotes et virales de la saline de Sfax a été étudiée au niveau de trois bassins de la saline de Sfax couvrant un gradient de salinité de 14 à 35% (saturation en sel). Nos résultats montrent que l'abondance des particules virales augmente avec la salinité pour atteindre environ 10^{10} VLM/ml au niveau de la table de cristallisation du sel. Quatre morphotypes viraux ont été détectés par microscopie électronique de transmission avec des proportions différentes en fonction de la salinité. De plus une interaction spécifique des halovirus avec les communautés d'archées a été détectée au niveau de la table de cristallisation du sel.

Keywords: Biodiversity, Tunisian Plateau, Coastal systems

Introduction
Les environnements hypersalins sont des écosystèmes aquatiques qui renferment les abondances virales les plus importantes pouvant atteindre 10^9 VLP/ml [1]. Dans ces environnements, où la prédation semble disparaitre, les halovirus représentent les facteurs biotiques les plus importants dans la structuration des communautés de procaryotes. Les communautés d'archées et de bactéries de la saline de Sfax ont fait l'objet de quelques publications [2]. Les résultats montrent que, pour les eaux de salinité > à 25%, les archées dominent les bactéries. Dans ce travail nous avons focalisés sur l'impact de la salinité sur la diversité des communautés virales et leurs interactions avec les communautés de procaryotes.

Matériel et méthodes
La saline de Sfax, située au Centre-Est de la Tunisie (34°39=N, 10°42=E) a été échantillonnée en octobre et mai 2009 au niveau des bassins C4, M1 et TS18 de salinité respective 14, 19 et 36%. Les échantillons d'eaux ont été fixés avec du paraformaldéhyde (7% de concentration finale) puis filtrés sur filtre millipore de porosité de 0,2 µm. Les cellules de procaryotes ont été marquées au DAPI pour le total cellulaire, alors que les communautés d'archées et de bactéries ont été déterminées par la technique FISH après hybridation respective avec les sondes Arc915 et EUB338 et observation par microscopie à épifluorescence [3]. Pour les communautés virales, après filtration des eaux sur filtre Anodisc 0,02 µm, l'abondance a été estimée par marquage au SYBER Green Gold, alors que la microscopie électronique de transmission (Joel JEM-2010) a servie pour la caractérisation morphologique. Pour déterminer la proportion des différents morphotypes viraux, plus de 900 particules virales ont été examinées.

Résultats et discussion
Dans ce travail, nous avons montré que l'abondance des communautés de procaryotes augmente avec la salinité et atteint $2{,}7 \times 10^8$ cellules/ml. Ces communautés sont dominées par les archées du genre *Halorubrum* et *Haloquadratum* au niveau de la station TS18 de saturation en sel (environ 60% du total cellulaire), alors que les bactéries du genre Salinibacter dominent au niveau de C4 et M1. Les particules virales de la saline de Sfax sont environ 10 fois plus abondantes que les cellules procaryotes hôtes pour atteindre plus de 10^{10} VLP/ml. De plus, 4 morphotypes viraux ont été détectés par microscopie électronique de transmission. Les virus sphériques dominent les eaux de la saline de Sfax pour atteindre 80% de la densité virale totale au niveau de la station C4. En fonction de la salinité, la densité des virus sphériques diminue en faveur des virus en forme citron et tête-queue. Ces résultats suggèrent une meilleure adaptation de ces morphotypes à la salinité. De plus, en fonction de l'augmentation de la salinité et de la densité des archées, un accroissement dans le rapport RVP (rapport virus procaryote) a été observé. Ce résultat suggère que pour des salinités proches de la saturation, les interactions halovirus-archées sont dominantes et jouent un rôle déterminant dans le contrôle et la structuration des communautés de procaryotes dans ce type d'environnement.

Abstract
A geomicrobiological investigation of various evaporitic facies of the Dead Sea sediments has been carried out within the framework of an ICDP drilling project. 16s rRNA gene sequences obtained from unique samples recovered from 0 to 200 m below lake floor show a relative diversity both in archaeal and bacterial sequences. The presence of these organisms in such sediments implies a potential ability to cope with concentrations of total dissolved salt as high as 340 g. L^{-1}. Although bacterial sequences have been found, Euryarcheota sequences from the Halobacteriaceae family seem to dominate in the Dead Sea subsurface.

Keywords: Evaporites, Bacteria, Levantine Basin

The ICDP Dead Sea Deep Drilling Project (DSDDP) is an internationally funded project that aims to reconstruct the paleoenvironmental and paleoseismicity histories of the Dead Sea Basin, in the Levant region. Several cores have been retrieved from two localities in the middle and western part of the lake and are currently being analyzed for petrographical, mineralogical and geochemical purposes. Here we present the preliminary results of a geomicrobiological investigation of the longest core (457 m), with emphasis on the ecological characteristics of the main facies of these hypersaline sediments. Climatic conditions in the Levant area have been recorded as specific lithological associations in the Dead Sea sediments. During the last glacial periods, humid conditions developed in the Dead Sea Basin leading to an increase in the lake level and stratification in an upper mixed layer and lower hypersaline anoxic brine [1]. These periods are characterized by facies of alternating evaporitic aragonite laminae and detrital mud laminae. During comparatively drier episodes, gypsum becomes the dominant precipitating mineral phase. Halite precipitates as the main phase during interglacial periods consecutively to increasingly arid conditions and heavy evaporation. Alternating aragonite and detrital mud occurs during short termed stratifications of the lake following heavy rainfall episodes. Today, increasingly harsh conditions coupled with the use of water from the Jordan catchment area by adjacent countries have led to salinities in the Dead Sea water column more than ten times higher than sea water. The Dead Sea sediments record the paleo-salinities of the lake basin enabling a comprehensive study of its biosphere in close relationship with extreme paleoclimatic variations. Multiple 16S rRNA gene sequences have been retrieved from halite at 0.24 m and 200 m depth, from gypsum at 67 m depth and in alternating aragonite and detrital mud laminae from 2m depth. In general, the highest microbial diversity is found in the oxic halite intervals. Nevertheless, the bacterial sequences recovered show little adaptation to hypersaline conditions and are thought to be weakly to not active in the sediments. They are dominated by β-proteobacteria of the Burkholderia genus for halite and gypsum samples. Their origin is discussed as organic matter has been identified within fluid inclusion of the halite. Among others, the halite samples also display sequences of γ-Proteobacteria of the Aeromonas genus and Deinococcus sequences specially adapted to high levels of radiations and dessication. Only four different bacterial sequences have been recovered from gypsum, all of the Burkholderia Ralstonia genus. All the five bacterial sequences from the aragonite intervals are unknown or fall within a candidate division in the KB1 group, closely linked to sequences retrieved from hypersaline environments like deep sulfidic brine pools of the Red Sea [2]. As a comparison, sequences from an aragonitic laminae found immediately below a microbial mat along the Dead Sea shore show much larger diversity and more numerous sequences, mainly of the KB1 group, Halanaerobiales order, and Desulfohalobiaceae order. Archaeal sequences are exclusively from the Euryarcheota phylum, and largely dominated by the Halobacteriaceae family. Most of the retrieved sequences are those of Archaea needing high salinities (over 150 $g.L^{-1}$) to thrive. Halite and gypsum samples exhibit strong similarities with only Halobacteriaceae sequences, regardless of the depth. The shallowest sample also shares similarities with sequences found in a microbial mat in pools along the Dead Sea shore. This indicates a rather stable and well developed archaeal community in the vicinity of the Dead Sea. The aragonitic laminae sample displays a unique and strikingly different community largely dominated by sequences from the division MSBL1, first described in the deep anoxic brine pools of the Mediterranean Sea [3]. This community seems to be specifically adapted to those anoxic conditions with high Mg^{2+} also encountered in the brine pools. Their metabolic activity is still questioned and could imply a role in the sulfur cycle as can be inferred from their closer branching group Gold Mine SAGMA-F/G and their association with the KB1 bacterial division members. A second hypothesis is an involvement in methanogenesis [3], also supported by the co-occurrence of one sequence of Methanomicrobia in this same level. The latter is similar to a group found at the brine water interface of the Shaban Deep, in the Red Sea deep brine pool and is thought to stand steep salinity gradient [4], also found in the stratified paleo-Dead Sea, during aragonite precipitation periods. These preliminary results report for the first time the existence of microbes in the deep sediments of the Dead Sea. They also set the emphasis on the variety of the Dead Sea sediment microbiomass. Although extreme, this environment hosts microbial communities that are able to cope to a different extent with the steep salinity gradients and high divalent cation concentrations. Finally it seems that the environmental conditions, originally ruling the lake chemistry and mineral precipitations, are indirectly setting the prerequisites for the development and conservation of specific microbial assemblages in the Dead Sea sediments.

Abstract
Ce travail consiste à réaliser une bioaugmentation *in vitro* par utilisation d'une microflore bactérienne indigène d'un port pollué par les hydrocarbures (Port de Teboulba, Tunisie) dans des essais expérimentaux de bioremédiation. Les rendements de la biodégradation sont évalués par extraction du pétrole résiduel après incubation, son fractionnement par CPL et son analyse par CG/SM et les pourcentages de biodégradation (%B) sont ainsi calculés. Les Résultats obtenus montrent l'efficacité de la biodégradation d'un pétrole brut par cette microflore dans les conditions expérimentales après leur optimisation.

Keywords: Biomass, North-Western Mediterranean, Coastal waters, Pollution

Introduction La suppression de la pollution par le pétrole repose principalement sur la dégradation biologique par les micro-organismes [1]. D'où la nécessité de l'intervention de l'Homme. Par ailleurs la composition et l'efficacité de la microflore seront fonction de plusieurs paramètres physicio-chimique [3]. La bioaugmentation consiste à utiliser une microflore ou un micro-organisme ayant la capacité de biodégrader le pétrole d'où la nécessité d'une prédétermination des conditions optimales pour le bon déroulement de la biodégradation.

Matériel et méthodes Nous avons choisi d'étudier, in *vitro*, l'efficacité d'une bioaugmentation dans la bioremedation d'eau de mer polluée par un pétrole brut tunisien de type Zarzatine. - *Pétrole utilisé:* Le pétrole utilisé est un pétrole tunisien de type Zarzatine fourni par la raffinerie STIR-Jarzouna et dont les caractéristiques sont les suivantes (densité : 810 ; Viscosité est de 3,4 à 20°C ; BSW (eau de sédimentation): 0,05). - *Biomasse bactérienne:*La biomasse bactérienne utilisée est une microflore indigène d'eau de mer du port de teboulba en Tunisie cette microflore a été acclimatée à différentes doses du pétrole. - *Test de bioremediation:* Les essaies de biodégradation sont réalisés en utilisant un plan d'expérience. Des témoins négatifs sont aussi préparés en ajoutant un inhibiteur de croissance bactérienne (Hgcl2). - *Détermination des taux de dégradation:* Après incubation le pétrole résiduel est extrait, fractionnés par CPL et analysé par CG/FID. L'évolution quantitative des différentes fractions du pétrole (HCS), (HCA) en présence et en absence de la biomasse bactérienne est ainsi étudiée. Les pourcentages de biodégradation (B%) correspondant à chaque condition sont calculés par rapport aux témoins.

Résultats

1. Optimisation de la dégradation du pétrole Pour mieux étudier les effets des paramètres qui réagissent lors de la bioremédiation la variation des pourcentages de la biodégradation des HCS et des HCA a été déterminée dans les différentes conditions déterminés à l'aide du logiciel « MINITAB 15.0» les courbes de variation de la moyenne de la réponse pour chaque facteur étudié à part ainsi que les courbes de contour ont été tracées (Figures 1).Seul le facteur concentration en pétrole à un effet négatif (-7,17), alors que les facteurs concentration en microflore et temps ont un effet positif respectivement de 5,83 et 10,87.

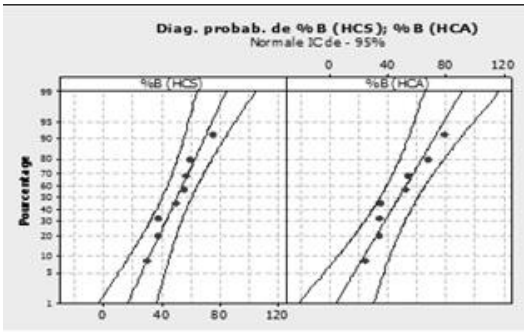

Fig. 1. **Courbe de probabilité normale du modèle M1 de la microflore M-EM.**
%B : pourcentage de biodégradation ; HCS : fraction saturée et insaturée non aromatique, HCA : fraction aromatique

2. Rendement de la biodégradation dans les différents milieux d'étude
L'examen des résultats relatifs des HCS et des HCA montre l'efficacité de la microflore M-EM dans les conditions expérimentales (Figure 2).

	Test 1	Test 2	Test 3	Test 4	Test 5	Test 6	Test 7	Test 8
HCS	37,91	30,22	57,35	38,27	65,11	50,67	75,58	59,36
HCA	34,04	24,98	53,92	35,44	67,34	34,54	78,93	52,38

Fig. 2. **Courbe de probabilité normale du modèle M1 de la microflore M-EM.** %B : pourcentage de biodégradation ; HCS : fraction saturée et insaturée non aromatique, HCA : fraction aromatique.

En effet, nous avons enregistré une dégradation sginificatives dans les conditions du test 7 dont les pourcentages atteignent plus de 70%.

Conclusion L'optimisation par les plans d'experience, nous a permis à déterminer les conditions optimales du procédé de bioremédiation du pétrole brut par la microflore indigène acclimatée de l'eau de mer de Teboulba qui s'est démontré efficaces à l'échelle du laboratoire ce qui montre l'intérêt d'une éventuelle application à grande échelle.

Abstract
Recent studies associate *Lingulodinium machaerophorum* to YTX toxicity. Our study shows that cysts of *L. machaerophorum* exist in the sediments of Bizerta Lagoon. Distribution of this dinoflagellate showed concentrations of about 82.42 cysts g^{-1} wet sediment with the highest average registered in the station 25 and 1.45 cysts g^{-1} wet sediment at station 91. Temperature average was about 25.11°C and salinity about 28.72 psu. Cysts of *L. machaerophorum* were striated at their base with grana on the distal ends. Most of them showed fully developed processes. Cyst distribution was mainly related to shellfish aquaculture farms areas.

Keywords: Dinoflagellates, Toxins, Toxic blooms, Lagoons, Tunisian Plateau

Introduction
Dinoflagellates are the most diverse group of phytoplankton in coastal and estuarine environments and one of the most important primary producers. They are known to cause outbreaks of harmful algal blooms (HABs) in coastal waters around the world, and can be extremely toxic, threatening local aquaculture and wild life. Among dinoflagellates, many species have been shown to produce resting cysts as a part of their life cycle. In the present work we studied the distribution of the harmful dinoflagellate (*L. machaerophorum*) in Bizerta Lagoon which is a semi-enclosed area located in northern Tunisia.

Materiel and methods
Sampling was carried out on June 2012 at 123 stations with 1km equidistance. Surface sediment was collected with a Van Veen Crab and water column with submersible pump. Temperature, salinity, pH and O_2 were measured with a WTW 25i multiparameter probe. The top 3cm of sediment samples were placed in black plastic containers and stored in the dark at 4°C. Ovoid germination was prevented by means of hermetic conservation. To calculate the water content, subsamples of 20g were oven dried at 60°C for 7 days. After 7 days, water content was calculated by the following formula: Water % = [(Ww-Wd) *100]/Ww Ww=wet weight Wd= dry weight. The resting cysts (RCs) were expressed as cysts g^{-1} dry sediment = cysts g^{-1} wet sediment / [1-(water content/100)] RCs were separated from the sediment fraction according to the modified gradient density method using Ludox CLX. Subsamples (1 g) were suspended in 20 ml of sucrose 24 % and sonicated for 3 min at 100 Hz in Wiseclean DAIHAN sonicator. The sonicated suspension was sieved through 120 µm and 20 µm mesh sieve. The slurry remaining on the 20 µm mesh sieve was washed with sucrose solution and placed in 50 ml Falcon tube for sonification (3 min at 100 Hz). The slurry was processed for cyst concentration and separation from the sediment using 20 ml of Ludox CLX (density 1.3 g cm^{-3}). The tube was centrifuged for 30 min at 3000 rpm at 16°C. This unstable phase containing RCs was extracted and sieved through 20 µm nylon membrane. The resulting sample was rinsed with distilled water and collected with 5 ml of filtered sea water and sonicated. Aliquot of final sample were counted in sedimentation chamber with an inverted microscope (Leica DM).

Results and discussion
Lingulodinium machaerophorum (Deflandre and Cookson, 1995) = *L. polyedrum* (Stein) Dodge, 1989 (Motile stage) = *Gonyaulax Polyedra* (Schiller, 1937). *L. machaerophorum* is a toxic dinoflagellate that produces yessotoxins (YTX). The toxic syndromes of YTX are not well defined in humans, but *L. machaerophorum* is often associated with the mortality of fish and benthic organisms. This species has been known to form blooms off the coast of California [1], and commonly forms blooms in the Adriatic Sea (along the Italian and Yugoslavian coastlines) [2], in Scottish Sea [3], Moroccan Atlantic coast [4] and Bizerta lagoon [5]. The first reported toxicity of this species found a toxin profile similar to the toxins of *Alexandrium catenella*, however, most recently more in-depth studies have linked this species with production of YTX. In the present study temperature average was about 25.11°C and salinity 28.72 psu. Cysts of *Lingulodinium are* striated at their base with grana on the distal ends. Most of them showed fully developed processes. Our species reaches a maximum abundance of 82.42 cysts g^{-1} at station 25 and 1.45 cysts g^{-1} wet sediment at station 91. It was absent from 43 stations. Cyst distribution is mainly related to shellfish aquaculture farms areas. Indeed the highest relative abundances of *L. machaerophorum* were recorded at the stations with low salinity due to dilution by river discharge. Moreover the increase of cyst forming of the phototrophic *L. machaerophorum* could be correlated to the increase of available nutrient. According to ANOVA, the abundance of *Lingulodinium* varies significantly with stations (ANOVA, F = 4.3455, p = 0. 039). We see in the figure below the highest concentrations are recorded at S25, S57 and S95.

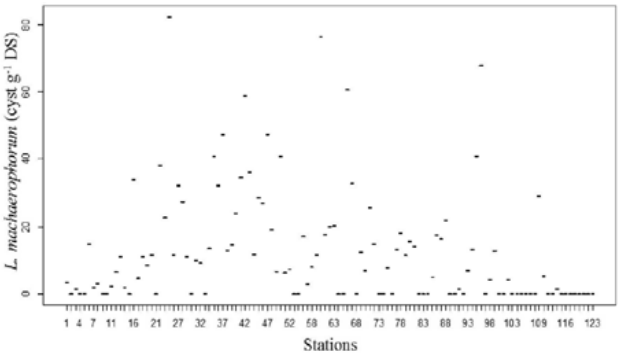

Fig. 1. Boxplots depicting the variation of *Lingulodinium* abundance according to sampling sites.

SUMMER HARMFUL ALGAL BLOOMS (HABS) IN A COASTAL BASIN DEVOTED TO THE MUSSELCULTURE AND IMPLICATION FOR THEIR MANAGEMENT

Carmela Caroppo [1]*, Giuseppe Portacci [1] and Giorgio Alabiso [1]
[1] National Research Council Institute for Coastal Marine Environment - carmela.caroppo@iamc.cnr.it

Abstract
In recent years HABs in Mar Piccolo in Taranto (Northern Ionian Sea) are becoming more frequent with heavy effects on the mussel production. A bloom due to the diatom *Cylindrotheca closterium* was responsible for massive mussel kills in summer 2008. The development of operational tools for rapid detection and timely prediction is a high priority for such important Italian farming area.

Keywords: Phytoplankton, Coastal management, Aquaculture, Blooms, Gulf of Taranto

Introduction
Mar Piccolo in Taranto (Gulf of Taranto, Mediterranean, 17° 13' -17° 19' E, 40° 28' - 40° 30' N) is a coastal area consisting in two sub-basins (Seno I and Seno II) strongly utilized for an intensive commercial mussel (*Mytilus galloprovincialis*) farming. Harmful algal blooms (HABs) have been responsible for massive mussel kills since 1938 [1] but in the last years the problem is worsening and recurrent summer anoxia crisis due to phytoplankton blooms are becoming more frequent. Particularly, in 2008 a heavy reduction (~ 35%) of the total commercial mussel harvest was detected in Mar Piccolo with a valued loss of ~ € 13 millions. Furthermore, the lost of the seeds compromised the harvest of the following year. The aim of this work was to assess phytoplankton abundances and composition during the summer of 2008 and to discuss the development of tools to managing and mitigating the effects of HABs in one the most important farming sites in Italy.

Material and Methods
Samplings were carried out in two stations located in Mar Piccolo in Taranto from June to September 2008. Water samples were taken at the surface using a 5 liter Niskin bottle. Environmental data were recorded by an Idromar IM5260 multiprobe. Phytoplankton samples were fixed with Lugol solution (larger phytoplankton) and pre-filtered glutaraldehyde (picophytoplankton). Larger phytoplankton was examined and counted according to the Utermöhl method [2] while picophytoplankton by using the procedure described in [3].

Results and discussion
In Mar Piccolo temperature ranged between 22.2 and 29.1 °C both registered in the Seno II. Salinity averaged values were slightly higher in Seno II (37.3 ± 0.4 psu) than in Seno I (36.8 ± 0.5 psu). Phytoplankton abundances (Fig. 1a) ranged between 99.9 and 3237.4 cells x 10^3 l^{-1}. The highest values were detected at the Seno II where in July a bloom of the diatom *Cylindrotheca closterium* (up to 3000 cells x 10^3 L^{-1}) was monitored. This diatom is known as a producer of foam, discoloration and repellent odour [4]. Furthermore, this species is considered responsible for the production of mucilage in the Northern Adriatic Sea where it is regularly the dominant species in large and aged phytoplankton aggregates [5]. The high stability of the column water, the input of nutrients and the increase of temperature could have promoted the growth of such opportunistic species.

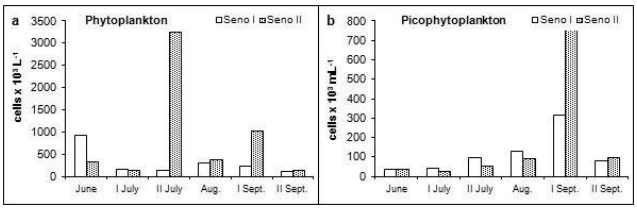

Fig. 1. Phytoplankton (a) and picophytoplankton (b) abundances (cells x 10^3 L^{-1} and cells x 10^3 mL^{-1}, respectively) in Seno I and Seno II in summer 2008.

Picophytoplankton abundances showed values comprised between 23.8 and 750.9 cells x 10^3 L^{-1} with a peak in September (Fig 1b). The community was represented mainly by prokaryotes (phycocyanin-rich and phycoerythrin-rich cyanobacteria) and their summer blooming in brackish environments has been already detected [6]. Our data will be useful to develop and implement plans for monitoring and management of HABs. These plans would include the integration of observation, forecast and communication into an action plan for rapid response to HABs [4]. Initiatives are urgently needed to improve the communication with authorities responsible for environmental protection, economic development and public health to continue previous experiences in the frame of the sustainable musselculture in Mar Piccolo [7].

Abstract
We report the application of a qPCR based method for estimation of the toxic benthic dinoflagellate *Ostreopsis* cf. *ovata* in the complex matrix of marine aerosol at Sant Andreu de Llavaneres (northwestern Mediterranean Sea). Toxic events in humans have been reported during *O.* cf. *ovata* blooms and were attributed to palytoxin (PLTX)-like compounds produced by this microalga. *O.* cf. *ovata* abundance in marine aerosol during the bloom varied in the range of 1−102 cells per filter. No PLTX was detected in the aerosol filters by analytical determinations, and the estimation of PLTX like-compound concentrations in microepiphytic assemblages varied between 0.1 and 1.2 pg/cell.

Keywords: Dinoflagellates, Aerosols, Genetics, Biotechnologies, North-Western Mediterranean

Marine aerosols are airborne particles of biological origin containing algal cells, bacteria, spores, and viruses, which are carried out by bubbles to the sea surface microlayer and to the atmosphere. Since the summer of 2005, in the Mediterranean Sea, growing concerns regarding exposure to harmful marine aerosols associated with toxic benthic dinoflagellate *Ostreopsis* spp. blooms have been reported, as they represent major health and economic risks to human populations [1]. *O.* cf. ovata is a toxic microalga that produces non protein palytoxin (PLTX) and PLTX analogs [2] such as ovatoxins (OVTXs) [3]. In this context, we developed a qPCR assay for the estimation of *O.* cf. *ovata* cells in marine aerosol during a bloom together with a determination of PLTX-like compounds using hemolytic assay and liquid chromatography. Marine aerosol samples collected at two stations at Sant Andreu de Llavaneres were analyzed by qPCR using designed primers for 204 bp specific amplified fragment [4]. In the air, the presence of a high concentration of biotic and abiotic particles could lead to cross-reactivity and bias in PCR assays. The inhibitory activity of the filter matrix was excluded in spiking experiments. Moreover, due to the stringency of washes of the aerosol complex matrix filters, *Ostreopsis* cellular loss needed to be evaluated. In order to normalize *O.* cf. *ovata* abundance in aerosol filters a recovery rate, ranging from 65 to 20%, was applied to qPCR results. The two sampling stations showed variable cell numbers ranging from 1 to 102 (Tab. 1) [5]. In order to obtain the correct quantification of *O.* cf. *ovata* cells, macroalgae and surface seawater samples were analyzed by qPCR assay. Abundance ranged between 7.0 x 10^4 and 7.6 x 10^5 cells/g fw in macroalgae and between 3.5 x 10^3 and 1.1 x 10^5 cells/L in seawater. A significant positive correlation (n = 6, Spearman r = 0.9276, P = 0.0167) was found between *O.* cf. *ovata* abundance in the surface seawater and marine aerosol samples collected at Station S on the beach, showing that higher abundance in the seawater is directly linked to an increased abundance of airborne *O.* cf. *ovata* cells. Instead, no significant correlation was found between the abundance in surface water and marine aerosol samples collected at Station A far from the beach (n = 5, Spearman r = −0.9, P = 0.0833). The palytoxin content, by analytical determinations ranged from 0.1 to 1.2 pg/cell in macroalgae during the bloom. It was not possible to define the palytoxin content in aerosol filters because of the LOD of the analytical assays employed. In conclusion, the developed qPCR assay is a highly sensitive and specific quantification method for toxic *O.* cf. *ovata* in a complex matrix, such as marine aerosol. In the future, the application of the developed molecular assay together with the analytical technique and epidemiological studies in areas affected by toxic blooms will allow us to relate the *Ostreopsis* abundance in marine aerosol with respiratory syndromes in humans.

APPLICATION OF BAYESIAN NETWORKS TO MODEL RELATIONSHIP BETWEEN TOXIC DINOFLAGELLATE KARENIA SELLIFORMIS AND HYDROCLIMATIC CONDITIONS IN GABES GULF

Wafa Feki [1]*, Asma Hamza [1], Malika Belhassen [1] and Ahmad Rebai [2]
[1] Institut des Sciences et Technologies de la Mer - wafafeki@yahoo.fr
[2] Centre de Biotechnologie de Sfax

Abstract
The growth of bloom-forming phytoplankton has been known to be mostly affected by abiotic environmental factors such as light, temperature, salinity and concentrations of organic and inorganic nutrients but little is known about the effect of environmental factors on occurrences of K. selliformis blooms as this species has been recently identified. Therefore, our study uses Bayesian network to apprehend the relationship between this species and hydroclimatic parameters. We found that development of K.selliformis was induced essentially by salinity, atmospheric temperature, rainfall and evaporation.

Keywords: Dinoflagellates, Salinity, Models, Gulf of Gabes

Introduction

Karenia selliformis occur regularly since 1994 in many coasts of Gabes Gulf (south of Tunisia) and it was responsible for an intensive fish kill [1] and serious problem of shellfish toxicity in this area [2], [3].
The data base collected in phytoplankton monitoring in the Gulf of Gabes during the past ten years showed that species bloomed frequently along the year and affect a specific area situated in Boughrara lagoon [4].
Otherwise, general linear model don't permit us to identify a particular parameter that induce the spatiotemporal distribution. Our goal, from the REPHY data, was to identify the main constraining variables (hydroclimatic parameters) that regulate occurrences of *K.selliformis* in Gabes gulf. The application of a Bayesian network permits us to describe the essentials parameters that regulate development of this dinoflagellate in ours coasts.

Material & Methods

Data were collected in the framework of the National Phytoplankton Monitoring Program in the shellfish harvest areas from 1995 to 2007 in Gabes Gulf. Fifteen sites are weekly sampled and phytoplankton is enumerated with Uthrmöhl method. Hydroclimatic parameters were simultaneous collected.
Meteorological data were provided by the Tunisian National Meteorological Institute). The tide amplitude in this coast was obtained from Tunisian Hydrographic and Oceanographic Services.
A Bayesian network consists of a graphical structure and a probabilistic description of the relationships among variables. It was learned from data using the R package « deal ».

Results & discussion

The plot obtained with this model (Fig.1) revealed a clear direct relationship between *K.selliformis* and salinity, atmospheric temperature, evaporation and rainfall. Salinity exceeding the limit of 42 psu suggested previously by Feki et al. [5] seems to be a regulator of the blooms and also of the related biological processof *K. selliformis*. The direct effects of atmospheric temperature, evaporation and rainfall are difficult to apprehend, we suspect that these could be indirectly related to salinity.

Tide, originally suspected to enhance species distribution and booms dispersion [4], seems to have an indirect effect likely related to sediment disturbance and might therefore contribute to resuspension events inducing nutrients release thatwere normally tied up in dissolved organic matter, in bacteria, or in the bottom sediment.

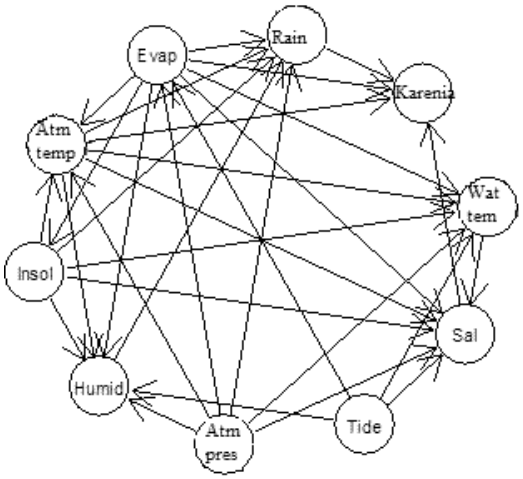

Fig. 1. Fig.1: Bayesian network plot: direct relationship between *K.selliformis* and hydroclimatic parameter.

Abstract
In coastal waters, many planktonic organisms produce resting cysts that have the potential to remain viable in the sediments for decades. These cysts probably derive from bloom processes and are able to refuel new blooms. The aim of this study is to explore the dinoflagellate cyst bank in surface sediments from Saronikos Gulf, an enclosed Bay in the Eastern Mediterranean Sea. A quantitative and qualitative study was performed in order to characterise dinoflagellate cyst assemblages, relate cysts to physico-chemical conditions and use them as bioindicators of eutrophication.

Keywords: Dinoflagellates, Aegean Sea, Eutrophication, Sediments

Red tide blooms have become fairly frequent worldwide and dinoflagellates in particular are a subject of increasing interest. A 'seed population' hypothesis consists of dinoflagellate resting cysts able to survive for long periods in the sediment and eventually inoculating the water column under favourable germination conditions [1]. Resting cysts may have a crucial ecological role as important seedbeds for the initiation of blooms [4]. The last decade scientific papers highlight the use of cyst signals as indicators of eutrophication and industrial pollution [2].
Sediment samples (0-10cm) were collected seasonally (December to September 2011) from Saronikos Gulf, an enclosed bay near Athens. Elefsis Bay (S1) is highly polluted by industrial activities and the shipyard area of Piraeus harbor (Fig 1). Subsamples (1 cm^3) from each sediment sample were further processed in the laboratory [3]. At least 200 cysts were counted and identified under the microscope (x 200). Cysts were photographed with an image PRO analysis system and then selected live species were isolated with a micropipette and transferred into tissue culture multi-well plates for germination.

