L'étude de l'âge et de la croissance du brochet de mer (*S. sphyraena* L, 1758) de la côte de Tunisie a porté sur 284 spécimens, de longueur totale comprise entre 18,7 cm et 46,8 cm et pesant entre 69,8g et 2350g. La détermination de l'âge a été effectuée à partir de la lecture de l'otolithe *in toto*. Pour valider la méthode de l'estimation de l'âge, l'allongement marginal est suivi mensuellement. Les croissances linéaire et pondérale ont été transcrites conformément au modèle mathématique de croissance de Von Bertallanfy [3]. La longueur totale correspondant à chaque âge est rétro calculée par la méthode de Lee [4]. La relation taille poids $W= aL^b$ est établie pour l'ensemble de l'échantillon.

Résultats et discussion
Le test de normalité de Shapiro-Wilk est W = 0.982, avec p = 0.0012, ce qui nous permet de dire que notre échantillon est extrait d'une population normalement distribuée. La figure 1 montre que l'allongement marginal présent deux minimums, l'un en février traduisant l'apparition d'anneau d'arrêt de croissance hivernal et l'autre en juin relatif à la période de ponte L'anneau d'arrêt de croissance hivernal plus net a donc été retenu pour estimer l'âge approximatif du *S. sphyraena,*

Fig. 1. Variations mensuelles de l'allongement marginal (AM) des otolithes de *S.sphyraena*.

La courbe de croissance linéaire montre que les mâles ont une croissance légèrement plus rapide que les femelles à partir de 2 ans (Fig. 2). Les équations des droites de régression, reliant le rayon de l'otolithe et la longueur totale du de corrélation de 0,96 montre une forte corrélation entre les variables LT et R_0 pour les mâles comme pour les femelles. Il est donc possible de déterminer la taille du spécimen à partir du rayon de l'otolithe et inversement, LT= 3,985 Ro + 1,967.

La méthode de rétro calcul a permis de considérer neuf groupes d'âge. La relation taille poids est exprimée par la relation $WT=4,89x10^{-3}Lt^{2,.96}$

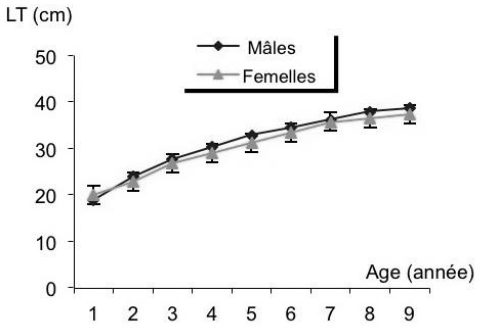

Fig. 2. Croissance linéaire chez *S.sphyraena* de la côte tunisienne.

AGE ET CROISSANCE DE *BALISTES CAPRISCUS* (TELEOSTEI: BALISTIDAE) DU GOLFE DE GABES

Hichem Kacem [1]* and Lassad Neifar [1]
[1] Université de Sfax- Faculté des Sciences - hichemkacem2007@yahoo.fr

Abstract
La lecture des coupes fines du 1er rayon de la première nageoire dorsale de 463 spécimens de *Balistes capriscus* (Gmelin, 1788) du golfe de Gabès (Tunisie) a permis de déterminer les paramètres de croissance en longueur de cette espèce. Ces paramètres, pour les deux sexes combinés, sont les suivants $LF\infty$ = 417,3 mm, K = 0,237 an^{-1}, t_0= -0,102 années.

Keywords: Growth, Fishes, Gulf of Gabes

Introduction

Balistes capriscus (Gmelin, 1788) occupe une aire de répartition extrêmement vaste. Elle est largement trouvée dans les eaux tropicales et tempérées tout au long des côtes Est et Ouest de l'océan Atlantique [1]. Depuis ces dernières décennies une augmentation considérable de la production du baliste a été constatée le long des côtes tunisiennes et en particulier dans le golfe de Gabès. La production est passée de 34 tonnes en 1990 à 187 tonnes en 2009 [2]. L'étude de l'âge et de la croissance de cette espèce, constituent un préalable indispensable pour une pêcherie durable.

Matériel et méthodes

Un total de 463 spécimens (206 mâles et 257 femelles), de longueur à la fourche comprise entre 139 et 427 mm et de poids total allant de 90,04 à 1967,41 g, provenant de la pêche au chalut benthique, ont été examinés durant la période comprise entre Juin 2005 et Juin 2009. La détermination de l'âge est réalisée par la lecture des coupes fines du 1er rayon de la première nageoire dorsale. L'observation des coupes obtenues est réalisée en lumière transmise à l'aide d'un système d'analyse d'image composé d'une loupe, d'une caméra, d'un PC et du logiciel TNPC. Le rayon total des tranches (Rt) et les rayons à la formation de chaque zone hyaline (Ri) sont mesurés. Le nombre des zones hyalines est aussi déterminé pour l'estimation de l'âge des balistes. La longueur à la fourche correspondant à chaque âge est rétro-calculée par la méthode de Lee [3]. Les croissances linéaire sont ajustées au modèle de Von Bertalanffy. Les paramètres $L\infty$, K et t_0 sont déterminés à l'aide d'un logiciel informatique FISAT.

Résultats et discussion

Les variations mensuelles de l'allongement marginal ont montré que les valeurs minimales sont enregistrées au mois de février aussi bien pour les mâles que pour les femelles. Les tailles des balistes aux différents âges sont rétro-calculées, en tenant compte de l'existence d'une corrélation significative entre la longueur à la fourche du poisson et le rayon de la 1ère épine de la nageoire dorsale ($r = 0,897$, $p \leq 0,01$). L'âge maximum des poissons péchés était de 5 ans. Les équations de croissance linéaire obtenues sont:

Mâles : $LF = 420,7\ [1-e^{-0,233\ (t+0,123)}]$;

Femelles : $LF = 417,0\ [1-e^{-0,238\ (t+0,074)}]$;

Sexes confondus : $LF = 417,3\ [1-e^{-0,237\ (t+0,102)}]$.

La comparaison biogéographique de la croissance linéaire de *B. capriscus* a mis en évidence des différences interrégionales (tab. 1). En effet ces dissemblances pourraient parvenir soit de l'échantillonnage, soit elle est liées à des variations génétiques, mais sont aussi largement dépendantes des conditions environnementales, tant physiques que biotiques [4].

La présente étude montre que l'âge maximum des balistes du golfe de Gabès est de 13 ans. Ceci est en accord avec les travaux de Johnson et Saloman [5] pour des balistes du Nord–Est du golfe du Mexique. En revanche l'âge maximal de ce poisson à l'Ouest du golfe de Guinée [6] et sur les côtes Sud -Est du Brésil [7] ne dépasse pas 11 ans. De nombreuses études ont montré que *B. capriscus* atteint la maturité sexuelle au bout de 2 ans mais ce poisson peut être mature à partir d'un an [8]. Par ailleurs, Manooch [9] a montré que l'âge de la première maturité sexuelle est atteint au Sud-Est des États-Unis au bout de 3 ans. Ce résultat a été aussi obtenu chez *B. capriscus* du golfe de Gabès. Les variations de l'âge de la première maturité sexuelle pourraient être dues à l'effet des conditions biogéographiques différentes ou bien à une augmentation de la pression de pêche.

AGE AND GROWTH OF THE JINGA SHRIMP, *METAPENAEUS AFFINIS* (H. MILNE EDWARDS, 1837) IN THE BAY OF IZMIR, TURKEY

Kostas Kapiris [1]*, Gulnur Metin [2] and Ilker Aydin [2]
[1] Hellenic Centre for Marine Research - kkapir@hcmr.gr
[2] Ege University, Faculty of Fisheries

Abstract
Seasonal sampling data – from November 2008 to January 2011 - were analyzed to determine the age and the growth of *Metapenaeus affinis* (jinga shrimp). The males presented 2-year modes, while females one more. The CL∞ and the k values were estimated to be 49,75 mm and 0,68 years-1 for females and 35,42 mm, 1,33 years-1, for males. The φ' value for the females was 2,84, while for males 3,22.

Keywords: Growth, Decapoda, Coastal waters, North-Eastern Mediterranean

Introduction
M. affinis is a dominant and highly valued penaeid shrimp along the Persian Gulf, Arabian Sea, S. China Sea and Hawaii [1]. It was recently noted in the Mediterranean (2008), at the inner part of Izmir Bay (Turkey) [2]. Age and growth of the species has also been described in Iran [3], Kuwait [4] and India [5]. This is the first work describing its age and growth of the species in the Mediterranean waters.

Material and methods
A total of 3038 jinga shrimp specimens were collected in a seasonal basis, from November 2008 to January 2011, in the Bay of Izmir (Turkey) by trammel nets. The samples were separated by sex and the carapace length (CL) was measured. Bhattacharya's method (FiSAT package) was used to identify and isolate the different, normally distributed, size groups per sex, taking into account the values of separation index (SI) for the different age group, the number of the identified age groups, and the standard deviation (S.D.). The Von Bertalanffy (VBGF) parameters (CL∞, k, to) were estimated using the non-linear regression (Statgraphics). The growth performance index φ' in the jinga shrimp was estimated using the equation $\varphi' = \log_{10}k + 2\log_{10}CL\infty$.

Results and Discussion
The general pattern showed that the males exhibited 2-year modes, while females showed more (3 year modes in summer). The same number of cohorts has been identified in Iran [3]. The FiSAT estimated modal mean lengths of males ranged from 19,25 (in winter) to 29 mm CL (Autumn) and the SIs appeared to be quite satisfactory. In females, the estimated modal lengths ranged from 24 to 31 mm CL (Table 1). The VBGF parameters for the females and males were: CL∞=49,75 mm, k=0,68 y^{-1}, to=-0,99 y and 35,42 mm, 1,33 y^{-1},
-0,05 y, respectively. Similar growth pattern of the same species has been estimated in Iran [3] and in Kuwait waters [4]. The growth coefficient (k) confirms different growth rates between sexes, but, like all penaeids, the species seems to grow faster than other decapods. The φ' value for the females and males was 2,84 and 3,22, respectively. Both k and φ' values suggest that males grow faster than females in the Izmir area.

RELATION TAILLE-POIDS, PONTE DE L'ANCHOIS ET DE LA SARDINE DU LITTORAL EXTRÊME EST ALGÉRIEN

S. Ladaimia [1]*, F. Z. Bouhali [1], N. Benchikh [1], A. Diaf [1] and A. B. Djebar [1]
[1] Université Badji Mokhtar – Annaba. Laboratoire d'écologie des milieux marins et littoraux (E.M.M - souad-lad@hotmail.fr

Abstract
La reproduction, la relation taille-poids de l'anchois *Engraulis encrasicolus* et de la sardine *Sardina pilchardus* ontété étudiées le long du littoral extrême Est algérie. Pour l'anchois la sex-ratio est constante, alors qu'elle est en faveur des femelles chez la sardine. Les périodes de reproduction ont lieu d'avril à octobre pour l'anchois et entre novembre et avril pour la sardine. Ces deux espèces ont une allométrie majorante.

Keywords: Reproduction, Algerian Sea

Introduction
L'anchois *Engraulis encrasicolus* et la sardine *Sardina pilchardus* sontdeux poissons téléostéens côtiers, petits pélagiques qui peuplent les côtes Algériennes et plus particulièrement l'extrême Est de l'Algérie. Ce sont les espèces dont l'exploitation a une importance stratégique sur le plan économique et social. Les prises annuelles moyennes varient ente 900 et 3714 tonnes pour la sardine et entre 59 et 490 tonnes pour l'anchois. [1]
Dans notre travail, nous nous somme intéressés à l'étude de la biologie reproductive et de déterminer les relations taille-poids de l'anchois et de la sardine, peuplant le littoral extrême Est algérien.

Matériels et méthodes
La présente étude a concerné la côte extrême Est algérienne. Près du port de pêche d'El kala et au cours d'un cycle annuel, un échantillonnage mensuel entre Septembre 2011 et août 2012 a été effectué. Nous avons réussis de collecter un total de 4241 poissons dont 1953 anchois et 2288 sardines qui ont été analysés dans le laboratoire. Pour chaque spécimen les paramètres suivants ont été relevés: la longueur totale(Lt) en centimètre près, le poids total(Pt), éviscéré(Pev), le poids des gonades(Pg) et le poids du foie(Pf) en g près. Le sexe est déterminé après dissection des poisons et observation macroscopique de leurs gonades.

Résultats et discussion
Chez la population d'anchois, La sex- ratio globale est égal à 0.98. Après traitement statistique par utilisation du test de Khi-deux (χ^2), on a trouvé qu'elle est constante (χ^2=0.27), on assiste donc à un équilibre entre les mâles (965) et les femelles (988), quant à la sardine la sex-ratio est égal à 0.82 elle est en faveur des femelles. Le suivi des variations mensuelles des valeurs moyennes du rapport Gonado-Somatique (RGS), nous a permis de situer la période de ponte de l'anchois qui s'étale entre Avril et Octobre (saison chaude). Les glandes sexuelles sont au repos de novembre jusqu'à février (saison froide). Quant à la sardine, la période de ponte s'étale de novembre jusqu'au Avril (saison froide), le poisson est en repos sexuel pendant la saison chaude (entre mai et octobre) Fig.1 (a,b). Nos résultats concordent avec ceux trouvés sur les côtes Est algériennes [2] et celui des côtes tunisiennes [3], [4]. En fait, la longue durée de la période de reproduction des deux espèces étudiées est expliquée par la faible amplitude des variations de l'environnement en méditerranée au cours d'un cycle annuel, où on ne note pas des variations saisonnières bien marquées L'analyse des variations mensuelles du Rapport Hépato-Somatique (RHS) Fig.1 (a, b), montre que l'anchois et la sardine sont des poissons de type gras et le foie n'intervient pas dans l'accumulation des lipides essentiels à la reproduction qui se fait d'abord sous la peau, dans le mésentère avant de passer dans les gonades pour assurer les besoins énergétiques lors de la reproduction. Les résultats de la relation taille-poids établie pour l'anchois et la sardine montrent qu'elle est de type allométrie majorante et les valeurs de b sont supérieurs à 3. Ils sont de l'ordre de 3.32 et 3.26 respectivement. Ce qui signifie que le poids éviscéré croit plus rapidement que la longueur totale chez les deux espèces.

DIMORPHISME SEXUEL ET CROISSANCE DU DENTÉ *DENTEX MAROCCANUS* DES CÔTES D'EL KALA (NORD-EST DE L'ALGÉRIE).

Rima Mohdeb [1]* and M. hichem Kara [1]
[1] Laboratoire de Bioressources Marines, Université BADJI Mokhtar, Annaba, Algérie. - rimamohdeb@yahoo.fr

Abstract
La morphologie du denté *Dentex maroccanus* (Valenciennes, 1830) des côtes d'El Kala est caractérisée et montre un dimorphisme sexuel pour la majorité des critères métriques considérés. La distribution des fréquences des tailles met en évidence six groupes d'âge. Les paramètres des modèles de croissance linéaire absolue et de la relation taille-poids sont donnés.

Keywords: Algerian Sea, Growth, Biometrics, Mediterranean Ridge

Introduction

Dentex maroccanus est un poisson sparidé qui vit en Atlantique Est, au Sud et à l'Est de la Méditerranée. Sur les côtes Est de l'Algérie, il occupe une place relativement importante dans les captures commerciales. Cependant, sa biologie reste très peu connue sur les côtes nord africaines (Chemmam-Abdelkader et *al*., 2002 et 2004). Ce travail aborde la morphologie, la dynamique et la croissance de *D. maroccanus* des côtes d'El Kala.

Matériel et méthodes

Au total, 806 individus ont été échantillonnés entre juin 2011 et septembre 2012 (10,5 cm <Lt< 26,8 cm; 15,22 g <Pt< 267,21 g). Leur morphologie est décrite par vingt et un caractères métriques et dix caractères numériques. Pour déceler un éventuel dimorphisme sexuel, nous avons utilisé le test t de Student, adapté aux axes majeurs réduits (Myrat, 1959). Les couples âge-longueur sont définis par la méthode indirecte de Battacharya en utilisant le programme FiSat II. La croissance linéaire absolue est décrite par l'équation de Von Bertalanffy (1938). La relation taille poids est donnée pour chaque sexe séparément.

Résultats et discussion

La majorité des caractères métriques considérés montrent un dimorphisme sexuel. La structure des tailles par sexe révèle l'existence de six cohortes (figure. 01), aussi bien chez les mâles que chez les femelles. Le modèle de croissance linéaire absolue s'écrit comme suit: $Lt = 21,94(1 - e^{-0,58(t-0,58)})$ pour les mâles et $Lt = 24,27(1 - e^{-0,45(t-0,24)})$ pour les femelles. Les équations de croissance relative sont $P = 0,0087L^{3,17}$ chez les mâles et $P = 0,031L^{3,05}$ chez les femelles. La comparaison de nos résultats avec l'unique travail consacré à cette espèce en Méditerranée (Chemmam-Abdelkader, 2002), montre que la croissance des dentés d'El Kala est plus rapide que celle des dentés des côtes Tunisiennes,aussi bien pour les mâles que pour les femelles.

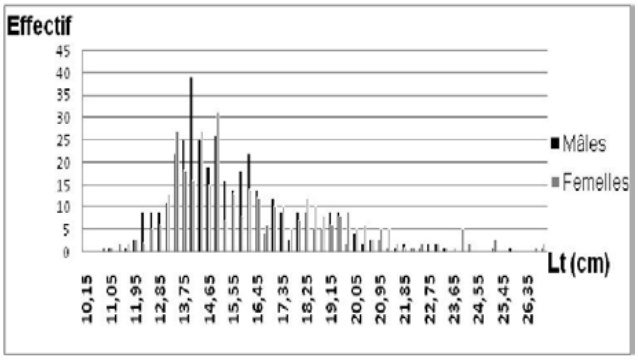

Fig. 1. Distribution des fréquences des tailles des mâles et des femelles de *Dentex maroccanus* des côtes d'El Kala.

CROISSANCE DU THON ROUGE *THUNNUS THYNNUS* (LINNAEUS, 1758) DES CÔTES ALGERIENNES

Ahmed Nouar [1]* and Naciba Labidi [1]
[1] Laboratoire Halieutique, FSB/USTHB - nouarahmed@live.fr

Abstract
Les captures de thon rouge *Thunnus thynnus* (Linnaeus, 1758) effectuées en Algérie de 2005 à 2009 par des palangriers japonais ont permis la détermination des paramètres de croissance par analyse des structures de taille sur un effectif total de 11715 individus dont 5302 mâles et 6413 femelles : $L\infty$ = 360,35cm, K = 0,09 an-1 et t0 = - 0,976 an-1 pour les mâles; $L\infty$ = 346,15cm, K = 0,098 an-1, t0 = - 0,903 an-1 pour les femelles et $L\infty$ = 373,33cm, K = 0,084 an-1, t0 = - 1,038 an-1 à sexes confondus. Les relations biométriques de l'espèce sont établies, en particulier la relation taille – poids indispensable pour la détermination de la croissance pondérale.

Keywords: Growth, Algerian Sea

Introduction
En Algérie, *Thunnus thynnus* est pêchée accidentellement par les senneurs et les petits métiers. Depuis 1995 en accord avec la Commission Internationale pour la Conservation des Thonidés de l'Atlantique (ICCAT) des quotas de pêche sont définis. Sur le plan scientifique, une seule étude concerne la croissance de cette espèce [1].

Matériel et méthodes
Les données proviennent des captures des campagnes de pêche commerciale des grands migrateurs réalisées par des palangriers japonais dans les eaux sous juridiction nationale algérienne. De 2005 à 2009, ces navires capturent le thon rouge du 15 avril au 1er juin. L'analyse des structures de taille sur un effectif total de 11715 individus dont 5302 mâles et 6413 femelles a permis la détermination des paramètres de croissance de l'équation de Von Bertallanfy par le logiciel FISAT II [2], en appliquant la méthode de Powell-Wetherall (1987, in [3]) pour la détermination du $L\infty$, la méthode de [4] pour K et de [5] pour to. Les relations biométriques concernent les longueurs totale (LT) et à la fourche (LF) ainsi que les poids total (WT) et éviscéré (WE).

Résultats
Les paramètres de croissance de *T. thynnus* sont reportés dans le tableau 1., avec les résultats des travaux entrepris en Méditerranée par d'autres auteurs [6], [7], [1]. La valeur de la longueur asymptotique L_∞ des mâles est supérieure à celle des femelles, en accord avec nos résultats sur les répartitions des tailles où les mâles sont, en moyenne, plus grands que les femelles. Les valeurs des paramètres K et t_0 sont proches pour les deux sexes. L'équation de la croissance linéaire est :
Mâles : $LF = 360{,}35\ (1 - e^{-0{,}090\ (t + 0{,}976)})$,
Femelles : $LF = 346{,}15\ (1 - e^{-0{,}098\ (t + 0{,}903)})$,
Sexes confondus : $LF = 373{,}33\ (1 - e^{-0{,}084\ (t + 1{,}038)})$

Chalabi et al., 2001	Confondus	298,5	0,240	- 0,860

Les résultats des relations biométriques sont consignés dans le tableau 2. La relation linéaire (LT/LF) indique une allométrie majorante de la longueur totale traduisant une croissance rapide de cette variable par rapport à la longueur à la fourche. Quant aux relations taille - poids liées aux états biologique et physiologique du poisson, la valeur du coefficient (légèrement inférieur à 3) indique une allométrie minorante du poids par rapport à la taille chez *T. thynnus* pour la période avant la ponte (avril et mai). Tenant compte des résultats de la croissance en longueur et ceux de la relation taille – poids, l'équation de croissance en poids est :
Mâles : $WT = 659{,}95\ (1 - e^{-0{,}090\ (t + 0{,}976)})^{2{,}3369}$
Femelles : $WT = 527{,}67\ (1 - e^{-0{,}098\ (t + 0{,}903)})^{2{,}135}$
Sexes confondus : $WT = 652{,}31\ (1 - e^{-0{,}084\ (t + 1{,}038)})^{2{,}2446}$

Tab. 2. Relations biométriques de *Thunnus thynnus*

Relation	Sexe	Equation
Longueur totale (LT) en fonction de la Longueur à la fourche (LF)	Confondus	LT = 1,0357 LF + 18,002
	Mâles	LT = 1,0441 LF + 16,091
	Femelles	LT = 1,026 LF + 20,067
Poids total (WT) en fonction de la Longueur à la fourche (LF)	Confondus	$WT = 0{,}0011\ LF^{2{,}2446}$
	Mâles	$WT = 0{,}0007\ LF^{2{,}3369}$
	Femelles	$WT = 0{,}002\ LF^{2{,}135}$
Poids éviscéré (WE) en fonction de la Longueur à la fourche (LF)	Confondus	$WE = 0{,}0005\ LF^{2{,}3744}$
	Mâles	$WE = 0{,}0003\ LF^{2{,}4671}$
	Femelles	$WE = 0{,}0009\ LF^{2{,}2593}$

>

Discussion
Thunnus thynnus pêchée en Algérie présente des tailles allant de 68 à 308 cm, avec dominance des mâles dans les premières et dernières classes de taille et celle des femelles dans les classes intermédiaires. Nos résultats basés sur l'analyse des structures de taille montrent que la croissance des mâles est supérieure à celle des femelles. Quelque soit le sexe, la longueur asymptotique est supérieure à la longueur maximale observée, ce qui n'est pas le cas en utilisant l'analyse des structures d'âge. En raison du manque de données et d'un dimorphisme sexuel peu apparent chez cette espèce les résultats de croissance à sexes séparés sont rares aussi bien en Méditerranée qu'en Atlantique. Ces travaux déterminent les paramètres par analyse des structures d'âge dont son application pour nos données présente des difficultés notamment pour l'attribution de l'âge aux différentes classes mal représentées dans nos échantillons issus d'une pêche limitée à 45 jours (du 15 avril au 1er juin). En comparaison avec les travaux méditerranéens, nos résultats satisfaisants sont proches de ceux de [7] qui utilise la lecture des vertèbres pour la détermination de l'âge.

ALTERATIONS IN TESTICULAR STRUCTURE OF MALE GRASS GOBY (*ZOSTERISESSOR OPHIOCEPHALUS*) IN BIZERTA LAGOON, TUNISIA.

Ibtissem Louiz [1], Mossadok Ben Attia [2] and Oum Kalthoum Ben Hassine [1]*
[1] Unité de Recherche de Biologie intégrative et Écologie évolutive et fonctionnelle des Milieux Aquatiques, Faculté des Sciences de Tunis, Université Tunis-El-Manar, 2092 El Manar, Tunisie - kalthoum.benhassine@gmail.com
[2] Laboratoire de Biosurveillance de l'Environnement, Faculté des Sciences de Bizerte, Université de Carthage, 7021 Zarzouna, Tunisie

Abstract
Testicular histology of mature grass goby (*Zosterisessor ophiocephalus*) collected in Bizerta lagoon showed several types of histological lesions. A high prevalence of these lesions was detected in stations influenced by discharges of industrial and/or urban activities. These results highlight the reproductive disturbance of gobies from Bizerta lagoon.

Keywords: Pathology, Reproduction, Pollution, Fishes, Tunisian Plateau

Introduction: Bizerta lagoon, a site of important halieutic and aquaculture activities, is located in an economically important area in northern Tunisia. This lagoon is faced to many anthropogenic pressures including urbanisation, industrial and agricultural activities. Thus, wastewater discharges lead to the chemical contamination of the lagoon by various toxic compounds. As a possible consequence of this state of disturbance, annual fish productivity of this lagoon records a drop which is accentuated from a year to another. Therefore we chose to study the prospective impact of this pollution on male Grass goby reproduction using a histopathological approach.

Materiel and methods: Five sampling stations, representative of the different anthropic pressures present in the study area, were chosen (NJ: Njila, MB: Menzel Bourguiba, MR: Maghrawa, MJ: Menzel Jemil et ML: Menzel Abderrahmen). A relatively undisturbed site [1] located at the seawards entrance of Ghar el Melh lagoon (GH) was selected as a reference station. A total of 25 adult males gobies were collected in breeding period that extending from March to Mai. These specimens were immediately processed for gonad histology.

Results and discussion: Histological sections of gonads revealed many types of histological lesion associated with degenerative changes.

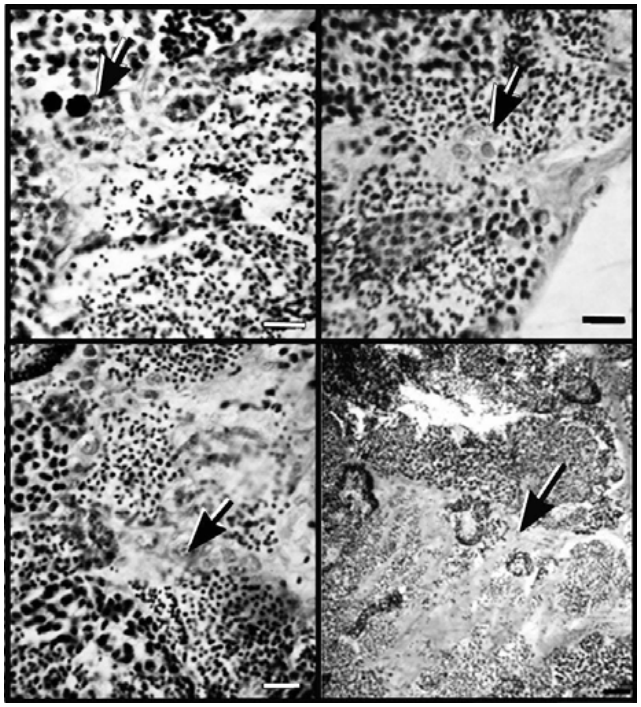

Fig. 1. Testis histological section showing some examples of degenerative findings include: (a) syncyatic cells« CSyn »; (b) hypertrophied Sertoli cells nuclei « SeCH »; (c) vacuolated germ cells (d) increased gaps in the interstitium between lobules « IG ». (H&E stained). Bar indicates 10 µm.

Histopathological alterations diagnosed in the testis of male from MB site were important and included germ cell syncytia (100 %) (Fig. 1a) associated with a high prevalence of Sertoli cell nuclei hypertrophy (67 %) (Fig. 1b) as well as misshapen seminiferous tubules. In ML and MJ stations, we noticed that testis exhibited increased gaps in the interstitium between lobules (IG) with huge span filled with connective tissue (13% and 10%, respectively) (Fig. 1d, Tab. 1).
These testes have as well vacuoles in the interstitial tissue (Fig. 1c) and melano-macrophage centers (MMCs) (Tab. 1). Predominance of histopathological lesions present higher values in MB station (Table 1), situated near of an industrial zone and exhibiting a high contamination by organotins [2], polycyclic aromatic hydrocarbons (PAHs) [1] and estrogen-like compounds [1] that can cause endocrine disruption in fish [3, 4].

Tab. 1. Testis histological lesions finding and associated prevalence and severities. N: sample size; P%: prevalence of histological lesions; S%: percentage of the gaps surface areas.

Sites	N	CSyn P%	SeCH P%	CSyn cell /view	CMM P%	IG S%
GH	4	0	0	0	0	4
NJ	3	0	0	0	0	5
MB	3	100	67	5.5	33	4
MR	2	0	0	0	0	4
MJ	3	50	0	2.3	50	10
ML	10	30	60	0.2	40	13*

Conclusion: The present work confirms that *Z. ophiocephalus* has been subjected to reproduction disturbances and showed histopathological lesions related with pollutants exposure.

Abstract
Trois aspects de la reproduction de *Sardina pilchardus* (walbaum, 1792) ont été étudiés: sex- ratio, période de ponte et taille à la première maturité sexuelle. La sex-ratio globale est en faveur des femelles (SR = 44,21 ; χ^2 = 25,77). La période de ponte s'étale d'Octobre à Mars. La taille à la première maturité sexuelle est de 11,28 cm pour les femelles et de 11, 50 cm pour les mâles.

Keywords: Fishes, Spawning, Reproduction, Algerian Sea

Introduction
En Algérie, la pêche pélagique est dominée au débarquement par la sardine qui représente 71% total capturé, les espèces concernées sont: la sardine (*Sardina pilchardus*, l'allache (*Sardinella aurita*), le chinchard (*Trachurus trachurus*) et le maquereau (*Scomber* scombrus) représentant en tonnage débarqué 80% des pêcheries [1]. Nous abordons dans cette étude, l'analyse des différentes phases de l'évolution du cycle reproducteur de *S. pilchardus.* Le stock ne peut se maintenir que si la biomasse féconde est suffisante pour compenser les prélèvements effectués par les pêcheries. Les connaissances de la taille de première maturité sexuelle, sa maturation ovarienne, sa ponte et sa phase de récupération ou repos sexuel sont nécessaires pour calculer la dimension du stock et son potentiel de renouvellement. Par ailleurs, dans la perspective d'étudier les stades larvaires et juvéniles, il est primordial de caractériser la reproduction tant aux niveaux spatial que temporel.

Matériel et méthodes
Durant un cycle de 12 mois (juillet 2010 et juin 2011) on a un effectif de 2266 individus collectés à partir des débarquements du port d'Annaba et el kala. La longueur totale a été mesurée en centimètre près,Le poids total (Pt), le poids éviscéré (Pév) et le poids des gonades (Pg) ont été pesé au gramme près. Le sexe et les stades de maturité sexuelle sont déterminés macroscopiquement grâce à l'échelle de maturité sexuelle [2].

Résultats et discussion
L'étude de la sex-ratio globale de *S. pilchardus* montre une dominance des femelles par rapport aux mâles (SR = 44,21; x^2 = 25.77). Les immatures sont moins représentés dans notre échantillon (14,87%). Cette dominance des femelles est aussi observée sur les côtes Tunisiennes [3], Cette dominance des femelles peut être expliquée par des différences de croissance selon le sexe [4, 5].
L'évolution du RGS nous a permis de situé la période de reproduction entre octobre et mars avec un pic en janvier.
La taille à la première maturité sexuelle (L50) est égale à 11,28 cm pour les femelles et à 11,5 cm pour les mâles. Ces valeurs sont proches à celles dans le même golfe (11,5 cm pour Mâles, 11,8 cm pour les femelles) [6]. Un résultat proche a été signalé sur les côtes tunisiennes (12,3 cm pour les femelles et 11,8 pour les mâles) [3], et elles sont inférieures à celles démonté dans les côtes Marocaines partie Atlantique [5] (16,3 cm pour Mâles, 17,5 cm pour les femelles).

REPRODUCTIVE STRATEGIES OF NW MEDITERRANEAN DEEP-SEA FISH COMMUNITY

Abstract
The reproductive strategies and fecundity of 13 species of the NW Mediterranean deep-sea fish community (750-2250 m depth) were analyzed. The results were compared with previous published data of shallower-living NW Mediterranean species . The results showed that all species analyzed present group-synchronous ovarian organization. All the species present the general pattern of large eggs and low Total Fecundity (TF) in comparison with shallower distributed fish species. TF is positively correlated with fish length. However, no significant relationship between length and depth was found, suggesting that the environmental factors associated with depth play an important role in determining fecundity.

Keywords: Continental margin, Demersal, Fishes, Life cycles, North-Western Mediterranean

Introduction Understanding reproductive strategies and the assessment of fecundity are fundamental in the study of biology and population dynamics of fish. Little is known about ovarian organization and fecundity in fishes, especially in deep-sea species. Fecundity values are related to several factors, such as food supply, population density, allocation of energy to reproduction and fish size [1],[2]. Fecundity is predicted to decrease with depth because of the assumed lower food availability in deep-sea habitats [2],[3]. This paper presents for the first time a comparative study of reproductive strategies of NW Mediterranean deep-sea fish, showing new data on fecundity and eggs size of the most abundant species. The results are discussed in relation to Mediterranean deep-sea environmental characteristics.

Material and methods Sampling was conducted between 700 and 2250 m depth, seasonally in 2008/9 and 2012/13. All the specimens from 13 different species were sexed, measured and the reproductive stage was macroscopically identified. In the laboratory, mature gonads were analyzed histologically to confirm macroscopic examination and the absence of post-ovulatory follicles. A sub-sample of 10 gonads per species, when available, was selected for oocyte-size frequency distribution analyses. A portion of these subsamples was stained, filtered, photographed and analyzed by image analysis software. The diameters of 100 oocytes were measured to determine the size of advanced yolk oocytes. Total fecunditywas calculated as: $TF= [O_i/W_i] \times W_0$; where *Oi* is the number of oocytes in the advanced vitellogenic stage, *Wi* is the weight of the ovary subsample, and *Wo* is the ovary weight [4]. Relative total fecundity (RF) was also estimated by dividing TF by the gonad-free weight of the fish. The results were compared with previous published data on shallower-living species. To evaluate length and depth influence on TF and RF of the NW Mediterranean fish community, linear regression were performed.

Results and discussion The oocyte size-frequency distribution results showed that all the species analyzed present two cohorts of oocytes in mature ovaries, suggesting group-synchronous oocyte development. This pattern is found in most of demersal species inhabiting cold marine waters [1]. The TF and RF of these 13 species were calculated for the first time in the present study. Marked differences in fecundity often reflect different reproductive strategies. In fact, over the species analyzed, TF was highest in the shallowest species *Phycis blennoides* (1643899 eggs/female), while the lowest TF was observed in the deepest vivipary species *Cataetyx alleni* (844 eggs/female). It is commonly accepted that total fecundity is positively correlated with fish length [1], [3] and the deep-sea fishes analyzed here were not an exception, where a positive relationship between mean TF and mean size of each species was observed ($P < 0.05$) (Figure 1). A positive relation between TF and depth was also found. The results are in accordance with previous published data from Atlantic fishes, were a similar pattern was observed [3]. This similarity between deep Mediterranean and deep Atlantic fishes suggest that rather than temperature, other environmental factors related to depth (i.e. low food availability, competition) might be determinant in the life histories of the deep-sea species. Even with our intense sampling survey, only a few mature females were found of *Phycis blennoides*, *Lepidion lepidion*, *Mora moro* and *Coryphaenoides guentheri* , suggesting biannual spawning as an adaptive response to the low food availability in deep-sea habitats, particularly in the oligotrophic Mediterranean Sea.

ASSESSING GROWTH BAND COUNTS FROM DORSAL-FIN SPINES FOR AGEING THE LONGNOSE SPINY DOGFISH

Vasiliki Kousteni [1]* and Persefoni Megalofonou [1]
[1] Department of Biology, Section of Zoology-Marine Biology, University of Athens, Greece - bkousten@geol.uoa.gr

Abstract
Age and growth of longnose spiny dogfish (*Squalus blainville*, Risso 1826), from the Eastern Mediterranean Sea, was studied by counting the bands at the external surface of the second dorsal-fin spines. The von Bertalanffy parameters were estimated separately for females and males.

Keywords: North-Eastern Mediterranean, Elasmobranchii, Growth

Introduction
In previous studies the age and growth of the longnose spiny dogfish were investigated by counting either the vertebral rings [1] or the growth bands in sections of the second dorsal-fin spine [2]. The aim of this study is to estimate the age and growth of the species using the external growth bands of the whole dorsal-fin spine and to compare the results of the method used with those of the previous studies in the Mediterranean Sea.

Materials and Methods
Out of 810 longnose spiny dogfishes that were sampled between 2004 and 2012 in the Greek Seas, 685 specimens were used for age estimation. Since the tip of the first dorsal-fin spine tends to be more worn down, leading to an underestimation of age, the second dorsal-fin spine was chosen for age estimation. All spines were read three independent times by the same reader. Out of the three readings the first one was rejected. Consequently, when the two last readings differed by 1 year the estimates were selected alternately, when they differed by 2 years the mean of the two readings was taken into account while those that differed for more than 2 years the spines were excluded from the analysis (±2-yr criterion). For large individuals with worn or broken spines, age was calculated according to Ketchen's method (1975) [3]. Since, Ketchen's correction curve was made for *Squalus acanthias* from the Pacific Ocean, a new correction curve was developed for *Squalus blainville* from the Eastern Mediterranean Sea. The precision of age estimations was calculated using both the coefficient of variation (CV) and the average percent error (APE). The total length-at-age data were fitted to the von Bertalanffy growth model.