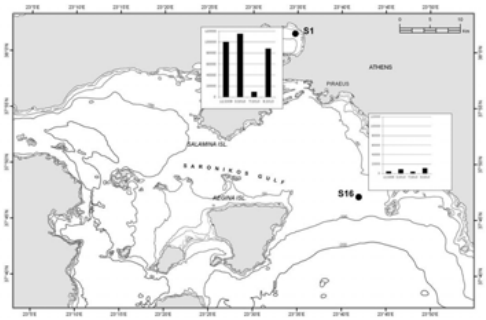

Fig. 1. Sampling stations at Saronikos Gulf. Bars represent dinoflagellate cyst abundance/g dry sediment.

Total cyst density varied from 1380–155000g^{-1} dry sediment. A 10fold higher abundance was recorded at station S1 (Fig. 1). Calcareous Peridiniales contributed more than 60% to the total abundance with the dominance of *Scrippsiella* group. Non calcareous Peridiniales occupied 12-19% of the total population (*Protoperidinium conicum, P.. cf minutum, Zygabigodinium lenticulatum*) whereas Gymnodiniales and Gonyaulacales were 5-11% και 9-15% respectively, (*Alexandrium cf affine, A. minutum, Lingulodinium polyedrum, Protoceratium reticulatum, Gymnodinium catenatum/nolerii).* Station S16 was characterised by non calcareous Peridiniales (46-67%), with the species *Protoperidinium conicum, P.cf minutum, P. sp.1).*

Cysts at station S1 were represented 84% by autotrophic dinoflagellates whereas the heterotrophic taxa had higher relative abundances (57%) at S16.

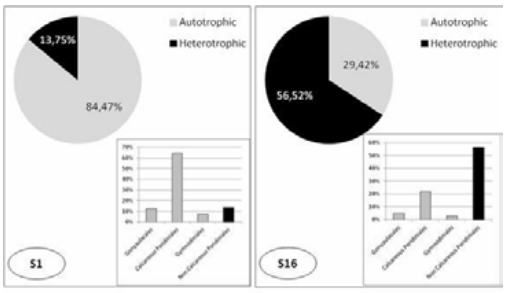

Fig. 2. Relative abundance of heterotrophic and autotrophic cyst taxa and % contribution of different dinoflagellate groups.

Several features of dinoflagellate assemblages reflect intense signal of eutrophication and industrial pollution at station S1. 1) very high values of cyst concentrations probably reflecting an increase in phytoplankton production 2) dominance (>50%) of one group (Scrippsiella) 3) significant amounts of specific cyst types such as *Lingulodinium polyedrum, Zygabigodinium lenticulatum* (extreme nutrient impact), *Polykrikos kofoidii* (hyper-eutrophication), *Protoperidinium conicum (*industrial pollution, significant presence of diatoms). However, more information from regional surveys should be collected in order to define certain cyst groups/species as proxies of different environments.

Abstract
Studies focused on the role of mucilage produced by *O. ovata* cells suggest its key-role in growth strategy and, possibly, during the process of micropredation. The aim of the present study is to highlight the potential toxic effect associated to mucilaginous filaments, performing a toxicity bioassay on *A. salina*.

Keywords: Ecotoxicology, Ligurian Sea, Dinoflagellates

Introduction
In the last decade, the harmful benthic dinoflagellate *Ostreopsis* cf. *ovata*, which produces many palytoxin congeners, has bloomed in the Mediterranean region with increasing frequency, intensity and distribution, causing mortality of benthic organisms and human health problems ([1]). An eco-toxicological investigation performed by Faimali et al. (2012, [3]) put in evidence an unexpected high sensitivity of the model organism *A. salina* towards *O*. cf. *ovata* and suggested that toxic effects on invertebrates arise only in presence of whole microalgal cells. In fact, the toxic effect of the growth medium alone (free of cells but possibly containing dissolved toxins) was not relevant if compared to the whole culture (growth medium + cells). Studies focused on the role of mucilage produced by *O. ovata* cells ([4], [5]) suggested its key-role in growth strategy and, possibly, during the process of micropredation. A conspicuous presence of microfilaments and of their connections with the cell wall was highlighted, but, so far, an active toxicological role of the mucilaginous matrix surrounding the microalgal cells was not yet proved. The aim of the present study was to highlight the potential toxic effect associated to mucilaginous filaments, carrying out a toxicity bioassay on *A. salina*. In order to put in evidence mucilaginous filaments associated to the cell wall, Atomic Force Microscopy (AFM) investigation was performed.

Materials and methods
Laboratory cultures of *O. ovata* were obtained from environmental samples collected from June to August 2012 in Quarto dei Mille (Genoa, NW Mediterranean Sea, Italy). Algae from the strain were cultured into sterilized plastic flasks closed with transpiring caps. All flasks were maintained at 20 °C ±0.5 °C in a 16:8 h light:dark (L:D) cycle (light intensity 85–135 µE m^{-2} s^{-1}) inside a thermostatic culture chamber. Cell counts were performed in three replicates for each flask every two days. Toxicity test was prepared on II-III stage larvae of the crustacean *A. salina* according to Artoxkit M, obtained by Microbiotest Inc., modified as in Faimali et al. 2012. In order to investigate the toxic effect due to direct or indirect contact with *O. ovata* cells, larvae were exposed different treatments: 1) untreated *O. ovata* culture; 2) filtered *O. ovata* cells, kept separated from *A. salina* during the incubation by using a 10 µm filter in order to let mucilaginous filaments pass through; 3) filtered *O. ovata* cells, kept separated by using a 0.22 µm filter, in order to stop mucilaginous filaments; 4) control (0,22 µm Filtered Natural Sea Water). Algal cell concentration of 400 cells/ml was prepared for each treatment (three replicates). Mortality of *A. salina* larvae was recorded after 48 hours. Few drops of *O. ovata* culture were laid on a glass slide and observed with a commercial AFM equipped with an optical microscope. Topography images were acquired in tapping mode.

Preliminary results
Our preliminary results show that a direct contact with *O. ovata* cells is required to cause high mortality percentages of *A. salina*. Lower (about 30% mortality) but significantly higher if compared to the other treatments, mortality values were recorded after treatments that allowed the mucilaginous filaments pass through the 10 µm net. On the contrary, treatments that did not allow filaments pass through the filter (0.22 µm mesh filter) resulted in no evident toxic effect.

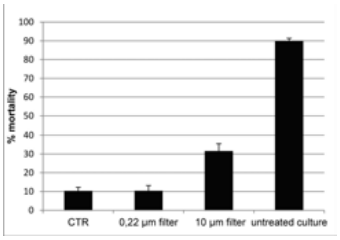

Fig. 1. Mortality (M±ES, N=3) after 48 h of *Artemia salina* exposed to several treatments of *O. ovata* culture.

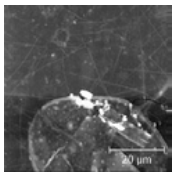

Fig. 2. Mucilaginous filaments and theca of *O. ovata* cell observed with a commercial AFM equipped with an optical microscope.

Future perspective
Given the preliminary results, we are carrying out a more complete toxic bioassay during three culture growth phases (exponential, stationary, senescent), combining the same experimental design performed by Faimali et al. (2012, [3]) with the present experiment, in order to better elucidate toxicity dependence of direct/indirect contact and to put in evidence potential differences depending on the growth phase within the algal life cycle.

Abstract
Various genetic aspects of the toxic diatom *Pseudo-nitzschia* species in the northwestern Adriatic Sea were investigated. Phylogenetic analyses identified strains belonging to *P. delicatissima, P. calliantha, P. pungens* and *P. mannii*. The quantitative real-time PCR (qrt-PCR) assay was developed to estimate the number of rDNA copies and their variation among *Pseudo-nitzschia* species and strains in relation to physiological activities and/or adaptative strategies. Northwestern Adriatic *P. delicatissima* strains produced domoic acid at low concentrations.

Keywords: Diatoms, Genetics, Toxic blooms, Central Adriatic Sea

In the northwestern Adriatic Sea, nothing is known regarding the genetic diversity and geographical pattern of *Pseudo-nitzschia* species, and relatively little is understood regarding the chemical toxin composition of *Pseudo-nitzschia* populations. Genetic approaches can play a fundamental role in solving taxonomic issues, as well as in geographical distributions and the level of genetic differentiation of populations [1]. Further, molecular method of qrt-PCR has the capacity to characterize the target rDNA copy number of a species or population in relation to physiological activities, such as adaptation strategies to the environment [2]. We aimed to identify and characterize strains of *Pseudo-nitzschia* spp. sampled in northwestern Adriatic area with regard to phylogenetic relationships, geographical patterns and quantitative content of nuclear rDNA. The sampling site was located at Pesaro, 500 m off the coast, in the northwestern Adriatic Sea (43° 55'50''N; 12°53'51''E). Net samples were collected throughout the water column. A total of 108 monoclonal strains were established and maintained in f/2 medium at 20 °C on 12:12 h light:dark cycle at an irradiance of 100 µmoL photons m-2 s-1. All strains were processed for phylogenetic (neighbour-joining, NJ; maximum parsimony, MP; maximum likelihood, ML; Bayesian Inference, BI), geographical (statistical parsimony analysis), molecular (real time quantitative-PCR), statistical and chemical toxin content analyses as described in [3]. Northwestern Adriatic Sea strains were included in the *P. calliantha, P. delicatissima, P. mannii and P. pungens* (clade I) genetic lineages. Networks of haplotypes inferred from Adriatic and worldwide strains revealed two main haplotypes in P. delicatissima from the Mediterranean and north Atlantic, with a single panmictic population in *P. calliantha, and Adriatic P. pungens* strains sharing the most frequent haplotype. The quantitative analysis of the ITS-5.8S copy number of Pseudo-nitzschia strains showed that the three species of P. delicatissima, P. calliantha and P. pungens (clade I) had a different average rDNA copy number, 39±22, 62±30 and 83±67, respectively. The difference was significant (P=0.0017) only in the case of the *P. calliantha* versus *P. delicatissima* comparison. Strains of *Pseudo-nitzschia* species were isolated monthly, and the rDNA copy number per cell did not show any differences among strains of either *P. calliantha* (P=0.1554) or P. delicatissima (P=0.1405), whereas a significant difference was found among *P. pungens* strains (P=0.0061). *P. pungens* rDNA copy number showed that the only significant difference was found between strains isolated in December and January (P=0.0150), potentially related to trophic conditions of seawater (Fig. 1). The presence of DA was detected only in seven strains of *P. delicatissima* and in one case DA reached the quantifiable amount of 0.063 fg cell-1[3].

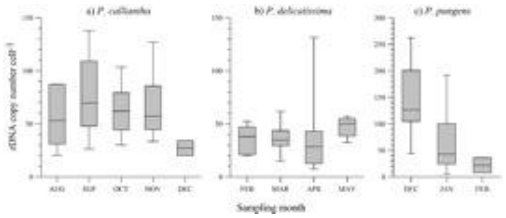

Fig. 1. The rDNA copy number per cell of northwestern *P. calliantha, P. delicatissima* and *P. pungens* strains determined by qrt-PCR and sampling period.

The genetic characterization of toxic *Pseudo-nitzschia* species may greatly improve our understanding of the composition and diversity of the *Pseudo-nitzschia* complex in the northwestern Adriatic Sea. Molecular qrt-PCR analysis offers more specific and sensitive tools to investigate the relationships between diversity and the ecological function of a species in the marine environment.

FACTORS DRIVING A LATE SUMMER/AUTUMN BLOOM OF *PSEUDO-NITZSCHIA* SPP.AND DOMOIC ACID IN BIZERTE CHANNEL (TUNISIA SW MEDITERRANEAN)

I. Sahraoui [1]*, I. Bouchoucha [1], M. Daly Yahia [1], H. Hadj Mabrouk [1] and A. Sakka Hlaili [1]
[1] Faculté des Sciences de Bizerte - ineskalif@yahoo.fr

Abstract
This study examines the dynamic of a *Pseudo-nitzschia* spp. bloom which has developed in late summer/autumn 2011 in Bizerte channel. *Pseudo-nitzschia* spp. reached highest cell densities (~2 × 10^5 cells l^{-1}) on 27 September, at the same time that domoic acid (DA) was detected (~1.56 µg DA l^{-1}). The Canonical Correspondence Analysis (CCA) results revealed that dissolved organic phosphorus (DOP) and nitrate were the main drivers of this bloom. This is the first time that DOP is proposed as a potential factor in *Pseudo-nitzschia* spp. bloom promotion.

Keywords: Toxic blooms, Diatoms, Lagoons, South-Western Mediterranean

Introduction
Recently, late-summer/autumn blooms of *Pseudo-nitzschia* spp. have been increasingly observed in Bizerte lagoon system [1], a semi-enclosed shallow water body subjected to intensive anthropogenic influences. Moreover, elevated levels of DA in the local seawater (0.5 – 2 µg DA l^{-1}) have already been documented, emphasizing the beginning of autumn as a potential period of risk for ASP events [1]. The potential role of organic nutrients in the development and persistence of *Pseudo-nitzschia* spp. blooms remains largely unexplored in spite of ample evidence elsewhere that the organic pool may exert an important role in the occurrence of *Pseudo-nitzschia* spp. blooms and toxicity [2]. The purpose of this study is to explore the potential role of organic nutrients in *Pseudo-nitzschia* spp. late-summer/autumn bloom development in Bizerte channel.

Materials and Methods
Sampling was carried out weekly, from 5 August to 18 October 2011, at one station located in Bizerte Channel. Water temperature and salinity were recorded *in situ* using a microprocessor conductivity meter (WTW-LF-197, Brives B.V., Germany). Seawater samples were taken from 2m depth for inorganic (nitrate, nitrite, phosphate and silicate) and organic (dissolved nitrogen (DON) and dissolved phosphorus (DOP)) nutrient analyses [3]. Sub-samples for identification and enumeration of *Pseudo-nitzschia* spp. were analysed following the Utermöhl method [4]. The bloom sample collected on 27 September was analyzed for DA, following the Mafra method [5].

Results and discussion
During this study, densities of *Pseudo-nitzschia* spp. were frequently of 10^4 order of magnitude, except on 27 September when they exemplified a bloom concentration of ~2.5 10^5 cells l^{-1}. The CCA results showed a significant positive relationship between DOP, nitrate and *Pseudo-nitzschia* spp. bloom development (Fig. 1).

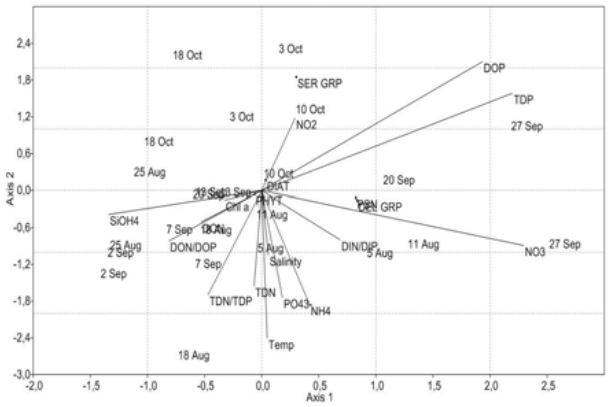

Fig. 1. CCA ordination diagram showing the relationships between environmental variables and *Pseudo-nitzschia* species distribution.

Utilization of DOP by phytoplankton is possible by the activity of several enzymes, e.g. alkaline phosphatase and C-P lyase, which are in general stimulated by critical dissolved inorganic phosphorus levels in the water [6]. DA was also detectable in the bloom sample with a concentration of 1.56 µg DA l^{-1}. The detected DA level may still be a sufficient amount to close shell?sh harvesting and cause toxic effects on seabirds and marine mammals in adjacent waters.

NITZSCHIA BIZERTENSIS SP. NOV.: A NEW TOXIC DIATOM ISOLATED FROM A SOUTHWESTERN MEDITERRANEAN LAGOON OF BIZERTE

A. Sakka Hlaili [1]*, D. Bouchouicha Smida [1], I. Sahraoui [1], N. Lundholm [2], W. Kooistra [3] and H. Hadj Mabrouk [1]
[1] Fac. Sci. Bizerte, Univ. Carthage, Tunisie - asma_sakka@yahoo.fr
[2] Univ. Copenhagen, Danmark
[3] Stazione Zoologica, Italie

Abstract
The abundance of toxic diatoms was monthly (November 2007 - February 2009) investigated in the lagoon of Bizerte. These microalgae were present over almost all the sampling period and exhibited a pronounced bloom in August 2008 (3 10^6 cells L^{-1}). The characterization of diatom strains, isolated from seawater, by light/electronic microscopy and molecular analyses allowed to identify a new species *Nitzschia bizertensis*. This specie was characterized by (1) linear-lanceolate valves with 1.38 - 2.91 µm width and 32.52 - 81.73 µm length (2) numerous fibulae in the eccentric raphe and (3) high density of interstriae. The domoic acid (DA) was detected in batch culture of *N. bizertensis* (4500 – 9500 pg DA mL^{-1}). *Nitzschia bizertensis* represents a new domoic acid-producing diatom and is the second toxin producing *Nitzschia* species

Keywords: Diatoms, Lagoons, Toxins, South-Western Mediterranean

Introduction
The occurrence of potentially toxic (PT) diatom blooms has increased in the Bizerte Lagoon [1], which is an important shellfish culture area. Some species of these algae were reported as toxic by of Amnesic Shellfish Poisoning (ASP) and thus may harm human health and represents a serious threat for both aquacultured and wild shellfish. Therefore, we investigated the temporal and spatial dynamics of harmful diatoms in the Bizerte Lagoon. We described species isolated from this area and examinated their toxicity in batch culture.

Materials and Methods
Diatom samples were collected monthly, from November 2007 to February 2009, at several stations in the Bizerte Lagoon, using a plankton net (20 µm diameter). Cell abundance was determined under inverted light microscope [2]. Several strains of PT diatoms were isolated, from seawater, and cultured in f/2 medium [3]. The batch cultures were maintained at a temperature of 20 °C, an irradiance of 100 µmol photons m-2 s-1 and a light:dark cycle of 12h:12h. The ultrastructure of the strains was examined using electron microscopy (scanning and transmission) and their genomes were sequenced at LSU and SSU units using the molecular biology techniques. DA in the whole culture (cells plus medium) was analyzed using a the ELISA test.

Results and discussion
During the study, the PT diatoms were abundant in warm, turbid and ammonium-rich waters. These algae exhibited several peaks of density, but the most pronounced bloom was in August 2008 (3 10^6 cells L^{-1}). Previous studies, in Bizerte Lagoon, showed that PT diatoms were exclusively represented by species of *Pseudo-nitzschia* [1]. In contrast, PT diatoms, isolated during our study, belong to the genus Nitzschia. Cells were described by light and electron (transmission/scanning) microscopy as well as genetically, using the nuclear rDNA regions: SSU, ITS1, 5.8S, ITS2 and D1–D3 of the LSU. The morphological and phylogenetic studies and comparisons with previously described Nitzschia species revealed the presence of a new species: *Nitzschia bizertensis* sp. nov. The linear-lanceolate valve (1.38 - 2.91 µm width and 32.52 - 81.73 µm lengt) was characterized by high density of interstriae (35.1 - 53.2 per 10 µm). The canal raphe was extremely eccentric with a central nodule and contains numerous fibulae (7.6 - 18.6 per 10 µm). In batch culture, *N. bizertensis* was able to produce the DA and cellular content varied from 2.3 to 3.6 10^{-2} pg DA $cell^{-1}$. The total DA level varied over time. It was high in exponential growth phase, and thereafter continued to increase during the stationary phase, when it reached 4500 – 9500 pg DA mL^{-1}.

ETUDE DES MICROALGUES ÉPIPHYTES TOXIQUES ET DU PHYTOPLANCTON TOXIQUE DE LA BAIE D'ANNABA ALGÉRIE

Imen Zard [1]* and Hocine Frehi [1]
[1] Université Badji Mokhtar, Laboratoire Bioressources Marines, Annaba, Algérie - www.imen-zard@hotmail.fr

Abstract
L'étude des microalgues et des épiphytes toxiques sur les feuilles de posidonie de la baie d'Annaba, nous a permis d'enregistrer que les dinoflagellés (*Alexadrium catenella* et *Gymnodinium catenatum)* toxiques sont présents en périodes printanières et estivales, pour les épiphytes, on a recensé la présence de *Prorocentrum lima* et *Ostreopsis ovata*

Keywords: Dinoflagellates, Algerian Basin, Toxic blooms, Phytoplankton

Introduction

Sur un total de 4000 espèces, 60 à 80 est le nombre d'espèces de microalgues potentiellement nuisibles [1]. Introduites généralement par les eaux de ballaste via le trafic maritime, elles s'adaptent et se concentrent dans les eaux côtières, ce qui est le cas de la baie d'Annaba. Cette étude a pour objectif de recenser les espèces microalgues planctoniques et épiphytiques toxiques dans la baie d'Annaba.

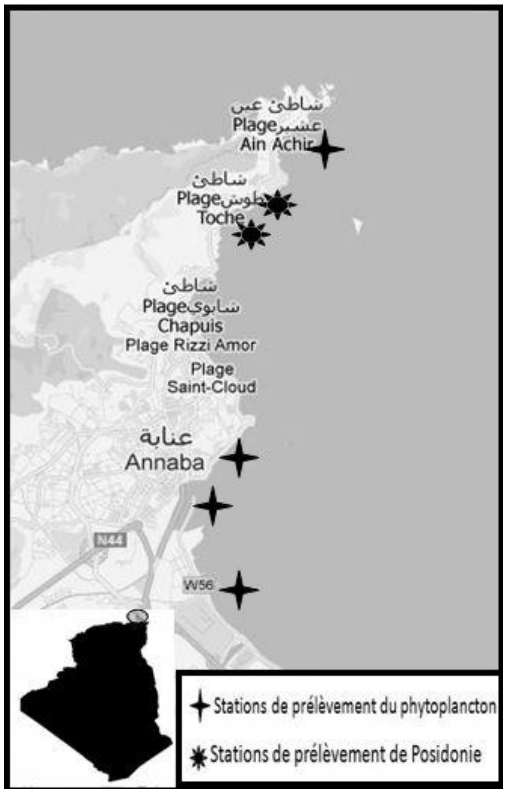

Fig. 1. Zone d'étude

.

Matériel et méthodes

Pour l'étude des épiphytes, les feuilles de posidonie prélevées à une profondeur de 3m à 4m, un grattage sur les feuilles de posidonie est réalisé, les espèces récoltées sont fixées au formol (5%). Un filet à plancton de 20µm de vide de maille a été utilisé pour l'échantillonnage du phytoplancton. Un multiparamètre type HANA été utilisé pour mesurer les différents paramètres physiques (Température, salinité, oxygène dissous, pH).

Résultats

Tab. 1. Microalgues recensées durant la période d'étude.

Espèces (épiphytes)	Densités	Période	Toxicité
- *Prorocentrum lima*	18-25 Cell.g^{-1} 87 Cell.g^{-1}	Hiver-printemps Eté	Acide okadaique [2]
- *Ostreopsis ovata*	3 Cell. g^{-1} 26 Cell. g^{-1}	Hiver Eté	Palytoxines [3]
Espèces (phytoplanctoniques)	**Densités**	**Période**	**Toxicité**
- *Lingulodinium polyedra*		Juillet 2012	Yessotoxines [4]
- *Dinophysis caudata* - *Dinophysis tripos* - *Dinophysis sacculus*		Mars- Aoute 2012	Dinophysis toxines
- *Alexandrium catenella* - *Gymnodinium catenatum*	10^6 Cell.L^{-1} 2,3. 10^6 Cell.L^{-1}	Avril 2012 Juillet 2012	Saxitoxines/Gonyautoxines[5] Gymnodimines

Conclusion

Sur la baie d'Annaba, nous avons constaté que les microalgues toxiques se développent dans les zones abritées à faible brassage, généralement en périodes chaudes ,en effet, les concentrations les plus élevées des microalgues épiphytes et planctoniques ont été enregistrée en périodes printanières et estivales, nous pouvons dire que dans les aires eutrophes de la baie d'Annaba, on a enregistré des proliférations importantes d'espèces toxiques en occurrence *Alexandrium catenella* et *Gymnodinium catenatum.*

INTERSPECIFIC COMPARISONS OF HOST- ASSOCIATED BACTERIAL DIVERSITY SUPPORT COEVOLUTION OF HAHELLACEAE AND GORGONIAN CORALS

Marie La Rivière [1]*, Joaquim Garrabou [2] and Marc Bally [1]
[1] Mediterranean Institute of Oceanography (MIO - UM 110) - marie.la-riviere@univ-amu.fr
[2] Institut de Ciències del Mar (ICM)

Abstract
Elevated temperature and bacterial infections cause recurrent mortalities of gorgonian corals in benthic communities of the Mediterranean coralligenous habitat. To gain an understanding of the disease outbreaks, a comprehensive overview of the gorgonian-associated microbial diversity is required. In this study, we explored the bacterial ecology of 3 sympatric gorgonian species and our results indicate that the host-bacteria partnership is highly specific, stable and possibly shaped by evolution.

Keywords: Bacteria, North-Western Mediterranean, Cnidaria, Mortality, Symbiosis

Introduction
In marine coastal ecosystems, mass mortality events and disease outbreaks of benthic invertebrates are increasing in frequency. Microbial interactions appear to play a key role in coral health and it has been proposed that a disruption of the integrity of the coral holobiont (the cnidarian host and its associated microbiota) in response to environmental stress can trigger diseases [1]. In North-Western Mediterranean, recurrent mass mortalities linked to high seawater temperatures and infections by pathogenic bacteria have been recorded in populations of several species of gorgonian corals [2]. The increasing threat caused by climate change can have particularly severe impacts on these long-lived, slow-growing macroinvertebrates and a better understanding of factors involved in gorgonian health and disease becomes an urgent need to elaborate future conservation measures. On the basis of the current knowledge on microbial interactions in tropical corals, we hypothesized that determining patterns of host-microbes associations in different gorgonian species might help to reveal common mechanisms through which bacterial communities and holobiont health status are interlinked. Thus, the main aim of the present study was to establish a comparison of baseline composition for bacterial assemblages in 3 sympatric gorgonians, *Eunicella singularis*, *Eunicella cavolinii* and *Corallium rubrum*, that were severely affected during the mortality events.

Material and Methods
The 3 gorgonian species *E. singularis*, *E. cavolinii* and *C. rubrum* were sampled in summer 2008 and winter 2009 at the Riou Island site (Marseilles, France). For each species, apical branch tips of 3 colonies were collected at a depth of 20 m. Total genomic DNA was extracted using a phenol-chloroform protocol. For T-RFLP analysis, bacterial 16S rDNA was amplified by PCR using fluorescent-labeled universal primers. PCR products were digested by *CfoI* and *MspI* endonucleases and the terminal-restriction fragments data collection for each sample was used for multidimensional scaling (MDS) analyses as previously described [3]. Clone libraries were generated by amplification of the 16S rDNA using universal primers and subsequent cloning in pGEM®-T vector. The sequences of the selected clones were determined and compared with the Genbank database using the Blast program. A phylogenetic tree of sequences belonging to the dominant ribotype clusters identified in libraries was generated by the PhyML algorithm using the online phylogeny.fr workflow (http://www.phylogeny.fr).

Results and Discussion
For each of the gorgonian species *E. singularis*, *E. cavolinii* and *C. rubrum*, the T-RFLP peak profiles obtained from 3 independent colonies were highly conserved. Furthermore, MDS ordination of T-RFLP profiles from summer and winter samples did not show seasonal pattern but revealed a clustering of bacterial assemblages by host species, suggesting that gorgonians harbor stable and species-specific bacterial communities. To assess the phylogenetic composition of bacterial communities, 16S rDNA clone libraries were compared for gorgonian colonies sampled in summer. Both the *E. singularis* and *E. cavolinii* libraries were strongly dominated by a unique ribotype affiliated to the *Hahellacae* family of Gammaproteobacteria. This ribotype accounted for 95.8% and 83.3% of the sequences from *E. singularis* and *E. cavolinii*, respectively. Interestingly, a closely related ribotype (>95% similarity) was previously identified as the dominant bacterial associate in the sympatric gorgonian *Paramuricea clavata* [3]. A Blast similarity search against the GenBank database revealed that the ribotype associated with the *Eunicella* spp. showed the best similarity score (>98% similarity) with a group of bacterial sequences from the tropical gorgonian *Gorgonia ventalina*. In the *C. rubrum* library, sequences related to *Hahellaceae* were detected at a low frequency, accounting for 8.8% of the clones. A phylogenetic analysis of representative sequences from the identified groups of *Hahellaceae* ribotypes evidenced a host-dependant clustering (Fig. 1), although the sequences recovered from *C. rubrum* were also related to *Endozoicomonas* and *Spongiobacter* bacteria isolated from other marine invertebrates. Unexpectedly, the phylogenetic tree of the sequenced bacteria corresponds to the systematic classification of their hosts and is not correlated with the geographic separation of gorgonian species. This suggests that *Hahellaceae*-affiliated symbionts may co-evolve with each host species and represent stable, obligate associates of the holobionts. These data support the view that *Hahellaceae* bacteria could play a pivotal role in gorgonians.

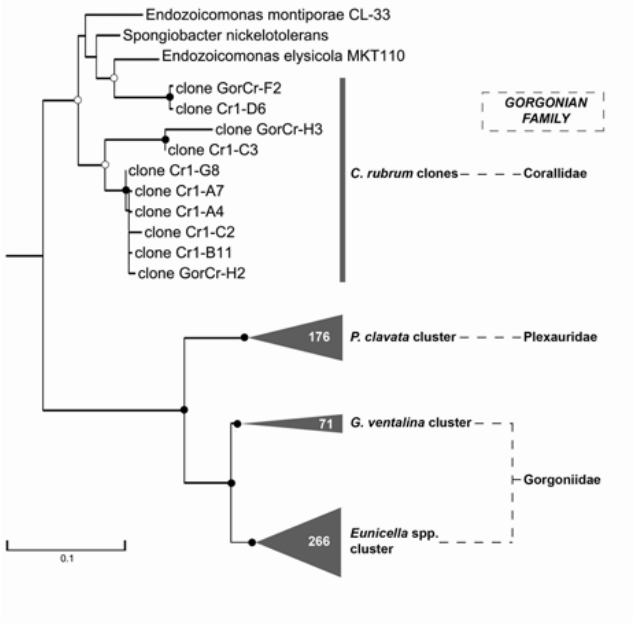

Fig. 1. Phylogenetic tree showing the relationships of *Hahellaceae* ribotypes obtained from gorgonians. Branch support values of >75% (filled circles) and 50 to 74% (open circles) and the number of sequences in each cluster are indicated.

TOXICITY OF TWO CYANOBACTERIAL STRAINS ON *MYTILUS GALLOPROVINCIALIS* HEMOCYTES

Patrizia Pagliara [1]* and Carmela Caroppo [2]
[1] DiSTeBA - University of Salento - patrizia.pagliara@unisalento.it
[2] National Research Council, Institute for Coastal Marine Environment, Taranto, Italy

Abstract
Cyanobacteria may produce a wide range of currently unknown toxins. Within this frame, the toxicity of two cyanobacterial strains (*Cyanobium* sp. and *Synechococcus* sp.) was tested on mussels (*Mytilus galloprovincialis*). Results evidenced that the two cyanobacteria did not affect the vitality of the individuals, but they exerted a toxic effect on the morphology and functionality of the mussels' hemocytes.

Keywords: Cyanobacteria, Mollusca, Toxins, Ionian Sea

Introduction
Massive proliferations of cyanobacteria have become a worldwide environmental problem because of the severe impacts on ecosystem functioning, by inducing as an example, disturbances to relationships among organisms and changes in biodiversity. Considering that 25 to 75% of cyanobacterial blooms are toxic [1, 2, 3], it is important to assess the risk for human and animal health. Cyanobacteria are able to produce a great variety of several secondary metabolites and unknown substances, considered potent toxins [see 4 for review]. In this work we studied the effects of twenty-four hours interaction between two coccoid unicellular cyanobacteria strains (*Cyanobium* sp. ITAC108 and *Synechococcus* sp. ITAC107) and *Mytilus galloprovincialis* individuals.

Material and Methods
Two cyanobacteria belonging to *Cyanobium* and *Synechococcus* genera were previously isolated from the sponge *Petrosia ficiformis*, collected in the Ionian Sea. Cyanobacteria were cultured in laboratory conditions and used to test their toxicity against *Mytilus galloprovincialis.* Mussels individuals were exposed to the cyanobacteria for 24h under control conditions. The Neutral red test was performed to assess toxicity of the two cyanobacterial strains against mussels hemocytes. Aliquots of hemolymph were also fixed and stained to evaluate changes in hemocytes morphology.

Results and discussion
Cyanobium sp. ITAC108 and *Synechococcus* sp. ITAC107 did not induce effect on mussels survival, but their hemocytes resulted modified in morphology and functionality. Mussels treated with *Cyanobium* sp. ITAC108 showed a lower lysosomal membrane stability than in controls, as revealed by the Neutral red assay. By the same test we verified that *Synechococcus* sp. ITAC107 interaction with mussels completely inhibited the hemocytes ability to incorporate the dye into lysosomes. Furthermore, we observed that the two cyanobacterial strains modified cell morphology of hemocytes that became round.
Between the two strains, *Synechococcus* sp. **ITAC107** seems to be more dangerous for mussel hemocytes, affecting their functionality.

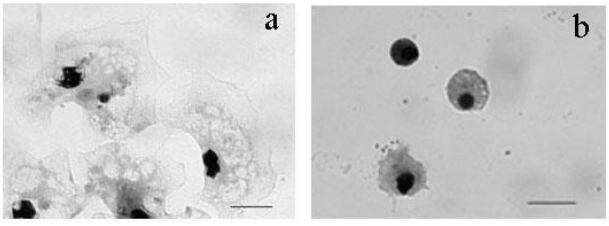

Fig. 1. Hemocytes from control mussels (a) and from cyanobacteria treated molluscs (b)

In Invertebrates, hemocytes mediate cellular defence; morphology and functionality changes of these cells represent a risk for animals health, since they could become more susceptible to disease. Our data evidenced a clear toxicity of the two tested cyanobacterial strains, even if no causative compound has been identified so far. In a previous work [5] we already evidenced the hemolytic activity of *Synechococcus* sp. ITAC107 and the ability of the two strains to interfere with sea urchin embryonic development. Further research is needed not only to identify new cyanobacterial bioactive metabolites, but also to investigate on possible additive, synergistic or antagonistic effects of the toxins they produce.

DIVERSITY AND DISTRIBUTION OF BACTERIA ASSOCIATED WITH THE CORAL *OCULINA PATAGONICA* IN THE WESTERN MEDITERRANEAN SEA

Esther Rubio Portillo [1]*, Alfonso Angel Ramos Esplá [1] and Josefa Antón Botella [1]
[1] Universidad de Alicante - esther.portillo@ua.es

Abstract

This study has applied culture-independent methods to examine the structure and composition of bacterial communities inhabiting in three different microhabitats (mucus, coral tissue and skeleton) of the coral *Oculina patagonica*, across two sites of the Western Mediterranean Sea, during a year. Differences among coral compartments and seasonal effects were detected; bacterial diversity was higher in coral tissue than in the mucus and skeleton, increasing during warm months in the three compartments.

Keywords: Symbiosis, Bacteria, Cnidaria, South-Western Mediterranean

Introduction

Corals consist of symbioses among the coral animal, endosymbiotic algae commonly referred to as zooxanthellae (Symbiodinium), and a large and diverse community of associated bacteria, archaea, fungi and viruses and this consortium has been termed "the holobiont"[1, 2]. The structure of the coral host provides three different potential microhabitats (a surface mucus layer, tissues and skeletal matrix) which have unique physiochemical characteristic that influence the bacterial community structure [3].

Materials and methods

In this study we have characterized bacterial communities of *Oculina patagonica* from three different microhabitats such as mucus, tissue and skeleton, and changes in microbial communities related to temperature. We have collected coral colonies every three months during a year, in two different locations of Alicante coast: Alicante harbour and the Marine Reserve of Tabarca, between 3-5 m. The prokaryotic community of the three different microhabitats has been analyzed by denaturing gradient gel electrophoresis (DGGE) of 16S rRNA gene fragments PCR amplified from DNA extracted from each of the coral compartments

Results and discussion

A total of 135 sequences were analysed and grouped into 56 phylotypes. Coral-associated microbial species were similar between two localities, although differences among coral microhabitats and seasonal effects were detected (Fig. 1). Bacterial 16SrRNA gene diversity was higher in the tissue than in the skeleton and mucus, increasing during warm months in three compartments. *α-Proteobacteria*, Bacteroidetes and Chlorobi were found in all three compartments while *δ- Proteobacteria* and Nitrospira were only detected in the tissue and skeleton, respectively. *α- Proteobacteria were* the most abundant in the mucus (75%) and tissue (47%), with phylotypes similar to *Pseudovibrio sp*. and *Roseobacter sp*., which could involved in cycling of nitrogen [3] and sulfur [4] within the holobiont, dominating in the mucus and tissue, respectively. During warm months, under heat stress, we found changes in bacterial communities associated with *Oculina patagonica* .In tissue the number of phylotypes related with *Bacteroidetes* increased while *α- Proteobacteria* and *δ-Proteobacteria* dicreased; stressed skeleton tissues harboured less *Chlorobi* and *Bacteroidetes*. Furthermore, *a* higher proportion of putative opportunistic bacteria belonging to *Acidobacteria, Chloroflexi* and *Cyanobacteria* were detected in the different coral compartments.

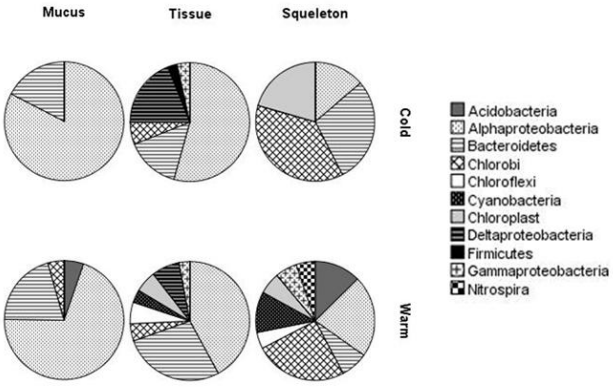

Fig. 1. Division-level diversity of bacterial 16SrRNA gene sequences obtained from the three different coral microhabitats (mucus layer, coral tissue and skeleton), and differences between cold and warm months.

TEMPORAL CHANGES IN SIZE-BASED PRIMARY PRODUCTIVITY AND CHLOROPHYLL CONTENT OF THE CILICIAN BASIN

Nebil Yücel [1]*, Zahit Uysal [1] and Süleyman Tugrul [1]
[1] Institute of Marine Sciences Middle East Technical University - nebil@ims.metu.edu.tr

Abstract
Changes in size-based primary productivity (PP) and chlorophyll (CHL) content were followed in monthly intervals (May 2010 - October 2011) at two stations (coastal, offshore) located in the Cilician basin of NE Med. PP varied in the range 0.024 – 14.42 and 0.007 – 1.48 in the euphotic zone, with water column averages of of 1.52 and 0.25 mg C. m^{-3} h^{-1} for the shelf and offshore, respectively. While larger cells (>5µm) and picoplankton have dominated nutrient rich shelf waters in an alternating manner, picoplankton remained as the sole contributor for the offshore waters. PP and CHL (n: 108, r: 0.356, P<0.01) were positively correlated in shelf waters. Annual primary productivity was estimated to be 65.4 g $C.m^{-2}$ for the offshore and 151.2 g $C.m^{-2}$ y^{-1} for the shelf waters of the Cilician basin for the 2010-2011 periods.

Keywords: Primary production, North-Eastern Mediterranean, Phytoplankton, Chlorophyll-A, Carbon

Introduction
Offshore waters of the eastern Mediterranean have oligotrophic properties [1]. However, river-fed coastal waters of wide self zone and bays in the Cilician basin of NE Mediterranean display either mesotrophic/eutrophic properties with daily PP rates ranging from 38.5 mgC m^{-2} d^{-1} in the offshore to 250 mgC m^{-2} d^{-1} in the coastal waters in 1991 and 1992 [2].

Material and Methods
Two stations (one with 50 m and the other with 200 m total depth), located in the Cilician basin (Fig. 1) were visited monthly from May 2010 to Oct 2011. To measure total and size fractionated PP, ^{14}C added seawater samples were incubated *in situ* during midday for about 3 hours. CHL was measured by the conventional fluorometric method and nutrients by the colorimetric methods using a multichannel auto-analyzer [3].

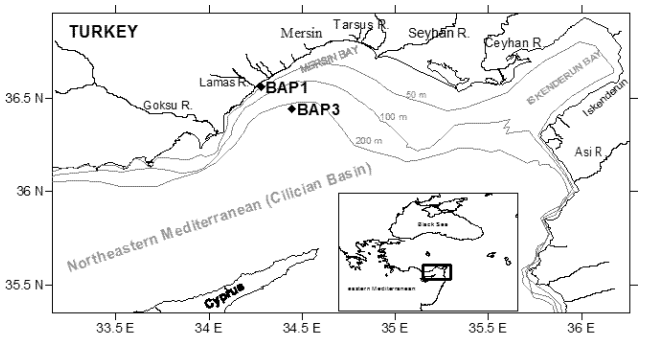

Fig. 1. Locations of the sampling stations visited monthly in the shelf zone of Cilician basin.

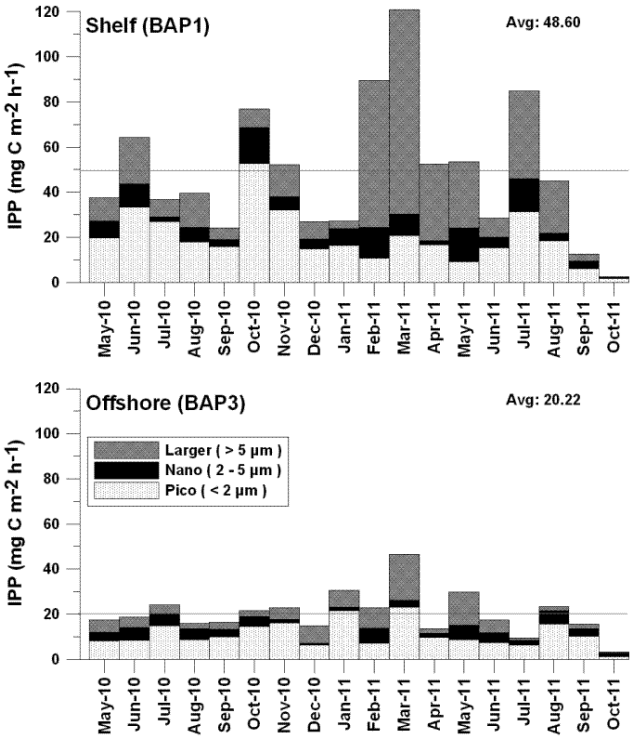

Fig. 2. Depth integrated PP at stations BAP1 (total depth = 40 m) and BAP3 (total depth = 100 m) stations.

Results
Rates of Integrated Primary Production (IPP) fluctuated monthly between 2.45 – 121 and 3.3 – 46.5 mgC.m^{-2} h^{-1} with the annual means of 48.6 and 20.2 mgC.m^{-2} h^{-1} for the shelf and offshore, respectively. Larger cells (>5µm) dominated phytoplankton composition during the first half (from February 2011 to July 2011, except June 2011) and picoplankton to dominate the rest of the year in shelf waters fed by river inputs decreasing markedly during the dry period. Picoplankton also dominated PP production in nutrient poor offshore waters throughout the year. Seasonal primary productivity rates were estimated as 32.6, 55.4, 57.3, 5.9 g $C.m^{-2}$ for the coastal and 12.9, 25.3, 14.6 and 12.58 g $C.m^{-2}$ for the offshore location, for winter, spring, summer and autumn, respectively. Based on POC/CHL ratios of cells, picoplankton (3.8) in shelf and nanoplankton (4.7) were the most active group of the algal total cells in the study area. Phosphate and nitrite+nitrate varied between 0.02-0.08 and 0.05-11.56µM in the study area, respectively.

MARINE PROTEOGENOMICS: SCREENING AND CHARACTERIZING MICROBIAL BIODIVERSITY WITH NEW OMICS TOOLS

Jean Armengaud [1]*, Guylaine Miotello [1] and Joseph A. Christie-Oleza [1]
[1] CEA, DSV-iBEB-SBTN-LBSP Institut de Biologie Environnementale et Biotechnologies - jean.armengaud@cea.fr

Abstract
Mass spectrometry is becoming essential for identifying and characterizing the different forms of life and their intimate mechanisms ([1-4]). We applied proteogenomics to study the lifestyle of environmentally relevant marine bacteria belonging to the *Roseobacter* clade. We revealed the different adaptive strategies they have adopted ([5-6]). We recorded large proteomic datasets to better annotate their genomes and proposed a pan re-annotation of the whole clade ([7]). Furthermore, we defined specific biomarkers to screen for new *Roseobacter* isolates on the basis of genomic and proteomic data. As a proof of concept, we sampled Mediterranean Sea water, analyse tens of isolates and could describe new specific bacteria belonging to a given genus ([8]), as well as to a more extended group of bacteria, the *Roseobacter* clade.

Keywords: Bacteria, Analytical methods, Biodiversity, Biotechnologies, Gulf of Lyon

Mass spectrometry is becoming essential for identifying and characterizing the different forms of life present on Earth and their intimate, complex, functional mechanisms. We recently reviewed the different applications of mass spectrometry and proteomic approaches in the field of environmental microbiology ([1], [2], [3]). Profiling approaches by whole-cell MALDI-TOF mass spectrometry or specific biomarker searches are reliable, quick and cost-effective methods for screening for new microorganisms and assessing microbial diversity. Several examples will be given to illustrate the potential of mass spectrometry in environmental microbiology, with specific emphasis on marine proteogenomics. Proteogenomics consists of high-throughput identification and characterization of proteins by extra-large shotgun tandem mass spectrometry approaches and the integration of these data with genomic data ([4], [5]). We compared twelve *Roseobacter* exoproteomes and revealed the different adaptive strategies these marine bacteria have adopted ([6]). We also recorded large proteomic datasets in order to better annotate their genomes and proposed a re-annotation of the whole marine *Roseobacter* clade ([7]).

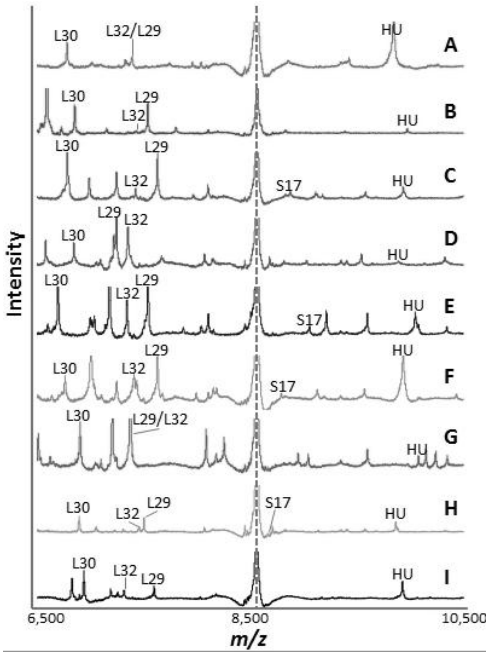

Fig. 1. Whole-cell MALDI-TOF spectra of nine *Roseobacter* representatives. Spectra were acquired on a MALDI-TOF BiflexIV mass spectrometer (Bruker daltonics) . The *m/z* range where the HU, L29, L30, L32, and S17 proteins are detected as monoprotonated ions is shown.

Furthermore, we defined specific biomarkers to screen for new *Roseobacter* isolates on the basis of genomic and proteomic data. Today, the analysis of environmental samples with the whole-cell MALDI-TOF mass spectrometry approach still represents a challenge due to the enormous microbial diversity existing on earth and the lack of a comprehensive database [8]. We defined widely distributed biomarkers for bacteria belonging to the *Roseobacter* clade. Figure 1 shows the highly divergent pattern of biomarkers for nine representative bacteria analyzed by MALDI-TOF mass spectrometry. These nine representatives were : *Oceanicola batsensis* HTCC2597, *Pelagibaca bermudensis* HTCC2601, *Roseobacter denitrificans* OCh114, *Phaeobacter gallaeciensis* 2.10, *Oceanibulbus indolifex* HEL45, *Roseobacter litoralis* OCh149, *Roseobacter* sp. MED193, *Roseovarius nubinhibens* ISM and *Dinoroseobacter shibae* DFL12.We could predict by proteogenomics the exact masses of three relevant biomarkers: HU, L29 and L30 proteins for all the sequenced organisms from the clade. We screened a collection of 93 isolates from water sampled from Mediterranean Sea and grown on marine medium. The three biomarkers resulted in six possible *m/z* (monoprotonated and diprotonated ions) amongst a list of 103 theoretical values. From the systematic MALDI-TOF analysis of these 93 isolates, we could identify and document three new *Roseobacter* strains: a novel representative of the *Phaeobacter* genus, a member of the *Thalassobacter* genus, and another *Ruegeria* strain (unpublished data). The later isolate originated from sea water sampling during a phytoplankton bloom. Due to its simplicity and effectiveness, this technique could be of immense value for monitoring bacteria.

Abstract
The appropriation of Marine Genetic Resources (MGRs) such as natural products or genes derived from marine organisms for medicine, cosmetics, and other industrial uses is growing exponentially. There are ongoing efforts to provide policies for equitable access and benefit sharing to these resources. However, there are a number of unresolved issues, which need to be addressed and which are particularly pressing in the Mediterranean. We propose a common pool of genetic resources for the Mediterranean as a simple and fair mechanism to simplify access and avoid conflicts of interests between the different Mediterranean states.

Keywords: Biodiversity, North-Central Mediterranean

Human appropriation of MGRs has been growing rapidly in the last few decades with over 18,000 [2] natural products and >6000 [1,2] genes of marine organisms associated to patents deposited worldwide. Gene patenting covers all major phyla in the tree of life from prokaryotes to vertebrates and the number of species involved in gene patenting has been growing at a rate of about 12% per year [2]. Yet, access to MGRs is limited by the availability of technological resources as demonstrated by the fact that 90% of the international patent applications belong to only 10 countries [1]. The Convention on Biological Diversity (CBD) and the Nagoya Protocol aim to achieve sustainable and equitable utilization of genetic resources by defining the ownership of genetic resources and thus, making it possible to reach bilateral agreements between the provider country and the users. Despite these efforts, tracing the benefits and the ownership of genetic resources remain challenging due to a lack of a clear mandate to disclose the geographical origin of the source organisms involved in gene patents. Moreover, the distribution of most species spans over different countries, further complicating negotiations between provider countries and final users of genetic resources. While all the caveats listed above are shared by both marine and terrestrial genetic resources worldwide, they are particularly relevant for the marine genetic resources of the Mediterranean. While the CBD defines clearly the ownership of MGRs within the national jurisdictions according to the Law of the Sea, there are significant sources of conflict in a relatively narrow sea like the Mediterranean. There are also significant differences in technological development between Mediterranean countries. The Mediterranean is home to >17,000 species of which a large proportion are endemic species, only occurring the Mediterranean [3]. Yet, these endemic Mediterranean species are shared among different Mediterranean states. Therefore, we propose that access to Mediterranean MGRs should be regulated through a common pool of genetic resources. In this framework, Mediterranean MGRs would be accessed under a common set of rules, thus simplifying access procedures for users and avoiding the conflicts due to MGRs shared by several states and the territorial disputes derived from the implementation of the exclusive economic zones in a such a narrow basin. Moreover, the organization managing this pool of MGRs should help ensuring fair access and benefit sharing for all the Mediterranean states and implement measures for capacity building in those countries less able to exploit their MGRs.

EXPLOITATION DE LA BIOTECHNOLOGIE MARINE PARTAGE JUSTE ET EQUITABLE DES AVANTAGES ET BIOLOGIE DE SYNTHÈSE

Jean-François Bloch [1*]
[1] consultant - jfbloch@ymail.com

Abstract
Les ressources génétiques marines sont de formidables sources pour le développement de nouveaux produits industriels dans de nombreux domaines. Il est déjà difficile de mettre en place des accords permettant un accès et le partage des avantages (APA) de l'exploitation de ces produits. Ce partage des bénéfices va se complexifier avec l'émergence des technologies de biologie synthétique qui n'utiliseront plus la ressource génétique en tant que telle mais uniquement une information dérivée de cette ressource.

Keywords: Biotechnologies, Bacteria, Biodiversity, Economic valuation, Extra-Mediterranean regions

Il ne fait pas de doute que les ressources génétiques marines ont un potentiel considérable d'exploitation commerciale. Les principaux secteurs susceptibles d'utiliser les ressources issues de la biodiversité sont les industries des sciences de la vie, et notamment les secteurs de la santé, de la chimie, de la cosmétique, de l'environnement, de l'alimentaire et de la bioénergie. L''APA découlant de l'exploitation aussi bien à des fins de recherche que commerciales des ressources génétiques marines soulèvent dès à présent de très nombreuses questions difficiles à résoudre.

Pourtant aujourd'hui un nouveau domaine est en pleine émergence: la biologie de synthèse. Si son acceptation sociétale n'est pas encore acquise et nécessitera un dialogue entre la communauté scientifique, les responsables politiques et les citoyens, l'usage de cette dernière est déjà effectif dans les laboratoires. Elle a pour but de concevoir de nouveaux systèmes biologiques en faisant de l'ingénierie rationnelle à partir d'informations. Ces informations peuvent bien sûr provenir de travaux sur des ressources génétiques marines. Selon les méthodes classiques de biotechnologie est extrait un gène spécifique d'un organisme pour être transféré dans un autre organisme, pour produire la protéine associée à ce gène. Avec cette nouvelle biologie la synthèse d'un gène peut se faire par des techniques chimiques ou des méthodes bioinformatiques. Certes la route est toujours longue, difficile et aventureuse pour aller de la prospection de la biodiversité marine jusqu'au produit commercialisé même avec les nouveaux outils de biologie synthétique. Il y aura toujours à chaque étape du développement des intervenants différents ayant des intérêts à la fois complémentaires et divergents. Il faudra encore prendre en compte les problématiques de la propriété industrielle pour l'exploitation commerciale. La mise sur le marché de nouveaux produits est rarement l'œuvre du bio prospecteur seul. L'exploitation actuelle de la biodiversité nécessite de mettre en place des partenariats entre les bio prospecteurs (universités, entreprises privées...) et les structure de R&D (laboratoires publics ou privés). Mais le spécialiste de la biologie de synthèse aura-t-il encore besoin d'une relation directe avec le bio prospecteur puisqu'il n'a plus techniquement besoin que de l'information souvent déjà publiée. L'accès à l'information devient plus important que l'accès aux produits. La bio prospection n'est que la phase amont des programmes qui ambitionnent de développer un produit issu de la biodiversité. L'entreprise du secteur marchand aussi vertueuse soit-elle a pour objectifs un produit ou un processus viables économiquement. Quelle sera alors la valeur réelle de la biodiversité ? Comment mettre en place une traçabilité de la ressource génétique marine dans les processus de création de nouveaux produits et procédés ? Quels seront les nouveaux partenariats pouvant garantir à chacun un juste retour conformément à la convention de la biodiversité? De nouveaux modèles efficients devront être imaginés et réalisés pour atteindre l'objectif d'un partage juste et équitable des avantages issus de l'utilisation de la biodiversité marine, en tenant compte des différents acteurs économiques de la chaîne de valeur et en y intégrant, dès maintenant, ce nouvel outil qu'est la biologie de synthèse. Il sera certainement nécessaire d'imaginer de nouveaux partenariats pouvant garantir à chacun un juste retour conformément à la convention de la biodiversité. Ainsi il faudra élaborer des modèles efficients permettant une juste mise en œuvre de l'APA de l'utilisation de la biodiversité marine pour tous les acteurs en y intégrant dès maintenant ce nouvel outil qu'est la biologie de synthèse.

Abstract

In this report, the study of *Alexandrium catenella* submitted to metallic stress (lead or zinc) was performed by 2D-electrophoresis. Comparisons of reference cultures and contaminated cultures were done in order to detect protein spots of interest, which were identified. The function of these identified proteins allowed us to speculate on the mechanisms by which *A. catenella* manage to survive in metal contaminated environments.

Keywords: Dinoflagellates, Metals, North-Western Mediterranean, Phytoplankton, Pollution

Introduction

The use of proteomics is more and more popular in aquatic toxicology [1]. With this method, the explanation of the stress tolerance could find an answer [2, 3]. Indeed, proteins are the last response of species against biotic or abiotic stress. The dinoflagellate *Alexandrium catenella* is a toxic phytoplankton which can cause harmful algae blooms (HABs). The occurence of these HABs have increased in recent years and could be induced by anthropogenic inputs resulting in eutrophication of the ecosystems [4]. Previously, in a coastal marine ecosystem perturbed by anthropogenic inputs (Bay of Toulon, trace metal contaminants [5]), the prevalence of dinoflagellates [6] and *Alexandrium* blooming [7] were shown. Our aim is to investigate how *Alexandrium* can survive in metal contaminated conditions and cause HABs.

Material and methods

A. catenella strain ACT03 was isolated in 2003 from the Thau lagoon (France, UMR 5119, Université Montpellier 2). Axenic cultures of this strain were maintained on f/2 medium [7], grown at 20°C and 135 µmol photons. m^{-2}. s^{-1} (light: dark cycle 12: 12). The culture medium was supplemented or not (reference) with different quantities of trace metals metal (Pb or Zn). Extraction of soluble and membrane proteins was realized before 2D-electrophoresis. Spots of interest were picked, and proteins were identified by LC-MS/MS (France, Ferme du Moulon, Gif-sur-Yvette).

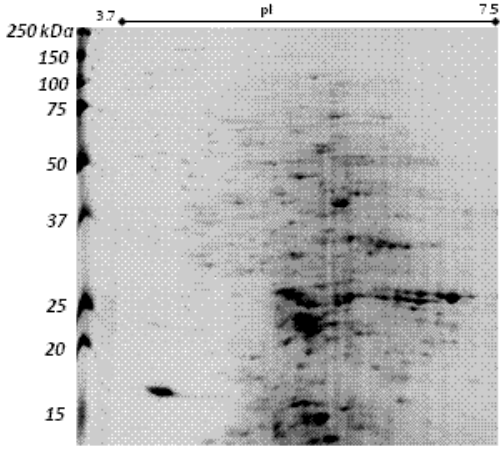

Fig. 1. 2D-electrophoresis map of the soluble proteome from referential *A. catenella* culture

Results and discussion

The proteins were characterized by their appearance/disappearance, or by their overexpression/underexpression, on the protein maps obtained from the *Alexandrium* cultures exposed to trace metals, in comparison to maps obtained for referential cultures. By this way, our objectives were (*i*) to find stress proteins potentially involved in the *Alexandrium* resistance to metal contamination, (*ii*) to understand the role of proteins in the dinoflagellate predominance and in the HAB expansion in marine perturbed ecosystems, (*iii*) to define *Alexandrium* protein markers of metal stresses. On the one hand, an increase in ATP synthesis, but also in the photorespiration, could explain how the toxic *Alexandrium* can survive under metal stresses. This dinoflagellate produced more energy (ATP) and reduced the level of reactive oxygen species (ROS) due to the photorespiration, so, the oxidative stress was decreased. On the other hand, a decrease in photosynthesis was observed. This phenomenon allowed *Alexandrium* to limit the production of ROS, and in the same way, the oxidative stress.

EVIDENCE OF CHRYSOPHSINS IN FARMED EUROPEAN SEA BASS MUCUS REVEALED BY A COMPLEMENTARY LC-ESI-MS AND MALDI-TOF APPROACH

Sonia Fekih-Zaghbib [1]* and Balkiss Bouhaouala-Zahar [2]
[1] INNTA National Institute Nutrition and Food Technology - fekihsonia@gmail.com
[2] Institut Pasteur Tunis

Abstract
Mass spectral profiling of fresh mucus from farmed *Dicentrarchus labrax* using MALDI-TOF and LC-MS spectrometry was carried out to investigate the infective/healthy status. As result, we identified antibacterial peptides (AMP) and three Chrysophsins within the mucus which display broad-spectrum bactericidal activity against Gram-negative and Gram-positive bacteria (MICs < 0.5 μM). Furthermore, sensitivity to yeast *Candida albicans* was shown by means of interesting MICs of less than 2 μM. We also demonstrated that the fish pathogen *Aeromonas salmonocida* is sensitive to Chrysophsins (MICs ranging between 5 and 14 μM). Our data provides evidence that Chrysophsins are secreted by immune cells, released in mucus of non-challenged farmed European sea bass and are therefore important widespread components of Teleostei defense against disease.

Keywords: Mediterranean Ridge, Analytical methods

Introduction Understanding the biological–ecological variables that modulate host–pathogen interactions is essential for a proper conservation and management of marine and fisheries resources [1]. The most important interaction is the acquisition of immunity after exposure to the pathogen in cultured and wild fish populations [2]. Fish epidermal mucus, one of the main components of innate immunity, is considered as the first immune barrier [3]. AMPs isolated from skins and gills of teleosts are cationic and amphipathic peptides displaying antimicrobial activities [4]. Most of them are structurally belonging to linear α-helical peptide group and members of the Piscidin family [5-8]. Indeed, recent studies demonstrated the widespread tissue distribution of that Piscidin and Piscidin-like AMPs suggesting their pivotal play in the nonspecific immune defense of teleost [9]. However, corresponding AMPs released from mucus have not been further investigated until now. This prompted us to investigate the mucus secreted antimicrobial peptides in non-challenged farmed sea bass fish in Tunisia coast.

Material and Methods A Maldi-Tof molecular mass mapping of pre-purified mucus is carried out on mucus samples of healthy *Dicentrarchus labrax* collected from a brackish 1,000-ha lagoon tunisian aquaculture station located in the open Bay of Hergla. Three peptides fractions selected by ESI-MS analysis were purified by HPLC and MICs of purified peptides were determined using our validate Hancock broth dilution assay [10]. ESI-MS primary sequence elucidation of purified antimicrobial peptides is submitted to the MS-Tag database search program of the Protein Prospector proteomics server (http://prospector.ucsf.edu). A Swiss Prot Database search confirmed the peptide identity.

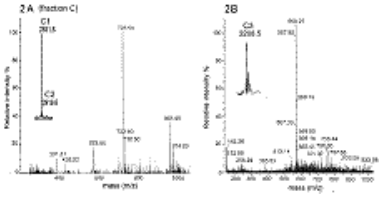

Fig. 1. **LCMS-IT and MALDI-TOF profiles of purified peptides C1, C2 and C3.** 2A, ESI-MS spectrum of fraction C; The inset shows the MALDI-TOF profile of C fraction with C1 and C2 peaks. 2B, ESI-MS spectrum of fraction C3; The inset shows the MALDI-TOF profile of peak C3.

Results and discussion Using MALDI-TOF and LC-ESI-MS analysis of eluted mucus fraction from a Vydac C4 column at 33-35% acetonitrile, we identified three peptides present in moderately high abundance with masses in the expected fitting values to Chrysophsins. We used peptide sequence tag query to confirm results obtained by manual peptide mass fingerprint analysis. Therefore, Chrysophsins1, 2 and 3 highly cationic and known Piscidin-like peptides of respectively, 25, 25, and 20 amino acids have been identified. Their common C-terminal RRRH sequence is most likely related to the strongly bactericidal and hemolytic activity of those AMPs [7]. Human tested pathogens, (i.e. *E. coli* and *S. aureus*) were found to be more susceptible to the mucus expressed AMPs than fish pathogen (i.e. *Aeromonas salmonocida*) which was sensitive to less than 15 μM. Direct estimation by MS tools of comparative AMP levels expression in mucus may throw light on the antimicrobial peptide functions in relation with the immune response in aquaculture conditions. Our data demonstrated that Chrysophsins are effective component closely associated to healthy farmed European sea bass. Our approach based on mucus MALDI-TOF followed by LC-ESI-MS analysis for exploring AMP proteome is helpfulness and highlights the MS approach to address an efficient analysis of anti-infective status within the mucus of perciforms.

THE MICRO B3 PROJECT: MARINE MICROBIAL BIODIVERSITY, BIOINFORMATICS, BIOTECHNOLOGY & THE OCEAN SAMPLING DAY INITIATIVE

F. O. Glöckner [1]*, A. Klindworth [2], R. Kottmann [2], M. Bicak [3], D. Field [3] and -. the Micro B3 Consortium [4]
[1] Jacobs University Bremen - fog@mpi-bremen.de
[2] Max Planck Institute Bremen
[3] University Oxford
[4] contact@microb3.eu

Abstract
The EU project Micro B3 which stands for marine, microbial biodiversity, bioinformatics and biotechnology started on January 1st, 2012. Its main goal is to make the vast amount of data from marine microbial research available for better environmental modeling and innovative biotechnological applications. The Micro B3 project is financed by an EU "Ocean of Tomorrow Grant" with a total of €9 million for a period of four years. 32 partner institutions from 14 countries participate in the project, which unites leading experts from eight disciplines. Central to the project is the creation of an integrative database and the development of a legal framework for genome-based environmental research as well as to coordinate a global, orchestrated site-based and fixed-in-time sampling effort - the Ocean Sampling Day.