Results and discussion
Our results showed that the point where the first annulus is formed was not affected by the fish size. The examination of embryos revealed also that spines were formed during the early stages of embryonic development. The obtained CV and APE precision indices, confirmed that the two last readings of the whole spines (CV= 8, APE= 5.7) were more reliable than the first one and the comparison between them indicated no appreciable bias (Fig. 1). Age estimations of large specimens with broken spines was obtained using modified Ketchen's correction curve $Y= 0.5634X^{2.3429}$ (where X= the diameter of the spine base in mm and Y = the missing annuli of the spine due to being worn).
Finally, age estimations of 2 specimens with broken spines as well as of 567 specimens that met the ±2-yr criterion were used in growth analysis (Fig. 2). It was noticed that females reached higher age (28 yrs) than males (22 yrs). Differences were also found in the von Bertalanffy growth parameters between females and males (females: $L\infty$ = 1097 mm, K = 0.031, t_0 = -5.58 yrs; males: $L\infty$ = 665 mm, K = 0.080, t_0 = -3.35 yrs). The comparison of the growth parameters for longnose spiny dogfish from the Greek Seas with those from the Sicilian Channel [1] and the Gulf of Gabès [2], revealed differences that could be attributed either to the different ageing methods followed or to the differences in growth rates between different stocks.

REPRODUCTION OF FEMALES OF THE DEEP-WATER PINK SHRIMP *PARAPENAEUS LONGIROSTRIS* (LUCAS, 1846) IN THE SOUTH ADRIATIC SEA (MONTENEGRIN COAST)

Olivera Markovic [1]*
[1] Institute of Marine Biology - omarkovic@ac.me

Abstract
The deep-weater pink shrimp, *Parapenaeus longirostris* (Lucas, 1846) is one of the most important commercial species in the Montenegrin trawl fishery. This paper describes reproductive patterns of females of this species. An estimate of the gonadosomatic index showed permanent reproductive activity all year around with two maxima, one in May and other in December. The carapace length at which 50 % of females were mature was at a carapace length of 20.9 mm CL.

Keywords: Decapoda, Reproduction, South Adriatic Sea

Introduction
The deep-water pink shrimp (*Parapenaeus longirostris*) inhabits the entire Mediterranean [1]. This species occurs in the deeper central Adriatic, in the Pomo-Jabuka pit, and in the southern Adriatic where is spread over the entire shelf area [2]. Despite the fact that in the Montenegrin traw fishery it represents the main target group of decapods, studies of this species have been mostly focused on population dynamics, while data on their reproduction are lacking.

Materials and Methods
Sampling was carried out on a monthly basis from September 2009 to August 2010. The samples were taken from commercial bottom trawlers which operates in the territorial Montenegrin waters at depths ranging from 50 to 250 m (Fig. 1.).

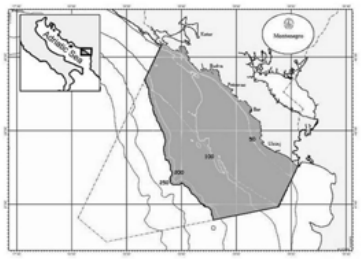

Fig. 1. Map of the study area

A total of 1550 specimens were measured, of which 83.3 % were females and 16.7 % males. The following parameters were measured: carapace length, total weight, weight of mature ovaries, sex of each specimen, and maturity stages of the females. The sex ratio, size at first maturity and the gonadosomatic index were estimated. Sexual ratio were calculated by size class, expressed as the ratio of females to the total number of specimens. Maturity for females was determined according to the scale proposed by MEDITS. Females with mature ovaries were used to determine the GSI which is defined as the ratio of the weight of the gonad (GW) to the total body weight of a female (TW). Finally, the percentages of maturity by size for females were calculated in order to determine the size at 50% first maturity, adjusting a logistic model.

Results and Discussion
The specimens showed a range in size between 15 and 37 mm CL with an overall average length of 27 mm CL. Females were larger than males. The carapace length of females ranged from 18 to 37 mm, with a mean size of 28.2 mm, while the carapace length of males ranged from 15 to 27 mm CL with an average of 21.6 mm CL. The overall sex ratio was in favor of females (0.83). The sex ratio by size class showed male predominance in the size range 16-22 mm while at lengths greater than 22 mm dominant sex were females and at lengths over 31 mm only females were observed. The carapace length at which 50 % of females were mature was calculated to be 20.9 mm. Dissimilar sizes for first maturity in different studies must be viewed with caution, because sample sizes and compositions may greatly influence the results found [3]. The gonadosomatic index of females showed a peak in autumn and winter while the minimum reproductive activity occurred in June.

ETUDE COMPARÉE DE LA SEX-RATIO ET DU CYCLE SEXUEL DE *VENERUPIS DECUSSATA* DANS DEUX LAGUNES TUNISIENNES: LAGUNES NORD DE TUNIS ET DE BOUGHRARA

Jihed Fradi [1], Ines Haouas Gharsallah [1], Okbi Rjeibi [1] and Nedra Zamouri Langar [1]*
[1] INSTM, Tunisie - nedra.zamouri@instm.rnrt.tn

Abstract
Une acquisition des connaissances biologiques et écologiques d'une espèce est primordiale pour identifier le stock exploitable et permettre sa valorisation tout en élaborant les bases de sa gestion rationnelle. La palourde, *Venerupis decussata* est le bivalve le plus exploité en milieu naturel sur les côtes tunisiennes. Une acquisition des connaissances biologiques et écologiques de cette espèce est primordiale pour identifier le stock exploitable. Dans ce contexte, une étude comparative de la sex-ratio et du cycle sexuel de la palourde a été menée dans deux lagunes : l'une au nord (lagune nord de Tunis) et l'autre au sud tunisien (lagune de Boughrara).

Keywords: Bivalves, Life cycles, Lagoons, Tunisian Plateau

Introduction
La palourde, *Venerupis decussata*, est le bivalve le plus exploité en milieu naturel sur les côtes tunisiennes. Une acquisition des connaissances biologiques et écologiques de cette espèce est primordiale pour identifier le stock exploitable et permettre sa valorisation tout en élaborant les bases de sa gestion rationnelle. Dans ce contexte, une étude comparative du sex-ratio et du cycle sexuel de cette espèce a été menée dans deux lagunes tunisiennes.

Matériel et méthodes
Dans chacune des lagunes, nord de Tunis et de Boughrara (figure 1), l'échantillonnage est réalisé d'une manière mensuelle, depuis le mois de mars 2010 jusqu'au mois d'août 2011.

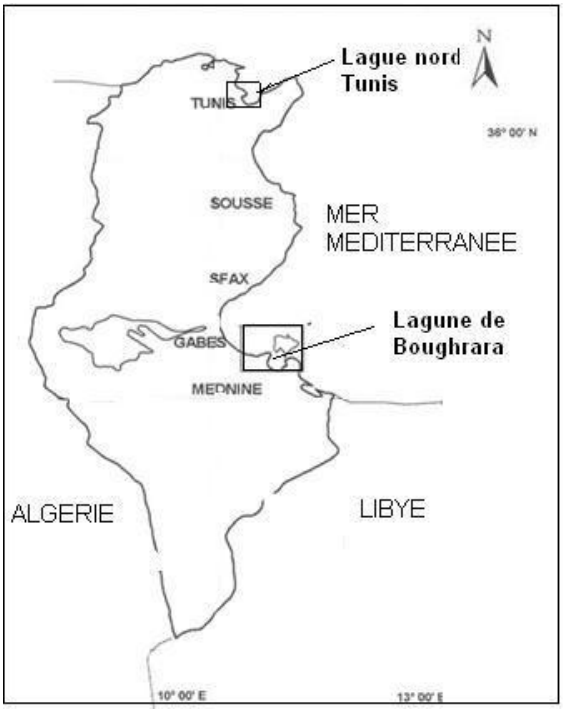

Fig. 1. Situation géographique des lagunes nord de Tunis et de Boughrara

L'étude de la sex-ratio a été effectuée pour une totalité de 977 individus de la lagune nord de Tunis et 1074 individus de la lagune de Boughrara. Cet indice est calculé globalement puis selon les saisons et selon les tailles. Sa variation saisonnière et selon la taille a été mise en évidence par le test de conformité χ^2 [1] au seuil de probabilité de 5%. Le cycle sexuel est abordé suivant deux approches : · la première qualitative : observations des frottis des gonades et de l'état du pied et l'histologie de la gonade. · la seconde quantitative : cycle pondéral.

Résultats et discussion
L'étude de la sex-ratio dans les deux lagunes a mis en évidence une dominance des mâles sauf pendant la période de la ponte où les femelles sont majoritaires. Par ailleurs, la dominance des femelles est remarquée pour les petites tailles dans la lagune nord de Tunis et pour les grandes tailles dans la lagune de Boughrara. Nos résultats diffèrent de ceux de Zamouri-Langar [2] qui a montré que, dans la lagune nord de Tunis, la sex-ratio est de 1:1,04 en faveur des femelles.
L'analyse de l'évolution temporelle du cycle pondéral, de l'état du développement des gonades, ainsi que les coupes histologiques a montré la présence d'une ponte principale en été, des émissions secondaires en automne et l'absence de phase de repos sexuel dans les deux lagunes étudiées. Néanmoins, la ponte principale débute en juin pour la lagune de Boughrara et en juillet pour lagune nord de Tunis. Nos résultats sont en accord avec les observations de [3] et de [4] qui ont montré la présence de deux périodes d'émissions gamétiques pour la population marocaine de palourdes, de la côte Atlantique et de la lagune de Mouley Bousselham. En revanche, [5] indiquent que pour la palourde d'El Hofra, et de Borj Ungha (golfe de Gabès, Tunisie), la gamétogenèse se déroule depuis mars jusqu'à décembre avec une seule phase d'émissions des gamètes (octobre/décembre) et une courte phase d'inactivité sexuelle. Ces auteurs supposent que la pollution par les métaux dans ces deux zones a engendré une perturbation du cycle reproducteur des palourdes.

Conclusion
La détermination de la sex-ratio ainsi que la description du cycle sexuel de la palourde *Venerupis decussata* dans les deux lagunes tunisiennes garde une signification "provisoire" puisqu'elles restent sous l'influence des fluctuations des paramètres du milieu.

GROWTH PERFORMANCE OF GREY MULLET, *MUGIL CEPHALUS*, AND CLAM, *RUDITAPES PHILIPPINARUM* IN IN INTEGRATED MULTITROPHIC SYSTEM

Soliman H. Abdel Rahman [1]*, Fatma A. Abdel Razek [1] and Mohammed A. G. El Absawy [1]
[1] National Inst. Oceanography & Fisheries - soliman2410@gmail.com

Abstract
Integrated systems were developed to mitigate negative impacts of intensive fish culture on environment and to increase profit. This IMTA system was established in NIOF, Alexandria and consisted of 3 seabream intensive tanks and 2 successive ponds for mullet and clam culture. Feed was supplied to seabream tanks only. Mullet grow on wastes of seabream tanks from 50 to 800 g in 240 days, and clams grow from 1.2 to 7.5 g in the same period. Feed efficiency increased by 25% and return on investment by 30% in IMTA. Dissociated ammonia decreased from 81at inlet of seabream tanks to 62µMole/l at the outlet of the IMTA system.

Keywords: Aquaculture, Nutrients, North-Eastern Mediterranean

Introduction
As a result of domestication success of gilthead seabream in the last 30 years, the production of this species in Mediterranean countries exceeded 140,000 ton in 2011 [1]. Sea bream is fed diets containing between 40-45% protein, but it consume only 25-30% of this protein and the rest is discharged to the environment as excretory products[2] . Researchers developed an integrated multitrophic system "IMT" to mitigate eutrophication impacts and increase profitability [3]. Intensive culture of seabream is a new field in Egypt, and some experimental IMT systems are in operation. Utilizing grey mullet and manila clams as detritus consumers are of great importance for this new business. Both species are endemic to Egyptian coastal water, consume detritus and of high economic value. This study was conducted to evaluate the use of flathead grey mullet, *Mugil cephalus* and manila clam, *Ruditapes philippinarum* as biological convertors of detritus produced from intensive seabream culture.

Material and Methods
Water flow from intensive seabream tanks (120 m^3 total water capacity, stocked at 2.5 kg fish/m^3) were discharged into two successive 300 m^2 earth ponds. First pond stocked with 50 g mullet fingerlings (1000 fish), and the second stocked with 1.2 g clam juveniles (15000 indv.). Seabream was fed with 42% commercial feed. No feed supplied to other ponds. The experiment continued for 250 days. Protein content in animals, ammonia-N and nitrate-N concentrations in water were measured using APHA standard methods [4]. Monitoring and control systems continuously measured water flow, water temperature, pH and oxygen in all compartments of the system.

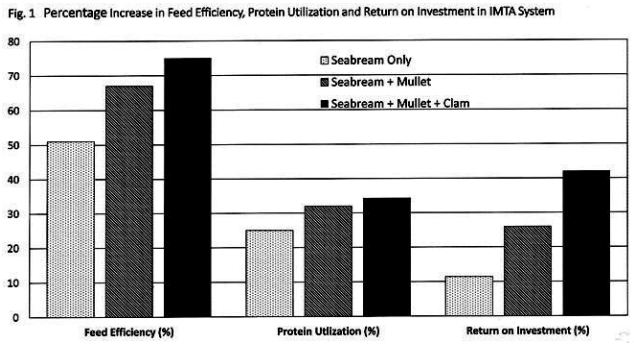

Fig. 1. Percentage increase in feed efficiency, protein utilization and return on investment using IMT system

Results and Discussion
Grey mullet grow from an average initial body weight of 50 g/fish to 801 g/fish during the rearing period (240 days) and the total biomass increased from 50 kg/pond at start up to 720 kg/pond at the end of the experiment. Manila clams increased in average weight from 1.2g to 7.5g/indiv. and the total biomass increased from 18.2 kg/pond to 86.5 kg/pond. Feed efficiency increased by 25% and return on investment by 30% in IMTA (Fig. 1).

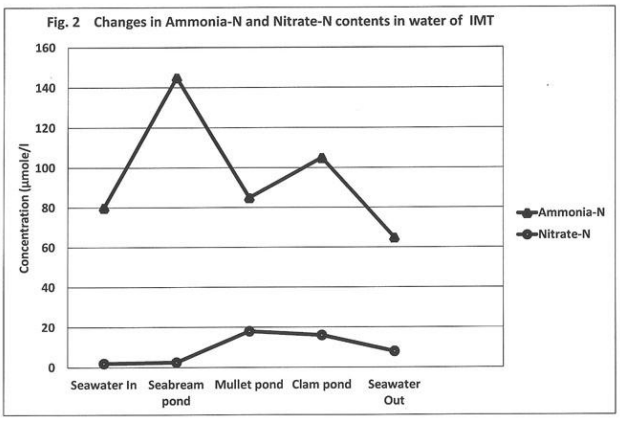

Fig. 2. Change in Ammonia-N and Nitrate-N in different locations of IMT

Water temperature ranged between 18^0C in winter to 27^0C in summer and salinity ranged between 34-36 ppt. Nitrate-N level was 2.1 µMol/L at the seawater input, increased to 17 µMol/L in fish ponds as a result of the high input of diet, and decreased at the outlet to 6.5 µMol/L. Ammonia-N was relatively high at the source (80 µMol/L) in fish ponds increased to 145.5 µMol/L in seabream tanks and maintained high level at mullet pond then decreased at the entrance of clam pond , increased to 105.6 µMol/L at the outlet of clams pond and finally decreased at the outlet to a low value of 62 µMol/L (Fig. 2). Ammonia and nitrate levels in different sites of the project revealed that their concentrations at the output are less than that of the input level. These results suggest that these compounds are being absorbed or oxidized in the sedimentation pond.

BILAN DE SURVEILLANCE HISTOPATHOLOGIQUE DE LA PALOURDE (*RUDITAPES DECUSSATUS*) LE LONG DU LITTORAL TUNISIEN

H. Attia El Hili [1]*, C. Ben Salah [1], W. Ayari [1], N. Ben Amor [1] and H. Dardour [1]
[1] Institut des Sciences et Technologies de la Mer, Salammbô, Tunisie - hedia.attia@instm.rnrt.tn

Abstract
Un suivi histopathologique de la palourde *Ruditapes decussatus* a été effectué pendant quatre années au niveau de treize zones de production naturelle réparties le long du littoral tunisien. Les parasites détectés sont: des protozoaires (*Perkinsus* sp.) parasites à déclaration obligatoire ; des stades larvaires de trématodes digènes : sporocystes, rédies et métacercaires; des procaryotes intracellulaires de type Rickettsien ou Clamydien, et enfin des grégarines observés chez un seul individu. Les prévalences des trématodes digènes, en particulier le stade métacercaire, sont souvent significativement supérieures à celles des autres parasites. Lorsque l'on considère séparément chaque zone d'échantillonnage, aucune corrélation entre *Perkinsus* sp. et les trématodes digènes en terme de prévalence n'a été détectée.

Keywords: Diseases, South-Eastern Mediterranean

Introduction

En Tunisie, la palourde (*Ruditapes decussatus*) est présente pratiquement tout le long du littoral tunisien. Elle fait l'objet d'une surveillance zoo sanitaire pour le dépistage des parasites notamment ceux à déclaration obligatoire : La Perkinsiose dont l'agent pathogène est *Perkinsus olseni* (protozoaire, *Apicomplexa*). Le présent travail récapitule les résultats de quatre années de surveillance anatomo-pathologique des échantillons de palourdes provenant de 13 zones de production.

Matériel et méthode

Le suivi a concerné 13 zones de production et il a été réalisé de l'été 2004 à l'été 2008. Une centaine d'individus par échantillon et par zone de production ont été prélevés en hiver et en été. Les organes de chaque individu ont été fixés dans une solution de Davidson pour une étude histologique. L'identification des parasites a été est réalisée grâce à l'examen microscopique de chaque coupe colorée à l'Hémalun- Eosine.