Keywords: Biodiversity, Biotechnologies, Bacteria, North-Central Mediterranean

Introduction
The integrated research project Micro B3 (Biodiversity, Bioinformatics, Biotechnology, www.microb3.eu) brings together teams of experts in bioinformatics, computer science, biology, ecology, oceanography, bioprospecting, biotechnology, ethics and law. The consortium's main aims are to merge the existing bodies of expertise in ecosystems biology, the processing and interpretation of data, modelling and prediction, and the development of intellectual property agreements for the exploitation of high potential commercial applications. At its core, Micro B3 aims to develop an innovative, transparent and user friendly open-access system, which will allow seamless processing, integration, visualisation and accessibility of the huge amount of data collected in ongoing sampling campaigns and long-term observations. This will, in turn, offer new perspectives for the modelling and exploration of marine microbial communities for biotechnological applications (Teeling and Glöckner 2012).

Fig. 1. The Micro B3 Logo and Keywords

Ocean Sampling Day
A key boost to Micro B3 will be provided by the Ocean Sampling Day (OSD, www.oceansamplingday.org), scheduled to take place on the summer solstice, 21 June 2014. OSD will run worldwide, with pilots conducted in 2012 and 2013 to establish standardized sampling techniques.
Recent developments in sequencing technology make sequencing of whole microbial communities from the environment a widely used and affordable routine task. Consequently, large scale sampling and sequencing efforts such as the Global Ocean Sampling (GOS) Campaign, the Malaspina Cruise and the Tara Oceans Expeditions are now exploring marine ecosystems in space and time. In contrast to these circumnavigations, no orchestrated site-based and fixed-in-time sampling effort has been initiated so far. Micro B3 is now taking action to organise the Ocean Sampling Day. **The OSD is open to any interested lab across Europe and beyond.** The resulting cumulative samples, fixed in time and space supplemented with a broad set of geo-referenced environmental parameters, will contribute to determine a baseline of marine biodiversity and functions at the molecular level. To ensure maximum usefulness of these samples, sampling and data analysis will be done across all sites using agreed upon best practices developed within Micro B3. Herewith, a high level of consistency between data points across Europe and beyond is ensured. In particular all sites will be expected to comply to the MIxS minimum information checklists of the Genomic Standards Consortium (GSC, www.gensc.org) (Yilmaz et al. 2011).

Fig. 2. The Ocean Sampling Day Logo

The Mediterranean Sea
A region of special interest for OSD is the Mediterranean Sea. Its unique geographical and political position in the heart of Europe, the diversity of habitats as well as the dense set of all kinds of geological, oceanographic and environmental data render it a prime target for OSD. A close collaboration with the Mediterranean Science Commission (CIESM) has been established to foster the implementation of OSD-Med as part of Micro B3's global OSD. If you are interested in participating, please send an e-mail to osd-contact@microb3.eu.

Summary and Outlook
Micro B3 with its OSD initiative is set to significantly improve Europe's capacity for bioinformatics and marine microbial data integration, to the benefit of a variety of disciplines in bioscience, technology, computing, standardisation and law. We expect that the integrated data will provide a reference dataset for generations of experimentalists to come. It should further function as a starting point for site-based monitoring of microbial communities as proposed by the Genomic Observatories initiative (www.genomicobservatories.org, Davies et al. 2012).
Micro B3 is financially supported by the FP7 Ocean of Tomorrow Grant #287589.

COMPARATIVE GENOMICS OF AROMATIC COMPOUNDS DEGRADATION PATHWAYS IN THE MARINE ROSEOBACTER CLADE

B. Nogales [1]*, C. Alejandro-Marín [1], J. Piña-Villalonga [1], M. Mas-Lladó [1], I. Brunet-Galmés [1] and R. Bosch [1]
[1] University of the Balearic Islands Dept. Biology - bnogales@uib.es

Abstract
Members of the Roseobacter clade predominate in marine environments chronically polluted with hydrocarbons. Genomic analyses shows that these bacteria might possess up to six pathways for aromatic hydrocarbon degradation. Our hypothesis is that bacteria of the Roseobacter clade have genetic structures and strategies for degrading and tolerating hydrocarbons that are different from those of the well-known marine hydrocarbon degraders, and that these differences might underlay their predominance in chronically-polluted marine environments. We have analysed gene organization for aromatic hydrocarbon degradation pathways in all available genomes from the Roseobacter clade. We present here the results for the beta-ketoadipate pathway, the one most frequently found in Roseobacter genomes

Keywords: Bacteria, Petroleum, Balearic Islands

The Roseobacter clade is a key component of marine bacterioplankton (Buchan *et al*., 2005), and plays key roles in biogeochemical cycles. They are generalist and metabolically versatile, with a suite of mechanisms for energy production and carbon acquisition that include aerobic anoxygenic phototrophy, litotrophy (carbon monoxide and sulfide oxidation), anaplerotic carbon dioxide fixation and chemoorganotrophy. Marine roseobacters are readily cultured in the laboratory and consequently there are more than sixty genera described. As a result, and due to their ecological interest, they have been the subject of many genome sequencing projects (there are about forty-three genome sequences, complete or as draft available so far). Comparative genomic analyses of members of the clade have been published (Moran *et al*., 2007; Newton *et al*., 2010).

Degradation of aromatic compounds by marine roseobacters was reported in year 2000, with the isolation of strains able to degrade aromatic compounds resulting from lignin degradation, and the confirmation of the presence of the protocatechuate branch of the beta-ketoadipate pathway in these bacteria (Buchan *et al*., 2000, 2004). More recently, genome analysis has revealed that marine roseobacters possess up to six catabolic routes for monoaromatic compound degradation, namely pathways for: benzoate, gentisate, homoprotocatechuate, phenylacetate, homogentisate, and protocatechuate (Moran *et al*., 2007; Newton *et al*., 2010). This has led to proposing a potential role for these bacteria in aromatic hydrocarbon degradation in marine environments. In addition, there are accumulating evidences showing a positive response of roseobacters after treatment with hydrocarbons in the laboratory (McKew *et al*., 2007; Lanfranconi *et al*., 2010), and their predominance of chronically-polluted environments (Nogales *et al*., 2007).

We are analyzing the catabolic potential for hydrocarbon degradation by isolates from the roseobacter clade obtained in Mallorca Island. As part of our research we are interested in analyzing genetic structures of aromatic compound degradation pathways in marine roseobacters, and therefore we are performing comparative genome analysis. We followed two different approaches. Firstly, we searched the available genomes for determining the presence of all genes involved in the six routes for aromatic hydrocarbon degradation proposed in marine roseobacters. We started with the protocachuate branch of the beta-ketoadipate pathway, which is the pathway most commonly found in these genomes (Newton *et al*., 2010). The key genes *pcaH* and *pcaG*, encoding the two subunits of protocatechuate 3,4 dioxygenase, were found in 70% of the genomes analyzed. In all but one of these genomes, the *pobA* gene for degradation of p-hydroxybenzoate, the precursor of protocatechuate, was also found. In most cases, *pobA* gene was located next to *pca* gene cluster and apparently under a common regulatory control, although this should be confirmed experimentally. Many differences in *pca* gene content and order were observed, but a basic structure of genes *pca(DC)HG* was observed. The presence of the LysR-like regulatory protein (PcaQ), and a hypothetical chaperone protein (Chp) was predicted in sixty percent of the roseobacter genomes analysed, confirming the proposed relevance of this regulatory mechanism of the protocatechuate pathway, as well as the importance of this putative uncharacterized chaperone in marine roseobacters (Buchan *et al*., 2004). Our second approach has been the generation of novel genomic data from a collection of seventeen roseobacters obtained from chronically-polluted environments in Mallorca Islands. As first approach, and with the aim of maximizing the exploration of the diversity of catabolic genes in these genomes, we grouped the isolates in four phylogenetically-coherent groups before pyrosequencing (Roche 454 technology). We analyzed the presence of genes for each one of the six predicted catabolic pathways in marine roseobacters. The genomic groups differed in the number of catabolic pathways that we could predict: one in group 3, three in group 4, 5 in group 2 and 6 in group 1. Genes for the protocatechuate pathway were present in all genomic groups. Except for group 2, these results agreed with the results of cultivation experiments, showing that the majority of the isolates were able to grow on protocatechuate as sole carbon and energy source.

Acknowledgments: Funds were obtained from Spanish MINECO project CTM2011-24886, and funds for competitive groups from the Government of the Balearic Islands (both with FEDER co-funding). THE COMPARISON OF THE LEVEL OF METABOLICALLY ACTIVE BACTERIA IN THE NORTHERN AEGEAN SEA AND THE SEA OF MARMARA, TURKEY.

Gulsen Altug [1]*, Mine Cardak [2] and Pelin S. Ciftci Turetken [1]
[1] Istanbul University Fisheries Faculty Department of Marine Biology - galtug@istanbul.edu.tr
[2] Canakkale 18 Mart University

Abstract
In this study the ratio of capsulated bacteria to the total number of bacteria in the surface water samples were investigated in order to determine the number of metabolically active bacteria. The percentages of metabolically active bacteria were compared for the first time in the sea water samples which were taken from northern part of the Aegean Sea and southern part of the Sea of Marmara, Turkey.

Keywords: Bacteria, Marmara Sea, Aegean Sea

Introduction
Metabolically active bacteria have a well-developed polysaccharide capsule whereas inactive bacteria rapidly release the capsule. (the term "capsulated bacteria was used in reference to "capsule bearing bacteria"). Active bacteria constantly renewing their capsular envelope and release a significant fraction of the polysaccharide layer into the ambient water (Stoderegger and Hendl 2001).
The Aegean Sea and the Sea of Marmara, Turkey which have different hydrodynamic and trophic characteristics were compared regarding the level of metabolically active bacteria. Metabolically active bacteria level can defect regarding the contribution of capsulated bacteria count to the total number of bacterioplankton community. In this study the level of metabolically active bacteria were investigated in the sea water samples were taken from northern part of the Aegean Sea and southern part of the Sea of Marmara.

Material and Method
The 105 unit sea water samples were taken from various depths ranging from 0-30 cm in the 9 stations from Northern part of the Aegean Sea northern part of the Aegean Sea. The 60 unit sea water samples were collected from various depths ranging from 0-30 cm to 50 m in the 11 stations from southern part of the Sea of Marmara in 2006 and 2007 (Figure 1). Capsulated and non capsulated bacteria were discriminated using principally the same method as Stoderegger and Herndl 2001 [1], modified of Plante and Shriver (1998) [2] staining method.

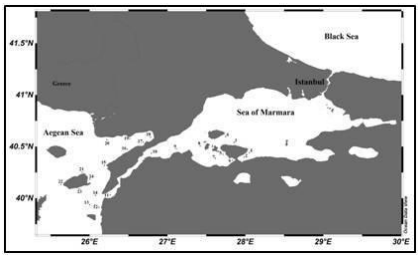

Fig. 1. Study Area

Resuls and Discussion
Contribution of capsulated bacteria to the total number of bacteria in the water samples was shown in Table 1.The highest metabolically active bacteria level was recorded in inner part of the Bandirma Bay (station 2) in the Sea of Marmara. According to the sampling area, bacterial activity level was recorded higher in the samples that were taken from the surface than other samples that were taken deeper. Metabolically active bacteria level were found higher in the eutrophic parts of the Sea of Marmara than the nothern part of the Aegean Sea.

Tab. 1. Level of Metabolically Active Bacteria %

Abstract
Given that various infections can be caused by the contact with the sand beach and sea water, our study has been focused on identifying other pathogenic bacteria species, in parallel with fecal coliforms and fecal streptococci from Mamaia beach. Knowing the existence of other potentially pathogenic bacteria species found in the sand beach and sea water, is needed for the future enlargement of the conventional indicators list of beaches pollution. Our epidemiological data suggest that global bacteriological monitoring of the sea water and sand beach quality offers a better protection for the people who uses this recreational beaches.

Keywords: Pollution, Bacteria, Black Sea

Introduction
Recreational use of marine waters is increasing in many countries. It is widely accepted that water and sand beaches with high indexes of fecal contamination can be potential sources of contamination and contribute to the dissemination of bacterial resistance. Our study was based on analytic control of bacteria contamination in the sands and sea water samples collected from Mamaia beach by using conventional indicator standards, in parallel with other potential pathogens bacteria species.

Material and methods
Dry sand, wet sand and sea water samples were collected from three different areas of the Mamaia beach (from both ends and from the central part of the beach) between 1 January and 30 December 2012. Each sand sample consisted of 100 g of surface sand that was collected at a maximum depth of 2 cm using sterile bottle and spatula. Each sea water sample consisted of 100 mL sea water collected in sterile bottle that was analyzed according to standard filtered membrane method. Bacteria species were isolated, after their initial growth in plates with differential media (CLED, McConkey, Bile Esculin Azide Agar) and identified by using the following biochemical tests: API20 Staph, API20 Strep - bioMérieux, Rapid ID NF Plus for non-fermentative bacteria, Rapid ID ONE - Remel, for fermentative bacteria. The data were statistically analized by using SPSS 17. The correlations were considered significant for p-value <0.05.

Results and discussion
A total of 560 bacteria species were present in the samples. From quantitative point of view, total coliforms isolated in the sea water had normal concentration (< 100 CFU/mL) in all samples harvested from Mamaia beach [1], except the ones obtained from the area near the site of communication with Tabacarie lake, where higher proportion of fecal coliforms flora (sea water - 160 CFU/mL; dry and wet sand - 350 CFU/g) were identified. The most frequent bacteria species identified in all three types of examined samples are presented in Table 1.

Tab. 1. Bacteria species identified in sand and sea water on Mamaia beach

Samples		Dry sand		Wet sand		Sea Water		Total
		Value	%	Value	%	Value	%	Value
Bacteria Species	*Escherichia coli*	60	34,7	77	44,5	36	20,8	173
	Proteus Sp.	10	26,3	12	31,6	16	42,1	38
	Klebsiella Sp.	10	31,3	12	37,5	10	31,3	32
	Pseudomonas Sp.	2	22,2	2	22,2	5	55,6	9
	Enterobacter	4	13,3	6	20,0	20	66,7	30
	Citrobacter	2	11,1	8	44,4	8	44,4	18
	Serratia Sp.	5	15,2	10	30,3	18	54,5	33
	Enteroccocus Sp.	32	40,0	28	35,0	20	25,0	80
	Staphylococcus aureus	43	29,3	51	34,7	53	36,1	147

A high correlation was found between *E. coli* from the sand (wet and dry) and adjacent sea water (Chi square test; p<0.0001) [2]. In the same time, there is a high correlation between the presence of *E. coli* and *Staphylococcus aureus* identified in wet sand and sea water (p=0.006) and in dry sand and sea water (p=0.01). Also, higher contamination for all three types of samples, collected in the summer compared to those collected in the winter, demonstrates that the human contamination is an important source of bacterial pollution for the beach [2], [3]. The presence of *Staphylococcus aureus* in the dry and wet sand is the proof of mainly human contamination. In this order, identifying this bacteria species on the beaches is needed in the future, because it could prevent possible contamination with methicillin-resistant *Staphylococcus aureus* and the possible transformation of public beaches in an environmental reservoir of this bacteria species [4]. The idea of introduction of the alternative indicators for the evaluation of the bacteriological pollution of the beaches is sustained in the world also by other authors [5].

Conclusions
Knowing the level of contamination of sea water and sand beaches allows us to implement the necessary specific prevention measures against the diseases generated by the use of contaminated sand and sea water of the costal area. Identification on the beach sand and sea water of other potentially pathogenic bacteria species makes it necessary that for the future to extend the list of conventional indicators with the alternative indicators.

Abstract

In present study, we assessed the effect of sediment characteristics (particle grain size and organic matter contents) on waterborne pathogen bacteria survival. The survival test was conducted *in vitro* in microcosms where the two pathogen species *Escherichia coli* (O55B5) and *Vibrio parahaemolyticus* (ATCC 17802) were separately incubated on lagoon sediments and brackish water brought from different coastal areas of Bizerte lagoon (Northern Tunisia).. The results obtained revealed (1) extended bacterial survival in sediments, (2) higher growth and lower decay rates of the two strains in sediments with high levels of organic matter and small grain size sediment, and (3) longer survival of *Vibrio paraheamolyticus* compared with *Escherichia coli*.

Keywords: Bacteria, Sediments, Organic matter, Mediterranean Ridge

Introduction:

Extended persistence of waterborne pathogen bacteria in coastal sediments and their potential remobilization during natural turbulence may induce an increased risk of human infections [1]. In aquatic ecosystems the sediments represent the main reservoir for almost heterotrophic bacteria due to high levels in nutrients and organic matter combined with different grain size that should influence microbial populations and their persistence [2] [3] [4]. Pathogen bacterial survival in sediments and their possible re-suspension constitute high threat of pollution with human or animal risk during recreational or faming activities principally in coastal shoreline [5]. The present study highlight the influence of coastal sediments on the survival of two waterborne pathogen species of bacteria: *Escherichia coli* and *Vibrio parahaemolyticus* assessed *in vitro* experiments using microcosms filled with three types of coastal sediments from Bizerte lagoon in Tunisia.

Material and Methods:

Microcosms consisted of Erlenmeyer flasks of 500ml and filled with sterilized sediment (200g, wet weight) collected from three different coastal stations, located in front of discharge areas in Bizerte lagoon. All microcosms were then filled with brackish water (300ml) inoculated separately with *Escherichia coli* enteroagregative and *Vibrio parahaemolyticus* strains (three microcosms for each species of bacteria for final concentration of 10^7cfu/ml). Three Microcosms filled each with one type of sterile sediment and brackish water were used as negative control. Suitable dissolved oxygen was provided for each microcosm carefully without disturbing the upper layer of sediment using aquarium air pumps. All microcosms were kept in dark at a temperature of 20±2°C. During experimentation, microcosm sediments were sampled for bacterial analysis (culturable and total cells count). Bacteria were detached from sediments aliquots by vigorous shaking for 120 s [6] and *E.coli* were selected on DL agar (incubated at 37°C after 24h) whereas. *Vibrio* were selected on TCBS agar (at 22°C for 24 h).. The total cells number (TC) were counted using the DAPI (4', 6-diamide-2-phenylindole-Sigma).

Results and discussion:

Sediments characteristics including particle grain size and organic matter and nutrient contents were measured at the beginning and the end of the experimentation. Sediments varied with a proportion of 81% of sand (>63µm) for sediment S1 to approximately 53% and 37% for S2 and S3 respectively. The results demonstrated that organic matter decreased during experimentation and bacterial concentration (10^7cfu/g) remained quite constant during the first ten days of the experiment for the two species of bacteria. Extended bacterial survival in sediment may be attributed to the greater content of organic matter provided than in seawater [2] [4]. The present results suggest that indicator and pathogen bacteria released into the coastal environment should accumulate in sediment, leading to increased persistence and therefore, their survival may induce an increased risk of human infection due to the re-suspension and release of these pathogens during natural turbulence.

Abstract

The influence of temperature salinity and starvation on the occurrence of *Salmonella typhimurium* was investigated using laboratory (C52) and a local (H_{10}) *Salmonella* strains incubated in marine water microcosms and exposed to natural sunlight (48h). Monitoring of growth and survival in microcosms showed a gradual decline in cultivability, respiratory and metabolic activities. For both strains we noted some biochemical and antimicrobial modifications. The virulence of Salmonella was maintained during seawater incubation for the two strains.

Keywords: Bacteria, Salinity, Brackish water, Mediterranean Ridge

Introduction:

Salmonella enteritidis ser. Typhimurium is common etiologic agents of intestinal-based disease of animals and humans. Pathogenic microorganism such *Salmonella* are released directly or through wastewater to coastal areas [1]. Factors affecting the survival of allochthonous bacteria in marine environment include predation, osmotic stress, solar radiation, nutrient availability, bacteriophage, algae, and temperature [2, 3, 4]. Under unfavorable environmental conditions, *Salmonella* as other bacteria may react by modification of their physiological and structural characteristics and have a survival strategy, entering a viable but not culturable (VBNC) state [5, 6].

Material and methods:

Salmonella enteritidis ser. Typhimurium C52 and wild strain isolated from clams (H10) cells were collected by centrifugation (3000 rpm/15 min) and washed twice. Strains were inoculated in sterile and filtered (0.2µm pore size membrane,Nucleopre) seawater microcosms (final concentration 10^6 cfu/mL). Microcosms were placed "*in situ*" in sea water under environmental conditions (sunlight, temperature) during 48 hours. The total number of cells (TC) and the altered cells (AC) were counted by using respectively the DAPI (4', 6-diamide-2-phenylindole- Sigma) and the Live/Dead® *Bac*Light™ kit. The respiratory (CTC) and metabolic activity (DVC) was performed during the experiment. The effect of sunlight on the virulence of Salmonella was studied using cytotoxicity test [7] and amplification of Pathogenicity Island.

Results and discussion:

The results of the evolution of cultivability and physiological states of *Salmonella typhimurium* C52 incubated in marine water microcosms (Fig.1) demonstrated that cellular activities, respiratory and metabolic activities decrease rapidly during the first 7 hours for the C52 strain (8.86%, 16.06% and 30.30% respectively). The H_{10} evolution during the first 7 hours is similar for the cultivability, but the percentage of respiratory (34.81%) and metabolic activities (50.58%) are largest than the C52 one. Whereas the rate of total cell count remains stable for the two strains.Results of the virulence test revealed the presence of two bands Hli and Hin, involved in the control system of variation phase in *Salmonella* strains and respectively amplify a region of 236 pb and 173 pb. One of these two bands is sufficient to detect *Salmonella* spp.

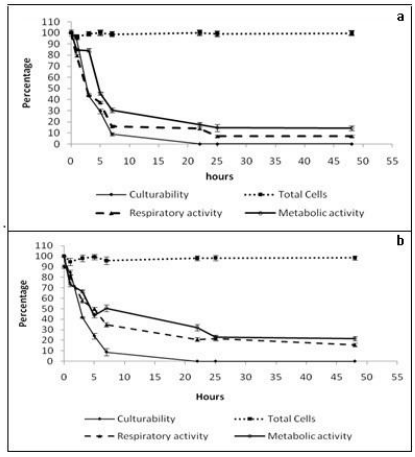

Fig. 1. Evolution of cellular activity of a *Salmonella typhimurium C52* (a) *and Salmonella* H_{10} (b) incubated in marine water microcosms

Abstract
Les résultats ont montré que les charges des différentes populations bactériennes testées dans l'échantillon de mulet frais sont réduites après les procédés de fumage de 0,5 à 2,5 ULog. Durant la conservation, les bactéries lactiques inhibées après le fumage à chaud, n'ont pas été détectées durant la conservation, par contre elles ont montré une prolifération de 1,5 ULog dans le cas du fumage à froid. La prolifération des staphylocoques durant la conservation est ralentie pour les filets de poisson fumés à chaud. Par contre, une importante prolifération des coliformes totaux (> 3ULog) a été notée tout procédé confondus.

Keywords: Bacteria, Biotechnologies, Fishes, Tunisian Plateau

Les filets de poissons sont répartis en deux lots. L'un subit un fumage à chaud à 75°C et l'autre un fumage à froid à 30°C. Une analyse bactériologique hebdomadaire a été réalisée par le dénombrement des populations des bactéries lactiques, coliformes totaux, staphylocoques, la charge mésophile totale et les bactéries lactiques sur les milieux de cultures sélectifs gélosés de Man, Rogosa et Sharpe (MRS) [1], Violet Red Bile Glucose (VRBG) [2], Chapman au mannitol et Tryptone Soja (TSA) [3] respectivement. Le dénombrement est réalisé par la méthode de Plate Counting Agar. La charge mésophile totale évolue progressivement au cours du stockage figure (1 et 2). Cependant, la croissance ne dépasse pas la limite inférieur « m » du plan d'échantillonnage à trois classes [4] ainsi les différentes pratiques de fabrication sont jugées satisfaisantes pour le fumage à froid. Tandis que, pour le fumage à chaud à partir de la deuxième semaine de stockage la concentration dépasse la valeur de « m » mais tout en restant inférieur à la valeur supérieur « M », le produit est alors jugé acceptable.Les résultats du dénombrement des bactéries lactiques présentes dans les différents échantillons montrent que le fumage à chaud provoque la destruction totale de la charge initiale en bactéries lactiques qui demeurent absentes dans les étapes suivantes du suivi. Cependant, le fumage à froid ne donne pas les mêmes résultats, mais plutôt une réduction de la charge en bactéries lactiques d'une moyenne de 0,5 ULog et un développement de la croissance à partir de la première semaine de stockage qui traduit la mise en place du processus d'altération. Le procédé de fumage a permis la réduction de la teneur en coliformes totaux d'une moyenne de 1,5 ULog. Les produits fumés à froid obtenus sont jugés satisfaisants, ce n'est qu'à partir de la deuxième semaine que la teneur de coliformes totaux dépasse la valeur inférieur « m » du plan d'échantillonnage à trois classes [4]. Pour les produits fumés à chaud la valeur de « m » spécifique à ce type de denrée alimentaire n'est dépassée qu'à partir de la troisième semaine.La population de staphylocoques présente initialement dans la chaire du poisson cru a été réduite d'une moyenne de 1,16 ULog pour le fumage à chaud et de 0,25 ULog pour le fumage à froid. L'augmentation de la température a permis lors du fumage à chaud une meilleure neutralisation des staphylocoques. Ainsi, lors du stockage la concentration de ces dernières, demeure inférieure à la limite inférieur « m » du plan d'échantillonnage à trois classes [4] et le produit est alors dit satisfaisant. Ce n'est pas le cas des échantillons de poisson fumé à froid, dont la concentration en staphylocoques dépasse la limite « m » d'une manière croissante tout au long du stockage. Le produit est alors dit « acceptable ».

Abstract
In this study indicated that diversity of culturable heterotrophic aerobic bacteria with respect to the areas from which they were isolated were compared in the eastern Mediterranean, northern part of the Aegean Sea and the Sea of Marmara. Three marine areas which have different trophic was compared regarding diversities bacteria. The composition of culturable hetetrophic aerobic bacteria was investigated in sea water samples collected different time periods throughout 2002-2010 Forty-five bacteria species belonging to 18 families are reported in this study as the first records for the Sea of Marmara, Eastern Mediterranean..

Keywords: Bacteria, Marmara Sea, Biodiversity, South-Eastern Mediterranean

Introduction
There is a need for international long term monitoring bacterial abundance and quantitative bacteria composition and also understanding ecological roles of the most abundant species. The most active group with respect to substance cycling is aerobic heterotrophic bacteria (AHB) at the euphotic zone in the marine ecosystem (1).Bacterial composition may differ according to their exposure to environmental factors in the areas from which they are isolated (2). Although the Sea of Marmara is an important basin between the Mediterranean and the Black Sea, data concerning bacterial composition for an understanding of ecological roles of the most abundant bacterial species are still scant in the area. In t his study, the composition of culturable heterotrophic bacteria was investigated in the Sea of Marmara, Southern Mediterranean and Northern Aegean Sea.This paper also reports species of culturable heterotrophic aerobic bacteria as new records for the Sea of Marmara.

Materials and Methods
Sea water samples were collected from Beirut (Lebanon), Lattakia (Syria) and the off shore area extending from the eastern part of Andros Island to the southern part of Gökçeada and Thasos Island during the months of August in 2007 and 2008 and also different time periods between 2002 and 2010 from the Sea of Marmara (Fig. 1).
.

Fig. 1. Study Area:Eastern Mediterranean,Aegean offshore area extending from the eastern part of Andros Island to the southern part of Gökceada and Thasos Island and Sea of Marmara.

The samples were transferred into 250-mL sterile brown glass bottles under aseptic conditions and processed on board the Istanbul University research vessel YUNUS-S.Identification analyses of bacterial strains were obtained using VITEC 2 Compact 30 (bioMérieux,France) automic micro identification system and HPC analyses were using spread plate method with Marine Agar were carried out (3).

Results and Discussion
This study increases the knowledge of composition and biochemical response of bacteria isolated from eutrophic and oligotrophic areas. 45 bacteria species belonging to 18 families are reported in this study as the first records for the sea of Marmara (Fig.2).

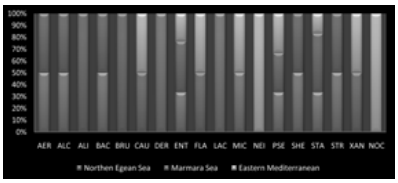

Fig. 2. There percentage distributions of the heterotropic aerobic bacteria family according to their isolate areas. AER:Aeromonadaceae, ALC:Alcaligenaceae, ALI:Alicyclobacillaceae, BAC:Bacillaceae, BRU: Brucellaceae, CAU:Caulobacteraceae, DER:Dermacoccaceae,ENT: Enterobacteriaceae, FLA:Flavobacteriaceae, LAC:Lactobacillaceae, MIC:Micrococcaceae, NEI:Neisseriaceae, PSE:Pseudomonadaceae, SHE:Shewanellaceae, STA:Staphylococcaceae, STR:Streptococcaceae, XAN:Xanthomonadaceae, NOC:Noctuoidea

The highest hetetrophic aerobic bacteria abundance was found in the coastal stations. This situation was evaluated to be a result of anthropological pollution input in the coastal areas. Species belonging to *Enterobacteriaceae* family was the most common taxonomic group in the Sea of Marmara, Northern Aegean Sea, Syria and Lebanon. Flavobacteriaceae family was the second most common group. Among all the strains, percentage of the Gram - bacteria in the coastal areas and the offshore area were 90 % and 2%,respectively. This situation suggests that those particular species have potential importance in organic matter turnover in these areas(2).Although these bacteria had not previously been reported from these areas, they may be ubiquitous in aquatic environments. The bacteria which were isolated from various marine environments have shown different compositions. There is a need for international long term monitoring studies for the purpose of detecting bacterial composition and their ecological roles in these areas.This study is intended to be first detailed description of the diversity of bacteria comparison of two different marine environments in order to put for the situation of the ecosystem as it is today.

Abstract
Epiphytic bacteria from red alga *Jania rubens* and brown one *Padina pavonica*, were isolated and identified. A total of thirty seven different bacterial strains were isolated on pure culture, nineteen from *J. rubens* surface and eighteen from *P. pavonica*. Isolates were identified based on their 16S rDNA sequences. *Proteobacteria and Firmicutes* groups were represented on both algae surfaces However, *Bacteroidetes* phylum was only isolated from *J. rubens* contrary to *Actinobacteria* phylum, which was only represented on *P. pavonica* surface These results highlighted differences observed for the two algae isolates communities.

Keywords: Algae, Bacteria, Biodiversity, Gulf of Tunis

Introduction Seaweeds have long been shown to support abundant populations of bacteria [1]. Previous investigations suggested beneficial relationship between algae and their epiphytic bacteria, which may play a protective role, releasing compounds into the surrounding seawater preventing extensive fouling and helping algae to develop properly. Thus, several species of seaweed from various parts of the world have been shown to live with close associated heterotrophic epiphytic bacteria [2]. Nevertheless, for most marine algae little is still known about microbial populations colonizing their surfaces [3] and specificity related to special microenvironments on their surfaces [4]. As, red alga *Jania rubens* and brown one *Padina pavonica* are abundantly present along Tunisian coast, especially at the northern Cap Zebib rocky shore, we have been interested through the present study to assess culturable bacterial populations associated to their surfaces in order to determine bacterial diversity and compare results obtained for the two algae.

Materials and methods *Sampling and Isolation of epiphytic bacteria: J. rubens* and *P. pavonica* were collected in 2007 from Cap Zebib (37° 16.2' N, 10° 3.6' E) (Northern coast of Tunisia). All samples were transferred, in dark, in sterile plastic bags filled with water brought from the same location. Seaweed samples were washed three times with autoclaved seawater to remove free living and loosely associated bacteria [5].Isolation of epiphytic bacteria was done as described in our previous work [6]. Extraction of DNA, PCR and DNA Sequencing are described in our previous work [6], universal 16S rRNA gene primers B8F and U1492R were used for PCR. Partial sequences of 16S rRNA genes from *J. rubens* epiphytic bacterial communities, coded (J1-J19), were submitted to GenBank and have accession numbers: (JN391160) to (JN391178). Those from *P. pavonica* epiphytic bacterial communities have the following accession numbers: P1-P8 (FN652906-FN652913), P9 (FR695065), P11 (FR695066), P12 (FR695067), P14 (FR695068), P17 (FR695069), P18 (FR695072), P19 (FR695074), P20 (FR695070), P26 (FR695071) and P27 (FR695073).

Results and discussion A total of 37 morphologically different bacteria were obtained in pure cultures with 19 from *J. rubens* and 18 from *P. pavonica* surfaces. Isolates were affiliated to four major groups, *Proteobacteria, Bacteroidetes, Firmicutes* and *Actinobacteria*. *Proteobacteria* and *Firmicutes* group were represented on both algae However, *Bacteroidetes* phylum was represented only on *J. rubens* with 4 isolates assigned to *Cytophaga, Flavobacteria and Aquimarina* genus, contrary to *Actinobacteria* phylum, which was only represented on *P. pavonica* surface by 2 isolates closely related to *Brevibacterium* genus. We noticed a difference between bacterial proportion colonizing *J. rubens* and those colonizing *P. pavonica* surfaces as shown in figure 1. In previous study, quantitative and qualitative variations of the bacteria population were described and correlated with changes of environmental factors [2]. Whereas, in our study, the two algae were sampled from the same geographic location and at the same period, this suggests that heterotrophic bacteria are probably specie specific. Bacteria isolated from surface of some seaweed have been shown to release compounds that repel other fouling bacteria, suggesting they may protect their host from fouling by other organisms [7]. In addition, some seaweed species seem to require bacterial biofilms on their surfaces in order to develop properly [8]. Our results revealed that *Cytophaga, Flavobacteria and Aquimarina* genus were present only on *J. rubens*, contrary to *Brevibacterium* genus which was only represented on *P. pavonica.* These bacteria strains may be involved in protective role of specific host against other fouling bacteria or with useful role in development of the alga. Other studies need to be done in order to confirm these hypotheses.

Abstract
The bacteria associated with marine sponges represent a rich source of active metabolites. The aim of the present study is the isolation and characterization of epibiont sponge's bacteria with antimicrobial activities in Tunisian coasts. Thus, 54isolates were assessed from the northern coast in Tunisia and their antibacterial activities were characterized against several human and marine pathogens using the diffusion agar tests. Among the whole collection assessed less than half (43%) of isolates are active with 63% of these active bacteria inhibiting more than four sensitive strains tested. The active isolates were identified on basis of 16S rDNA sequences as *Proteus mirabilis* (9 isolates), *Enterococcus faecalis* (3 isolates) *and Serratia sp.* (11 isolates).

Keywords: Bacteria, Porifera, Gulf of Tunis

Introduction
Nowadays, sponges were considered as main source for natural products of pharmaceutical relevance that is partially correlated with their epibionts (1).The bioactivity of the isolated substances includes antiviral, antitumor, antimicrobial or generally cytotoxic properties and considerable biotechnological interest (2). The present study aimed to investigate antibacterial activities of epibiotic bacteria isolated from *Ircinia fasciculata, Ircinia spinosula and Hymeniacidon perlevis* collected from a northern Tunisian coast (Korbous)and molecular identification of these bacteria.

Materials and Methods
Three sponges species *Ircinia fasciculata, Ircinia spinosula and Hymeniacidon perlevis* were sampled by scuba diving at depths of 7m in Korbous (northern Tunisian coast) between 2005- 2007. Sponges samples were processed and loop full of sponge surface tissues. The homogenated and plated on different enriched media (Zobell marine agar, TCBS, DSC agar and TSA). The plates were incubated at 20°C for 7 days before selection of bacterial isolates morphologically and biochemically characterized. All isolates were tested for their antibacterial activities in triplicate using the agar diffusion method against the sensitive bacteria genus (*Aeromonas, Pseudomonas, Vibrio, Salmonella, Streptococcus, Staphylococcus aureus, E. coli, Enterococcus* and *Candida albicans*. The antibacterial activity was evaluated by measuring the inhibition zone (in mm). For all isolates, molecular identification by sequencing 16SrDNA was realized (extraction and PCR amplification using kit Qiagen, then DNA sequencing analysis by BLAST program).

Results and Discussion
Fifty four bacterial isolates were obtained from a total of three species of marine sponges. 43% of all isolates obtained, showed antimicrobial activity against at least one of pathogenic bacteria tested (Table 1). The active isolates were identified by PCR amplification and 16SrDNA gene sequencing. Among them, twenty were gram-negative, assigned to *Proteobacteria* (Gamma).Three strains were gram-positive. *Gamma-Proteobacteria* subclasswas represented by *Serratia sp.* (11 isolates) *and Proteus mirabilis* (9 isolates). Our results are in agreement with a previous review showing a high percentage of Proteobacteria isolates (1).Three Isolates (61- 74- 43) of *Proteus mirabilis*, one isolate(75) *of Enterococcus faecalis and* two ones (45-46) *of Serratia sp.* showed highest antimicrobial activity (between 20 and 21 mm of diameter). All the potential producers invariably showed inhibitor activity against Gram+ bacteria and particularly against *Staphylococcus aureus ATCC 6538. Proteus mirabilis* has the strongest activity against most of indicator bacteria tested. The strain 45 of *Serratia sp*. showed the largest antibacterial and antifungal spectrum activity against 10 pathogenic bacteria and *C. albicans*.

HEAVY METAL TOLERANCE OF SEDIMENT BACTERIA ISOLATED FROM COASTAL CITY (IZMIR,TURKEY)

Asli Kacar [1]*, Ali Kocyigit [2] and Esin Uluturhan [1]
[1] Dokuz Eylul University Institute of Marine Sciences and Technology - asli.kacar@deu.edu.tr
[2] Ege University, Department of Biology

Abstract
In this study, it was aimed to determine of heavy metal resistance of bacterial isolates from coastal city sediment (Izmir Bay). Thirty isolates (*Bacillus, Marinibacillus, Halobacillus*) were identified by phylogenetic analysis and these strains were investigated in respect of the MICs of heavy metals (Hg, Cu, Cd, Cr, Ni and Pb). The MICs of heavy metals were different for each strain but the general order of resistance to the metals was found to be as Ni>Pb>Cu>Cr>Cd>Hg. It can be concluded that bacterial isolates were sensitive to Hg but were highly resistant to Ni (13mM) and Pb (6mM). Additionally, the highest concentrations of metals were found in the inner part of the bay, where intensely industrialized compared to the middle and outer parts of the bay.

Keywords: Izmir Bay, Bacteria, Biodiversity, Sediments

Introduction
Izmir Bay is located on the Eastern Coast of the Aegean Sea in Turkey. The area along the Izmir coast is densely populated. Since it includes extensive agricultural lands, food and chemical industries, there is a lot of industrial and domestic discharge [1]. Heavy metals are major pollutants in the coastal environment [2]. Presence of these metals in the marine environment may pose a serious threat to the environment because of their ability to persist for several decades. Heavy metal resistant microorganisms could be useful as indicators of potential toxicity to other forms of life and are important in studies of genetic transfer in metal resistance mechanism. Thus, bacterial strains will develop their capacity to survive under toxicological stress and will be of importance in future bioremediation strategies [3].

Materials and Methods
Sediment samples were collected using Van Veen Grab from surface sediments in Izmir Bay at five locations. Heavy metal analyses were performed by AAS (Varian Spectraa) [4]. Samples for microbiological analyses were inoculated on ZoBell 2216e Medium and R2A Agar Medium. Bacterial colonies showing different morphological characteristics were selected and thirty isolates were identified by phylogenetic analysis using 16S rDNA sequences. The Minimum Inhibitory Concentrations for each bacterial isolate was determined using Mueller–Hinton Agar containing Hg, Cd, Cr, Cu, Ni, Pb [5].

Results and Discussion
The highest concentrations of metals were found in the inner part of the bay (especially, Zn: 279mg kg^{-1}, Cr: 169 mg kg^{-1}), where intensely industrialized (chemical industries, textile industries, antifouling paints, chlorine-alkali plants and a very busy harbour) compared to in the middle and outer parts of the bay. Thirty bacterial isolates were obtained from Izmir Bay sediments and phylogenetic analysis using 16S rDNA indicated that the strains belong to *Bacillus, Marinibacillus, Halobacillus (M. campisalis, B. simplex, B. megaterium B. halmapalus, B. marisflavi, B. pumilus, B. indicus, B. subtilis, B. aguimaris, B. firmus, B. thurigiensis, B. safensis, B. endophyticus, B. cereus, B. baekryungensis, H. Campisialis*). Minimum inhibitory concentrations of heavy metals are shown in Table 1. Bacterial isolates showed higher tolerance to Ni (13mM) and Pb (6mM). On the other hand, Hg was the highest toxic metal against to the all isolates. In various studies, it has been reported that the sediment bacteria existed in heavy metal contaminated environments. Nithya et al., [5] found that sediment bacteria which were isolated from Palk Bay (India) and which exhibited high resistance against Cd, Pb, Co, As, Hg were subjected to 16S rRNA analyses and identified as *B. arsenicus, B. pumilus, B. indicus, B. clausii* and they suggest that sediment bacteria could be biological indicators of heavy metal contamination. Although bacteria are sensitive to low concentrations of heavy metals, in specific environmental conditions, they rapidly adapt to the conditions so that they can reproduce in the presence of heavy metals. Therefore, the isolates may be useful as indicators of potential toxicity of heavy metals in coastal area and they could be designed as bioremediation tools by advanced studies.

Abstract
The well-known food-borne pathogen, *Staphylococcus aureus*, rarely has been implicated in cases originating from consumption of smoked seafoods. This bacterium may be contributed through human handling of the raw seafood and products.The aim of the presented work was the risk assessment of distribution and prevalence of *Staphylococcus aureus* in smoked fish. There were totally analyzed 50 samples of fish.Staphylococcus aureus was detected in % 4 of analyzed samples . The Food and Drug Administration (FDA) [1] established that effective doses of staphylococci enterotoxins can be achieved when populations of *Staphylococcusaureus* are greater than 10^2organisms per gram of contaminated food. This limit was not exceeded in any of the studied samples

Keywords: Diseases, Fishes, Aegean Sea

Introduction
Safety of fish products and their quality assurance is one of the main problems of food industry today. *S. aureus* is one of the major bacterial agents causing foodborne diseases in humans worldwide [2]. These bacteria are salt-tolerant and therefore can contaminate all cured preparations such as cold smoked fish, caviar and fish-based preserves [3]**.** Fish contains large amount of proteins and their breakdown into amino acids support the growth of *Staph.aureus.* Even though fish are smoked, the heat supplied might not kill all the pathogens. Smoked fish could be stored satisfactorily for three weeks at 5°C and less than one week at 10°C. The need for proper refrigeration cannot be over-emphasized. The finished product should not be distributed until it has been properly cooled to 4.2° C or below. Furthermore, because of perishable nature of smoked fish, it is imperative that finished product be maintained in a refrigerated condition at 4.2° C or below until consumed . Most food poisoning outbreaks related to smoked fish have been related to abusive storage temperature conditions. The isolated *S.aureus* were due to the contamination of fish during capture and subsequent unhygienic handling and processing [4]. Isolated *Staphylococcus aureus* in fishery products and fish processing factory workers. Small numbers of this bacterium in fishery products is not a serious problem but food poisoning may occur if the product is handled carelessly during processing, resulting in high multiplication. Therefore, consumption of such products may cause a risk of *Staphylococcus aureus* intoxication in consumers. The purpose of the present work was to study the incidence of *Staphylococcus aureus* in fishery products and fish processing factory workers.

Material and Methods
The samples (25 g) were weighed into sterile stomacher bags, diluted with 225mL buffered peptone water (BPW) (Oxoid, Unipath, Hampshire, UK) and homogenized in a Stomacher (Classic) about 10 min. The samples were further diluted with buffered peptone water (BPW), and 0.1 mL portion of various dilution levels were spread on the surfaces of Baird-Parker agar (BP) (Oxoid) supplemented with tellurite and egg yolk emulsion (Oxoid) and incubated at 37C for 32-48h. Convex, black, shiny colonies with narrow white magrin surrounded by clear zone were regarded as *S. aureus.* These colonies were confirmed by conducting gram staining, coagulase test, catalase test and anaerobic utilization of glucose and mannitol [5].

Results and Discussion
In this study, random samples of fifty smoked fish were taken at regular intervals.This samples were divided into decimal groups and total numbers of Staphylococcus aureus were determined. After enumeration on the groups were defined respectively 1.0×10^1cfu/g, 2.7×10^1cfu/g,1.2×10^2cfu/g, 1.7×10^1cfu/g and 3.0×10^1.

Tab. 1. The total numbers of *Staphylococcus aureus* in sample groups

Groups	1	2	3	4	5	Recomended
Staphylococcus aureus (cfu/g)	1.0×10^1	2.7×10^1	1.2×10^2	1.7×10^1	3.0×10^1	$< 10^2$

(10 samples in each group)

According to these data we assume that the isolated *Staphylococcus aureus* were due to the contamination of fish during sampling and subsequent unhygienic handling and processing [5].

Tab. 2. A characteristics of *Staphylococcus aureus* in seafood [6]

Bacteria	Estimated minimal Infectious dose	Sympthoms	Associated seafood	Importance
Staphylococcus aureus (cfu/g)	toxin level 10^5- 10^6	vomiting,diarrhoea weakness	contamination from infected persons	frequency of intoxication

Isolated *Staphylococcus aureus* in fishery products and fish processing factory workers. Small numbers of this bacterium in fishery products is not a serious problem but food poisoning may occur if the product is handled carelessly during processing, resulting in high multiplication(>1×10^5 cfu/g). Therefore, consumption of such products may cause a risk of *Staphylococcus aureus* intoxication in consumers. As the *Staphylococcus aureus* is an indicator of hygiene and sanitary conditions, the presence of this organism indicates the unhygienic condition during processing, storage etc. The contamination of the product could be due to a food poisoning. It is recommended to use sanitary gloves for handling processing foods to reduce the problem of *Staphylococcus aureus* contamination.

Abstract
We analysed the diversity of *Vibrio* bacteria associated with the non-indigenous species *Caulerpa racemosa*. The surface of the macroalgae constitutes a suitable substrate for the colonization of eukaryotic and prokaryotic microorganisms. This algae may gain vital elements from the associated bacteria, which, in turn, protect their hosts from micro- and macrofouling by the production of bioactive compounds, possibly playing a key role in the spread of this non-indigenous species.

Keywords: Alien species, Algae, Bacteria, Coastal systems, South Adriatic Sea

Introduction

The ecological threats of invasive seaweeds on ecosystem functioning have been largely documented in the marine environment [1]. Their effects vary according to the spatio-temporal scale considered. Knowledge of the mechanisms involved in the spread of these species is therefore critical.

Caulerpa racemosa is a non-indigenous species, introduced from the Red Sea. It was observed for the first time in the Mediterranean Sea in Libya in 1990 [2]. From then on, it has colonized all available habitats and substrata leading to profound alterations of indigenous assemblages [3,4].

Here, we investigated the *Vibrio* community colonizing the surface of the invasive *Caulerpa racemosa*. Several seaweeds live associated with many bacteria, leading to interactions with potential relevant functional significance [5]; however, the mechanisms underlying the processes of cospeciation and host–symbiont specificity, are poorly understood.

Material and Methods

C. racemosa was collected within the Marine Protected Area of Torre Guaceto (Brindisi, Italy) at shallow water depth, on a rocky substrate. In the laboratory, the seaweed was washed in sterile seawater (0.2 µm pore-filtered) and homogenized for 90 s in a sterile Waring blender at 5°C. Serial dilutions of the homogenate were plated onto TCBS agar (thiosulphate/citrate/bile salts/sucrose agar) to characterize the *Vibrio* community.

In addition, abundances of vibrios on the surface of *Caulerpa racemosa* have been quantified. Phenotypic characterization of the isolates was also performed by several morphological cultural tests, completed with 16S rDNA sequence analysis using EzTaxon-e, a prokaryotic 16S rRNA Gene sequence database[6]. DNA alignment of the 16S rDNA sequences was carried out using BLAST® software.

Results and Discussion

The results of microbiological cultural analysis using TCBS agar documented that vibrios accounted for 1.1 X 10^3 cfu/ml thus representing about the 4% of the total *C. racemosa* surface culturable bacteria. 16S rDNA amplicons, obtained by polymerase chain reaction (PCR) using 16S rRNA gene-specific primers, was employed in order to characterize the *Vibrio* community at species level (Tab. 1)

Tab. 1. Vibrios isolated from the surface of Caulerpa racemosa: 16s rDNA sequence identity using EzTaxon-e sequence database.

ISOLATES	SEQUENCE IDENTITY	HOMOLOGY (%)
V -1	*Vibrio jasicida* TCFB 0772^T	100.00 %
V -2	*Vibrio neptunius* LMG 20536^T	99.70 %
V -3	*Vibrio owensii* DYO5^T	99.85 %
V -4	*Vibrio campbellii* ATCC 25920^T	99.07 %
V -5	*Vibrio sagamiensis* LC2-047^T	99.15 %
V -6	*Vibrio maritimus* R-40493^T	99.50 %
V -7	*Vibrio diabolicus* HE800^T	99.89 %
V -8	*Vibrio tubiashii* ATCC 19109^T	99.88 %

The association observed between the community of *Vibrio* and *Caulerpa racemosa* has an ecological and epidemiological significance and the seaweed may therefore function as a particular habitat providing specific environmental conditions for the microbial colonization, taking into account that some isolated *Vibrio* species are quite different from those in the surrounding environment [7,8].

Abstract
The aim of this study is to detection of the fecal coliform bacterium *Escherichia coli* in marine environment of Kapidag Penunsula, using the polymerase chain reaction and gene probes, based on amplifying regions of the *uidA* gene. Nine sampling stations were selected from Kapidag Peninsula (Marmara Sea). The seawater samples were taken and primary hydrographic parameters (temperature, salinity, and dissolved oxygen) were recorded seasonally from 2010-2011. The results reveal that in all stations *E.coli* found with *uidA* gene and faces bacteriological pollution. Analysis of *uidA* gene using PCR showed temporal and spatial genetic homogenity in these *E.coli* populations. Waste water treatment management strategies will be great help to solve the sources of fecal pollution at the study stations.

Keywords: Bacteria, Bio-indicators, Surface waters, Pollution, Marmara Sea

Introduction
Monitoring of water-borne pathogens is important to safeguard public health. Recreational water quality assessment utilizes various indicator organisms to establish the sanitary quality of a particular body of water. *Escherichia coli* being present in very high numbers in the gut of warm-blooded animals, is widely used as an indicator of faecal pollution, to estimate the risk of exposure to other types of pathogenic organisms present in animal or human wastes [1]. Detection of *E.coli* remains a key factor in determining the microbiological quality of surface sea water. Use of uid-targeted PCR for the direct detection of *E. coli* may be useful and faster than other methods. After DNA extracted of *E.coli* from the polluted surface sea water, we use tructural region designated uidA was performed using primers UAL-1939 and UAR-2105 for detection. PCR-DGGE technology was adapted for specific detection and profiling of *E. coli* populations differing in a fragment of the functional uidA gene. The uidA gene product is a frequently used enzymatic marker for *E. coli* identification in recently developed detection media. In this study, various limitations inherent in the traditional culture methods, the feasibility of using the polymerase chain reaction (PCR) to monitor *E.coli* was investigated.

Materials and Methods
Monitoring stations were selected locations at coastal ecosystem of Kagidag Peninsula, seasonally in 2011-2012. Six stations (K1-K6), taken from surface, were coastal area and three stations and different depths (5 m, 10 m, 20 m and 30 m) of open sea were north, west and east locations (Figure 1). The enteric bacteria were isolated using the MPN Method and the detailed analyses were applied [2]. To determine the specificity of uidA for E.coli detection, DNA was extracted from exponential cultures [3]. A 0.166-Kb fragment was amplified from the *uidA* gene of *E. coli* using primers UAL-1939 (5'-TATGGAATTTCGCCGATTTT-3') and UAR- 2105 (5'-TGTTTGCCTCCCTGCTGCGG-3') [4].

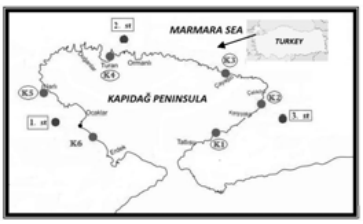

Fig. 1. Study area of Kapidag Peninsula

Results and Discussion
The set of primers, UAL-1939 and UAR-2104, located at the carboxyl coding region of the uidA gene produced amplified DNA bands of 166 kb for E.coli (Figure 2a-b). Except K1 and K6, we shown all the stations have same band for E.coli. This result pointed to parallel emphases that these stations were selected at locations that were either highly urbanized or where the coastal ecosystem was heavily deteriorated. Especially, K1 and K6 stations are used as a public beach during summer months. So, not only E.coli but also other enteric bacteria could be shown in these stations and recorded during sampling period. And the bands were indicated the differences between stations and depths. But the samples of the depth of 30 m weren't shown the same results. It means that, these samples included different species of enteric bacteria except *E.coli*.

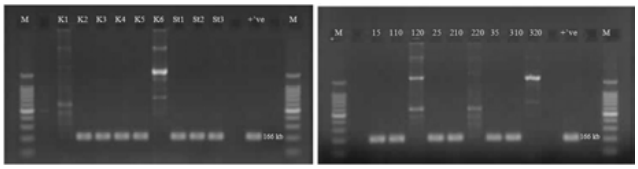

Fig. 2. A. Surface samples b. Depths of stations 1,2,3

Results of the present study show that the PCR is a potentially powerful technique for the rapid detection of enteric bacteria in routine water quality monitoring. In addition, in this study indicate that PCR provide a powerful supplement to conventional methods for more accurate risk assessment and monitoring of pathogenic bacteria in the marine environment. The ability to rapidly monitor for various types of microbial pathogens would be extremely useful not only for routine assessment of water quality to protect public health, but also allow effective assessments of water treatment processes to be made by permitting pre- and post-treatment waters to be truly analyses [1]. At the last, because of the indigenous nature of *E. coli* considerations must be made about the importance of this bacterium as an indicator of recent fecal contamination and the necessity of knowing the source of contamination if public health is to be protected.

SPATIAL DISTRIBUTION AND VERTICAL VARIATION IN BACTERIOPLANKTON ASSEMBLAGES ACROSS THE MEDITERRANEAN SEA

R. Alvariño [1], M. M. Varela [1], M. Álvarez [1]*, E. Teira [2] and V. Hernando-Morales [2]
[1] Instituto Español de Oceanografía (IEO) Centro Oceanográfico da Coruña - marta.alvarez@co.ieo.es
[2] Universidade de Vigo

Abstract
We analysed the vertical variation of bacterioplankton assemblage composition along a transect of 3500 km in the Mediterranean Sea, to determine the factors driving bacterioplankton community structure. Bacterioplanckton community composition (BCC) was assessed by a fingerprinting method, automated ribosomal intergenic spacer analysis (ARISA). Non-metric Multidimensional Scaling (nMDS) showed that the BCC in the surface waters of the eastern and western sub-basins of the Mediterranean Sea was significantly different. We also found the occurrence of a vertical profile of bacterial communities across the water column, related to different variables as the depth of collection (pressure), and salinity and temperature values. Our results suggest both spatial and environmental factors control bacterioplankton community structure.

Keywords: Bacteria, Biogeography, Deep waters, Vertical profile, North-Western Mediterranean

Prokaryotes are key players in sea ecosystems both in terms of biomass and phylogenetic diversity and for their role in biogeochemical cycles. Only recently, due to the development and advance of molecular tools, marine scientist undertook the investigation of microbiome distribution and adaptation to specific environmental conditions in oceans. The MedSea is a marginal sea with high temperature and salinity through the water column and with an anti-estuarine circulation pattern, where the formation of deep water occur both the western and eastern basin (i.e. renewal time of the water masses is < 100 years). These characteristics make the Mediterranean Sea a very special ecosystem in terms of biodiversity hotspots. However, most of the reports on ecological structuring of prokaryotes in the Mediterranean Sea have been conducted on a small number of stations, generally located in a narrow area [1, 2]. In this paper, we studied the vertical and longitudinal distribution of bacterial populations in different sampling stations located across the whole Mediterranean Sea.

Sampling was carried out during the cruise M84/3 held on April 2011 on the R/V Meteor. Sampling stations were located along a longitudinal transect of ~3500 km in the Mediterranean Sea. Water samples were collected from the subsurface, meso- and bathypelagic layers. Prokaryotic abundance was evaluated by epifluorescence microscope and BCC by applying automated ribosomal intergenic spacer analysis (ARISA) [3].

Prokaryotic abundance decreased throughout the water column of eastern and western Mediterranean basins. Non-metric multidimensional scaling (nMDS) analysis showed that the subsurface and deep (meso- and bathypelagic) waters host significantly different bacterial communities. Furthermore, nMDS displayed that the surface bacterial community structure in the eastern and western sub-basins of the Mediterranean Sea were significantly different (Figure 1).

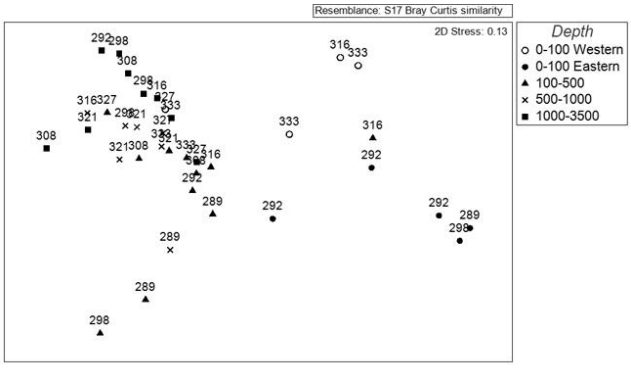

Fig. 1. Non-metric multidimensional scaling (nMDS) results based on qualitative ARISA fingerprinting of the samples across the water column, showing the distribution of surface (circles), upper mesopelagic (triangles), lower mesopelagic (crosses) and bathypelagic (squares) samples.

To evaluate the relevance of spatial and environmental variables (depth, salinity, oxygen, temperature, nitrate, silicate, latitude and longitude) driving the distribution pattern of BCC we carried out a DISTML analysis (distance-based linear models). According to the DISTLM model, depth explains 11.57% of the variation observed in the BCC. Temperature and salinity also contribute significantly (11.56% and 5.83%, respectively) to the variability of the BCC (Figure 2).

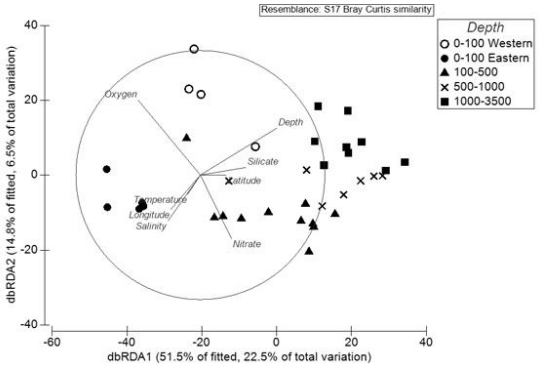

Fig. 2. Distance-based redundance analysis (dbRDA) ordination of the presence ⁄ absence ARISA dataset overlaid with the partial correlations of the tested environmental variables

Our results indicated that the bacterial populations are stratified across the water column according to environmental variables, such as temperature and salinity. Recent investigations have found that these parameters showed a correlation with zonation of bacterial communities in the Mediterranean Sea [1]. These results demonstrated that bacterial taxa distribution was spatially patterned, exhibiting different populations in the surface, meso- and bathypelagic realms of the eastern and western Mediterranean sub-basins.

UNCOUPLING BETWEEN DINITROGEN FIXATION AND PRIMARY PRODUCTIVITY IN THE EASTERN MEDITERRANEAN SEA

E. Rahav [1], B. Herut [2], . Stambler [1], E. Bar-Zeev [1], M. R Mulholland [3] and I. Berman-Frank [1]*
[1] Bar Ilan University, - ilana.berman-frank@biu.ac.il

Abstract
We measured dinitrogen (N_2) fixation and primary productivity (PP) during the stratified summer period in different water regimes of the Eastern Mediterranean including the Cyprus Eddy (CE) and the Rhodes Gyre (RG). Low N_2 fixation rates were measured throughout the basin excluding 10 fold higher rates in the RG and CE. Corresponding PP increased from east to west with relatively higher productivity recorded in the RG and CE. These measurements demonstrate that N_2 fixation in the photic zone contributes only negligibly by direct inputs to PP (i.e. cyanobacterial diazotrophs) and is in fact uncoupled from PP. In contrast, N_2 fixation was significantly coupled to bacterial productivity (BP) and to net-heterotrophic areas suggesting that heterotrophic N_2 fixation may in fact be significant in this ultraoligotrophic system.

Keywords: Cyanobacteria, Phytoplankton, Primary production, Bacteria, Levantine Basin

N_2 fixation controls total nitrogenas the supply of new nitrogen (N) to the N poor surface waters of the ocean by diazotrophs usually stimulates both the autotrophic and heterotrophic communities of the planktonic and microbial food webs [2]. Thus, N_2 fixation should be positively correlated to PP in two ways: 1) Directly, via photoautotrophic diazotrophs currently assumed to be the dominant component of the diazotrophic community in the photic zone with sunlight providing the required energy for the energetically expensive process of N_2 fixation. 2) Indirectly via the contribution and recycling of the products of this "new N" (i.e. either assimilated N; ammonia leakage, breakdown of diazotrophic blooms, etc.) stimulating PP by non-diazotrophic photoautotrophs. In this study we evaluated the contribution and relationship of N_2 fixation from the photic layer to PP in different water provinces of the Eastern Mediterranean. To this end we measured *in-situ* N_2 and carbon fixation from different depths within the photic zone and performed on-board microcosm experiments in 11 different locations throughout the Levantine basin, including the cyclonic RG and anti-cyclonic CE, over 3 consecutive years (2007-2009) during the stratified period. Measured PP rates across the Levantine basin revealed an east-west gradient with lowest values at the easternmost stations getting progressively higher toward the western Levantine stations (~200 and > 2000 µmol C m^{-2} d^{-1} respectively). In contrast, areal N_2 fixation rates did not exhibit the spatial trend observed for PP and were low throughout the whole basin (0.8 to 3.2 µmol N m^{-2} d^{-1}), except for the CE and RG where rates higher by an order of magnitude were measured (~ 20 µmol N m^{-2} d^{-1}). Furthermore, the percent contribution of the biologically fixed N to PP ranged from 0.7 to 2 % (n=96) except for both gyres (> 6 %, n=24). Our results show that during the stratified period, excluding the RG and CE, N_2 fixation was uncoupled from PP across the Levantine basin (P= 0.3, n= 19, Figure 1), which contrast studies from varying oceanic regions demonstrating a positive correlation of PP with N_2 fixation in the photic illuminated layer under stratified conditions (R^2= 0.54, P = 2 x 10^{-6}, n= 26). This uncoupling in the Eastern Mediterranean may be explained by examining the characteristic composition and structure of the pelagic primary producers and the resulting microbial food web. We suggest that in this system, where heterotrophic bacteria compete with the primary producers for the limited nutrients [3], heterotrophic N_2 fixation can be significant and may extend also deep into the aphotic depths.

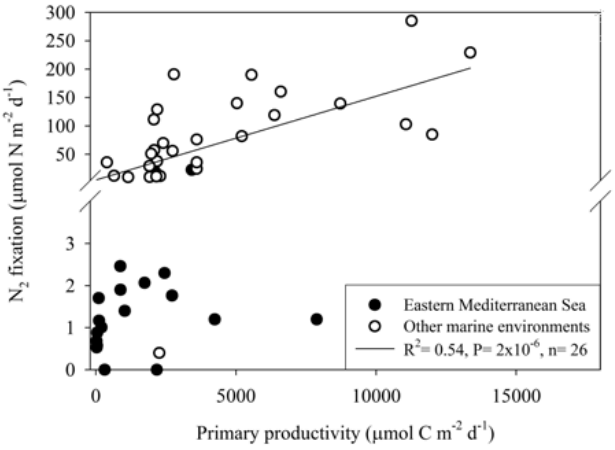

Fig. 1. Correlation between N_2 fixation rates and PP for the illuminated photic depths of varying marine environments, including the Eastern Mediterranean Sea, anti-cyclonic eddies within the Mediterranean Sea, DYMAMED station in the Western Mediterranean Sea, Station ALOHA near Hawaii, South China Sea, the tropical and subtropical western North Pacific, the Gulf of Mexico, Atlantic Ocean, the Baltic Sea, and the south Pacific Gyre.