Résultats et discussion

Le dépistage parasitaire a montré la présence de *Perkinsus* sp. parasite à déclaration obligatoire ; des stades larvaires de trématodes digènes : sporocystes, rédies et métacercaires; des procaryotes intracellulaires de type Rickettsien ou Clamydien, et enfin des grégarines observés chez un seul individu. En terme de prévalence les trématodes digènes, en particulier le stade métacercaire, sont souvent significativement supérieures aux autres parasites (figure 1). Les prévalences des infestations parasitaires par des stades larvaires de trématodes digènes au niveau des zones de production ne sont pas liées ni à la période de prélèvement. ni à la zone de production. Cependant des auteurs ont montré l'importance des facteurs biotiques comme la température [2], la densité de la population-hôte amont et la présence des macrophytes [3] qui peuvent être des facteurs potentiels régissant la répartition et la transmission des trématodes digènes. Les prévalences de l'infestation parasitaire du protozoaire *Perkinsus* sp. au niveau des zones de production ne sont pas liées ni à la période de prélèvement. ni à la zone de production. Ces résultats ne concordent pas avec certaines études. Ainsi, Villalba *et al.* en 2001 [5] ont dénoté une corrélation positive entre l'élévation de la température et l'augmentation des prévalences et des degrés d'infestation. Alors que Park et Choi en 2001 [4] ont constaté qu'aussi bien les prévalences que les intensités d'infestation à *Perkinsus* chez l'espèce *philippinarum* de la côte ouest de la Corée sont assez élevés même à une température de l'eau de l'ordre de 3,1°C. Les résultats montrent par ailleurs que l'infestation aux procaryotes intracellulaires de type Rickettsien ou Clamydien ne concerne que quelques zones de production et elle est surtout localisée au niveau des branchies. Les prévalences les plus élevées ont été observées en hiver au niveau de deux lagunes : le lac de Tunis et le lac Biban qui sont des zones relativement fermées. Les grégarines qui sont des Protistes sporozoaires ont été observées au niveau des branchies chez un seul individu. Ils sont souvent associé à une réponse inflammatoire localisée mais sans effet appréciable sur la santé des animaux [1]. Par ailleurs, quand on compare les prévalences à *Perkinsus* sp. et aux trématodes digènes pour chaque zone d'échantillonnage, aucune corrélation entre ces parasites n'a été détectée.

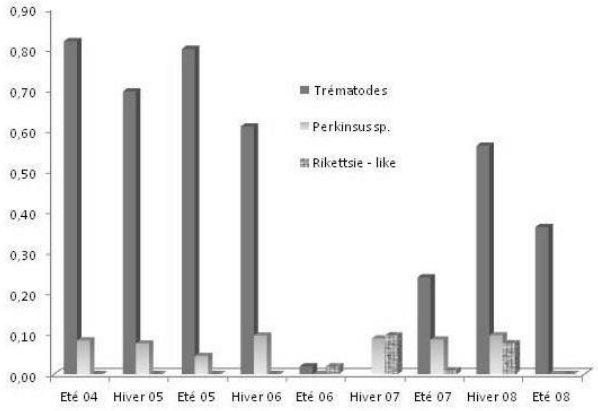

Fig. 1. Prévalence de *Perkinsus* sp., de Trématode digène et de Rickettsie-like chez *Ruditapes decussatus* dans la lagune de Bizerte.

SIZE AT MATURITY OF *SQUALUS MEGALOPS* (MACLEAY, 1881) AND *SQUALUS BLAINVILLEI* (RISSO, 1826) FROM THE GULF OF GABÈS

Sondes Marouani [1], Hasna Kadri [1], Abderrahmane Bouain [1] and Mohamed N. Bradai [1]*
[1] Faculté des sciences de Sfax BP.802 - mednejmeddine.bradai@instm.rnrt.tn

Abstract
Size at maturity was estimated for *Squalus megalops* and *Squalus blainvillei* from the Gulf of Gabès (Tunisia). Females of *S. blainvillei* and *S. megalops* reach maturity at 62.5 cm TL and 56.41 cm TL, respectively. Males mature at 44.39 cm TL for *S. megalops* and 52.3 cm TL for *S. blainvillei*.

Keywords: Reproduction, Gulf of Gabes

Introduction
Both *Squalus megalops* and *S. blainvillei* are viviparous aplacental demersal sharks. The former is distributed throughout the Mediterranean Sea [1] while the occurrence of *S. megalops* was recently confirmed in the area [2]. In the Mediterranean Sea, data on the biology of *S. blainvillei* were scarce [3] while those on *S. megalops* were lacking. Maturity size is crucial for quantitative analysis of the populations and is useful in fisheries management. This study aims to estimate size at maturity for both dogfishes *S. megalops* and *S. blainvillei* off the Gulf of Gabès.

Materials and methods
A total of 630 specimens of *S. megalops* (323 males and 307 females : 18.8 – 76 cm TL) and 232 individuals of *S. blainvillei* (108 males and 124 females : 23.8 - 100 cm TL) collected from the commercial catches in the Gulf of Gabès during the period between January 2007 and May 2009 were examined. Sexual maturity stages (juveniles, subadults and adults) for both sexes were determined according to Braccini *et al.*, (2006) [4]. The size at maturity L50 was defined as the length at which 50% of the individuals were mature.

Results and Discussion
In the Gulf of Gabès, *S. megalops* matured at 62.5 and 74.22% of their maximum length respectively for males and females whereas *S. blainvillei* matured at 62.26 and 63.41% of their maximum length respectively for males and females.

Both males and females of *S. blainvillei* reached first sexual maturity at larger size than *S. megalops* (Tab. 1).

Tab. 1. Size at maturity in *Squalus blainvillei* and *Squalus megalops* from different localities

Species	Location	TL max (cm)	Maturity (mm TL)	Maturity $\%TL_{max}$
Squalus blainvillei	Central Mediterranean Sea (Present study)	♀100.0 ♂83.4	62.5 (L50) 52.3 (L50)	63.41 62.26
	Western Mediterranean Sea (Sion *et al.*, 2003)	♀78.5 ♂66.4	60.1 (L50) 45.0-51.0	77.0 68.0-77.0
	Eastern Mediterranean Sea (Kousteni & Megalofonou, 2011)	♀77.9 ♂79.9	65.4 45.7	-- --
Squalus megalops	Central Mediterranean Sea (Present study)	♀76.0 ♂69.0	56.4 (L50) 44.3 (L50)	74.22 62.5
	South Africa, SE Atlantic (Watson & Smale, 1998)	♀78.2 ♂57.2	50.0 (L50) 40.0 (L50)	64.0 70.0
	SE Australia (Braccini *et al.*, 2006)	♀63.5 ♂47.0	45.9-49.5 (L50's) 37.3-39.8 (L50's)	72.0-78.0 79.0-85.0

;

In both species females matured sexually at a larger size than males. Comparisons between populations show that *S. blainvillei* off the Gulf of Gabès, off Western Mediterranean [3] and off Eastern Mediterranean Sea [5] reaches maturity at a comparable size.

Compared to populations studied of Australia [4] and South Africa [6], *S. megalops* off the Gulf of Gabès reaches maturity at a greater size.

In fact, there is considerable geographical variation in the size at maturity for *Squalus* species. Besides, regional variation in elasmobranchs reproductive parameters is common, but, some part of the variation in *Squalus* species could be a result of taxonomic confusion [7].

REGIME ALIMENTAIRE DE *ROSTRORAJA ALBA*, RAIE BLANCHE, DANS LE GOLFE DE GABES (TUNISIE)

Hasna Kadri [1]*, Sondes Marouani [1], Abderrahmen Bouain [1] and Mohamed N. Bradai [1]
[1] Faculté des Sciences de Sfax - hasnakadri@yahoo.fr

Abstract
L'étude du régime alimentaire de *Rostroraja alba* a été réalisée sur 320 individus capturés dans le golfe de Gabès. L'analyse du régime alimentaire révèle que les téléostéens sont les proies essentielles suivis par les crustacés et les mollusques.

Keywords: Food webs, Elasmobranchii, Gulf of Gabes

Introduction *Rostroraja alba* est une espèce atlanto-méditerranéenne en danger critique d'extinction en Méditerranée [1]. Aucune étude sur le régime alimentaire de cette raie n'a été fournie dans cette zone. Dans ce travail, nous contribuons à la connaissance du régime alimentaire de *R. alba* dans le golfe de Gabès par l'analyse de certains indices alimentaires.

Matériel et méthodes Les contenus stomacaux de 320 individus (30 < LT< 160 cm), sont examinés pour l'étude du régime alimentaire. Pour chaque individu, nous notons le sexe, la longueur totale (LT) au cm près et l'état de réplétion est noté. Les proies sont identifiées, recensées puis pesées. l'indice de l'importance relative (IRI%) combinant les pourcentages d'occurrence (F%), numérique (N%) et pondérale (M%) a été utilisé pour décrire l'alimentation de cette espèce [2].

Résultats et Discussions Le coefficient de vacuité calculé pour les 312 estomacs pleins est de 2.56 % indiquant la voracité de l'espèce. Ce coefficient ne varie pas en fonction du sexe (x_2 = 0,13 ; dl=1 ; p>0,05) mais varie en fonction de la taille (x_2 = 0,02 ; dl=2 ; p<0,05). L'analyse des proies ingérées montre que cette espèce présente un spectre alimentaire peu varié renfermant quelques groupes zoologiques et un comportement de prédation aussi bien pélagique que benthique. La présence des Rajidae dans certains contenus stomacaux de *Rostroraja alba* montre la compétition interspécifique qui existe entre les habitants d'un même biotope
(Tab.1).

L'analyse du régime alimentaire révèle que les téléostéens sont les proies essentielles suivis par les crustacés et les mollusques. L'analyse multivariée (MANOVA) a montré que la consommation des téléostéens, crustacés et mollusques varie en fonction de la taille mais pas en fonction du sexe et des saisons (Tab.2).

AGE ET CROISSANCE DU POCHETEAU NOIR, *DIPTURUS OXYRINCHUS* (LINNAEUS, 1758), DANS LE GOLFE DE GABES (TUNISIE)

Hasna Kadri [1]*, Sondes Marouani [1], Abderrahmane Bouain [1] and Mohamed N. Bradai [1]
[1] Faculté des Sciences de Sfax - hasnakadri@yahoo.fr

Abstract
Dipturus oxyrinchus du golfe de Gabès montre un seul arrêt de croissance par an, il se situe entre mars et avril. Les femelles atteignent des tailles et des âges plus importants que ceux des mâles. La croissance chez les mâles est plus rapide. Les paramètres biologiques de Von Bertallonfy sont :L_∞= 123,9±2,56 cm, k= 0,08 ±0,04 et t_0= -1,26±0,04 pour les femelles et L_∞= 102,1±3,23 cm, k= 0,12± 0,0710^{-3} et t_0= -1,18±0,03 10^{-1} pour les mâles.

Keywords: Growth, Elasmobranchii, Gulf of Gabes

Introduction
Dipturus oxyrinchus est une espèce atlanto-méditerranéenne en danger critique d'extinction en Méditerranée [1]. Aucune étude sur l'âge et la croissance de cette raie n'a été abordée en Méditerranée. Dans ce travail, nous contribuons à la connaissance de l'âge et la croissance de cette espèce dans le golfe de Gabès.

Matériel et méthodes
L'âge de *Dipturus oxyrinchus* a été estimé à partir d'échantillons (n= 240) en provenance du golfe de Gabès de taille comprise entre 15,5 et 105 cm LT. Pour chaque poisson nous avons relevé la longueur totale (LT), la masse du poisson entier (Mp) et la masse du poisson éviscéré (Mev). Nous avons prélevé 8 à 10 vertèbres de chaque spécimen. Durant cette étude nous avons effectué des coupes fines sur les vertèbres. La lecture a été effectuée à l'aide d'une loupe binoculaire (Lumière réfléchie) munie d'un micromètre oculaire. Nous avons analysé les variations mensuelles de l'allongement marginal (AM).

Résultats et Discussion
Les marques d'arrêt de croissance s'inscrivent nettement sur les vertèbres. Egalement l'alternance des bandes opaques et des bandes translucides est clairement visible sur les vertèbres entières. Nous avons obtenu de faibles valeurs de l'indice du pourcentage moyen d'erreur (PME) (3,12 %) ce qui indique une bonne précision dans l'identification des vertèbres. L'analyse des fluctuations de l'allongement marginal des vertèbres en fonction du temps, nous a permis d'établir la date de formation de l'anneau d'arrêt de croissance et d'en valider la périodicité, un seul arrêt de croissance par an, il se situe entre mars et avril (fig.1)

.

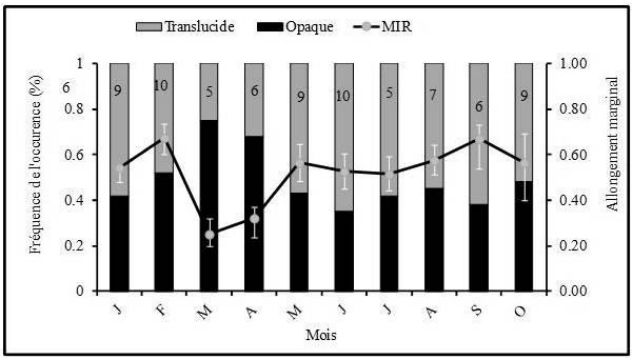

Fig. 1. Variations mensuelles de l'allongement marginal et des fréquences de bandes opaques et translucides dans les vertèbres chez *Dipturus oxyrinchus* du golfe de Gabès

Les paramètres de l'équation de Von Bertallonfy sont : L_∞= 123,9±2,56 cm, k= 0,08 ±0,04 et t_0= -1,26±0,04 pour les femelles et L_∞= 102,1±3,23 cm, k= 0,12± 0,07 10^{-3} et t_0= -1,18±0,03 10^{-1} pour les mâles. L'âge maximum observé est de 25 ans chez les femelles et de 22 ans chez les mâles (fig. 2).

THE PRODUCTION OF TRIPLOID BROWN TROUT (*SALMO TRUTTA*) USING CAFFEINE TREATMENT

Funda Turan [1]*, Damla Yigitarslan [1], Fahriye Arslan [1] and Cemal Turan [1]
[1] Marine Science and Technology Faculty, Mustafa Kemal University, Iskenderun, Hatay, Turkey - turanfunda@yahoo.com

Abstract
In the present paper suitable conditions were determined for caffeine treatment that is safe and inexpensive for the induction of triploid brown trout. To suppress the second meiotic division, fertilized eggs were exposed to three different concentrations (5- 10 and 15-mM) caffeine solution for 10 min beginning at 15 min after fertilization. After that, the eggs were incubated at ambient temperature until hatching. Incidence of triploid fry was determined from flow-cytometric analysis. There was no significant difference in the mean triploid rates all caffeine treatments and not observed successful results in these groups.

Keywords: Aquaculture, Iskenderun Bay

Introduction
Triploidization as one of the modern genome manipulation methods in aquaculture is most often applied to salmonids. Triploids are organisms with three sets of chromosomes in their somatic cells instead of the usual two in diploids. The importance of triploid animals in aquaculture arises from this predisposition for sterility. Triploids can also be produced by crossing tetraploids with diploids (Liu et al., 2004). Chemical treatments such as cytochalasin B (CB) (Sun et al., 1992; Maldonado et al., 2001 and Liu et al., 2004) and 6-dimethylaminopurine (6-DMAP) (Yan and Chen, 2002 or Liu et al., 2004) are simpler than physical treatments because specific equipment is not required. However, CB is highly toxic, and careful handling is necessary. Moreover, both CB and 6-DMAP are very expensive and not realistic for large scale treatment in commercial hatcheries. Caffeine, a chemical that is a recognized food constituent in many countries, is safer and cheaper than either CB or 6-DMAP. Therefore, caffeine is a promising agent for the mass production of triploids (Okumura et al., 2007). But, triploid induction by caffeine treatment have been only reported exclusively in bivalves by Scarpa et al.1994 and abalon by Okumura et al., 2007, rainbow trout by Turan et.al., 2012. Therefore, in the present study we intended to ascertain whether induction of triploidy by caffeine treatment in the brown trout Salmo trutta

Materials Methods
The experiment was carried out in Kahramanmaras trout farm of Kiliç Holding Co. in Turkey. The fertilized eggs were exposed to three different concentrations (5- 10 and 15-mM) caffeine solution for 10 min beginning at 15 min after fertilization. Diploid controls were originated from the same parents but not subjecting them to caffeine treatment. A pool of fertilized eggs from different spawners was distributed in triplicate for each trial and one control group. The fertilization was carried out in water at a temperature of 9.5 ±0.5 ° C. The survival rate was evaluated after hatching (d.p.h). The larvae were sampled from each treatment group at 3 day after hatching (d.p.h) and fixed with 70% ethanol and stored at -20°C until analysis (Nomura et. al., 2004). For measurement of the relative DNA content, flow cytometry (FCM) was conducted using a BD FACS Canto flow cytometer. The method of FCM analysis followed the protocol described by Cakmak, (2011). Results are presented as mean±standard deviation of the mean and statistical testing to verify differences between the groups was carried out using a one-way analysis of variance.

Results and Discussion
Treatments for caffeine treatment triploidy induction and their corresponding survival and triploidy rates are shown in Table 1. The survival rate was ranged from 83.24% to 77.54%, and there was no statistical difference between experimental and control groups (Table 1). There was no adverse influence of caffeine treatment on survival fry in the present study. There was no significant difference in the mean triploid rates between caffeine treatments, and thus caffeine concentration had no significant effect on triploidy rates of brown trout fry. Up to date, there was no published information on triploidy induction by caffeine treatment in brown trout. On the other hand, Turan et al., (2012) reported that triploid percentages in rainbow trout were 45.40% in 15 mM caffeine treatment. This percentage may be low but indicate that caffeine treatment on triploidization of rainbow trout is effective. Therefore, further detailed investigation is required to examine the effect of caffeine treatment in order to realize a 100% triploid population which suggests that this kind of treatments can be dependent on species.

Tab. 1. Treatments for caffeine treatment triploidy induction and their corresponding survival and triploidy rates

Treatment	Time after fertilization (min)	Shock duration (min)	Survival rate*	Ploidy**	
				Percent Diploid (2n)	Percent Triploid (3n)
Control	15	10	82.51±4.96[a]	100	-
5 mM	15	10	80.42±3.63[a]	98.11	1.89
10 mM	15	10	81.64±3.54[a]	95.83	4.17
15 mM	15	10	83.46±4.39[a]	93.52	6.48

*Values (mean ± S.D. of triplicate) with same superscripts in each line indicate not significant differences (P<0.05).
**Based on the relative DNA content measured by flow cytometry

This is a first report to our knowledge regarding the potential use of caffeine treatment on induction of triploidy in brown trout. As described previously, caffeine treatment is simple, safe, and inexpensive. Furthermore, other dosage of caffeine should be tried for induction of triploidy of trout in order to get success.

Acknowledgements. We thank to Taner SEKER from the KILIÇ HOLDING Co. for allowing this experiment in their farm. Also, we thank the Izmir Institute of Technology for its support.

Abstract
Pour développer la filière ostréicole dans la région de Dakhla et afin qu'elle devienne une référence dans ce secteur d'activité, une étude comparative de la croissance de l'huître creuse en élevage a fait l'objet de ce présent travail. Les naissains T6 importés d'écloserie atteignent la taille commerciale en 7 mois. En parallèle, les premiers essais de captage de naissains sur des tuiles chaulées ont été réalisés en 2005. Les résultats ont montré que l'hydrodynamisme de la baie favorisent le captage de naissains et par la suite le développement d'une telle production.