Abstract

The annual variations of temperature effects on heterotrophic prokaryotic production and respiration and on macromolecular hydrolysis (phosphatase and protease) have been investigated during one year in the Bay of Marseille. We present the Q10 data range, variability, seasonal trends and their consequences on the functioning of degradation pathways within the microbial food web under increased temperatures

Keywords: Temperature, Bacteria, Enzymes, Geochemical cycles, North-Western Mediterranean

The dynamics of heterotrophic prokaryotes are influenced by many parameters, particularly in coastal areas (temperature, nutrients, organic matter inputs (allochtonous, autochtonous) abundance of communities, urban/human pollution…). Hence, to understand the impact of one forcing factor it's necessary to study one parameter at a time. Temperature, with OM availability, is one of the main factor influencing heterotrophic prokaryotic activity [1]. It is not well known how this temperature control varies seasonally, and if this control is different according the heterotrophic process studied. This study investigates temperature effect at the fixed French observatory station SOMLIT in the Bay of Marseille (60 m depth). Natural samples were incubated at 8 different temperatures ranging from 10 to 30°C encompassing the in situ temperature, to estimate total community respiration (CR), heterotrophic prokaryotic production (BP), phosphatase activity (phos) and leucine aminopeptidase (prot) activity. Samples have been collected monthly during one year (from 01/02/12 to 28/02/13).

Figure 1 displays an example of temperature kinetics obtained on the 9 July survey. At 26°C, BP optimum is reached then shows a temperature inhibition, while phos and CR continuously increased and leucine aminopeptidase reached a plateau at 26°C.

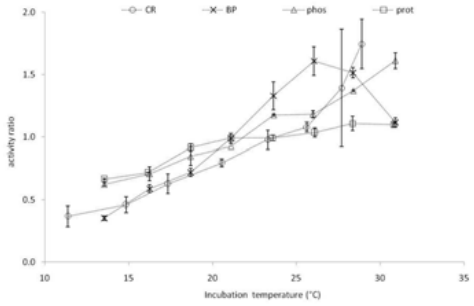

Fig. 1. Temperature kinetics obtained on the 9 July survey for 4 activities: community respiration (CR), bacterial production (BP), phosphatase (phos) and leucine aminopeptidase (prot) Activity ratio is the activity measured at a given temperature divided by the activity measured at in situ temperature.

Q10 factor describes the relative process increase for a temperature raise of 10°C within the Arrhenius law domain. Q10 is estimated from the linear part of the linear regression plot of Ln (rate) versus 1/T, T being expressed in °K. Q10 of Community respiration (Q10CR), heterotrophic prokaryotic production leucine aminopeptidase (Q10BP) and phosphatase (Q10phos) showed the greatest values and ranges, varying annually up to 4 times (Figure 2).

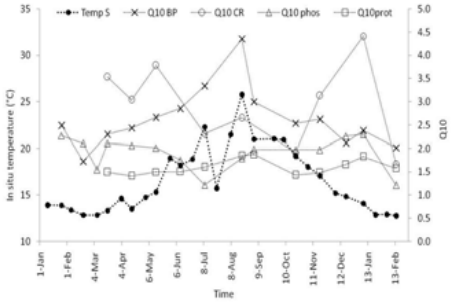

Fig. 2. In situ sea-surface temperature (Temp S, 1 m depth) and Q10 evolution during the Jan 2012-Feb 2013 survey: Q10 of community respiration (Q10 CR), of bacterial production (Q10 BP), of phosphatase (Q10 phos) and of leucine aminopeptidase (Q10 prot).

(Q10phos) showed the greatest values and ranges, varying annually up to 4 times (Figure 2). Q10CR ranged from 1.67 to 4.41. Q10BP ranged from 1.72 to 4.36. Q10phos showed a lower variability, ranging from 1.21 to 2.30. Finally, Q10 of leucine aminopeptidase (Q10prot) exhibited the lowest variability, ranging from 1.41 to 1.87. Q10BP was positively correlated to the in situ temperature, decreasing in winter down to 1.72 in cold waters (13°C), and reaching up to 4.36 in summer in warmer waters (26°C). At the opposite, Q10phos and Q10CR are more or less decreasing with increasing in situ temperatures. Such results would have consequences on temperature effects on the bacterial growth efficiency, as BP and RB had different Q10 values. We'll discuss seasonal trends, possible links with development of the phytoplankton bloom and limiting factors and we'll examine what are the consequences of slight increases of temperature on the functioning of degradation pathways within the microbial food web in the context of global change.

Abstract
The Gulf of Gabès, one of the largest continental shelves in the oligotrophic to ultra-oligotrophic Eastern Mediterranean Basin, is a very highly productive area under strong anthropogenic pressure. The ultraphytoplankton (< 10 µm) summer distribution determined In the Gulf by flow cytometry in June 2008 unveiled a very abundant and unknown cell group. In contrast, the abundance of usually observed photosynthetic cell groups was found abnormally low considering the absence of nutrient limitation, which would suggest a top-down control of ultraphytoplankton by predation activity. Flow cytometry analysis of samples collected in the same area in July 2012 yielded similar results. Cell sorting followed by scanning electron microscopy revealed the presence of choanoflagellates, however the unknown cell group could not be identified.

Keywords: Phytoplankton, Gulf of Gabes

Introduction
The Eastern Mediterranean Basin is the most oligotrophic region [1] in the Mediterranean Sea. In contrast, the Gulf of Gabès, one of its largest continental shelves, is highly productive, contributing about 65% to the Tunisian fish production. Nitrate is never fully exhausted [2], probably upon the effect of re-suspension favoured by very large tides, and also of Saharan dust deposit [3]. We report here the first investigation in the Gulf of Gabès of ultraphytoplankton (< 10 µm) distribution at the single cell level by using flow cytometry.

Materials and Methods
This study was conducted from 12 to 16 June 2008 in the frame of the national POEMM project (Planktonic Ecosystem and Oceanographic Monitoring and Management), on board of the R/V HANNIBAL.

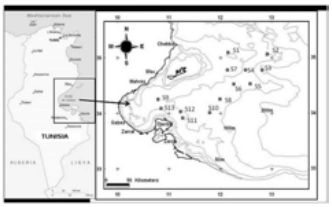

Fig. 1. Location of the study area to the South-East of Tunisia (Gulf of Gabès). Stations occupied during the POEMM Summer cruise (15-16 June 2008) are numbered in the order of their sampling.

A second cruise took place in the same area in July 2012 and provided a new set of samples to undertake further investigations. Autotrophic pico-nanoplankton analysis and sorting by flow cytometry (FCM) was conducted at the Regional Flow Cytometry Platform for Microbiology (PRECYM, http://precym.com.univ-mrs.fr) of the Mediterranean Institute of Oceanography (MIO) in Marseille (France). The observations of sorted samples were performed by HRSEM (high resolution scanning electron microscopy) JSM-6320F (JEOL Company) at the electron microscopy facility of CINaM (Centre Interdisciplinaire de Nanoscience de Marseille).

Results and discussion
FCM resolved 5 cell groups nanoeukaryotes (photosynthetic eukaryotic cells belonging to the size class 3-20 µm), picoeukaryotes (<3 µm), *Prochlorococcus* and *Synechococcus* and one cluster of unknown cells (UC) that was the most abundant (0.1-2.9 10^6 cells.cm^{-3}) and apparently >2 µm. These cells were characterised by low red and orange fluorescence signals whereas from their apparent size, they should emit a red fluorescence signals at least as large as that of nanoeukaryotes.

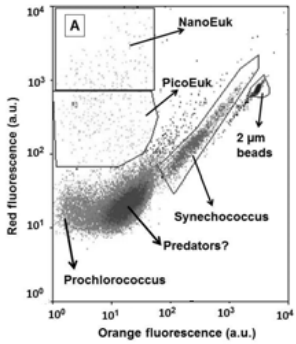

Fig. 2. Group-resolving flow cytometry cytogram.

The ultraphytoplankton abundance was similar to that observed in winter in the eastern Mediterranean Basin [4], well below that reported in the western Mediterranean Basin in spring [5]. Because nutrients in the Gulf of Gabès are never fully exhausted, the abnormally low abundance level was explained by predation activity applying a top down control on the ultraphytoplankton. The 2012 samples enabled sorting cells of the UC group and their observation by scanning electron microscopy. Though a choanoflagellate species could be detected, the dominant cells in the UC group could not be identified. DNA sequencing is considered to achieve their identification. Despite this unresolved question, results support the existence of a top-down control of photosynthetic pico- and nanoplankton, insuring a rapid transfer of matter and energy to higher trophic levels, consistently with the well-known high productivity of the Gulf of Gabès. Nanoflagellates are likely candidates to run this top down control.

Abstract
Les variations spatio-temporelles des communautés ultraphytoplanctonique et bactérioplanctonique (≤10µm) dans le Golfe de Gabès ont été étudiées lors de deux campagnes, juin 2008 et mars 2009. Les résultats obtenus ont été confrontés aux variations des paramètres environnementaux afin de connaître l'influence de ces derniers sur l'abondance de chacune des populations résolues par cytométrie en flux.

Keywords: Gulf of Gabes, Cyanobacteria, Phytoplankton, Water transport

L'étude de la distribution spatiale de l'ultraplancton dans le Golfe de Gabès a été réalisée lors de deux campagnes (juin 2008 et mars 2009) conduites dans le golfe de Gabès sur la zone située entre 33°N-36°N et 10°E-13°E. Au cours de chacune de ces deux campagnes, 14 stations réparties entre la côte et le large ont été échantillonnées à différentes profondeurs. Les échantillons destinés à l'analyse par cytométrie en flux ont été fixés à bord avec du paraformaldehyde puis congelés dans l'azote liquide et conservés à -80°C jusqu'à leur analyse sur la plate-forme régionale de cytométrie pour la microbiologie (PRECYM, http://precym.com.univ-mrs.fr/) du MIO à Marseille. Les groupes de cellules ont été différenciés à partir des signaux de fluorescence et de diffusion de chaque cellule.

L'étude de l'ultraphytoplancton a permis de reconnaître quatre groupes cellulaires, dont deux groupes d'eucaryotes, pico- et nanoeucaryotes ainsi que deux groupes de cyanobactéries, *Prochlorococcus* et *Synechococcus*, l'analyse du bactérioplancton a signalé la présence de deux groupes cellulaires distincts qui ont été identifiés comme étant des cellules HNA (high nucleic acid) et des cellules LNA (low nuleic acid). Les relations entre abondances cellulaires, concentrations des éléments nutritifs et autres variables environnementales ont été recherchées.

Les différences de situations entre période estivale et printanière ont été déterminées et montrent que durant la saison printanière le milieu était particulièrement riche en cyanobactéries en comparaison avec la période estivale, contrairement aux eucaryotes qui étaient plus présents en juin 2008 essentiellement dans la région côtière. Cet enrichissement cellulaire est favorisé par la présence de certains éléments nutritifs à certains niveaux de la colonne d'eau ainsi que par l'action de quelques paramètres physiques tels que la densité et la salinité.

L'analyse du bactérioplancton a prouvé que l'abondance du bactérioplancton était nettement inferieure durant la compagne de juin 2008. Au cours de la période printanière, le milieu était toujours assez riche en cellules HNA essentiellement dans la région du large de la zone d'étude la ou se développe également les cyanobactéries, contrairement à la période estivale qui l'a précédé ou les cellules LNA formaient la majorité des cellules bactériennes présentes dans le milieu.

Tab. 1. Concentrations moyennes des différents groupes ultraphytoplanctoniques (*Synechococcus*, *Prochlorococcus*, picoeucaryotes et nanoeucaryotes) et bactérioplanctoniques (groupement HNA, et LNA) résolues par cytométrie en flux dans les stations échantillonnées au cours des compagnes juin 2008 et mars 2009 au large et vers la cote de la zone d'étude, et les moyennes en paramètres physiques (température, salinité et densité) ainsi que les moyennes correspondantes en éléments nutritifs.

EFFECT OF DENSE WATERS ON THE DIVERSITY AND METABOLISM OF PLANKTONIC BACTERIA IN THE SOUTHERN ADRIATIC SEA

Abstract
During winter, the northern Adriatic Sea is subjected to cold outbreaks, resulting in generation of cold and dense waters which sink and eventually move southward. This water mass contributes to ventilate deep waters in the Eastern Mediterranean Sea, and can potentially influence prokaryotic diversity and metabolism at large spatial scales. We collected water samples of dense bottom currents in the Southern Adriatic Sea in March 2012, and measured bacterioplankton diversity (using fingerprinting techniques and 16S rDNA pyrosequencing) and key functional variables of microbial metabolism (heterotrophic C production, respiration and degradation rates). Our results indicate that bacterial diversity and metabolism are influenced by the dense water passage, and this has important consequences for the ecosystem functioning of the entire area.

Keywords: South Adriatic Sea, Bacteria, Biodiversity, Deep waters

Planktonic microbes are key players in the fluxes of matter and energy in the sea [1], yet their diversity, distribution and functional response to episodic events (such as dense water inputs) are poorly known. Heterotrophic bacteria process about half of the net primary production and play a dominant role in the microbial carbon pump, by altering and transforming labile organic matter into refractory forms that persist in the ocean [2]. An uncoupling between prokaryote-mediated production and degradation processes can have important consequences on the functioning, carbon sequestration and the ecological efficiency of marine ecosystems [3], especially in the warm Mediterranean Sea [4].

During the winter, the northern Adriatic Sea is typically subjected to intense cooling associated with dry and cold north-easterlies (the Bora wind). The resulting water mass (Northern Adriatic Dense Water, NAdDW), cold and dense, sinks and flows southward [5], typically reaching the proximity of Bari in the early spring. NAdDW eventually mixes with other Adriatic water masses to form the Adriatic Deep Water (ADW), which contributes significantly to the ventilation of deep water in the whole Eastern Mediterranean [6]. This episodic event has the potential to influence prokaryotic diversity and metabolism at large spatial scales, with unpredictable effects which deserve in-depth investigations.

In spring 2012, we collected seawater samples along three transects in the Southern Adriatic Sea during the outflow of dense water generated after a severe cold spell occurred in early February 2012. Several stations were clearly sampling the veins of the dense water, with potential density anomaly as high as 29.7 Kg/m and temperature as low as 10.5°C (Figure 1).

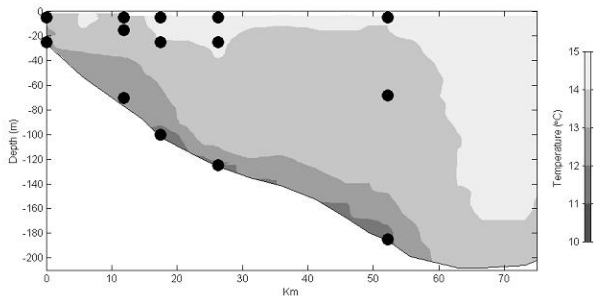

Fig. 1. Isoclines of temperature along one of the sampled transects. Dots indicate the sampling depths and location.

We measured bacterial diversity and key functional variables of prokaryotic metabolism, including prokaryotic heterotrophic carbon production rates (using the 3H-leucine incorporation method), potential respiration rates (via the Electron Transport System assay) and organic matter degradation activities (aminopeptidase, ß-glucosidase and alkaline phosphatase). Biodiversity was assessed by a combination of molecular fingerprinting (Automated Ribosomal Intergenic Spacer Analysis, ARISA) and 16S rDNA tag pyrosequencing.

In sub-surficial layers, the specific water masses were identified basing on their distinct temperature-salinity characteristics and the oxygen content. The analysis of bottom waters indicated that NAdDW samples, when compared with LIW samples collected at similar depths, were characterized by higher abundance of prokaryotes, higher respiration and organic matter degradation rates, while the carbon production rates were apparently unaffected by the dense water passage. Significant differences in the community composition of deep bacterial assemblages were observed between NAdDW and the other water masses. Our results indicate that diversity and metabolism of bacterioplankton are influenced by the dense water passage, suggesting that this episodic event may have large-scale consequences for the ecosystem functioning and the biogeochemical cycles in the Southern Adriatic Sea.

Abstract
Bioluminescence is of major interest in the dark-deep sea and among all organisms able to produce light, bacteria are the most abundant ones. This chemical reaction is regulated by the *lux* gene operon and provoked by the enzyme luciferase. Water-sampling, CTD-profiles and continuous bioluminescence reccords have been done to characterize presence and activity of such bioluminescent micro-organisms among the year 2011 as well as possible links with environmental variables. Molecular analyses have been performed on 16S-DNA and 16S-RNA to characterized, quantify and detect the presence of *lux* genes and active *lux* genes.

Keywords: Deep waters, Bacteria, North-Western Mediterranean

Darkness is one of the major characteristic of deep-sea environment that can be disturbed by a biological phenomenon named bioluminescence. Bioluminescence is the process of light emission by living micro- or macro-organisms. Amongst the bioluminescent organisms, marine luminous bacteria are ecologically versatile and can be found as free-living forms, epiphytes, saprophytes, parasites, symbionts in the light organs of fishes and squids, and commensals in the gut of various marine organisms [1, 2]. Metagenomic analysis from deep eastern-Mediterranean water samples shows a surprising high number of *lux* genes directly involved in bacterial bioluminescence [3].

The ANTARES site is located 40km off the french Mediterranean coast at 2475m depth. The site is firstly dedicated to the high energy particles (i.e. neutrinos) research. This structure has also been equipped with deep photonic sensors which also provide data on bioluminescence from deep-sea organisms. These datasets provide an extraordinary approach for real-time and high-frequency deep sea ecology studies. Water-samples and environmental time-series at this deep location is one original way to answer two main questions. Firstly, how bacteria are related to the high variability of bioluminescence intensity observed throughout the year? Secondly how the environmental variables may impact this bioluminescence intensity?

The dynamic of bacterial bioluminescence in the deep-sea-water samples have been collected over the year 2011, at the ANTARES site. Samples have been collected for ARN and ADN analyses in January, March, May, June, August and October 2011.

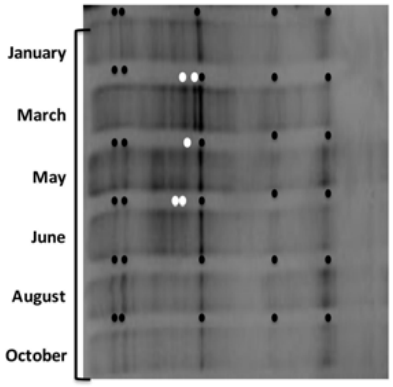

Fig. 1. Bacterial diversity analysis by fingerprint (16S rDNA DGGE) of 2011 water samplings. Black dots represent main bands appearing on almost all sampling periods and white dots represent main bands appearing only for specific sampling times.

At the same time, a CTD-profile is performed in order to characterize the environmental variables into the sampled-water mass. Filters sampled are analyzed in order to characterize presence and activity of *lux* genes. We performed DNA extraction, amplification and quantification using qPCR with several primers defined at lab. qPCR done on DNA-samples from October 2011 contains higher number of *lux* genes ($1.36x10^2 \pm 2.04x10^1$) than other samples during the year. Pyrosequencing has been performed on specific DGGE-bands to determine strains occurring into the water mass. Possible links between the presence of bioluminescent active genes and environmental variables have been highlighted.

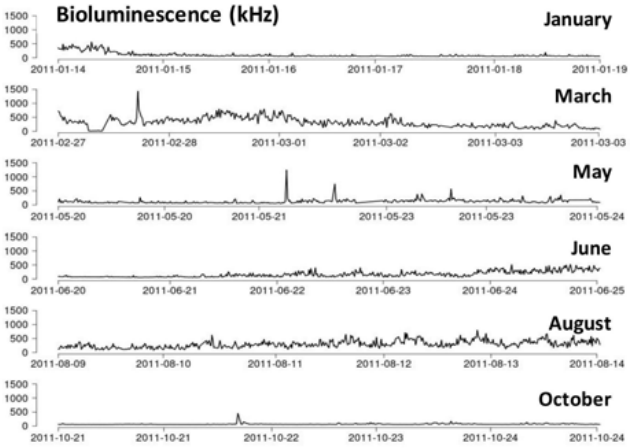

Fig. 2. Time series of bioluminescence intensity (kHz) recorded using photomulipliers at 2000m depth at the ANTARES station. The photon emission rate is recorded few days before and after the water sampling.

Abstract
Most N_2 fixation studies are designed to fit the traditional assumption that phototrophic diazotrophs have an ecological advantage in the illuminated layer that has sufficient energy to drive this costly process. In this study we measured N_2 fixation in the fully oxygenated, NO_3^- rich and aphotic mesopelagic layer of the Levantine Basin and Gulf of Aqaba. Aphotic N_2 fixation ranged from 0.02 to 0.38 nmol N L^{-1} d^{-1} and accounted for 35 -77 % of the total integrated rates. The rates obtained were correlated with bacterial productivity and heterotrophic diazotrophs were identified. We suggest that heterotrophic N_2 fixation may be supported by sinking organic material and high C:N micro-environments (such as TEP), and that aphotic waters may represent a significant source of new N via N_2 fixation that is not currently included in N budgets.

Keywords: Deep sea ecology, Levantine Basin, Bacteria

Biological dinitrogen (N_2) fixation mediated by prokaryotic organisms (diazotrophs) contributes new nitrogen (N) to oceanic basins where primary production is limited by the availability of dissolved inorganic N. Thus, most oceanic N_2 fixation studies are restricted to the illuminated euphotic layer where photoautotrophic diazotrophs are dominated [1]. Phylogenetic and N_2-fixation data show that heterotrophic diazotrophs from α, β, γ, δ and ε-proteobacteria, as well as methanogenic archaea are distributed in geographically diverse oceanic environments including systems with high dissolved inorganic N concentrations, and deep oxygen minimum zones (OMZ) [2].

In the Eastern Mediterranean Sea (EMS), new nitrogen inputs via N_2 fixation in the euphotic zone are generally very low with rates ranging from 0.01 to 0.3 nmol N L^{-1} d^{-1} and contributing only 1-2% to new production in the Levantine Basin (LB) [3,4]. In the Gulf of Aqaba (GA), a single study reported low N_2 fixation rates ranging from ~0.05 to 2 nmol N L^{-1} d^{-1}, yet no information is found on their contribution to new and primary production [5].

In our search for N sources required to sustain primary productivity in these oligotrophic environments, we describe here for the first time, significant N_2 fixation rates from the aphotic, oxidized waters of the LB and GA. Aphotic depths yielded N_2 fixation rates ranging from 0.02 to 0.38 nmol N L^{-1} d^{-1} at all locations. Rates obtained at the GA during the mixed period averaged 0.10 ± 0.10 nmol N L^{-1} d^{-1} and 0.30 ± 0.10 nmol N L^{-1} d^{-1} during stratification. In the LB station, aphotic N_2 fixation was uniformly low during the mixed period; 0.01 ± 0.01 nmol N L^{-1} d^{-1} and increased during the stratified period; 0.12 ± 0.09 nmol N L^{-1} d^{-1}.

Integrated water column N_2 fixation from the surface to the deepest depth sampled (720 m) revealed that aphotic N_2 fixation accounted for ~ 50 % of the total N_2 fixation in the LB stations and 37 to 75 % in the GA station. The substantial role of aphotic N_2 fixation in the LB and the GA is especially important given the low rates of euphotic N_2 fixation (below detection to 0.1 nmol N L^{-1} d^{-1} in the LB and 0.35- 0.60 nmol N L^{-1} d^{-1} in the GA during summer) of both these nutrient-poor environments [3-5]. Furthermore, N_2 fixation rates obtained in both the euphotic and aphotic depths were positively correlated with bacterial productivity (BP) (R^2 = 0.70, p = 0.001, n = 12 and R^2 = 0.58, p = 0.003, n = 10 respectively), while no correlation was apparent between N_2 fixation rates and primary productivity (PP).

Previous molecular characterization of diazotrophs actively expressing *nifH* genes from the euphotic zone of the LB and GA demonstrated a diverse array of heterotrophic bacteria and cyanobacterial phylotypes [2]. Our phylogenetic analyses of *nifH* from the aphotic depths in the LB substantiate our data revealing that diazotrophic phylotypes were predominantly comprised of heterotrophic bacteria, including α and γ proteobacteria.

Our results provide new evidence that heterotrophic bacterial N_2 fixation is a considerable source of new N in the aphotic zones of both LB and GA. Yet these regions have not been previously considered a significant source of N_2 fixation as they are dark, oxygenated (~ 200 µmol L^{-1}), and NO_3 – rich (up to 6.24 µM). Why should heterotrophs fix N_2 in inhibitive NO_3 -rich environments, how could they overcome the high oxygen concentrations detrimental to nitrogenase activity, and what energy sources enable this costly process in the absence of sunlight?

Accordingly, we propose that N_2 fixation within the aphotic oxygenated environments is promoted and enhanced by microenvironments rich with organic carbon (C). Thus, we describe a plausible scenario of microenvironments based on planktonic "hot spots" that include microgelatinous transparent exopolymer particles (TEP), heavily colonized by bacteria, and defined as protobiofilms. In aphotic (energy poor) zones of oligotrophic systems these protobiofilm shuttles contribute significantly to the organic carbon pool; the high C: N ratios of TEP [6] can enhance C availability (as DOC, POC) for heterotrophic metabolism, while the relatively low N concentrations in TEP may promote heterotrophic N_2 fixation. Moreover, bacterial colonization on such particles causes high metabolic consumption of oxygen typically resulting in decreasing oxygen gradients from the surface to the anaerobic centre of the aggregates [7]. Thus, we suggest these anaerobic, high C, low N environments will promote the presence and significant activity of heterotrophic diazotrophs at depth.

Abstract
Dinitrogen fixation rates were measured during early spring across the Mediterranean Sea surface waters. N_2 fixation rates, measured using $^{15}N_2$ enriched seawater, were lowest in the eastern basin and increased westward with a maximum at the Strait of Gibraltar (0.10 - 2.35 nmol N L^{-1} d^{-1}, respectively). These rates were 3-7 fold higher than N_2 fixation rates measured previously in the Mediterranean Sea during summertime. Higher contribution of N_2 fixation to primary production (4- 8 %) was measured in the western basin compared to the eastern basin (~2%). Our data indicates that these differences between basins may be attributed to changes in N_2-fixing planktonic communities; while heterotrophic diazotrophy may play a significant role in the Eastern Mediterranean; autotrophic diazotrophy has a more dominant role in the Western basin.

Keywords: Bacteria, Pelagic, Primary production, North-Eastern Mediterranean, North-Western Mediterranean

Reported rates of N_2 fixation from the Mediterranean Sea (MS) are limited to a few studies from the last six years and most are restricted to surface waters and the summer season. Typical rates of N_2 fixation during summer from both the eastern and western basins of the MS are generally low, ranging from undetectable to ~ 0.15 nmol N L^{-1} d^{-1} (reviewed in Berman-Frank and Rahav, 2012 [1]), however, N_2 fixation rates at the central zone of the Ligurian Sea station in the NW Mediterranean (i.e. DYFAMED) are higher ranging from 2-17 nmol N L^{-1} d^{-1} [2].

Here we present first direct measurements of N_2 fixation rates in surface-waters across the MS during springtime (Figure 1). N_2 fixation rates obtained across the MS exhibited a strong zonal gradient from the eastern to western basins. The lowest N_2 fixation rates were measured in the eastern basin, ranging from 0.10± 0.02 nmol N L^{-1} d^{-1} in the Ionian Sea, to 0.15± 0.01 nmol N L^{-1} d^{-1} at station affected by the Rhodes Gyre. N_2 fixation rates increased gradually toward the west ranging from 0.22 ± 0.03 in the Tyhrranean Sea to 2.35± 1.12 nmol N L^{-1} d^{-1} at the westernmost station at the Strait of Gibraltar. The springtime rates of N_2 fixation at all stations were 3-7 fold higher than measurements published previously during summertime.

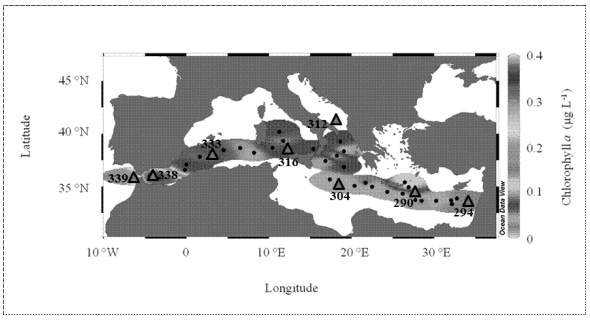

Fig. 1. Map of the sampling locations (triangles): NW Levantine basin (St. 290), anticyclonic Shikmona eddy (St. 294), Ionian Sea (St. 304), Adriatic Sea (St. 312), Tyrannian Sea (St. 316), Alboran Sea (St. 333), Strait of Gibraltar (St. 338) and Gulf of Cadiz (St. 339). Background (circle): Spatial distribution of chlorophyll *a* concentrations in surface waters (6-8 m) along the Meteor M84/3 cruise track (n= 94).

The eastern MS stations sampled exhibited low nutrient and chlorophyll concentrations and N_2 fixation did not correlate with primary production (R^2= 0.18, n=9, t-test, P> 0.05). This suggests that N_2 fixation is attributed mainly to heterotrophic bacteria or that diazotrophs and non diazotrophic phytoplankton is limited or co-limited by different nutrients. On contrary, higher NO_2+NO_3 and chlorophyll concentrations were measured in the more productive western MS. Concurrently, N_2 fixation rates were also higher (ANOVA, P < 0.05) and correlated with primary production (R^2= 0.82, n=12, t-test, P< 0.05), suggesting photoautotrophic associated N_2 fixation.

To further test estimate the relative contribution of autotrophic versus heterotrophic diazotrophy we measured N_2 fixation rates obtained under ambient light and complete dark (48 h). In the western basin, light:dark estimates of N_2 fixation were always > 1, suggesting the predominance of autotrophic N_2 fixation. In the eastern basin light:dark N_2 fixation rates were < 1 suggesting a preponderance of heterotrophic diazotrophs (Figure 2).

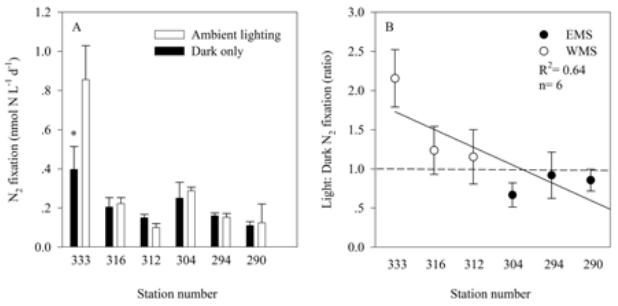

Fig. 2. A) N_2 fixation rates of surface-waters from stations across the Mediterranean Sea for bottles incubated under ambient lighting (white bars) and in complete darkness (dark bars). The asterisk above the columns represents statistically significant differences (one-way ANOVA, P< 0.05) for mean values of N_2 fixation rates in each station, and B) the resulting ratio between rates of N_2 fixation from ambient lighting and dark incubations. n= 3 for each incubation type at each station.

Abstract
This study, investigating monthly planktonic abundance from 1995 to 2012 in Toulon bays, allowed identifying drivers of plankton dynamics and trophic interactions in two shallows coastal bays characterized by a different pollution degree. On average, we detected three phytoplanktonic blooms in both bays per year, driven by abiotic factors like rainfalls and temperature. Data didn't suggest evident seasonal relationships between phytoplankton and zooplankton taxonomic groups.

Keywords: Plankton, Population Dynamics, Pollution, North-Western Mediterranean

The aims of this study was to understand the mechanisms driving phyto- and zooplankton productions and their shifts in communities in two neighboring coastal ecosystems differently affected by pollution. Plankton represents the first stage of the marine trophic web and because its rapid response induced by environment modifications, it is a good indicator of human impact and climate changes ([2]). In addition, plankton, especially phytoplankton, acts on carbon cycle and on sequestration of anthropogenic carbon dioxide ([1], [6]). Little Bay (S_1:43°06'N, 5°55'E) is a shallow and semi-enclosed bay harboring military port and an effective industrial activity. This bay is characterized by a low hydrodynamics and longtime resident water ([4]). This geographic situation conferred it to get urban runoffs particularly during rainfalls and to be concentrate in heavy metals (zinc, lead, copper and cadmium) ([3], [5]). Little Bay and its related results will match with a polluted notified ecosystem. Large Bay (S_2:43°05'N, 5°56'E) is a shallow ecosystem, largely opened to the Mediterranean Sea without a direct influence from the port. This particularity allows increasing the hydrodynamic and reducing its capability to concentrate pollution. Previous studies indicated that the Large Bay would be less polluted than Little Bay ([5]). Results and conclusions about the Large Bay will contribute to modelize a classical Mediterranean shallow coastal marine ecosystem. Planktonic abundance was estimated by monthly subsurface samplings in the two bays from 1995 and 2003 (respectively for zooplankton and phytoplankton). Zooplankton samples were performed using a 90-µm mesh net. Zooplankton samples were conserved in 5% formaldehyde. Aliquot of 20 L of water sampled was reducing in 50 ml by inverse filtration using a 1.2 µm mesh membrane to estimate microphytoplankton abundance; samples were preserved in Lugol solution. Cells recognizing and counts were performed under inverted microscopy. Temperature, Salinity and dissolved Oxygen were also measured by micro-processor oxymeter WTW OXI 196 at 3 meter depth at each site. Nutrient concentrations ($N\text{-}NO_3$ and $P\text{-}PO_4^{3-}$) were obtained from 2005 to 2007 using spectroscopy method. Currently, our preliminary investigations indicated a seasonal pattern for phytoplankton abundance. Indeed, between 2 and 3 phytoplankton blooms occurred each year in both bays. The first one occurred in early-spring and was driven by increasing of temperature and photoperiod. The second and third blooms were produced in mid-spring and early-autumn because of important rainfalls which increased nutrients concentrations. Correlations between nutrients and biotic factors suggested phosphate as a limiting factor for phytoplankton production, especially in Large Bay. Trophic correlations between phyto- and zooplankton abundance were not significant. However, some zooplankton peaks seemed to be correlated with the increasing of phytoplankton community. So, effect of phytoplankton size on zooplankton predation was studied.

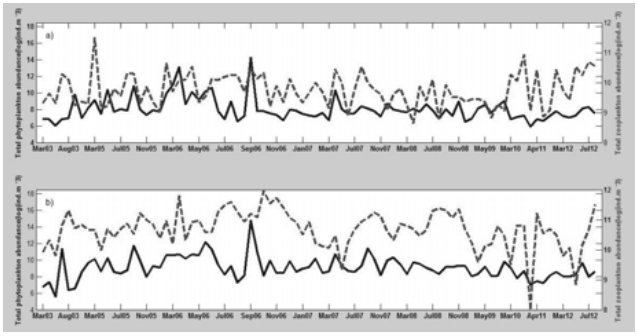

Fig. 1. Interannual evolution of phytoplankton (solid line) and zooplankton (dotted line) in Large Bay and Little Bay of Toulon (NW Mediterranean Sea) (respectively a and b).

Abstract
Microplankton composition was analysed in the inner and middle part of Boka Kotorska Bay, during July 2009. The impact of human activity on this area has been greater and faster as a consequence of increased settlement in coastal area. Value of microplankton reached up to 10^6cell L^{-1} and species indicators of nutrient-enriched waters were noticed.The microplankton communities consisted mainly of diatoms throughout period of investigation.

Keywords: Phytoplankton, South Adriatic Sea

Introduction Boka Kotorska Bay is a unique coastal ecosystem in the south-eastern Adriatic Sea. In this area, anthropogenic influences has become evident, for assessment of any negative impact of human activities, it is essential to determine phytoplankton assemblages in marine areas [1]. The results presented in this study describe summer aspect of phytoplankton community structure in the Boka Kotorska Bay.

Materials and methods Sampling was carried out in July 2009 twice per month, at 5 stations in the inner part (Kotor Bay) and middle part (Tivat Bay) of Boka Kotorska Bay (Fig.1). Samples were taken using 5l Niskin bottles at three depths at three positions and at five depths at two positions (Fig.1). Nutrients (nitrates, nitrites and phosphates) concentrations were determined using standard methods [2]. After sampling, phytoplankton was preserved in 250 ml bottles using a 2% neutralized formaldehyde solution. Cells were identified and enumerated using Leica inverted microscope in subsamples of 25 ml after 24 h of sedimentation, following Utermöhl [3].

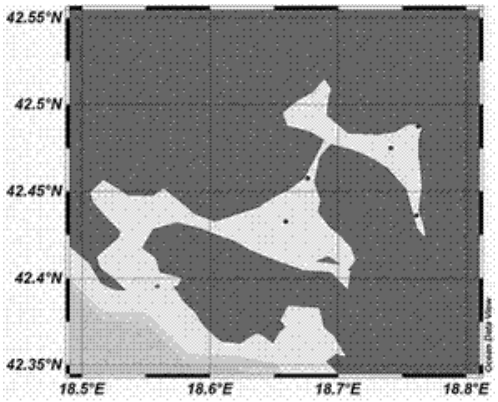

Fig. 1. Investigated area

Results Nutrients (phosphates, nitrates and silicates) ranged from low values to the maximum values of 0.581, 9.915 and 14.014 µmol L^{-1}, respectively. In July 2009, the highest value of microplankton was found in the inner part of the Bay - Kotor Bay (2.84 x 10^6cells L^{-1}). Second smaller peak of microplankton (1.35 x 10^6cells L^{-1}) was also noticed in the inner part of the Bay. In the middle part of the Bay -Tivat Bay microplankton abundances were lower on the order of 10^5 cells L^{-1}. Higher values of microplankton in the Kotor Bay are caused by lower water dynamics and higher nutrients inflow.

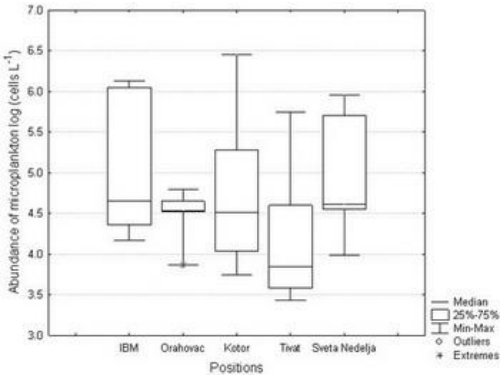

Fig. 2. Abundance of microplankton (cells L^{-1})

Dominant phytoplankton group during July 2009 was diatoms (with maximum of 2.83 x 10^6 cells L^{-1}), as was already noticed [4]. Presence of dinoflagellates were lower with highest values up to 10^4 cells L^{-1}. Frequently present diatom species were: *Chaetoceros affinis, Navicula* spp., *Pseudo-nitzschia* spp. and *Thalassionema nitzschioides*. The majority of the dominant diatoms recorded in this study prefer nutrient - enriched conditions, indicating increased inflow of nutrients. Often occurred dinoflagellates were: *Dinophysis fortii*, *Gonyaulax* spp., *Gymnodinium* spp. and *Prorocentrum micans*. Stronger input of nutrients in summer period of stratification can be explained with increased tourism and problem that works on wastewater treatment plants have not been completed yet. Some noticed species were toxic indicating that in future studies emphasis needs to be on that. **Conclusion** The high frequency of the eutrophic species, especially *Thalassionema nitzschioides* and peaks of phytoplankton abundance on the order of 10^6 cells L^{-1} in summer, both suggest increased anthropogenic influences in Boka Kotorska Bay. The presence of the potentially toxic and toxic phytoplankton species such as *Pseudo-nitzschia* spp., *Dinophysis* species and *Prorocentrum micans* indicate the importance of monitoring and research in the case of possible occuring of toxic algal blooms in this area.

Abstract
Relevant phytoplankton data sets are needed to understand its role in biogeochemical fluxes but also the influence of environmental changes on the community composition and succession schemes. In this study, in situ high frequency automated flow cytometry and remote sensing were combined to characterize the phytoplankton community structure and dynamics. The presented results concern the fast shift in phytoplankton structure (includind Habs) induced by (i) an early spring bloom in the North western Mediterranean Sea and (ii) the occurrence of sporadic event in one of the biggest Mediterranean brackish lagoon.

Keywords: Phytoplankton, North-Western Mediterranean, Monitoring

The Mediterranean ecosystem has been forecasted as one of the most sensitive areas as far as the forthcoming climate change is concerned. It is also one of the hotspots for the planet's biodiversity. In addition, water management in the Mediterranean region is a strategic issue as highlighted in numerous publications (CIESM Monographs). Increase in temperature is also an important issue as it will lead to dry and windy periods (see references in Durrieu de Madron et al 2011). Stratification will be balanced by important water mixing, with amplitudes that should be higher than the ones currently observed. In addition, atmospheric pollution (induced by human activities) and natural dust deposits will affect surface marine ecosystems. The first may damage cells; the second may add valuable nutrients for phytoplankton growth. Phytoplankton is the very first level of the food web and thus fuels the entire ecosystem. As all of the perturbation mentioned above will happen on short time scales (few days maximum, sometimes only few hours), they will escape the traditional long term times series with usual weekly or monthly sampling strategies. Furthermore, each of these events will have specific influences on the phytoplankton structure and functionality. The dominance of one of these events may completely modify the behavior of the phytoplankton community, and thus affect (i) the usual succession scheme, (ii) the trophic structure, and (iii) the biogeochemical processes of a studied area. Although phytoplankton resilience to environmental changes was shown to be strong as observed in very nutritive areas such as the North Sea, the situation in oligotrophic areas (such as in the Mediterranean Sea) is not obvious, since phytoplankton communities are driven by nutrient pulses and light . Phytoplankton found in oligotrophic areas is known to quickly react to short events, some picophytoplankton groups evidencing a two order of magnitude increase in abundances within few hours following a strong wind event (Thyssen et al 2008b). Autotrophic picoplankton has been shown to be of importance at the onset of the spring bloom, and it is hypothesized that any change could induce an influence on the settlement of the usual succession pattern of the spring bloom, and by consequence on the herbivorous food web and higher trophic layers. These various changes in the community structure are strongly influenced by hydrology, nutrient content, irradiance, chemical contents, and turbulence conditions. The understanding of the role of all of these variables can only be studied by building a sampling system able to take into account the various frequencies of the observed features. This is why the MIO is working with a high frequency automated in situ flow cytometer. This instrument, coupled to other *in situ* sensors, is the heart of an automated platform capable to analyse several times per hour the abundance and diversity of phytoplankton groups associated with the environmental variables. This new automated platform has been tested on the EOL Buoy offshore Villefranche-sur-mer and in the Berre Lagoon, both in the North Western Mediterranean Sea, and has massively increased the number, quality and availability of the observations.

Fig. 1. Picture of the EOL Buoy (a) and of the cytometer installed on it (b)

The results clearly evidence the influence of sporadic events (wind) on the fast reaction of ultraphytoplankton and bring new insights on the *in situ* functioning of this compartment. Analyses performed at the single cell level up to twice an hour show rapid shifts, not only in abundances but also in the cell cycles of the various groups observed. Interestingly, all the groups do not behave the same way : some phytoplankton groups (the smallest) tend to benefit from these shifts in environmental conditions, while some others (particularly the biggest) do not. The high-throughput and high quality of the data recorded during this project could feed directly into marine observation and data network. The aim of such a network is to help industry, public authorities and researchers to find and use the data in a more effective way to develop new products and services.

PICOPLANKTON COMMUNITY STRUCTURE RELATED TO ENVIRONMENTAL FACTORS FROM A SPRING CRUISE IN THE GULF OF GABÈS (TUNISIA, EASTERN MEDITERRANEAN SEA)

W. Medhioub [1]*, A. Belaaj-Zouari [1], A. Hamza [1], C. Brunet [2] and M. Belhassen [1]
[1] National Institute of Marine Sciences and Technologies - medhwalid@yahoo.fr
[2] Stazione Zoologica Anton Dohrn di Napoli

Abstract

The spatial distribution of pigments was recorded throughout the Gulf of Gabes (South Ionian Sea) in April 2011, and was related to patterns of the physical structure and the nutrient concentrations. Three distinct water masses were identified based on the temperature and salinity (T–S) analysis. There was no significant difference in the mean nitrogen and phosphate, concentrations between the different water masses. High Chlorophyll a was recorded in typical surface MAW station. Four taxonomic groups were detected throughout the three water masses. The cyanophytes and diatoms groups were dominant in the MAW and MMW especially in surface stations. However, the prymnesiophytes and chlorophytes were poorly represented at the MAW stations.

Keywords: Gulf of Gabes, Pigments, Vertical profile

Introduction

The Gulf of Gabès (south-east coast of Tunisia) is an important nursery for several species of fish. It is one of the key places for fishing activity in Tunisia and is a highly productive zone, one of the highest in the eastern Mediterranean. Quantifying the picoplankton community composition in this area is essential to understanding the structure and the dynamics of marine ecosystems. It is also important to evaluate the role of the physical and chemical processes on the biological responses of the ecosystem. The present paper investigates the picotoplankton community distribution in mid-spring with a high spatial resolution (21 stations and 3-5 depths in a 0-200 m layer) coupled to various environmental factors.

Samples collection and pigments analysis Sampling was performed during a cruise on board the R/V Hannibal from 20th to 26th April 2011 in the Gulf of Gabès. In each station, measurements of temperature, salinity and water density were collected. Sub-samples (2 L) for the pigments analysis were successively filtered through GF/D and GF/F Whatman filters. Pigments measurements were conducted following the method of [3].

Results and discussion

Three major water groups were identified . The first group, included coastal stations situated to the west of 11°E longitude and was characterized by range temperature (between 15.5°C and 17.7°C) and salinity (between 37.7 and 37.9 PSU) referred as the Mediterranean Mixed Waters (MMW) [1]. The second group, represented the stations situated between 11.3°E and 12.9°E longitude with range temperature (between 14.7 and 17.7°C) and salinity (between 37.2 and 37.5 PSU) identified as the Modified Atlantic Water (MAW) [1] . The third group, included offshore stations situated between 12.5° and 12.9°E and was characterized by low temperature (between 14 and 14.7°C) and salinity (between 37.4 and 38.8 PSU) referred as Ionion Waters (IW) [2]. Nitrate and phosphate concentration showed some local maxima in the MAW and MMW, especially in surface stations.

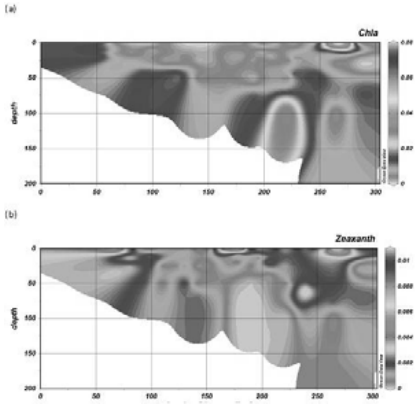

Fig. 1. Vertical profiles of (a) Chlorophyll a (µg l^{-1}), (b) Zeaxanthin (µg l^{-1})

Almost all the pigments were detected in the GF/F filters. No significant signals were reported in the GF/D filters. Chlorophyll a concentrations from picoplankton (GF/F) were generally low than 0.02 µg l^{-1} and did not exhibit a clear spatial pattern except for the presence of subsurface maxima in the typical MAW station with a maximum of 0.08 µg l^{-1} (Fig.1a) . The contribution of each taxonomic group in the picoplanktonic community was characterized by the omnipresence of cyanophytes throughout the three water masses with higher dominance especially in the MAW and MMW surface station (Fig.1b). This result could be justified by the ability of this group to develop adaptation processes related to environmantal factors. The MAW station was essentially dominated by the diatoms group which contributed up to 59% of total chlorophyll a. Chlorophytes and prymnesiophytes were poorly represented throughout the MAW station. The most relevant result of this study showed the dominance of picoplankton classes during the spring period which was in agreement with results already documented in this area [1].

RE-EVALUATING THE RELATIONSHIP BETWEEN SIZE STRUCTURE AND METABOLISM OF THE PHYTOPLANKTON COMMUNITIES IN THE ALBORAN SEA

Abstract
Shifts in the taxonomical composition of the microplankton size fraction along the coast-offshore gradient modulated the usage of light and nutrients by phytoplankton communities of the Alboran sea. These changes could not be predicted from differences in community size structure.

Keywords: Phytoplankton, Alboran Sea, Diatoms, Primary production, Nutrients

Introduction. The size constraints are often used to explain the macro-ecological distribution patterns of the phytoplankton. Thus, predominance of communities dominated by large cells in upwelling or variable environment areas is related to their higher growth rates and carbon-specific photosynthesis in comparison with small phytoplankton [1]. In contrast, dominance of picoplankton in open ocean is normally attributed to its relatively higher affinity for nutrients. These hypotheses have been tested in the Alboran Sea by comparing biomass size distribution and metabolic features of phytoplankton communities isolated in the northern coastal upwelling and the western Alboran anticyclonic gyre.

Materials and Methods. The sampling was carried out in the northwest Alboran Sea between 9-14 May 2008. Ten stations distributed into two transects following a gradient perpendicular to the coast line were sampled. Abundances of *Prochlorococcus*, *Synechococcus*, eukaryotic picoplankton and nanoplankton were determined by flow cytometry. Abundance of dinoflagellates and diatoms were determined by the Utermöhl's technique. For each group, cell bio-volume was calculated by using the most appropriate formulas according their geometric shape. Light absorption properties of the phytoplankton community were estimated from filters according to [2]. Uptake rates of inorganic carbon, nitrate and ammonium were estimated from incubations onboard in medium enriched with sodium bicarbonate-^{13}C, potassium nitrate-N^{15} and ammonium-N^{15} sulphate.

Results and Discussion. Diatom contributed by 60-80% to the phytoplankton biomass in the coastal stations while dinoflagellates dominated in the anticyclonic gyre stations (63-25%). Pico-plankton biomass was lower than 7% in the coastal stations and increased up to 15-20% in the anticyclonic gyre stations. Among the diatoms, *Chaetoceros* cells with equivalent spherical diameter (ESD) lower than 50 µm were the main size-class contributing to the community biomass (Fig. 1). The ratio of chlorophyll *a* to POC (Chl/POC in Fig. 2) was significantly higher in the coastal stations than in the anticyclonic gyre indicating that <50 µm diatoms had higher chlorophyll *a* cell content. Theses changes run parallel to increase in the efficiency of light absorption (a* in Fig. 2). Furthermore, light absorption efficiency and ESD mean of the diatom community were positively correlated. The biomass specific rates of carbon (*V*DIC) and nitrate ($V NO_3$) uptake were about four-fold higher in the coastal stations that in the anticyclonic gyre. *V*DIC and $V NO_3$ were correlated with <50 µm diatoms biomass and ESD mean of the whole diatom community. $V NH_4^+$ in the coastal stations was from 5 to 20 times lower than the corresponding $V NO_3^-$. On the contrary, $V NH_4^+$ was higher than $V NO_3^-$ in the anticyclonic gyre stations. $V NH_4^+$ was correlated negatively with *V*DIC as well as abundance of diatoms, pico-eukaryotes and nano-eukaryotes. The reported data indicate that acclimation strategies dependent on the taxonomical composition of the diatom community modulated the light usage and nutrients of the whole community. Several authors have demonstrated that the slope of the size-scaling function of the phytoplankton metabolic rate is far from the expected one (the so called 3/4 rule) [3]. These authors attributed the deviation between the metabolism rates predicted from their cell size and those measured to the acquisition of taxa-specific physiological strategies by species in certain size class. Our data support this hypothesis and emphasize the necessity of considering the acclimation capacity of the communities to predict their role in the carbon budgets.

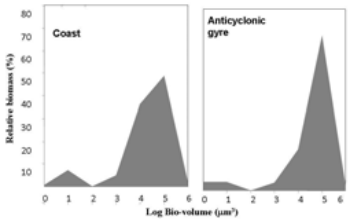

Fig. 1. Examples of biomass size-class distribution of the phytoplankton communities collected in coastal and anticyclonic gyre stations.

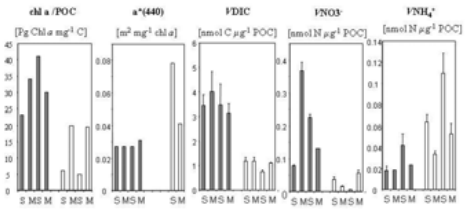

Fig. 2. Physiological performances of the phytoplankton communities sampled in the coastal (dark columns) and anticyclonic gyre stations (white columns). S, surface samples; M, sub-surface chlorophyll a fluorescence maximum samples. Chl/POC: ratio of chlorophyll a to particulate organic carbon concentration; a*(440), 440 nm light absorption efficiency; *V*DIC, $V NO_3^-$ and $V NH_4^+$ biomass specific uptake rate of inorganic carbon, nitrate and ammonium, respectively.

ETUDE QUALITATIVE ET QUANTITATIVE DES PEUPLEMENTS PHYTOPLANCTONIQUES DE LA BAIE DE BOU-ISMAIL

Dina Lila Soualili-Mezali [1]* and Mustapha Boudjenah [1]
[1] Université Abdelhamid Iben Badis, Faculté des Sciences de la Nature et de la Vie - soualilid@yahoo.fr

Abstract
Cette étude est une contribution à l'évaluation quantitative et qualitative du phytoplancton récolté au niveau de deux sites « les Trois Suisses » et « le Vivier ». A cet effet, l'analyse des paramètres physicochimiques n'a montré aucune différence significative entre les deux sites (test U de Mann - Whitney). Par ailleurs, deux blooms ont été identifiés en (Mai) et en (juillet-Aout), caractérisés par la dominance des diatomées. La comparaison des diagrammes rang-fréquence, a permis de mettre en évidence des communautés pionnières qui apparaissent à chaque fois au stade 1, donc un début de succession caractérisée par des espèces engendrant.

Keywords: Blooms, Diatoms, Dinoflagellates, Toxic blooms, Algerian Sea

Les changements dans les structures de la communauté du phytoplancton, peuvent avoir des implications importantes pour l'ensemble de l'écosystème marin, à travers la chaîne alimentaire et les cycles biogéochimiques [1]. Le but principal de cette étude est d'explorer la diversité des peuplements phytoplanctoniques et de statuer sur les capacités productives des sites étudiés. Les échantillons mensuellement ont été prélevés en 2011. Les mesures des paramètres (pH, la salinité, l'oxygène dissous, la température) ont été effectuées à l'aide d'un Multiparamètre. Les échantillons du phytoplancton ont été fixés au Lugol, les dénombrements étant effectués en microscopie inversée d'après la méthode de [2]. Différentes métriques ont été calculées (diversité globale, richesse spécifique et indice de Shannon). Sur l'ensemble des variables étudiées (la salinité, la température, l'ammonium, les nitrites, les nitrates et le phosphore), peu de différences ont été décelées entre les deux stations. Par ailleurs, les teneurs en éléments nutritifs analysés restent toujours inférieures à 0,2mg/l. Un total de 306 espèces a été identifié dans les deux sites, représenté par 69% de diatomées et de 31% de dinoflagellés. Par ailleurs, au mois de Mai, dans "le Vivier" se sont les diatomées, qui dominent avec 76%, alors que dans le site "les Trois Suisses", le pourcentage des diatomées est similaire à celui des dinoflagellés (Fig 1 et Tab 1). La comparaison des diagrammes rang-fréquence mensuels a mis en évidence des communautés pionnières au stade 1, donc on a présence d'espèces engendrant, représentées par des diatomées sauf en Mai dans "le Vivier".

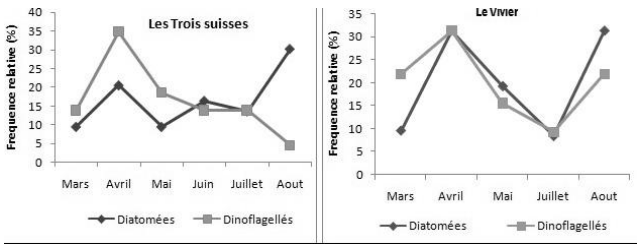

Fig. 1. Répartition mensuelle en pourcentage des diatomées et des dinoflagellés au niveau des deux sites.

Tab. 1. Genres de diatomées et de dinoflagellés dominants dans les deux sites.

Mois	Genres de diatomées dominants		Genres de dinoflagellés dominants	
	Les trois suisses	Le vivier	Les trois suisses	Le vivier
Mars	Chaetoceros	Chaetoceros	Ceratium	Peridinium
Mai	Coscinodiscus	Rhizosolenia	Ceratium	Ceratium Prorocentrum
Juillet	Navicula	Navicula	Ceratium	Prorocentrum
Aout	Nitzschia	Navicula	Amphidinium	Katodinium

Enfin, les assemblages phytoplanctoniques essentiellement constitués de diatomées montrent que ces sites sont en bonne santé et cela est confirmé par la rareté des espèces Chaetoceros curvisetus, Leptocylindricus danicus et Skeletonema costatum citées par [3] comme espèces indicatrices d'eutrophisation.

Abstract

Relevant phytoplankton data sets are needed to understand its role in biogeochemical fluxes but also the influence of environmental changes on the community composition and succession schemes. In this study, in situ high frequency automated flow cytometry and remote sensing were combined to extrapolate at the basin scale the phytoplankton community structure. The presented results concern the deep water convection zone in the north western Mediterranean Sea.

Keywords: North-Western Mediterranean, Mapping, Monitoring, Ocean colours, Phytoplankton

Phytoplankton plays a major role in oceanic biogeochemical processes (mainly carbon, nitrogen, silicate, phosphate, iron cycles) since it converts inorganic material into organic matter, the feeding source of the entire marine food chain. Some phytoplankton groups are distinguished by specific metabolic pathways, or indicate a specific trophic system, or evidence an adaptation to given environmental conditions, and as such, they are defined as plankton functional types (PFT, [1]). The most common traits found behind the concept of PFT are diazotrophy, calcifiers, silicifiers, mixotrophy, size classes, motility, DMS-producers. For a better understanding of the role of phytoplankton community structure and dynamics, there is a need for significant data sets that include sub-meso and hourly scale resolutions because the system is highly dynamic (daily cell cycles, prey-predator relationships and hydrodynamism at the meter scale). This can be achieved by combining *in situ* high frequency single cell analysis ([2], [3], [4]) and remote sensing novel PFT discrimination from water-leaving radiance (PHYSAT, [5], [6]). Combining both techniques helps in understanding the impact of highly hydrodynamical areas on phytoplankton community structure, phytoplankton succession schemes and finally, on the food chain structuration and the potential organic matter export. To study the influence of the deep water convection phenomenon in the Northern Mediterranean Sea, known to uplift nutrients into the euphotic layer and further trigger the onset of spring phytoplankton bloom, an automated high frequency (every hour) and remotely controlled flow cytometry (FCM) analysis of surface waters was conducted (Figure 1) during two DEWEX cruises in February and April 2013 in the frame of the MERMEX project. A previous example of successful coupling between remote sensing (PHYSAT) and automated FCM associated with a FerryBox equipment in the North Sea (INTERREG IVA "2seas" DYMAPHY project) leading to regional North Sea mapping of community structure will be presented as a support to the present investigation in the northwestern Mediterranean Sea. Preliminary results from the DEWEX cruises will be presented. They will be used to empirically calibrate the PHYSAT algorithm for the description of PFT from satellite normalized water-leaving radiance anomalies, in order to map the distribution of the main PFT at the basin scale.

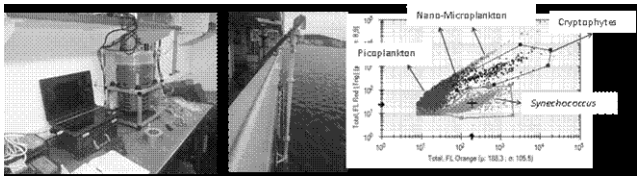

Fig. 1. A. Automated flow cytometry dedicated to the phytoplankton analysis. B. Continuous water collecting system onboard the N/O Le Suroit (IFREMER). C. A cytogram resuming the main phytoplankton groups analysed. Pictures of the microphytoplankton were collected in April 2013 and will be presented.

COMITÉ 5

Ressources vivantes et écosystèmes marins

Co-Présidents : Ferdinando Boero et Cemal Turan

Rapports des modérateurs

Ageing techniques and growth

Kapiris Kostas, Greece

Résumé

Several studies were presented relating to the relative growth, biometry, relationships between total length-weight, age of some small pelagic, benthopelagic, and pelagic species. The relative growth of Engraulis encrasicolus is positive, according to many morphometric characters, isometric and negative, in other cases, depending on the sex, in the Gulf of Annaba (E. Algeria). The sexual dimorphism of Dentex maroccanus in different age groups was presented with regard to absolute growth in specimens caught in NE Algeria.

Other communications presented reproductive aspects of Engaulis encrasicolus and Sardina pilchardus from E. Algeria; the age and growth and the otolith?s length-total length relationships in both sexes of Sphyraena sphyraena along the Tunisian coasts and of Balistes capriscus in the Gulf of Gabes; the absolute and relative growth of both sexes of Thunus thynnus as estimated in 11,715 specimens caught by japanese long lines along Algerian coasts; the age and growth of both sexes of the decapod Metapenaeus affinis studied in individuals caught in the Bay of Izmir (Turkey) which is the first report coming from the whole Mediterranean basin.

Ageing techniques and reproduction

Fatima Zohra Bouhali, Algérie

Résumé

Cette session, la dernière du 40ème Congrès, a débuté par une courte introduction donnant une idée générale sur deux aspects (âge et la reproduction), avant de donner la parole aux six auteurs présents.

Les discussions et les questions furent peu nombreuses, à part quelques interventions concernant l'importance de la communication entre tous les pays de la Méditerranée via le réseau de recherche de la CIESM qui favorise chercheurs et étudiants.

Aquaculture - growth

N/A

Résumé

Modérateur absent

Aquaculture - Invertebrates

Serpil Serdar, Ege University, Faculty of Fisheries, Izmir, Turkey

Résumé

The session started with a general introduction by the moderator, who recalled the importance of invertebrates, their general phylum characteristics and the rationale for their aquaculture. The first communication focused on the growth of mussel (Mytilus galloprovincialis) in two tunisian sites, as affected by bacteriological load. Others presented the depuration time and ability of Manila clams (Ruditapes philippinarum) with respect to Escherichia coli, Salmonella typhimurium and Vibrio parahaemolyticus; larval recruitment and mortality of Crassostrea gigas spat in a Mediterranean lagoon. The last speaker sudied the growth and survival rate of carpet shell clam (Tapes decussatus) in high stocking density in Turkey. The concluding general debate concerned the main reasons of oyster spats? mortality, availability of bacteriological load and virus in aquaculture areas, clam culture and depuration techniques and systems.

Biodiversity hotspots

Mohamed Menioui, Maroc

Résumé

Les communications étaient très diverses, comprenant i/ Populations structure of the endemic species Paranemonia vouliagmenjensis, Attika, Greece par (V. Anagnostou); ii/ species richness and anthropogenic pressures in French coralligenous assemblages (F.Holon); iii/ First results of fish diversity associated with Posidinia oceanic meadows in the Aegean Sea (Kalogirou); iv/ Les actiniaires des rivages tunisiens, inventaire et distribution (S. Tekaya); v/ Biodiversity in the sea of Marmara and the affecting factors par A.Yuksek. Le débat a largement porté sur la zone 'Hotspot' présumée de la biodiversité au sud des côtes marocaines. La côte marocaine est baignée par des eaux à hydrologie particulière due aux upwellings et les espèces nouvelles qui y ont été observées se situent une zone de transition entre le courant froid des Canaries et le courant chaud NW africain.

Cartilaginous fish distribution

Mohamed Nejmeddine Bradai, Tunisie

Résumé

The session was introduced by the moderator by a brief presentation on the Status of elasmobranches in Mediterranean and Black Sea focusing on distribution, threats, by-catch and on the lack of knowledge on biology, ecology, systematic and critical habitats of this group.

The ten programmed communications were presented. The main topics highlighted have concerned the observation and monitoring of some species, by-catch, critical habitats and age determination. One of these communications reported the main outcomes of a three-year research programme of GFCM launched in 2010 to improve the knowledge and asses the status of elasmobranchs in the Mediterranean and Black Sea. The programme will be extended for the next three years.

Following the diagnostic of the situation of elasmobranchs in the Mediterranean and Black Sea, the participants recommended some priorities for Sharks of the region:

· Developing research programs on systematic, general biology, ecology and population dynamics for species of concern.

· Identifying and mapping critical habitats.

· Taking action to collect reliable statistics on landings and Bycatch of elasmobranchs and to develop research programs to reduce elasmobranchs bycatch.

Cartilaginous fish ecology

Sebastián Biton Porsmoguer, MOI, Marseille, France

Résumé

What is the sharks situation in the Mediterranean Sea? Eighty-five species of sharks and rays were identified in this area. Among them 40 percent are either endangered or threatened according to the IUCN. Mediterranean Sea is a very important reproduction area for sharks, especially for the great white shark (Carcharodon carcharias) and sandbar shark (Carcharhinus plumbeus) in Italian and Tunisian waters for example. In the last decades, in the Mediterranean Sea, sharks and rays strongly declined in both diversity and abundance. The intensive exploitation and growing market of fins, meat and cartilage are the main reasons to explain these tendencies.