Keywords: Aquaculture, Growth, Izmir Bay

Introduction
Dans le cadre de la gestion des zones conchylicoles, la constitution de base de données forment un référentiel nécessaire à l'évaluation du milieu. Les connaissances relatives à la variabilité spatio-temporelle des croissances permettent d'évaluer les tendances au niveau des cheptels. L'élevage de l'huître creuse C. gigas est pratiqué dans la baie de Dakhla seulement depuis 2004 pour pallier la faible production ostréicole de la lagune de Oualidia. Ainsi, le suivi de la croissance et de la mortalité de l'huître creuse mise en élevage dans la baie a été étudié durant la période 2004–2006 à DunaBlanca et 2005-2007 à Boutalha.

Matériels et Méthode
Deux lots de 3600 individus chacun sont distribués dans des poches ostréicoles et accrochées à des tables métalliques. Des prélèvements mensuels de 100 individus d'huître, ont été effectués et ont servi à l'étude comparative de l'évolution saisonnière des paramètres morphometriques et pondéraux.

Résultats et Discussion
Les paramètres hydro-biologiques de la baie [1, 2] sont favorables à une croissance allométrique et pondérale rapide des huîtres mises en élevage (fig. 1). Ainsi, quelque soit la zone d'élevage, une croissance en longueur rapide est enregistrée au cours de la première phase d'élevage avec des taux de croissance mensuels moyens de 30,9 ± 11% et 30,5 ± 25,9 % respectivement dans la zone de Duna Blanca et la zone de Boutalha. Aussi, les naissains d'écloserie pesant 1,15g atteignent un poids compris entre 60 et 80g au bout de 7 mois respectivement à Boutalha et DunaBlanca. Ce ci se traduit par un gain journalier de 1g/j pour les huîtres élevées à Boutalha et 0,7g/j pour les huitres élevées à Dunablanca.

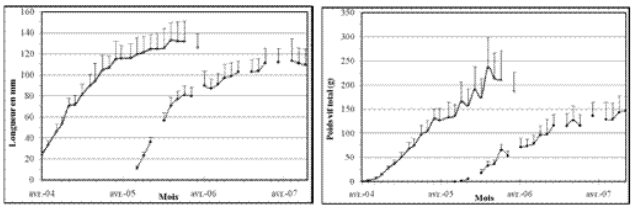

Fig. 1. Croissance en longueur et en poids vif des huîtres mises en élevage à Duna Blanca (avril 2004-mars 2006) et Boutalha (juin 2005-août 2007).

En comparaison avec des travaux antérieurs [3, 4, 5] qui ont montré qu'avec un poids de départ compris entre 15 et 30g, les huîtres atteignent, à 30 mois, un poids compris entre 58g et 99g (Tab.1), le cycle de production de l'huître creuse à Dakhla reste le plus court. Ce qui permettra aux ostréiculteurs de cibler les périodes de hausse demande.

Tab. 1. Taux de croissances de l'espèce *C. gigas* mis en élevage dans différents sites.

Région et l'auteur	Poids vif (g) après 12 mois	Poids vif (g) après 24 mois
Oualidia [4]	43g	120g
Marénne Oléron [5]	48g	60g
Arcachon [6]	15g (18 mois)	58g (30 mois)
Bretagne sud [6]	28g	99g
Baie de Dakhla (Duna Blanca) présente étude	127g	188g
Baie de Dakhla (Boutalha) Présente étude	79g	129g

Les analyses macroscopiques de la gonade couplées à l'évolution de l'indice de condition des huîtres ont montré que la maturité sexuelle se développe après trois mois d'élevage : les naissains mis en eau en avril 2004, voient leurs gonades se développer en juillet et la libération des gamètes se fait en Octobre 2004. Aussi, les premières évaluations de ce captage par les tuiles chaulées encouragent le développement d'une telle activité. Or l'évolution du taux d'accroissement des naissains d'huîtres captés, ne dépasse pas 35 cm pendant une année d'élevage, ce qui laisse penser que les naissains collectés sont des huîtres hybrides entre l'huître naines indigènes *Ostreola Stentina* et l'huître creuse introduite. Au cours de cet élevage le taux de mortalité ne dépasse pas 10%, il reste le plus faible en comparaison avec d'autres études [3].

Conclusion
Les performances de la croissance de l'huître dans la baie de Dakhla est du à la grande capacité nutritive de la baie; Cette dernière est relative à l'extension des projets aquacoles et touristiques dans la baie; ce qui nécessite un suivi régulier de l'évolution du degré de la capacité trophique de l'écosystème.

REPRODUCTIVE PERIODICITY OF SEA CUCUMBER *BOHADSCHIA VITIENSIS* (ECHINODERMATA: HOLOTHUROIDEA) IN HURGHADA AREA, RED SEA, EGYPT

Fatma Abdel Razek [1]*, H. A. Omar [1], S. H. Abdel Rahman [1] and N. A. El Shimy [2]
[1] National Institute of Oceanography and Fisheries Qayet Bay - fatma_abdelrazek@hotmail.com
[2] Zoology Department, Faculty of Science, Assiut University

Abstract
A small scale sea cucumber fishery began in Egypt in 1998 on the northern part of Red Sea coast fig. (1). By the year 2000, its fishery had expanded dramatically, leading to over exploitation. Evidence from previous study [1] indicates that four years after banning sea cucumber fishery in Egyptian Red Sea, some commercial species are returning to some of the sites, but there is no evidence of stock recovery. B. vitiensis was studied during 2003-2004 and a population analysis of 417 individuals showed significant abundance of males. Reproductive studies showed also that during June and July an intensive period of spawning occurred with size at 1st maturity of 24.5 and 26.1 cm for males and females respectively. The oocyte diameter of ripe females ranged from 87.5 to 162.5 µm during active spawning period.

Keywords: Reproduction, Red Sea, Echinodermata, Spawning

Introduction

Holothuroid fauna of the Red Sea attracted attention of many investigators for many years ago. In the various habitats of the Red Sea 98 holothuroid species were recorded, including *Bohadschia vitiensis* the subject of this study. Still, little is known about maturation and spawning periodicity of most commercial sea cucumber species in Egyptian Red Sea fisheries.

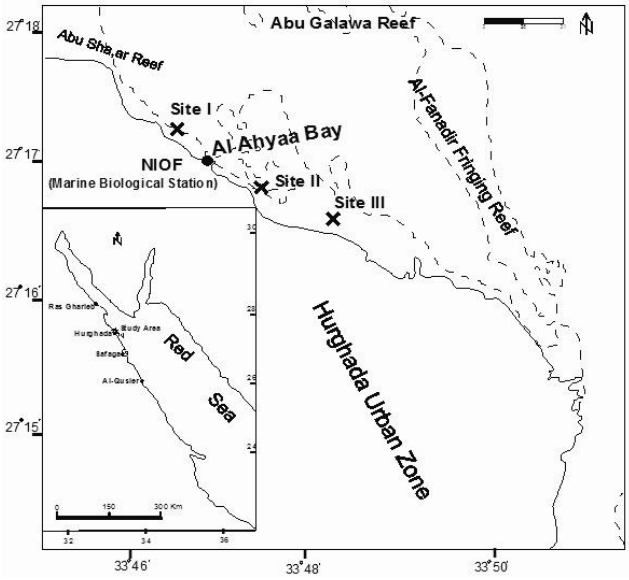

Fig. 1. Locations of sampling sites of *Bohadschia vitiensis*

Materials and method

Monthly samples of *B. vitiensis* of about 10-15 individuals were randomly collected by SCUBA divers from selected sites Fig. (1). Measured were done after relaxation in 2.5% $MgCl_2$ (w/v) to overcome the error resulting from contraction and relaxation. Gonads were removed and preserved. T.L & T. body wt. were recorded. G.S.I were calculated as Gonad weight/body weight X 100 . Four maturity stages were determined according to colour length & diameter of gonad tubules [2]. Oocyte diameters were measured.

Results & Discussion:

Population analysis were done, T.L range of *B. vitiensis* was from 16.0 to 42.0 cm. Which is consider one of the large species found in comparison with *H. atra* of T.L range from 9.5 to 28.5 cm [3]. There is a shift in sex ratio from unity towards significantly more males and this is not due to impact of fishing pressure as in case of *H. hawaiiensis* and *H. atra* [4]. The maximum reproductive activity was observed in summer and the minimum (resting) in late autumn and winter using G.S.I as well as tubule length and diameter as in tab. (1). There is a synchrony between males and females as in case of *H. scabra* [5]. More studies focusing on fecundity per size distribution and estimating the ideal size to capture to avoid over exploitation.

Tab. 1. Macroscopic characteristics of *B. vitiensis* gonads at each of the stages of sexual maturity

Stage of Maturity	Sex	Tubule Characteristics		GSI range
		T.L. (mm) range	Diameter range (mm)	
I Immature	♀+♂	2.5 - 21 .0	0.2 - 1.0	1.00 - 3.5
	♂	2.0 - 22.0	0.2 - 0.9	0.40 - 3.1
II Maturing	♀+♂	15.0 - 50.0	0.4 - 1.3	7.50 - 16.7
	♂	18.0 - 66.0	0.4 - 1.2	0.80 - 0.9
III Ripe	♀+♂	67.0 -130	1.9 - 2.5	28.2 - 9.7
	♂	90.0 -125	1.5 - 2.0	16.2 - 7.2
IV Spent	♀+♂	19.0 - 350	0.5 - 0.7	0.50 - 1.5
	♂	12.0 - 46.0	0.3 - 0.9	0.40 - 10.8

As mentioned before there are 4 stages of maturity in *B. vitiensis*. In immature and spent stages both female and male gonads appear alike in shape and color. While during mature and ripe stages differentiation appear between in shape and color. During maturing stage the tubules of female are Long, thick, branched and the ovary is pale red, while in male tubules are Long, thin, branched and creamy-white. During the ripe stage, the female tubules are Long, thick swollen, branched and red in color, while in male tubules are long, swelling with white beaded filaments. The female tubules have spherical oocytes mostly ripe of 75 - 150 micron in diameter and with clearly visible nucleus while the male tubules have numerous swimming spermatozoa.

ETUDE COMPARATIVE DES PERFORMANCES DE LA CROISSANCE DE LA MOULE (*MYTILUS GALLOPROVINCIALIS*) EN MER OUVERTE ET EN MILIEU LAGUNAIRE

Rym Ben Kheder-Dhaoui [1]*, Imen Boukef Ben Omrane [2], Sondes Milliti [3] and Mohamed Chalgaf [1]
[1] Institut Supérieur de Pêche et d'Aquaculture ISPA Bizerte - benkheder_rym@yahoo.fr
[2] Laboratoire du Microbiologie, Institut National Des Sciences et Technologies de la Mer (INSTM), Rue du 2 mars 1934, 2025, Salammbô, Tunisie
[3] Faculté des Sciences de Bizerte

Abstract
Dans cette étude, nous avons comparé deux milieux en tant que site conchylicole : la lagune de Bizerte *vs* la baie de Bizerte (Tunisie). Cette étude porte sur les performances de croissance de *Mytillus galloprovincialis* dans les deux sites ainsi que les variations de la qualité bactériologique. Le choix de ces deux stations nous permettra d'évaluer l'influence des différentes conditions du milieu sur les moules élevées pendant 4 mois consécutifs du 20/02/2012 au 20/06/2012.

Keywords: Lagoons, Open sea, Mollusca, Mediterranean Ridge

Introduction

Mytilus galloprovincialis présente de nombreuses adaptations aux conditions environnementales. Outre leur valeur biologique, leur exploitation à des fins conchylicoles les classe avec les ostréidés parmi les bivalves de grande valeur économique générant des revenus financiers importants. En Tunisie, *Mytilus galloprovincialis* est présente sur les côtes nord jusqu'à la pointe du Cap Bon. Le cantonnement de cette activité dans la seule lagune de Bizerte témoigne de la sous exploitation de cette espèce en Tunisie. Une éventuelle saturation des capacités spatiales et biologiques de ces milieux exigus laisse envisager la conquête d'autres espaces et l'expansion de cette activité en mer ouverte. L'objectif de ce travail est de comparer les performances de croissance de la moule *Mytilus galloprovincialis* en mer ouverte et en milieu lagunaire en parallèle avec une étude bactériologique. Le choix de ces deux stations nous a permis d'évaluer l'impact des différentes conditions du milieu sur les moules élevées.

Matériels et Méthodes

Cinq lots de 100 individus de moules (*Mytillus galloprovincialis*) sont suspendus chacun dans la lagune de Bizerte et cinq autres lots en mer ouverte. Les paramètres physico-chimiques de l'eau (température, pH, salinité, oxygène dissous) sont mesurés *in situ* à l'aide d'une sonde multiparamétrique étanche. Le dosage de la *chlorophylle-a* est réalisé par une méthode fluorimétrique. Dans chaque station, quarante individus sont prélevés mensuellement pour l'étude biométrique, 6 individus pour l'étude biochimique (dosage des lipides [1] et des protéines [2]) et dix individus vivants sont échantillonnés tous les quinze jours pour l'étude bactériologique. Les dénombrements bactériens des coliformes totaux (CT), des *Vibrionaceae* (VB) et des bactéries hétérotrophes cultivables (BHC) sont effectués pour l'eau de surface et pour les moules.

Résultats et discussion

Les résultats révèlent une croissance meilleure dans la lagune avec un accroissement mensuel en taille de 0,9 cm *vs* 0,5 cm en mer et un gain en poids total de 7 g dans la lagune contre seulement 0,5 g en mer. Ceci peut être expliqué principalement par la température de l'eau ($T°C_{lagune} > T°C_{mer}$) ainsi que par la richesse nutritive de la lagune [3]. En effet le dosage de la *chlorophylle-a* montre des taux plus élevés dans la lagune d'une part (3,86 µg/l *vs* 2,19 µg/l en mer ouverte) et en fonction de la température d'autre part où les valeurs les plus élevées coïncident avec l'augmentation de la température de l'eau. Cette richesse nutritive du milieu lagunaire se traduit d'ailleurs par la colonisation rapide des élevages par des moules épibiontes issues de captage naturel responsables de mortalités importantes. Par ailleurs, les analyses biochimiques révèlent, quel que soit le site, que chez les moules les réserves énergétiques sont majoritairement composés de carbohydrates (75%). Ensuite, les protéines constituent le deuxième composé important avec une moyenne d'environ 20 % sans toutefois de différence majeure entre les deux lots. Les lipides, composé le moins abondant, affichent une différence de presque le double 3,28 % et 7,32 % respectivement chez les moules issues de la lagune et celles provenant de la mer. La chromatographie en phase gazeuse a identifié une quinzaine d'acides gras dans les lipides totaux des mollusques bivalves. Le profil lipidique des acides gras (AG) de la chair des moules révèle que la fraction des acides gras saturés (AGS) est la plus dominante dans les deux sites (44 %). Elle est représentée par l'acide myristique C14:0, l'acide acide stéarique C18:0 et l'acide palmitique C16:0 qui se trouvent en proportions quasi-similaires chez les moules issues des deux stations. A l'opposé, la prédominance des AGPI a été signalée chez d'autres espèces telles que *Argopecten purpuratus* [4] et *Nodipecten subnodosus* [5]. Les pourcentages élevés en AGS enregistrés seraient liés à la richesse du milieu en détritus organiques constituant une importante source de C14:0, C15:0, C16:0 et C18:0 comme mentionné par Freites *et al.* [6]. Les acides gras polyinsaturés représentent la fraction intermédiaire des acides gras totaux (36 et 41 % respectivement chez les moules issues de la mer et de la lagune). L'acide gras polyinsaturé le plus abondant chez les moules de la lagune est l'acide linoléique (C18 :2n-6 ; 23 %), il représente presque la moitié chez les moules de la mer (13 %). Les autres acides gras polyinsaturés existent presque avec les mêmes proportions chez les deux groupes analysés. Notons que les acides docosahexaenoïque (DHA, C22:6 n-3) et eicosapentaenoïque (EPA, C20:5 n-3) figurent également en parts presque égales chez les deux lots. Enfin, les acides gras monoinsaturés représentent la fraction la plus faible des acides gras totaux (17 %). Ce sont en majorité les acides gras C16:1 n-7, C18:1 n-9 et C18:1 n-7. Concernant l'étude bactériologique, des concentrations bactériennes plus importantes ont été détectées dans la lagune aussi bien dans l'eau de surface que dans les moules. Il est à noter que la charge en *Vibrionaceae* est corrélée avec la variation de la température et de la salinité. Le suivi d'un cycle d'élevage complet s'avère nécessaire pour une comparaison inter-sites plus globale ainsi qu'une étude modélisant la croissance de la moule en mer et en lagune en intégrant la température et la richesse nutritive du milieu.

Abstract
Present study was performed to determine the depuration time and ability of manila clams contaminated with of *Escherichia coli, Salmonella typhimurium* and *Vibrio parahaemolyticus*. Manila clams were contaminated with each bacterium at the level of 7 $\log_{10}$ cfu g^{-1}. Then clams were analyzed in every 3 hours in the first 24 hour time period and in every 6 hours until the 72nd hour. Results of this study indicate that the depuration time for the commercial-sized *R. philippinarum* contaminated with the pathogenic bacteria at the level of 7 $\log_{10}$ cfu g^{-1} is 66 h.

Keywords: Bacteria, Marmara Sea, Bivalves

Introduction : *Ruditapes philippinarum*, manila clam, is a bivalve species which lives in sandy sediments of tidal flats or shallow coastal areas with a depth lower than 5m. Significant proportion of foodborne diseases arised from shellfishes are mostly caused by bacteria especially *Vibrio* spp., *Salmonella* spp., and *Esherichia coli* (1). Depuration is a common practice to reduce level of microorganisms in live shellfish processing. The aim of this study was to determine the depuration time and ability of manila clams contaminated with *E. coli ATCC 25922, S. typhimurium ATCC 14028* and *V. parahaemolyticus ATCC 17802* in depuration system according to legislations. **Materials and Methods** : *Ruditapes philippinarum* was harvested from offshore natural beds located in the Çanakkale Strait to Marmara Sea (Turkey). Sample contamination was conducted in 100 liters polyethylene tanks filled artificial seawater, which was inoculated with specific bacterial suspensions to reach the concentration of 8 $\log_{10}$ cfu ml^{-1}. The used inoculums were fresh overnight cultures of each organism (*E. coli, S. typhimurium, V. parahaemolyticus*). Appropriate amounts of the overnight broths were added to the uptake tank. Samples were removed from depuration tanks at 0, 3, 6, 9, 12, 18, 24, 30, 36, 42, 48, 54, 60, 66, and 72nd hours for analyses. Microbial groups were enumerated using the plate count method as described by Food and Drug Administration (3). **Results and Discussion** : Depuration process is utilized in bivalves to reduce the level of pathogenic microorganisms which have important proportion of shellfish-borne poisoning (4). This study was performed to determine the depuration time of *R. philippinarum* contaminated with *E. coli*, *S. typhimurium*, and *V. parahaemolyticus.* The depuration process was performed in 1000 liters of depuration tanks designed according to both Turkish Fisheries Legislations and European Commission Directives (5). Contamination of shellfishes via marine water by *E. coli* is mainly due to the disposal of wastewater and it indicates the possible presence of pathogenic microorganisms. Therefore, *E. coli* concentrations are recognized as shellfish quality indicator by national and international regulations. The legal limit of *E. coli* level for marketable live bivalves is 230 cfu $100g^{-1}$ (5). In *R. philippinarum*, after 66 hours of depuration, the count of *E. coli* was reduced to limit level from its initial count of 7.3 $\log_{10}$ cfu g^{-1} (Fig 1).

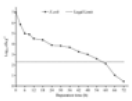

Fig. 1. Changes of *E. coli* level in *R. philippinarum* during depuration process.

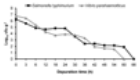

Fig. 2. Changes of *V. parahemolyticus and S. typhimurium* level in *R. philippinarum* during depuration process

In the first six hours, the level of *E. coli* has decreased rapidly to the level of 5 $\log_{10}$cfu g^{-1}. The decreasing continued and it was undetectable at 72th hour. Barile *et al*. (6) reported that *Chamelea gallina*, which was contaminated with 4 $\log_{10}$ cfu g^{-1} *E. coli*, can be marketable after 48 hours depuration. The results of this study indicated that *R. philippinarum* contained 6.2 $\log_{10}$ cfu g^{-1} of *S. typhimurium* achieved to regulatory standards after 60 hours of depuration. Initial level of *S. typhimurium* decreased sharply to 4.8 $\log_{10}$ cfu g^{-1} after 6 hours and it was undetectable at the 66th hour. (Fig.2) It was noticed that depuration time of *Salmonella* spp. requires a longer period of time than *E. coli*. *Vibrio* species, are naturally occurring bacteria in tropical and subtropical marine waters, and remain viable in this environment for very long times even in the absence of organic matter . Initial count of *V. parahaemolyticus* in *R. phliphinarium* was 6.7 $\log_{10}$ cfu g^{-1}. According to Turkish legislation on fisheries, *V. parahaemolyticus* should be negative in 25 g of meat and intravalvular liquid of marketed live shellfishes. This requirement was met in the experiment at 60th hour. Barile *et al.* (2009) noticed that *V. parahaemolyticus* was not determined in *M. galloprovincialis* after 36-48 hours of depuration.The differences between our findings and the others' mentioned above may be originated by the diversity in the depuration systems and bivalve species.(2) Pathogenic bacteria that are well known to survive in a marine environment for long times, can be accumulated to bivalves and poses health risk to consumers. Depuration helps to improve shellfish quality and helps to prevent consumers from foodborne diseases. A better knowledge of the parameters affecting the kinetics of the processes of depuration against various bacterial strains should be well documented with experimental studies in the future.

Abstract

We bring new items in connection with the origins of the natural recruitment variability of the Pacific oyster *Crassostrea gigas* in Thau lagoon. A poor relationship between " number of larvae" and "number of spat" in 2012 shows a biological lock around oysterculture areas during the metamorphosis in spite of better success of recruitment outside shellfish farming zone. A comprehensive analysis of environmental factors effects and the development of prognosis tools are planned to assist oysterfarmers in rationalization of natural oyster recruitment around Mediterranean lagoon.

Keywords: Bivalves, Aquaculture, Recruitment, Gulf of Lyon

Introduction

Unlike other shellfish farming area of the French Atlantic coast, the Mediterranean basin has never used the possibility of natural catchment for oysters [1,2]. The rising cost of spat associated with very high mortality [3] brings Languedoc producers to consider an in situ production of seed. Since 2010, the interannual variability in recruitment of oysters is analyzed in shellfish farming ecosystems off the Atlantic [1,2] and Mediterranean [4] French coasts by the national Velyger network [5] at the regional level through the project PRONAMED (PROduction de NAissain en MEDiterranée). This project, led by Ifremer and the Regional Committee of the Mediterranean Shellfish in partnership with Cepralmar, is twofold: to advance the understanding of environmental factors controlling the recruitment of *Crassostrea gigas* in a Mediterranean lagoon and identify potential blocking points in the reproductive cycle of this species within this particular environment.

Material and methods

The study focuses on Thau lagoon. The project allowed, in its first phase (2010-2011), the set up of a regional observatory of the natural oyster catchment in farming areas. The second phase (2012-2014) broadens the observatory across the lagoon in and out shellfish farming areas, and involves a thorough environmental monitoring including the study of phytoplankton and zooplankton communities as well as benthic organisms. A review of the reproductive strategy (gametogenesis, synchronization of spawning, quality and quantity of gametes) and the development of cohorts in relation to environmental fluctuations are investigated in this project.

Results and discussion

Our results showed a high interannual variability of settlement intensity in the shellfish farming areas of the Thau lagoon proving that oyster spat may be potentially harvested locally. In addition, the surviving oyster spat better resist the high rate mortality usually observed the following year: the spat captured in the Thau lagoon in 2010 show better resistance to mortality with survival rates of 62 to 78% in September 2011 [5] compared to survival rates observed by the Réseau d'observations conchylicoles (37% survival). Observations in 2012 (figure1) showed that oyster settlement in areas outside shellfish farming zones was important (up to 70 individuals per collector's cup compared to less than 5 individuals).

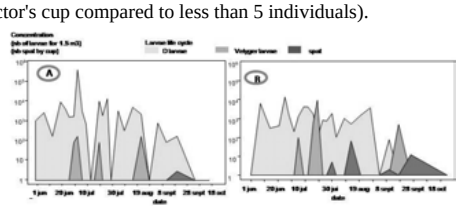

Fig. 1. Larval developpment and spat settlement inside (A) and outside (B) shellfish farming zones.

These results tend to show that Thau lagoon could host a potential oyster spat catchment area outside the farming zones. The potential of these catchment areas and their exploitability by the Mediterranean shellfish industry needs to be addressed. The second phase of the Pronamed project will attempt to answer this question by analyzing the overall influence of various environmental factors on the natural settlement [6]. An analysis of the dynamics of larval dispersal and connectivity between oyster populations will be proposed based on the model MARS-3D Thau [7.8]. Optimization of cultural practices around the management of collectors will be realized. The physiological quality of the larvae (energy reserves) will also be studied.

CULTURE OF *TAPES DECUSSATUS* IN HIGH STOCKING DENSITY IN MERSIN BAY, IZMIR-TURKEY

Serpil Serdar [1]*, Aynur Lok [1] and Aysun Kucukdermenci [1]
[1] Ege University, Faculty of Fisheries, 35100, Bornova-Izmir, TURKEY - serpil.serdar@ege.edu.tr

Abstract
In this study, growth and survival rate of carpet shell clam (*Tapes decussatus*) were investigated in high stocking density in Mersin Bay, Izmir-Turkey throughout one year. Clams were sown 900 ind. /m^2 in plastic box. At the end of the study, clams shell length and total weight reached 30.54±0.42 mm and 5.63±0.21 g, respectively. Survival rate was calculated 20 % at the end of one year.

Keywords: Aquaculture, Bivalves, Aegean Sea

Introduction An effect of stocking density on growth and survival rate is a critical factor in shellfish aquaculture. Optimal stocking density in commercial culture is determined by site specific physical factors (horizontal seston flux), biological factors (species-specific filtration rate) and economic factors such as gear and labor coasts. Lower stocking densities will eventually result in less competition for food and faster growth rates, but this increase comes at the expense of more investment in gear, more labor to maintain it, and a higher lease requirement [1, 2]. On the other hand higher stocking density of shellfish leads to a higher return of harvestable product. Therefore the aim of this study was the effect of high stocking density on growth and survival rate of carpet shell clam in Mersin Bay, Izmir- Turkey.

Material and Methods This study was carried out in Mersin Bay (38º 12' 77"N, 26º 25' 46" E), Aegean Sea about 80 km west of Izmir, Turkey. Water temperature was measured using a mercury in glass thermometer (-10 to 100 ± 0.5 °C) and salinity was determined using a hand refractometer at the sampling area. Chlorophyll-a and seston concentration were determined according to [3] method for each month. Clams were sown at densities of 900 ind./m^2 in plastic boxes with three replicates. Initial of the study clam length, width, height and total weight were 27.52 ±0.17 mm, 19.10±0.14 mm, 11.87±0.10 mm and 3.61± 0.07 g, respectively. The shell length was measured on the anterior-posterior axis using a calliper (±0.1 mm). The instantaneous growth rate (K), was calculated using the following equation [4]; $K=(\ln W_2-W_1)/(t_2-t_1)$, $K=(\ln L_2-L_1)/(t_2-t_1)$. W_1 andW_2 are total wet weight. L_1 andL_2 are the shell length at the beginning and end of experiment time (in month), respectively. The duration of experiment (months) is expressed by (t_2-t_1). Survival (%) was estimated as (N_t/N_0) x 100, where N_t is the number of live clams removed from the culture area after t and N_0 is the number of clams at the beginning of the experiment.

Results and Discussion Water temperature and salinity were measured between 14ºC and 23ºC and 36-37 ‰ throughout the study, respectively. Chlorophyll-a concentration was determined the lowest value (1.98 µg l^{-1}) in January and the highest (7.20 µg l^{-1}) in May. Amount of seston ranged between 7.4 mg l^{-1} and 27.2 mg l^{-} By the end of the rearing cycle, clams reached 30.54 ± 0.42 mm shell length, 21.17 ± 0.36 width, 13.57 ± 0.26 height and 5.63 ± 0.21 g total weight (Fig. 1).

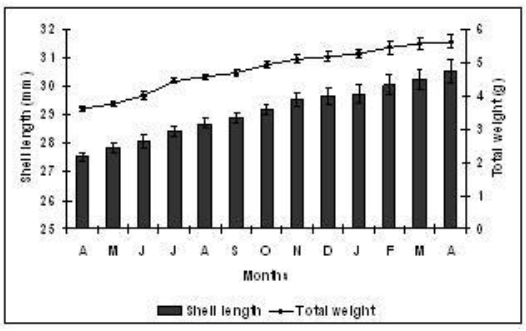

Fig. 1. Variations of shell length and total weight of clam.

Maximum growth rate of shell length, width, height and total weight was determined 0.0123 in June, 0.0139 in October, 0.0183 in September and 0.1018 in June, respectively (Fig. 2). The maximum growth rate was significantly higher in late spring compared to other periods of time. Survival rate was determined 20 % at the end of one year.

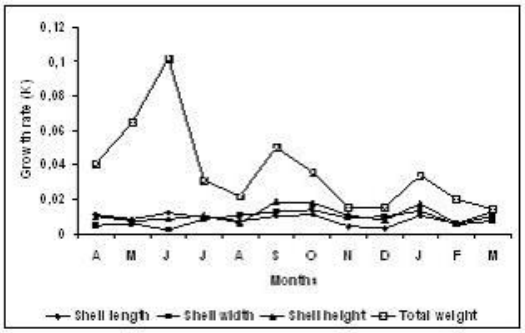

Fig. 2. Instantaneous growth rate of clam.

Clam growth is affected by environmental factors and stocking density. Temperature, salinity and food availability vary from location to location. Food availability in high density clam culture limits growth and survival rate because of competition [5]. In this study growth rate of clam was lower than Sufa Lagoon [6]. In conclusion, stocking density affects the growth and survival of clam and it is the aim of a farm manager to find the correct balance between optimal growth and optimal economic gain according to environmental factors.

POPULATION STRUCTURE OF THE ENDEMIC SPECIES *PARANEMONIA VOULIAGMENIENSIS* IN VOULIAGMENI LAGOON (ATTIKA – GREECE)

Vasileios Anagnostou [1]*, Chariton C. Chintiroglou [1] and Panagiotis Damianidis [1]
[1] School of Biology, Aristotle University of Thessaloniki, 541 24, Thessaloniki, Greece - damian@bio.auth.gr

Abstract
The population of the endemic anemone *Paranemonia vouliagmeniensis* is studied in Vouliagmeni Lagoon, Greece. The spatial dispersion and the biometric characteristics of the species are investigated and analyzed and abiotic parameters are seasonally measured. The diameter of the pedal disc was used to determine the size classes which vary seasonally between 3 and 5. The distribution of the population is random and densities are affected by anthropogenic activities.

Keywords: Aegean Sea, Lagoons, Population Dynamics, Biometrics, Endemism

Introduction
Vouliagmeni Lagoon (known as Vouliagmeni Lake) is a geological karst formation in the coastal area of Attika, Greece (37°48´27.42"N, 23° 47´08.24"E). It totals an area of 7500 m^2 and exhibits euryaline lagoon characteristics. The lagoon is characterized by a unique ecosystem with particular environmental conditions and the presence of the endemic anemone *Paranemonia vouliagmeniensis* Doumenc, England, and Chintiroglou, 1987 (Actiniaria, Anthozoa) [1]. Vouliagmeni Lake is used as bath resort and human pressure is intense, therefore its biodiversity has been the subject of scientific research [2],[3]. The present work focuses on the study of the population structure and functions of the endemic anemone.

Materials and Methods
Five seasonal measurements and sampling surveys were carried out (May, August and November 2011 and February, May 2012). For each period of time the relative physicochemical characteristics of the lagoon water were measured. Samples of individuals were collected from three different stations. The biometric characteristics of 750 individuals of *P. vouliagmeniensis* were measured (diameter of pedal disc, mouth disc, body height, body diameter, length of tentacles and body weight in addition to the examination of the allometric relationship between these characteristics and biomass of anemones). The data obtained was treated using different statistical techniques and software (Excel, FiSAT). Modal progression analysis using Bhattacharya's method [4] was applied to biometric data of pedal disc and also used to form conclusions regarding the biological cycle of the species and the anthropogenic pressures.

Results and discussion
The environmental conditions are characterized by temperature from 21,2-22,7 °C, a pH of 7-7,3, DO_2 8,3-10,4 mg/l, conductivity 10.480-23.300 μs/cm, O.R.P. -115-(-15)mV and Salinity 7-18‰. Significant seasonal changes were observed in conductivity and salinity of the water.
Spatial dispersion of *P. vouliagmeniensis* in the three investigated sampling sites follows random distribution in space, something which is explained by the low observation of densities, as illustrated by maps using the Kernel density estimator [5]. Comparisons of the maps show correlations of anthropogenic disturbances in the observed densities and proved that the population has been reduced by more than 50% from previous recordings [6].
The biometrical results show that the diameter of pedal disc is a parameter indicating the age of the species and also the trend of the species to fix on the substratum, according to the age, in order to establish a more stable life style. The diameter of the pedal disc is also a reliable indicator for the study of age-classes of anemone. The seasonal variation of the number of age classes fluctuates between 3 and 5, showing that the life span of the species is approximately 5 years.
In general, *P. vouliagmeniensis* shows an extended reproduction period. The disturbance to the normal age representation of the population is also correlated to anthropogenic activities. Regular maintenance work conducted by the local authorities includes the cleaning of the bottom of the lagoon, by removing the benthic flora during the summer period, which destroys the appropriate habitat of young individuals. During the winter a recovery from this disturbance was detected.

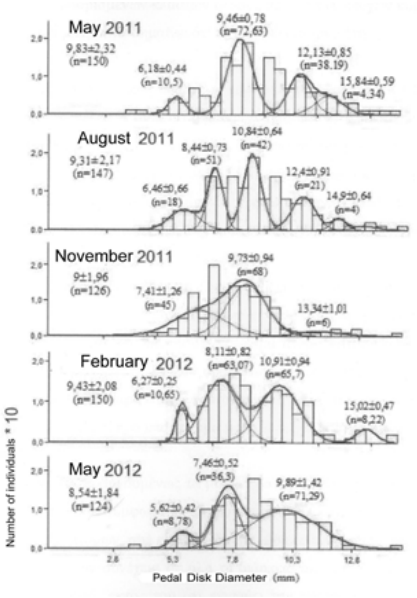

Fig. 1. Modal progression analysis (Bhattacharya's method) of basal disk diameter length classes of *Paranemonia vouliagmeniensis*.

[3] Agence de l'eau Rhône Méditerranée Corse

Abstract
Coralligenous concretions are biogenic reefs built by sciaphilic algae and animal builders. The resulting patchwork of complex micro-habitats and species present richness, biomass and productivity equivalent to tropical reefs. Hard to reach with classical diving methods, coralligenous concretions are poorly studied in comparison to their high ecological importance. RECOR is a monitoring network (Agence de l'eau RMC / Andromède océanologie) surveying coralligenous concretions at 120 stations along the French Mediterranean coast since 2010. We present here the first results concerning the totality of the 120 stations. We are interested in the link between anthropogenic pressures and species diversity distribution.

Keywords: North-Western Mediterranean, Biodiversity, Algae, Zoobenthos

Introduction

Coralligenous concretions are biogenic reefs built first by sciaphilic algae and secondly by animal builders [1]. The resulting patchwork of complex micro-habitats present richness, biomass and productivity equivalent to tropical reefs [2]. Hard to reach with classical diving methods, coralligenous concretions are poorly studied in comparison to their high ecological importance. RECOR is a monitoring network (Agence de l'eau RMC / Andromède océanologie) surveying coralligenous concretions at 124 stations along the French Mediterranean coast between 17 and 90 m depth (Fig. 1). Based on field date, the goals of this study are to describe species diversity and then link anthropogenic pressures and species diversity distribution.

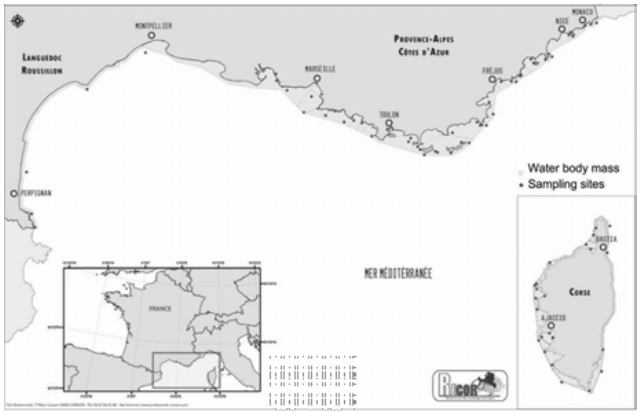

Fig. 1. Field sites (several stations per site, one station = one depth) sampled during the study (RECOR data)

Materials and methods

Each RECOR station (a minimum of one per costal body mass) was sampled once using 30 photographic quadrats (see [3] for the method, Fig. 2). A first index (CAI, coralligenous assemblages index) was used in order to describe the "ecological quality" of coralligenous habitats [4]. This index linked to anthropogenic pressures measured locally mixed bryozoans, major builders and sludge percent covers [4]. In the present study, anthropogenic pressures were obtained from "Agence de l'Eau RMC / IFREMER - Anthropogenic pressures data base" for each coastal body mass. We extracted data concerning land use, harbor number and size, fishing, population density, anchorage area, aquaculture, total N, etc.