During the two last centuries, the landed biomass of the four most important pelagic sharks, decreased by ninety-seven percent for the Blue shark and by ninety-nine percent for the Shortfin mako, Hammerhead and Thresher shark. The scientific community during the last ten years studied three relevant biological aspects of sharks: reproduction, growth, and diet. Forty-three species were studied for reproduction, only 12 species for age and growth, and 35 species for their diet. We can conclude that many species still need to be studied. Moreover, many other biological and ecological aspects need to be developed for these species. For example: Stock assessment, Migration, Genetic analyses, Parasites, Pathologies, Modelling, and Conservation. We all know the important role that sharks used to play in the structure and functioning of the marine ecosystems and we have to find solutions for conservation of their populations and to propose new projects to study all these species and aspects.

During the session cartilaginous fish ecology, the different presentations showed interesting results about biological and ecological aspects of many cartilaginous species. They concerned the diet of Dasyatis pastinaca, Rostroraja alba, Prionace glauca and Isurus oxyrinchus, and the reproduction and size of maturity of Galeus melastomus, Squalus megalops, Squalus blainvillei and Dipturus oxyrinchus. Finally, we could see different methods to determine the age and growth of Dipturus oxyrinchus and Squalus megalops. Different methods are used: identification of prey in the stomach for the diet and study of vertebrae for determinate the age for example. Most of the cartilaginous species studied were benthic and not targeted. They were captured by commercial fisheries and especially by trawler vessels. The conservation of this species is a very important objective.

Connectivity

Anne Chenuil, France

Résumé

Scientific knowledge of marine connectivity is an important matter, both from a fundamental point of view (connectivity begin a primordial parameter affecting adaptation, speciation, thus ecology and evolution in general) and for for biodiversity management and conservation purposes ((i) extinction risk is increased by excessive fragmentation, (ii) the design of marine protected areas (MPAs) and MPA networks gains a lot from taking into account connectivity patterns) (e.g. posters 4201-4211). Connectivity among marine populations of a given species can be considered as made up of three components: habitat connectivity, species ability to actively disperse, and water mass connectivity (which can enhance or oppose other components). We can also distinguish three approaches to characterize connectivity: (1) habitat mapping, (2) approaches focusing on species (direct approaches studying behavior or life cycles, or population genetics approaches, which patterns result from the three components) and (3) physical oceanography characterizing and modeling the movements of water masses using, with a strong dominance of Lagrangian models, by far the most adequate tools. Recent research programs often include work packages dedicated to habitat mapping. One poster (4213) dealt exclusively with habitat connectivity (coralligenous). Marine caves are examples of highly fragmented habitats (e.g. poster 4204) and water column habitats represent the most connected category of habitats.

The majority of posters (six or seven) presented population genetic data, and two posters dealt with physical oceanography (4201-4209). Combined approaches are rare both in the literature and in this session (one poster compared physical and genetic connectivity matrices (4212). This reflects a general difficulty which may be due to knowledge gaps concerning the biology of the studied species: (i) season of emission of planktonic offspring, (ii) behavior of the species, in particular vertical movements which represent the necessary behavior information for Lagrangian models (and sufficient to reach a satisfying realism), and (iii) physical characteristics such as buoyancy of the life stage submitted to water currents (and its evolution during development). Thus can we predict the future of connectivity studies? Already more than 800 papers report population genetic data from Mediterranean marine species. However, despite this number, understanding of common or particular processes and patterns of marine connectivity remains extremely partial. This is due to both the absence of studies combining different approaches, the limits of most genetic studies (low sampling size and unsuitable distribution of localities, use of a single genetic marker) and the absence of synergies among studies (shared sampling locations among study species are exceptional instead of being the rule (but see Poster 4202). Improvements will be obtained owing to the availability of universal genetic markers (Chenuil et al., 2010; Gérard et al, in press, Marine Genomics) (posters 4214-15), new sequencing and genotyping technology (NGS-NGG), comparative approaches among species with common sampling schemes, studies to obtain basic biological knowledge on behavior and life cycles, and finally on close collaboration between physicists and biologists (ex of the French research group, the GDR ?MARCO?).

Ecological trends

Vesna Macic, Inst. Marine Biology, Kotor, Montenegro

Résumé

In this context were presented findings for 'flag species' such as the seagrass Posidonia oceanica, for economically important species such as the fish Micromesistius poutassou and for invasive species such as the alga Caulerpa racemosa. Although this session was limited to a small group of four presentations, important issues like monitoring and acquisition of long time series of data were raised during the presentations and the general discussion.

Improved monitoring programs and greater availability of existing data in a number of countries were underlined as a necessity for appropriate evaluation of ecological trends.

Functional traits

Claudia Kruschel, Croatia

Résumé

The session went well. It started with an introduction to the subject of functional traits and functional diversity by the moderator, touching on research areas that are recently reevaluating the usefulness of functional trait information to answer open and fundamental questions in ecology and evolution, including community assembly (e.g. along environmental gradients), the relationship between biodiversity and ecosystem processes and function, and our ability to predict ecosystem service maintenance in the face of strong anthropogenic drivers and stressors.

All participants kept to the three minute agreement, and so there was ample time for a debate. The main subject of the debate period was the presentation given by Leonid Svetlichny on the migratory behavior of the copepod Calanus euxinus in the Black Sea. These organisms are spending nights in anoxic and colder depths, which seems to result in an eightfold decrease in metabolism. The debate circled around the possibility of an alternative explanation for the behavior. Suggestions included predator escape as the primary selection for the migratory behavior followed by selection for tolerance to anoxia favored by the gain of fitness via energy

conservation. Also discussed was the importance of seasonality in the sampling scheme and possible seasonal variation in the migratory behavior.

Overall the new format was really appreciated There is a lot to say in 3 minutes!

Gelatinous plankton distribution

Davor Lucic, University of Dubrovnik, Croatia

Résumé
Nine communications were presented in which the authors point to the following topics:

a) the role of oceanic transport and climatic/oceanographic conditions in redistributing existing jellyfish populations at regional and basin scale;

b) population dynamics and seasonal changes in gelatinous plankton diversity and distribution;

c) the influence of environmental factors on the distribution and abundance of gelatinous plankton.

Special interest and discussions were given to presentations that included modeling and simulation of dispersion and aggregation of species. It was underlined that for better knowledge of the distribution and abundance of gelatinous organisms a better understanding of their life cycles is needed. To this end, it is necessary to combine all available information, from reports of citizen science to the results of scientific research and modeling simulations.

Gelatinous plankton ecology

Tamara Shiganova, Shirshov Inst. of Oceanology, Acad. of Sciences, Moscow, Russia

Résumé
In recent years native gelatinous species considerably increased population size and distribution in the coastal areas of the Mediterranean Sea, some of them expanding into the Sea of Marmara and even in the Black Sea. In addition non-native gelatinous species are recorded more and more often, particularly in the eastern basin of the Mediterranean.

This session discussed recent findings.

The debate highlighted the interest of the various talks regarding the ecological aspects of the gelatinous species (mainly Mediterranean) studied. The appendicularian study in the Adriatic Sea , the presentation of gelatinous species blooms in Spanish waters, and the impacts, distribution patterns and adaptative strategy of Mnemiopsis leidyi attracted most of the discussion. In the latter case, the variability of morpho- physiological features, genetic diversity, patterns of spatial and temporal population dynamics in the Black, Azov, Caspian, Baltic, and several areas of the Mediterranean seas are seen as a response to different conditions of salinity, temperature, prey concentration. It was concluded that ecology study of increasing populations of gelatinous species are crucial for understanding changes in ecosystem functioning. Special attention should be paid to non-native species, in particular to the aggressive invader Mnemiopsis leidyi.

Good Environmental Status, assessment

Slim Gana, SAROST, Tunisie

Résumé
At the start of the session, the concept of "Good Environmental Status" and how to undertake assessment according the Marine Strategy Framework Directive (MSFD-2008/56/EC), was introduced. MFSD establishes a framework for marine environmental policy up to the 200 nm limit of the European EEZ, while the European Water Framework Directive (WFD) (Directive, 2000/60/EC) develops the concept of ecological status for assessing the quality of water bodies.

MSFD requires Member States to carry out an Initial Assessment, based on existing data, of their marine waters covering three key elements:

- An analysis of the essential features and characteristics and current environmental status of their waters;

- An analysis of the predominant pressures and impacts (including human activity) on their waters;

- An economic and social analysis of the use of their waters and the cost of degradation of the marine environment

The issue of GES assessment was not addressed by all the presentations. During the discussion, given the spatial extent of the MSFD, the need for innovative approaches and descriptors required to allow meaningful monitoring and assessment was mentioned. On the basis of an operational, management-oriented definition, we discussed the available methodologies that could be used for coastal and marine assessment, with an emphasis on integrated approaches (i.e. ecosystemic) accounting for physico-chemical and biological components, and combining both pelagic and benthic symptoms of degradation, thus keeping with the holistic nature of the MSFD.

Regarding the implementation of the MSFD in non-EU Mediterranean countries, the bottom-up approach was recommended by strengthening the awareness of young engineering groups working in national institutions dealing with environmental issues.

Good Environmental Status, indicators

Beatriz Guijarro, IEO, Palma, Spain

Résumé

The aim of the Marine Strategy Framework Directive (MSFD) is to protect the marine environment across Europe. This directive sets a target of Good Environmental Status (GES) which must be achieved in EU marine waters by 2020. According to the MSFD, the GES are defined as ?the environmental status of marine waters where these provide ecologically diverse and dynamic oceans and seas which are clean, objective and productive?. GES means that the different uses made of the marine resources are conducted at a sustainable level, ensuring their continuity for future generations. The Ecosystem Approach to Management is a central point in the MSFD, as it integrates the connections among different compartments of the ecosystem: from the structure and evolution of the water resources (physical and chemical conditions and hydrodynamics) to the maintenance of biodiversity and the effect of human activities, such as pollution and fishing exploitation.

The communications had in common the need of monitoring different compartments of the ecosystem while covering a wide range of topics, areas and species. Some presentations discussed foraminifera, barnacles, mussels or fish, as potential indicators of water pollution. Another showed a synthetic indicator of phytoplankton group composition to be used in the assessment of chlorophyll concentrations and two presentations focused on fishery exploitation and the analysis of trends for demersal species.

Good Environmental Status, tools & methods

Marc Bouchoucha, France

Résumé

The acronym G.E.S. refers to two different concepts. The first one stems from the Water Framework Directive and means ?Good Ecological Status?. The second one, more recent, is the ?Good Environmental Status of the Marine Strategy Framework Directive.

These two concepts are somewhat different. According to WFD, good ecological status is achieved if all the basic components of the ecosystems are in a good status whereas, according to the MSFD, good environmental status is achieved if all the functions of the ecosystems are fulfilled.

The session 21 presentations refer either to the good ecological status and are related to one of the five particular ecological indicator of the WFD or to the good environmental status and provide more ecosystem functioning data. In practice today, the two definitions are often confused in scientific literacy and the following functional definition is often found: ?good environmental status means the environmental status of marine waters where these provide ecologically diverse and dynamic oceans and seas which are clean, healthy and productive within their intrinsic conditions, and the use of the marine environment is at a level that is sustainable, thus safeguarding the potential for uses and activities by current and future generations (?)

In any case the conceptual scheme to assess the status and its evolution toward GES is more or less the same. Data are collected directly or by the way of operational tools. They serve to feed models or indicators to provide information which is compared to reference conditions in order to assess environmental status. Data are also used to evaluate pressures that enter in some models or indicators conception.

For a number of those steps, especially within the MSFD framework and its 11 descriptors with large spatial application, need for additional scientific information or further development has been identified. Also, increasing scientific knowledge on the marine environment and its processes is required and, to tackle that objective, innovative tools are needed.

In session 21, the presentations were diverse in their coverage (a gap analysis tool, operational tools, models, satellite imagery analysis, video system, a models prediction assessment, a model of reference conditions, a tool to assess difference between reference conditions and evaluated status or a anthropogenic pressures modelling) but each of them enlightened a tool that fulfil one of the numerous scientific identified gaps within the MSFD framework.

Indo-Pacific aliens biology

Bella Galil, Israel

Résumé

Introduction of Indo-Pacific biota into the Mediterranean Sea interferes with multiple aspects related to marine life, including the conservation of biodiversity, structure and function of ecosystems, sustainable exploitation of natural resources, and it negatively impacts upon industries and poses threats to human health.

Recognition of the significant threats posed by NIS is evident in the European Community Marine Strategy Framework Directive (MSFD) and Biodiversity Strategy. Of the eleven descriptors that constitute the basis for the evaluation of ?Good Environmental Status? (GES) of marine ecosystems in the MSFD, NIS are second only to biodiversity. Of the 887 multicellular NIS reported in the European Seas, 677 from the Mediterranean Sea, over the period 1970-2012 their numbers grew by 204%! The Suez Canal, a pathway unique to the Mediterranean Sea, is responsible for an increased inflow of new thermophilic NIS into the warming sea.

Yet, the UNEP MAP "Draft Decision on the Ecosystems Approach including adopting defition of Good Environmental Status (GES) and targets" to be voted upon in the 18th Ordinary Meeting of the Contracting Parties to the Barcelona Convention and its protocol, on 3 December 2013, excludes species introduced through the Suez Canal from its NIS & IAS GES. Today we received ample scientific evidence as to the prevalence and impacts of Indo-Pacific NIS in the Mediterranean ? we can not ignore it, and we can not allow UNEP MAP to ignore it.

In conclusion: all presenters were present, with smooth delivery of results. The session was well attended, in fact, people were streaming in thru the session. Post presentation discussion engaged the audience and session ended with lively applause.

Indo-Pacific aliens impacts

Jamila Ben Souissi, Institut National Agronomique de Tunisie, Tunisie

Résumé

This session offered the opportunity to the many participants to exchange their views and experience as well as identifying several areas of common interests in the Mediterranean and Black Seas. The participants highlighted that both economic and ecological impacts of alien species are poorly documented and that several issues, such as drastic regulation of ballast waters, should be addressed as a matter of urgency. According to several case studies presented (mainly in Eastern basin), certain species heavily and negatively affect key environmental and economical sectors, such as fishing, aquaculture and tourism, in addition to human health.

The discussion emphasized that prevention is the best way to avoid newcomers. Various tools exist to prevent the introduction of NIS but unfortunately the laws are rarely enforced. According to some participants, it is too early to estimate the environmental impacts in the Mediterranean region because the ecosystem is not yet stable. Participants deplored the lack of data in Libyan waters (a key area for the settlement of lessepsian migrants), which prevents an efficient early warning system to alert neighbor countries.

Comparative studies in countries with long period records of NIS were recommended in order to highlight the changes in biodiversity (collapse of endangered endemic species in favour of invaders, etc?). The eradication of NIS, once established, becomes very difficult, and so attempts should be made to exploit them for value when possible (the example of Siganid fishes, toxic Tetraodontidae, gelatinous megaplankton, was given). Particular attention should be paid to anti-Lessepsian migration and to developing a database of bioinvaders' impacts.

Indo-Pacific aliens records

Tarek Temraz, Suez Canal University, Egypt

Résumé

The record of indo-pacific aliens into the Mediterranean session commenced with a brief introduction on the different routes of migration especially the aquatic corridors such as Suez Canal and the role of aquaculture through intentionally or accidently released organisms. The discussion focused on the need for accurate and precise taxonomy to allow proper identification of migrated species, especially macrophytes and fishes. Proper use of the following terms ?aliens/non indigenous/ exotic? as well as awareness of the new range of occurrence as the case of Oculina patagonica and whether it is endemic to the Mediterranean or migrated from the Atlantic. The role of Suez Canal as a main route of migration to be stopped or to be monitored via early monitoring stations about potential migrants, was hotly debated.

E. Azzurro emphasized the need to know the exact number of alien fish species in the Mediterranean Sea through reconstruction of

occurrence records collected from published literature into one database. The database includes so far 85 Lessepsian migrant species, 44 migrants from the Atlantic, plus others introduced by man for a total of 172 fish taxa. Furthermore, Azzurro presented a new interactive website (SEAWATCHERS) acquiring geo-referenced observation of exotic fish species along the Mediterranean. The website generated 74 records in 10 months including the questionable record of Abudefduf saxatilis.

M. Verlaque updated the CIESM website of exotic macrophytes in the Mediterranean to include 129 taxa. S. Katsanevakis presented the European Alien Species Information Network (EASIN) as an efficient tool to create distribution map for alien species into the Mediterranean depending on the introducing pathway of alien species.

B. Cicek illustrated the importance of conducting monitoring programs to reveal exotic species as he recorded Caulerpa taxifolia for the first time along the northern coast of Cyprus. D. Golani emphasized the role of temperature rise and the deepening of the Suez Canal in the invasion of Lessepsian Red Sea fish species into the Mediterranean where no less than 33 species migrated in less than one decade, creating faunal shift.

E. Serrano, stressed the role of temperature rise in estimating the spread of Oculina patagonica along the Iberian Peninsula. J. Zaouali, identified the role of floating cages as providing a substrate for exotic species along the Tunisia coast. T. Temraz recorded Plototus lineatus for the first time along the Egyptian coast of the Mediterranean.

Marine Mammals, Turtles and sea Birds

Adriana Vella, Malta

Résumé

This session was introduced by considering the reasons why marine mammals, turtles and seabirds are important indicator - and flagship - species in the Mediterranean. This fact together with the clear gaps of knowledge on the various species inhabiting the Mediterranean Sea promotes the relevance of research and monitoring of these species. Climate change and the various anthropogenic impacts on these species were also introduced, paving the way to the interesting presentations of six speakers that presented their scientific work and findings. The papers presented covered topics from monk seals, sea birds and cetaceans to species association studies and impacts of climate change on turtle nesting beaches. Fin whale stranding data were found to furnish useful life history knowledge that would be important in population dynamics considerations, while monk seal and seabird studies in selected sites brought in vital information on the presence of these species adding interesting insight on the distribution of these species. The work on species associations in Central Mediterranean also contributed useful knowledge to better appreciate the complex and changing dynamics of species distributions and different species associations. Long-term and year-round studies are essential in order to understand such dynamics.

Various questions were discussed, yieding a lively debate on the need to work further on how these diverse species distribute themselves according to their life history needs, seasonality, and climatic changes affecting marine life in the Mediterranean Sea. A discussion on whether fixed marine conservation areas or more widespread conservation management is required for these large distance ranging species in the Mediterranean was also briefly considered. The discussion was relevant to the effective and long-term conservation of these species in a region where various proposals have been brought forward but with limited success on effective long-term conservation research, monitoring and management of the various species. It was agreed that greater collaborative work among Mediterranean scientists is required and that CIESM is an ideal forum to sustain and develop further such collaborations.

MPAs conservation and management

Nataliya Milchakova, Inst. of Biology of the Southern Seas (IBSS), Sevastopol, Ukraine

Résumé

Fifteen communications were presented in this session by scientists from nine countries bordering the Mediterranean and Black Seas; most works have been conducted in the Mediterranean basin, with only two of them in the Black Sea. At present MPAs are supposed to cover 4.56% of the Mediterranean Sea area and 1,76% of the Black Sea (?Status of MPAs in the Mediterranean Sea?, 2012; Milchakova, 2011). But only 49% and 14% of them have a management plan, and many of them lack coherence and ecological representativity.

The results presented did reflect the different aspects of conservation planning and management, biodiversity and population structure, and the socio-economic impact of MPAs. Many presentations have demonstrated the role of MPAs in biodiversity conservation, including cetaceans, fish, mussels and macroalgae species. Proposals for new MPAs to be created by 2020 were presented, as well as data using the MARXAN techniques in conservation planning, and the impacts of OWF on marine biota.

One of the main conclusions is that, without national and international strategies, conservation planning and management, MPAs and their ecosystem cannot be saved, especially in the most vulnerable coastal areas.

Rocky shores and artificial reefs
Pierre Cresson, Ifremer, La seyne sur Mer, France

Résumé
Presentations in this session revolved around three main questions:

First, what are the main ecological functions of rocky zones? The first answer can be it is one the major biodiversity hotspot in the Mediterranean. Five presentations were devoted to a better assessment of this biodiversity, investigating parameters such as community composition, dominant species or demography, and then trying to find environmental variables explaining these patterns. This zone is also crucial, as it is involved in reproduction or recruitment of numerous fish and invertebrates, as shown in two presentations.

Then, how anthropogenic threats affects rocky shore functioning? Amongst others, invasive species, like Caulerpa spp., overfishing or chemical pollution are threats of great concern, and the effect of such pressures on coastal ecosystems composition and functioning formed also an important part of this session.

Finally, the last question of this session concerned artificial reefs ? are they more than ?human-made reefs?? Artificial reefs are currently considered efficient tools to restore and to manage coastal zones. They can effectively play this role, but only if they show a similar functioning with natural rocky zones. Results ensuring this similarity were presented, for example by comparing community composition, trophic organization or kinetics of colonization.

It was a dense but interesting session, with 14 presentations given by researchers from numerous countries and with results gathered from various Mediterranean and Black Sea shores. This diversity reflects the importance of this topic in current Mediterranean research, and also the importance of these zones in the whole functioning of the Mediterranean Sea.

Soft bottoms
Charles F. Boudouresque, France

Résumé
A variety of soft bottom habitats were described from the Mediterranean and Black Sea, from beaches and shallow waters down to abyssal depths, with or without a canopy of seagrass or metazoan epibionts. In addition to these habitats, the Mediterranean harbors a unique type of habitat, the Posidonia oceanica meadow, whose characteristics are intermediate between soft and hard bottoms, via the building of a semi-hard bottom, the ?matte?. Soft bottoms occupy more than 99% of the Mediterranean surface area, even in coastal zones, such as the Port-Cros National Park (98.7%). For many policymakers and stakeholders, and even for some scientists,

muddy and sandy habitats (with the exception of P. oceanica meadows) are a sort of desert, with very low species diversity. They are therefore (in their opinion) the perfect place for dumping dredged sediments, sewage discharge, coastal development and land reclamations and restoration programs such as the setting up of artificial reefs. As a matter of fact, species diversity can be quite high in soft bottoms habitats (not only in P. oceanica meadows), as reported in several presentations. In addition, it is worth noting that species diversity is not only (if definitely not!) ?How many species?? but more correctly ?What species are present?? Many habitats with naturally poor species diversity are actually of higher heritage value than habitats whose high species richness results from human impact. The giant bivalve Pinna nobilis, both emblematic and vulnerable, was the subject of several presentations.

Soft bottoms are habitats under siege, as largely reported during the session: trawling (especially in P. oceanica meadow), anchoring, dumping, beach replenishment, sewage outfall, solid waste from sea surface boats and invasive species. The Australian Chlorobionta (?green alga?) Caulerpa cylindracea is invading many soft bottom habitats at a Mediterranean-wide scale, though local (short-lasting?) regression of the invasion may occur, as reported in Malta. Managers? attention is (logically) focused on P. oceanica meadows, though their regression (if any) may be slight in some areas (e.g. Corsica), while other impacts on soft bottom habitats occur under the general indifference of the authorities and of most scientists.

Species interactions

Chafika Rebzani, Université Houari Boumédiène, Alger, Algérie

Résumé

This was a dense session, comprising various, interesting, but quite diverse themes (17 speakers) about benthic communities and their interactions with the environment. These organisms (endemics, invasives species) are a good bioindicator of changes of the Mediterranean littoral environmental quality.

The session included interesting presentations on topics concerning the organism and their relationships and, in fine, the protection and preservation of the biodiversity through appropriate conservation strategies. However no discussion was possible given the time constraints (3mn by 17 speakers).

A diversity of topics was covered, ranging from community structure (6 presentations), mollusks (5), echinoderms (2), sponges (2), and corals (2).

Traceability - Invertebrates

Evrim Kalkan, Turkey

Résumé

Broadly speaking, genetic traceability is based on the identification of both animals and animal products through the study of their DNA. In this concept, DNA profiling is simply used for identifying the similarities and differences between individuals, species and populations. Following the progress in molecular methods, DNA data are frequently used for the determination of source populations, the estimation of genetic differences between populations and the verification of the claimed population of origin from sea foods. Nowadays, genetic tracing techniques are very useful for the effective conservation management of natural species resources.

Under this session (Traceability- invertebrates), five studies related with the population genetic structure and genetic diversity of nine invertebrate species (Paracentrotus lividus, Arbacia lixula, Sphaerechinus granularis, Psammechinus microtuberculatus, Diadema setosum, Pinctata radiata, Octapus vulgaris, Eunicella cavolini and Pachygrapsus marmoratus) were represented. Considering all these studies, it was seen that the genetic structure and diversity of both indigenous and non- indigenous species in the Mediterranean Sea are not known in great detail. The findings presented suggest the need to acquire more information about the population structure, diversity and differentiation of the invertebrates to be able to better monitor the changes occurring in the Mediterranean ecosystem.

Unique ecosystems

Ricardo Aguilar, Spain

Résumé
Cold water coral reefs, long-lived black corals communities, sponge aggregations and other important habitat forming organisms are becoming more and more important on the understanding and knowledge of the deep-sea in the Mediterranean region. Many of these habitats can be found on geological features like submarine canyons, seamounts, knolls, mud volcanoes, caves, etc., that provide an environment that allows the settlement of species and communities that have declined or disappeared from other areas, are rare or new to science; therefore making them unique ecosystems.

The Mediterranean region is considered a biodiversity ?hotspot?, but the influence of this sea goes beyond the Gibraltar strait. Unique ecosystem that shares the biological richness of the Mediterranean can be found in the Atlantic Ocean. Do they are Mediterranean or Atlantic ?hotspots? ?

Water column habitats - 1

Mouna Bellakhal, Tunisie

Résumé
This session, where eight presentations were presented, dealt with the diversity and ecology of pelagic habitats.

The discussion was relevant and rewarding and included two key recommendations :

- recognize the importance of dormant stages and resting cysts while investigating bio-ecological cycles of pelagic and benthic species that are closely related to the sediment and to the water column. It is imperative to consider these phases of dormancy in order to understand and elucidate the dynamics and interactions with the environmental conditions.

- the second recommendation proposes the standardization of studies of phytoplankton biomass would facilitate the understanding of the dynamics, migration and introduction of marine species in the Basin. For example systematically recording Chl a and nutrients together with phytoplankton biomass may help the understanding of the dynamics of pelagic species.

Water column habitats - 2

Boris Espinasse, MIO - UMR 7294, Université Aix-Marseille, France

Résumé
Dans un premier temps la discussion a traité de l'extension du sprat (petit poisson pélagique) dans le Golfe du Lion aux dépens de la sardine et de l?anchois, et donc de l?adaptation de cette espèce à des températures qui ne lui convenaient pas précédemment. La discussion a ensuite tourné autour de l?importance d?une approche intégrative, de l?identification des processus physiques et du couplage benthos/pélagique pour mieux comprendre la dynamique de populations des espèces.

[1] Université Badji Mokhtar – Annaba. Laboratoire d'Ecobiologie des Milieux Marins et Littoraux. Université Badji Mokhtar Annaba,Algérie. - nadira.benchikh@yahoo.fr

Abstract
Ce travail est une contribution à l'étude de la Croissance relative et les relations biométriques chez l'anchois *Engraulis encrasicolus* (linné, 1758) du golfe d'Annaba, Est algérien.La croissance relative et les relations morphométriques basées sur le traitement statistique des données de variables biométriques de l 'anchois commun durant l'année 2012. Chez la population *Engraulis encrasicolus* (Linné, 1758).les résultats de la croissance relative est de type allométrie majorante chez *E.encrasicolus* avec (b=3,360/N = 178) et en ce qui concerne la morphometrie on note une allométrie de croissance isométrique sur 10/14 critères métriques, Les 4 autres paramètres restants (Lpo, Do, Hc, Ec) montrent une allométrie minorante et à mis en évidence une disparité du type de croissance morphologique lorsqu'on compare les deux sexes.

Keywords: Fishes, Growth, Biometrics, Algerian Sea

Introduction
En Méditerranée, les petits pélagiques tels que les sardines, anchois, maquereaux, sprats ou encore sardinelles totalisent presque 58% des débarquements totaux annuels de pêche [1]. La pêche le long des côtes algériennes cible particulièrement la faune ichtyologique et surtout les poissons bleus de valeur moindre dont les captures représentent presque 93%. L'anchois *Engraulis encrasicolus* et la sardine *Sardina pilchardus* sont les espèces les plus importantes en termes d'intérêt commercial et de biomasse [2, 3]. Nous présentant ici les résultats sur la croissance relative à la longueur total - masse éviscérée et les relations biométriques de *E. encrasicolus* du golfe d'Annaba, Est Algérien.

Matériel et méthodes
Un échantillonnage de 178 anchois provenant des débarquements de sardiniers et chalutiers pratiquant dans le golfe d'Annaba durant l'année 2012. Des données de variables morphométriques basé sur 15 critères métriques d'une population de l'anchois commun *E. encrasicolus* (Linné, 1758) des côtes Est d'Algérienne. La longueur totale et la masse éviscérée ont été respectivement exprimées en cm et en g. La conformité du coefficient d'allométrie est déterminée par le test t de Student [4].

Résultats et discussion
Pour la croissance relative la taille-poids éviscère Chez *E. encrasicolus on à trouvé* une croissance de type allometrie majorante chez la population totale ; les males et les femelles les valeurs de la pente(b) sont respectivement: 3,360; 3, 280 et 3,262. Ces résultats concordent avec ceux trouvés dans les côtes Est algériennes [5]. Contrairement aux résultats observé dans plusieurs régions de la méditerranée qui montrent une croissance isométrique dans la baie de skikda [6] et dans les côtes Algéroises [7]. En ce qui concerne l'étude morphométrique, chez la population total 10/14 paramètres qui sont : longueur à la fourche , longueur maxillaire, longueur standard, longueur céphalique, longueur pré-dorsale, longueur post-orbitaire, longueur prés-pectorale, longueur post-pectorale, longueur pré-anale, et l'hauteur du pédoncule caudal présentent une isométrie de croissance, alors que Les 4 paramètres restant (la longueur prés-orbitaire ,le diamètre orbitaire, la hauteur et l'épaisseur du corps) montrent une allométrie minorante ce qui explique que ces paramètres croient moins vite que la longueur céphalique et la longueur total.

Chez les mâles l'analyse des paramètres métriques montre que 11 paramètres présentent une isométrie de croissance qui sont : longueur à la fourche, longueur maxillaire, longueur standard, longueur céphalique, longueur pré-dorsale, longueur post-orbitaire, longueur pré-orbitaire. longueur pré-pectorale, longueur post-pectorale, longueur pré-anale, et diamètre orbitaire ,par contre on trouve que l'épaisseur du corps et la hauteur du pédoncule caudale (Ec, HPc) croient plus rapidement que la longueur total (allomètrie majorante) ,sachant qu' un seul type d'allomètrie minorante de croissance est observé pour la hauteur du corps (Hc) .

Cependant chez les femelles on trouve 12/14 paramètres métriques qui présentent une isométrie de croissance qui sont : longueur à la fourche , longueur maxillaire, longueur standard, longueur céphalique, longueur pré-dorsale, longueur post-orbitaire, longueur pré- pectorale, longueur post-pectorale, longueur pré-anale, diamètre orbitaire , la hauteur du corps et la hauteur du pédoncule caudale ;Cependant les deux autres caractères la longueur prés-orbitaire et l'épaisseur du corps se croient rapidement par rapport à la longueur total et la longueur céphalique avec une allometrie majorante . Néanmoins il serrait judicieux de corrélé ces changement avec les facteurs environnementaux [8] car L'analyse de la dynamique des petits pélagiques nécessite des programmes de recherche à long terme et pluridisciplinaires combinant l'éco-biologie, l'halieutique et l'hydrologie [9].

Abstract
L'étude de l'âge et de la croissance du brochet de mer *Sphyraena sphyraena* de la côte tunisienne, est fondée sur la lecture de 284 otolithes de spécimens. Cette étude a permis d'estimer les paramètres de croissance de l'espèce selon le modèle de Von Bertalanffy. Une clé âge-taille et une clé âge poids ont été présentées séparément pour les mâles, les femelles et sexes confondus. Pour l'ensemble de l'échantillon, la longueur asymptotique est estimée à 50,1cm, le coefficient K à 0,158 an^{-1}et l'âge théorique t_o à-2, 29 ans. La relation entre le rayon de l'otolithe R en cm et la longueur totale en cm a été calculée.

Keywords: Fishes, Gulf of Tunis, Growth

Introduction
Le brochet de mer *Sphyraena sphyraena (Linnaeus, 1758*) de la côte de Tunisie a fait l'objet d'une seule étude biologique concernant la période de reproduction, le sex-ratio et la maturité sexuelle [1]. Il a donc paru intéressant et utile de présenter dans ce travail, les premières données sur l'âge et la croissance de cette espèce qui possède, de surcrôit, un intérêt économique certain [2].

Matériels et méthodes