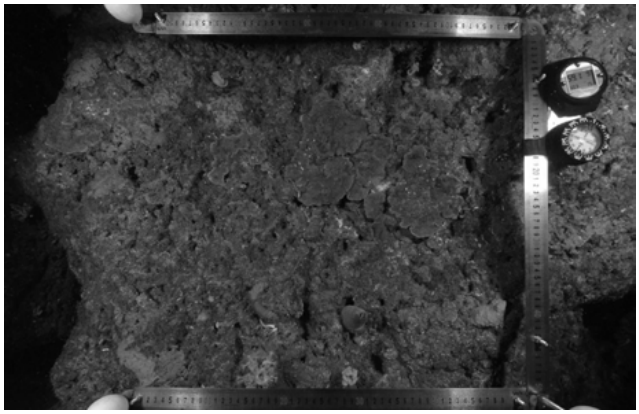

Fig. 2. Example of a photographic quadrat used for coralligenous assemblages sampling (30 quadrats per station are used).

Results and discussion

We present here the first results concerning species richness (non mobile macro-species) characterizing the 120 stations (-17 to - 90 m depth). Twenty two to 59 taxa (species or genus) were identified depending on the station. Encrusting red macroalgae covered 0 to 51 %, bryozoans 0 to 24 %, sponges 0 to 40 % and gorgonian 0 to 23 %. Quadrats were covered by 0 to 64 % of sludge, 0 to 8 % of organism rubble and 0 to 2 % of waste (old nets, bottles, etc). CAI calculated for each station remained relevant excepted in Corsica where assemblages seemed to be different and the index needs to be adjusted.
Statistical analyses are still in progress but results will be presented during the congress.
The link between species assemblages and water quality will be discussed.

Abstract
Spatial variation in density, and diversity of littoral fish species associated with nearshore *Posidonia oceanica* meadows from the Aegean Sea was studied during the period 2008-2009. A total of 318980 littoral fishes were collected with boat seine from 12 locations in the Aegean Sea, belonging to 47 families and 137 species. Total number of species per location varied between 25 and 54. Throughout the study, schooling planktivorous species such as *Spicara smaris*, *Boops boops* and *Chromis shromis* were dominant in terms of density. Mean number of individuals varied between locations and ranged between 600 and 4500. For most of the locations, diversity of species did not vary significantly.

Keywords: Fishes, Teleostei, Posidonia, Aegean Sea

Introduction
Posidonia oceanica meadows provide key ecological services to the coastal zone, ranking among the most valuable ecosystems in the biosphere and are protected by EU legislation (Habitat directive), the Bern and Barcelona Conventions and national legislations. Fishing regulations limit trawling activities near the shore (either above 50 m or a certain distance from the coast), which constitute an indirect protection measure for the species (EC Council Regulation N° 1967/2006 and national regulations). Important shallow coastal habitats, such as seagrass meadows, may provide a habitat for food, shelter, reproduction, settlement and serve as a nursery habitat with high quality for many fish species (Kalogirou et al. 2010; Kalogirou et al. 2012). In this study we focused on one of the most important habitat, *Posidonia oceanica* meadows. Through quantitative data collected over a broader spatial scale the aim of this study was to examine geographical differences in fish diversity associated to *P. oceanica* meadows in the Aegean Sea.

Materials and Methods
The study was performed at 12 shallow (5–35 m) locations in the Aegean Sea (Aegina, Chios, Eretria, Karistos, Koilada, Lesvos, Marmari, Neapoli, Paros, Rhodes and Salamina). All 12 locations selected for this study had sandy sediment with a patchy distribution of *P. oceanica* meadows. In Hellenic waters, the boat-seine fishing method, used in this study, is banned from 1 April to 31 September. For this reason the sampling was performed during 1 October to 31 March. Daylight sampling was undertaken at all locations in order to study spatial variation in fish diversity. The boat-seine fishing method was used to sample fishes from the *P. oceanica* habitats with the help of a local fishing boat. The seine is hauled at a constant speed of *c.* 0·3 m s^{-1}. The total time elapsing from deployment of the start line with an anchor to the time the seine was taken onboard was *c.* 35 min. Mesh-size decreased from the outer end of the wing towards the centre in the sequence 500, 180, 32–34, 12 and 11 mm, with a minimum mesh-size of 8 mm in the codend. Due to unequal sample size per location, three sweeps were randomly chosen from each locality. All fishes were immediately identified to species level Whitehead *et al*., 1986), weighed in g and measured (total length, *LT*). Fish species diversity for each sample was estimated using the Shannon-Weiner equation.

Results and Discussion
In total 137 species belonging to 47 families were identified during this study. Dominant species I terms of number of individuals included *Sardina pilchardus*, *Boops boops*, *Chromis chromis*, *Spicara smaris*, *Mullus surmuletus*, *Atherina hepsetus* and *Coris julis*. Number of species varied between locations and ranged between 25 and 54, with Chios Island representing the lowest number of species (25) and Karistos the highest (54) (Fig. 1). Mean number of individuals ranged between 600 and 4500, with Eretria representing the lowest (600) and Paros the highest (4500) (Fig. 2). Diversity of species between localities with Chios Island representing the lowest (0.6) and Karistos the highest (1.9).

Abstract
The mesophotic coralligenous outcrops dominated by *Corallium rubrum* are among the most diverse marine benthic communities in the Mediterranean. To assess the potential impacts of perturbations associated to global change on these communities robust baselines are urgently needed. Here, we analyzed decadal trends on composition and diversity indices associated to *Corallium rubrum* communities in the NW-Mediterranean. Our results demonstrate the extremely low variability of the descriptors of the community in terms of similarity, species richness, diversity indices and evenness over one decade. Thus, this study provides baseline data to detect potential effects due to global change.

Keywords: Biodiversity, Rocky shores, Conservation, Global change, North-Western Mediterranean

Introduction
The Mediterranean Sea is considered a hot-spot for marine biodiversity [1]. Regardless of this important value, the Mediterranean Sea is threatened by the increase of disturbance regime associated to global change [2]. The mesophotic coralligenous outcrops dominated by *Corallium rubrum* are among the most diverse Mediterranean benthic communities [3]. Despite its importance, long-term descriptive and quantitative studies of its species composition and dynamics are few and rare. This study is devoted to characterize quantitatively the *C. rubrum* community structure over one decade.

Material and Methods
We analyzed photographic series obtained between 2000 and 2011 in two localities of the NW Mediterranean (Marseilles and Corsica). At each locality, three permanent plots of 3.200 cm^2 were photographically monitored using quadrats of 20x20 cm (400 cm^2) to facilitate species identification [4]. Long-lived sessile benthic species mainly belonging to encrusting algae, protozoans, sponges, anthozoans, polychaetes, bryozoans and tunicates were identified. We used cover area as estimate of abundance. For detailed analyses of diversity we calculated the species number and exponential Shannon-Wiener (exp(H')). In this way we converted the biodiversity values in effective number of species for further comparison over time [5]. Changes over time in abundance, species richness and diversity metrics were tested by PERMANOVA analyses [6].

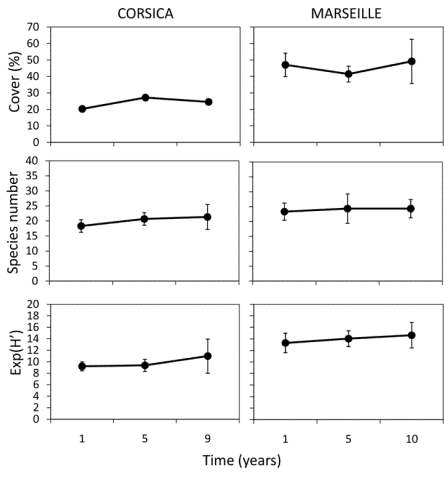

Fig. 1. Means (± SD) over time in Corsica and Marseilles for slow growing macrobenthic sessile species: relative cover area, number of species and diversity metrics (effective number of species).

Results
Our results demonstrate that there were no significant decadal changes in the community structure (in terms of specific composition and abundance). Likewise, there were no significant differences with all the diversity parameters analyzed over time in the two localities (Figure 1).

Discussion
The lack of robust baseline of biodiversity structure and dynamics for the rich mesophotic coralligenous outcrops is hindering the assessment of the impacts at community level which are already affecting these communities [7,8,9]. Our results are contributing to fill the current gap on and provided insights on the parsimonious dynamics of these emblematic Mediterranean communities.

LES ACTINIAIRES DES RIVAGES TUNISIENS (CNIDAIRES,HEXACORALLIAIRES) : INVENTAIRE ET DISTRIBUTION

Saïda Tekaya [1]* and Amel Guettiti [1]
[1] Université de Tunis El-Manar, Département de Biologie - saida.tekaya51@gmail.com

Abstract
Plusieurs secteurs des rivages tunisiens ont été explorés. Cette prospection nous a permis d'identifier et de signaler pour la première fois la présence de cinq espèces d'actiniaires. *Anemonia viridis* est rencontrée dans presque toutes les stations prospectées. Les autres espèces sont *Actinia equina, Bunodactis verrucosa, Condylactis sp* et *Calliactis parasitica*. Elles ont été rencontrées seulement dans quelques sites. En outre, un aperçu sur les caractéristiques écologiques de chaque espèce est donné.

Keywords: Cnidaria, Tunisian Plateau

Introduction
En Tunisie, aucun travail sur la biodiversité des anémones de mer n'a été réalisé jusqu'à présent. Il y a seulement une étude sur les tentacules d'*Anemonia viridis* récoltée à Sousse et dont le but était la détermination de la composition chimique du venin (1). Le présent travail constitue une première contribution à la connaissance de la biodiversité et de la répartition géographique des actinies des côtes Tunisiennes.

Matériel et Méthodes
Plusieurs secteurs de la côte tunisienne appartenant à des étages bioclimatiques différents ont été explorés. Les prélèvement ont été effectués dans neuf stations réparties comme suit : Tabarka , Bizerte au nord du pays, le Golfe de Tunis (Salammbô et la Goulette), la région du Cap-Bon (Korbous, Hammamet et l'île Zembra), le Sahel (la Chebba), Sfax et Djerba au sud. Ces stations sont caractérisées par des rivages plus ou moins rocheux et une eau peu profonde. La station de Sfax était une plage polluée, surtout au niveau de la région de Thyna.
Notre travail a porté sur des échantillons récoltés tout au long du rivage, à des profondeurs variant de quelques centimètres à un mètre. Le substrat de fixation des actinies est rocheux dans la plupart des stations, cependant il est sableux au site de la Goulette.

Résultats
Cinq espèces ont été identifiées. Il s'agit d'*Anemonia viridis* (Forskal, 1775) , *Actinia equina* Linné, 1767, *Bunodactis verrucosa* Pennant, 1777, *Condylactis* sp et *Calliactis parasitica* Couch, 1838.
Caractères écologiques et Répartition des actinies signalées:
Les échantillons d'*Anemonia viridis* sont trouvés dans les plages rocheuses lorsque la lumière est peu intense, la mer à eau calme, renouvelable et à température de l'ordre de 20- 25°C. La taille des animaux augmente de la surface en allant vers la profondeur.
D'après nos résultats, cette espèce est particulièrement abondante à Tabarka, Bizerte, l'île de Zembra, le Golfe de Tunis et précisément les stations de Salammbô et de la Goulette. Elle présente un polymorphisme de couleur : au niveau des rivages les anémones ont l'extrémité des tentacules colorée en violet alors que vers la profondeur ils sont entièrement de couleur brune à grise. Cette distribution semble dépendre de l'éclairement et de la qualité de l'eau. Nos observations sont en accord avec les données bibliographiques (2-5)

Actinia equina, l'actinie rouge ou tomate de mer est une espèce des zones médiolittorale et infralittorale très commune en mer Egée (6). Elle est signalée en Méditerranée, Atlantique et mer du Nord (2-4). En Tunisie, nous l'avons rencontrée dans la région de Tabarka et à l'île de Zembra.

Bunodactis verrucosa est récoltée dans une plage sableuse de la station de la Goulette, pendant l'automne à 80 cm de profondeur environ, la colonne enfouie dans le sable où la lumière est peu intense, l'eau calme, renouvelable et la température de l'ordre de 24°C

Condylactis sp : Un seul spécimen a été récolté à Djerba.

Calliactis parasitica, vit dans un biotope en mode calme, de zéro jusqu'à 20 m de profondeur, en association avec l'algue verte *Enteromorpha*. Elle est souvent fixée sur une coquille de mollusque habitée ou non par un pagure (Bernard l'Ermite) (6). Cette espèce vit en symbiose avec le pagure. Elle est répandue en Méditerranée et en Atlantique jusqu'à la Manche (2, 7). C'est une espèce de la zone infralittorale et circalittorale (3). En Tunisie, elle a été rencontrée à la Goulette.

Discussion
Neuf stations dans les rivages tunisiens ont été prospectées. Cinq espèces d'Actiniaires sont identifiées. *Anemonia viridis* est rencontrée dans presque toutes les stations. Elle a montré un polymorphisme de couleur et une diversité morphométrique, en particulier les spécimens prélevés à Korbous sont de grandes tailles (10-15cm) alors que les représentants de la population de la plage polluée de Sfax sont remarquablement de petites tailles. Une étude biométrique des différentes populations est intéressante à réaliser dans un travail ultérieur. *Actinia equina* rencontrée en Tunisie est de grande taille (7-10cm) par rapport à ce qui est signalé dans la bibliographie (5-6cm) (7,6). Un polymorphisme de couleur des verrues est signalé pour *Bunodactis verrucosa* (5).

BIODIVERSITY IN THE SEA OF MARMARA AND THE AFFECTING FACTORS

A. Yuksek [1]*, A. Kideys [2], A. Olgun [3], C. Polat-Beken [3] and H. Altiok [1]
[1] Istanbul University, Institute of Marine Sciences and Management - ayuksek@istanbul.edu.tr
[2] Institute of Marine Sciences, Middle East Technical University
[3] Environment Institute, Marmara Research Center-TUBITAK

Abstract
The ecosystem of the Marmara Sea of Marmara is defined "high" category by EBSA criteria. According to the IUCN Red List, four species are at CR level. The Sea of Marmara is an important migration area of fish and marine mammals migration area, and in the meantime, is under the pressure of over fishing and other anthropogenic factors.

Keywords: Biodiversity, Marmara Sea

The Sea of Marmara has fulfilled the first six criteria of EBSA (Ecologically or Biologically Significant Marine Areas) labelled "high" category. Being a transitional system between two hydrologically diverse sea basins (the Mediterranean and Black Sea), it is the migration route of protected marine mammals (Ozturk et al., 2001) and fish species of high economic value such as Xiphia gladius (Swordfish), Scomber scomberus (Atlantic Mackerel), Sardra sardra (Atlantic bonito), Pomatamus saltatrix (Bluefish), and Engraulis encrasicolus (European anchovy). These species inhabit the Sea of Marmara during specific periods of their life-cycle for breeding and feeding. The plankton rich waters of the Sea of Marmara serve as unique pasture for the larval stages of these species.

According to the IUCN Red List, the status of native Mediterranean marine fish species (2012) in the Sea of Marmara shows that 4 species are classified CR (Critically Endangered) namely (Squatina squatina, Oxynotus centrina, Rostroraja alba, and Pomatoschistus microps), a further 4 species are EN (Endangered) (Mustelus mustelus, Mustelus asterias, Squalus acanthias,and Thunnus thynnus), 6 species are VU (Vulnerable) (Merluccius merluccius, Labrus viridis, Umbrina cirrosa, Sciaena umbra, Dentex dentex, and Pomatoschistus minutus), 12 species are NT (Near Threatened) (Scyliorhinus stellaris, Dasyatis pastinaca, Raja clavata, Psetta maxima, Pleuronectes platessa, Platichthys flesus, Syngnathus acus, Scomber colias, Hippocampus hippocampus, Syngnathus typhle, Xiphias gladius, and Dicentrarchus labrax) and 26 species are classified LC (Least Concern). In addition, there are 2 protected and 16 important areas for migrant and water birds according to the RAMSAR Convention. Three major factors affect the biodiversity of the Sea of Marmara;

1. Natural pressures (Bottom layer dissolved oxygen)
2. Anthropogenic pressures
3. Over fishing and erroneous fisheries policies

The Sea of Marmara comprises a two-layered system. The density differences between the upper and lower layers influence the deep dissolved oxygen distribution. The waters of Mediterranean origin flowing from the Dardanelles Strait follow the southern shelf of the Sea of Marmara and spread to the north. For this reason, the lower layer is rich in dissolved oxygen in the southern region of the sea. This feature is an important factor affecting biodiversity. Dissolved oxygen determines the distribution of macrozoobenthic species which are found at the lower levels of the food web and are important components of the biodiversity. Macrozoobenthic distribution in the Sea of Marmara indicates that their abundance is high but their diversity is low in the northern Marmara shelf. This is a result of the increase in populations of certain species through their adaptation to hypoxic conditions. Biodiversity is greater in the southern shelf where the deep dissolved oxygen values are higher. Conversely, in the bays of Izmit and Gemlik, where there is both low circulation in deep waters and impacts of human-induced eutrophication, both abundance and biodiversity are very low because of extremely poor dissolved oxygen levels.

Unfortunately, over the last decade fish populations have dramatically decreased due to over fishing and the application of improper fishing techniques in the southern shelf of the Sea of Marmara. In addition, some methods such as bottom and beam trawling have particularly damaged habitats and adversely affected the macrobenthic diversity. Fisheries regulations must be improved for the southern shelf of the Sea of Marmara which is not heavily affected by pollution and benefits from better oxygenation due to Mediterranean waters and hence has a chance of maintaining favorable ecosystem conditions. Nowadays, even though recoveries in the pelagic system of Izmit Bay have been observed since local authorities applied preventative measures against pollution, the demersal system is still exposed to unfavorable conditions.

The assessments presented in this study may contribute towards the definition of "good environmental status" and targets for the Sea of Marmara as referred to in the EU MSFD. A biodiversity assessment for the Sea of Marmara is currently under preparation as part of a national scale project designed to support the technical implementation of this Directive.

OUTCOMES OF THE GFCM THREE-YEAR PROGRAMME ON ELASMOBRANCHS IN THE MEDITERRANEAN AND BLACK SEA

Pilar Hernández [1], Aurora Nastasi [1] and Federico Alvarez [2]*
[1] General Fisheries Commission for the Mediterranean (GFCM), Food and Agriculture Organization of the United Nations (FAO)
[2] Instituto Español de Oceanografía (IEO) - Centro Oceanográfico de Baleares, Palma de Mallorca, Spain - federico.alvarez@ba.ieo.es

Abstract
Reverse shark and ray populations' decline is one of the main objectives of national and regional management plans aimed at guaranteeing the sustainability of fisheries activities worldwide. The biological characteristics of the elasmobranchs make them severely vulnerable to fisheries which, nowadays, are targeting elasmobranchs species that in the past were discarded. This document reports the main outcomes of a three-year research programme of the General Fisheries Commission for the Mediterranean (GFCM) launched in 2010 to improve the knowledge and asses the status of elasmobranchs in the Mediterranean and Black Sea.

Keywords: Elasmobranchii, Conservation, Stock assessment, Black Sea, South-Central Mediterranean

Sharks, skates and rays, collectively referred to as elasmobranchs (Class Chondrichthyes) form a relatively small and evolutionarily conservative group that has functioned successfully in diverse ecosystems for over 400 million years. Despite their evolutionary success, many species are increasingly threatened with extinction as a result of human activities. Because of their biological characteristics such as slow growth, late maturity, and low fecundity, elasmobranchs have very low rates of population increase and limited recovering potential from overfishing (direct or indirect) and other threats, such as pollution and habitat destruction [1]. In light of this international organizations developed action plans, such as the FAO International Plan of Action for the Conservation and Management of Sharks and Rays 1998 (FAO IPOA-Sharks), the Action Plan for the conservation of the cartilaginous fishes in the Mediterranean (UNEP-RAC/SPA, 2003), the EC Action Plan for the Conservation and Management of Sharks, aimed at promoting responsible fisheries practices and environmental strategic policies which converge into the protection of the elasmobranch stocks. In this view, regional fisheries management organizations (RFMOs), such as the General Fisheries Commission for the Mediterranean (GFCM), have the fundamental role of providing administrations with indications based on the most accurate scientific background. In 2010, the GFCM started a three-year programme on elasmobranchs with the aim of identifying and filling priority gaps in the current knowledge of the status of elasmobranchs populations in order to better assess and manage their stocks in the Mediterranean and Black Sea. The programme was divided into three periods of activities. The first period was financed by the GFCM regular budget and included the organization of the First Expert Meeting on the status of Elasmobranchs in the Mediterranean and Black Sea (September 2010), which served as common ground for experts to share valuable information on research carried out in their respective countries and to collate the scarce and disperse knowledge on elasmobranchs in terms of life cycles, population dynamics, ecology, taxonomy and fisheries [2]. The meeting also selected seven species according to various criteria (existing data on age and growth, abundance, conservation status, economic value, knowledge of biological parameters) for which stock assessments were considered a priority. The second and third periods of activities were supported by the European Commission (Agreement Number SI2.603726) and included the workshops on Stock Assessment of selected species of Elasmobranchs (December 2011) and on age determination of elasmobranchs in the GFCM area (October 2012). During the stock assessment workshop, 8 stocks of 6 different elasmobranch species were assessed and discussed (Tab. 1). Identification of biological reference points (BRPs) and maximum sustainable yield (MSY) proxies and issues related to the biology, by-catch, growth parameters, trends in catches and sampling approaches of the species were also discussed [3]. The Workshop on age determination of elasmobranchs in the GFCM area consisted in a practical course on age reading and it was a hands-on exercise with an important training component. Prior to the meeting some preparatory work included the preparation of biological raw material with the assistance of the lecturer. A technical manual on age determination of Elasmobranchs, suited to both novice and experienced age readers, was prepared and is going to be published by the end of 2013 [4]. This detailed guide reviews the best methods for ageing sharks, skates and rays with emphasis on vertebral sections and image analysis techniques as applied to elasmobranch species from the Mediterranean basin. Finally, a bibliographic review to sum up the information gathered during the above mentioned meetings, including the outputs of the Workshop on Stock assessment was prepared and published in 2012 within the series GFCM Studies and Reviews [5].

Abstract
Bycatch is of great concern both ecologically and in terms of fishery management, particularly in shrimp fisheries. The Deepwater Pink Shrimp (*Parapenaeus longirostris*) is the mean crustacean fishery of the Marmara Sea. The chondrichthyan bycatch in 117 tows of the beam trawl fishery was surveyed seasonally between October 2011 and February 2013 in the Marmara Sea. Eight species were recorded: *Raja clavata, Raja miraletus, Dasyatis pastinaca, Scyliorhinus stellaris, Scyliorhinus canicula, Torpedo marmorata, Squalus acanthias* and *Oxynotus centrina*. Bycatch per unit of effort and biomass are given for each species.

Keywords: Marmara Sea, Elasmobranchii, Trawl surveys

Introduction
The deep water pink shrimp *Parapenaus longirostris* (Lucas 1846) fishery is the main crustacean fishery in the Marmara Sea and is targeted by the beam trawl. It is now well known that bycatch is of great concern both ecologically and in terms of fisheries management, particularly in shrimp fisheries [4]. Elasmobranch by-catch is often not recorded [2], or where it is recorded, the species composition is unknown. This lack of information prevents the use of conventional stock assessment methods to determine the status of populations. The main purpose of this work is to identify chondrichthyan species in the bycatch of the Deepwater pink shrimp fishery and to estimate, by species, spatial distribution, catch per unit of effort (CPUE) and biomass.

Materials and Methods
Sampling was carried out between October 2011 and February 2013 with beam trawler vessel operating in the Marmara Sea as seasonally (Fig. 1). All chondrichthyan were separated from tow each fishing day. Each specimen was identified to species level, measured, weighed and sexed. The data of each tow were registered (date, latitude, longitude, tow speed, catch of shrimp and depth). Average tow speed was 2 mile h^{-1}. Biomass was calculated based on the swept area method [3].

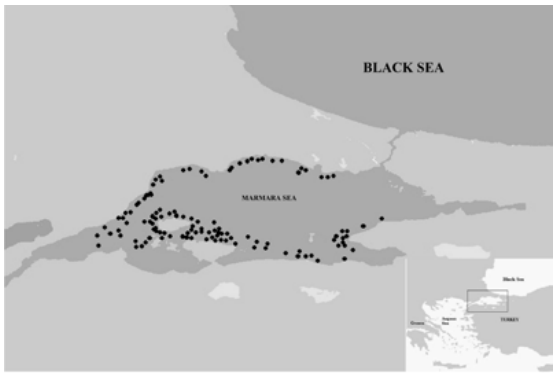

Fig. 1. Map of the study area with the sampling stations indicated by solid circle.

Results and Discussion
8 species (6 Families) have been recorded in the shrimp fishery by-catch (Table 1). The Rajidae and Dasyatidae have the highest number of species recorded in by-catch. Of the elasmobranch species 3% are taken as by-catch in the Marmara Sea. The low diverse by catch because of the sampling method or location. There are no long-term data available from which changes in catch rates of elasmobranch species can be examined. In the Marmara Sea, [1] and [7] surveyed numerically the by-catch rate of the elasmobranch 0.13%, 0.01%, respectively. Previous studies showed that elasmobranchs are impacted by a range of fisheries, both target (including gillnet, longline and dropline fisheries) and by-catch fisheries fisheries (including dropline and gillnet fisheries that target teleosts and trawl fisheries that target teleosts or prawns) [5]. The largest fishery in northern Australia is the Northern Prawn Fishery (NPF), elasmobranch contribute 4% of the total by-catch weight of this fishery [4]. Cedrola et al. (2005) reported that in shrimp fishery, all chondrichthyans are released at sea probably alive (handling time between tows averages 15 min and discarding occurs immediately after the opening of the nets) although post-capture mortality is unknown. Haul time is very variable (from several minutes to up to 3 h, with average haul of 85 min), and the post-mortality rate would be related to the tow duration. Although the survival rate of discarded fish is unknown, the ICES Report of Study Group of Elasmobranch Fishes in 1995 considered it to be quite high [6]. Walker and Hislop (1998) emphasized the need to identify the spatial distribution of the different life cycle stages of chondrichthyan species, and to reliably estimate fishing and discard mortality in order to understand the impact of fisheries on this species. This study is a first step of fisheries of our seas on these species.

THE MOST RELIABLE VERTEBRAE FOR AGE DETERMINATION IN DASYATIS PASTINACA

N. Basusta [1]*, A. Basusta [1], E. I. Ozer [1], M. Calta [1] and H. Girgin [1]
[1] Fisheries Faculty, 23119 Elazig, Turkey - nbasusta@hotmail.com

Abstract
This study was aimed to determine the most reliable vertebrae for age determination in *Dasyatis pastinaca*. For this purpose, total 23 fish samples were used. The first 32 vertebrae in the abdominal cavity were removed and prepared for age determination. Age readings were made by three independent readers. According to results, the vertebrae between 22 and 32 in the abdominal cavity were found more reliable for age determination in *D. pastinaca*. Because the lowest mean age, standard errors, ageing errors and absolute difference were obtained after 22nd vertebra. Precision of readers has been estimated from the percentage agreement of 3 readings. The agreement of 3 readers was found higher than 70% after 22nd vertebra. The highest agreement amongst readers was 78% in only 4 vertebrae.

Keywords: Elasmobranchii, North-Eastern Mediterranean

Introduction
Age determination is very important for fisheries biology research. Usually, vertebrae are used for age determination in cartilaginous fishes (Basusta et. al., 2008; Basusta and Sulikowski, 2012). But all vertebrae could not suitable for age determination. So, this study was aimed to determine the most reliable vertebrae for age determination in *Dasyatis pastinaca*.

Materials and Methods
In this study, total 23 *Dasyatis pastinaca* samples were provided from a commercial fishery trawler in Iskenderun Bay. The samples were transferred to Firat University Fisheries Faculty Fish Ecophysiology Laboratory in a freezer. The first 32 vertebrae in abdominal cavity were removed from each fish and prepared for ageing according to procedure (Turkmen et. al., 2005). The vertebrae were examined under a binocular microscope with 2x magnification and top lighting. Each vertebra was examined by three readers. A total of 2208 readings were made (32 vertebrae x 23 fish samples x 3 readers). The readers examined each bony structure independently without getting any information about fish such as length, weight and sex. Mean ages for each vertebra were estimated from readings of three readers (23 fish x 3 readers = 69 readings). Standard errors, ageing errors, absolute difference and percentage of precision of readers on each vertebra were calculated.

Results Discussion
This study was aimed to determine the most reliable vertebrae for age determination. According to results given in Table 1, the vertebrae between 22 and 32 in the abdominal cavity were found more reliable for age determination in *D. pastinaca*. Because the lowest mean age, standard errors, ageing errors and absolute difference were obtained after 22nd vertebra. Precision of readers has been estimated from the percentage agreement of 3 readings (Table 2).The agreement of 3 readers was found higher than 70% after 22nd vertebra. The highest agreement amongst readers was 78% in only 4 vertebrae (see Table 1).

ON THE OCCURRENCE OF THE GREAT WHITE SHARK (*CARCHARODON CARCHARIAS*) IN TUNISIAN COASTS

Mohamed Nejmeddine Bradai [1]* and Bechir Saidi [1]
[1] INSTM, Tunisie - mednejmeddine.bradai@instm.rnrt.tn

Abstract
Data concerning the presence of *Carcharodon carcharias* along the Tunisian coasts is presented. The capture by fishing gear, seasonality and population structure of the species in the area are analyzed and discussed based on 59 captures.

Keywords: Elasmobranchii, Fisheries, Tunisian Plateau

Introduction
Although the great white shark, *Carcharodon carcharias,* has never been the subject of specific studies along the Tunisian coasts, its presence in these waters has been known for a long time [1]. This paper presents the occurrence of the white shark off Tunisian coasts and contributes to the knowledge of its population in the Mediterranean Sea.

Materials and methods
Data on white sharks from the Tunisian coasts were performed by bibliographical researches and on our observations undertaken since 1992. For each case, whenever possible, the following data were collected: date and location of the record, total length (TL) in cm, mass in kg, sex, fishing method and depth.

Results and discussion
A total of 59 reliable captures of white sharks were reported along the Tunisian coasts from 1953 to 2012, most of them (57%) were registered after 2000. Sex and total length were reported for only 44 specimens, 24 females and 20 males. The total length of females and males ranged, respectively from 145 to 605 cm and from 165 to 485 cm. Length-frequency distribution showed that 48.78% were neonates and juveniles smaller than 200 cm TL (Fig.1). Four males and 11 females were adults of which two were pregnant. Captures were concentrated in the Gulf of Gabès (56%), where white shark was caught mainly by trawl and purse seine. Trawls capture only neonates and juveniles (TL<241 cm) during winter and spring with a peak in February while purse seine caught mainly adults through December to July (Fig.2). In the north coasts, 21 records were reported, most of them (76%) were in tuna trap which disappeared since 2004. Tuna trap captured mainly adult individuals between Mars and April (Fig.2). Some seasonal differences in the spatio-temporal occurrence of the species can be observed; along the northern and central Tunisian coasts, adult white sharks are in pursuit of tuna and migratory fish in spring and summer while juveniles are concentrated during winter in the Gulf of Gabes where temperatures are relatively higher. The occurrence of neonates, small juveniles and pregnant females shows that the Tunisian waters and mainly the Gulf of Gabès is a nursery for this species. Previous suggestion considers also Sicilian Channel and its adjoining environs as reproductive and nursery areas for the species [2; 3].

STATUS AND TRENDS OF DEMERSAL ELASMOBRANCHES IN SARDINIAN SEAS (CENTRAL WESTERN MEDITERRANEAN)

M. Follesa [1]*, A. Cau [1], R. Cannas [1], A. Mulas [1], P. Pesci [1], C. Porcu [1] and A. Sabatini [1]
[1] Department of Life Science and Environment University of Cagliari - follesac@unica.it

Abstract
The status of demersal Elasmobranchs species in Sardinian Sea was investigated through data collected in 17 years of MEDITS trawl surveys carried out between 1994 and 2011. Both density and biomass indices of the totality of Elasmobranches caught in the macrostrata 10-800 m and in the shelf (10-200 m) showed statistical increasing trends. The species showed stable and/or statistical increasing trends of the abundance indices. Only one statistical decreasing trend was observed for both indices of *Squalus blainville* In spite of the general status of Elasmobranches in the Mediterranean, our analyses highlighted that the demersal cartilaginous species do not show any sign of decline in the Sardinian seas (Central western Mediterranean).

Keywords: Elasmobranchii, North-Central Mediterranean

Introduction
In many areas of the world as the Mediterranean sea, a decline in cartilagineous fish species landing has been observed [1]. There is evidence that the Elasmobranches of the Mediterranean are declining in abundance, diversity and range due to the intense fishing activity also in response to a rapid increasing demand for skin fins, meat and cartilage [2]. Their particular biological characteristics (low fecundity, late maturity and slow growth rates) also make Elasmobranches vulnerable to fishing pressure. Among 85 species estimated to be present in the Mediterranean, only 71 were assessed within the framework of the IUCN red list [3]. More than 40% are vulnerable and endangered to critically endangered. Within the 71 assessed species, 18 are data deficient [3]. In this paper the status of demersal Elasmobranches present in the Sardinian seas was estimated in order to give a further contribution to the knowledge of elasmobranches fisheries.

Material and methods
Data come from the trawl surveys MEDITS (MEDiterranean International Trawl Survey) carried out in the Sardinian seas between 1994 and 2011. All specimens of each species were numbered and weighed in each haul following the MEDITS protocol [4]. The mean occurrence (N° of positive hauls/total hauls planned for the survey*100) within the entire period of study was calculated at species level. The trend of biomass and density indices of each species collected during every annual survey were analyzed. The statistical soundness of the temporal trend was investigated by the Spearman test [5].

Results
Both density and biomass indices showed statistical increasing trends during the years 1994 – 2011 in the macrostrata 10-800 m and in the shelf (10-200 m) of Sardinian seas (Spearman test P=0.004 and P= 0.001 for 10-800 and P=0.002 of both indices for the shelf respectively). A stable trend was found in the slope (200-800 m). The species with the highest value of occurrence is *Scyliorhinus canicula* (44.1%) followed by *Galeus melastomus* (33.1%). The species showed stable and/or statistical increasing trends of the abundance indices (Tab.1). Only one statistical decreasing trend was observed for both indices of *Squalus blainville*. Captures of rare species, not comprised in Tab.1 (occurrence %<1), like *Dalatias licha*, *Leucoraja circularis*, *Centrophorus granulosus* were registered in several years.

Discussion
In contrast to what is reported for some areas of the Mediterranean basin, data collected in the Sardinian seas within the framework of MEDITS (1994 – 2011) scientific trawl surveys showed that both abundance and biomass indices are quite constant or even slightly increasing both in shelf and slope. Similar conclusion can be obtained considering the percent of the hauls in which the species were found, suggesting that the species are not to be considered as endangered or threatened. Only some concerns can be raised up for *S. blainville* that shows critical decreasing trends of abundance. Anyway, as reported by [6], the scarcity of knowledge on distribution, biology and ecology of some species, as well as trends in abundance, suggest the need to improve scientific investigation and enlarge it to all Mediterranean countries.

Abstract
The MedSeaCan and CorSeaCan campaigns managed by the French marine protected areas agency, explored the French Mediterranean canyons, and collected *in situ* images (videos and photographs) from 30 to 800 m depth using a ROV and a submarine. Species of Elasmobranchii and Holocephali were identified and geo-localised.

Keywords: North-Western Mediterranean, Canyons, Elasmobranchii

Introduction
The canyon exploration campaigns, MedSeaCan and CorSeaCan, took place between November 2008 and august 2010 using COMEX S.A. equipment and with a major contribution from the scientific team associated with the program. The aim was to establish a baseline of 43 sites relatively to habitats, protected and commercial species, ecosystems and anthropogenic impact, using the same methods and prospection gear.

Material and methods
On the continent, the study zone stretched from the Spanish frontier to Monaco and on the west coast of Corsica, from Cap Corse to the Bonifacio strait. The data processing of the 297 dives, representing 520 km, 550 hours of videos and over 20 000 photographs, was carried out by means of the ZOODEX information system (ZOOlogical data Exploration system) developed by GIS Posidonie [1].

Results and discussion
Extraction of information concerning Elasmobranchii and Holocephali reveals the observation of 14 taxons geographicaly referenced (Table I).

Tab. 1. Inventory and number of occurrences of cartilaginous fish observed during the MedSeaCan and CorSeaCan campaigns.

Order	Family	Taxon	Total number of occurrences on 43 sites investigated
		Unidentified Elasmobranchii	12
Carcharhiniformes		Unidentified Carcharhiniformes	14
Carcharhiniformes	Scyliorhinidae	*Galeus melastomus*	188
Carcharhiniformes	Scyliorhinidae	Unidentified Scyliorhinidae	5
Carcharhiniformes	Scyliorhinidae	*Scyliorhinus canicula*	98
Hexanchiformes	Hexanchidae	*Hexanchus griseus*	2
Holocephali	Chimaeridae	*Chimaera monstrosa*	36
Rajiformes	Rajidae	*Dipturus oxyrinchus*	1
Rajiformes	Rajidae	*Raja clavata*	5
Rajiformes	Rajidae	*Raja polystigma*	1
Rajiformes	Rajidae	Rajidae non identified	2
Squaliformes	Dalatiidae	*Etmopterus spinax*	54
Squaliformes	Dalatiidae	*Oxynotus centrina*	1
Squaliformes	Squalidae	*Squalus acanthias*	1
		Total	420

All the species are listed on the IUCN Mediterranean or world red list. Amidst the species observed, two specimens of *Hexanchus griseus* were sighted (with an estimated length of 2 and 2.5 m) and a specimen of *Squalus acanthias* captured, both being considered as vulnerable species. Moreover, a specimen of *Oxynotus centrina* (considered as critically endangered in the Mediterranean [2]) was photographed in the Lacaze-Duthiers canyon. The other most frequently observed species in terms of total occurrences were: *Galeus melanostomus*, *Scyliorhinus canicula* and *Etmopterus spinax*. Cartilaginous species were observed in nearly all canyons and mainly on soft bottoms between 90 and 700 m depth (Figure 1).

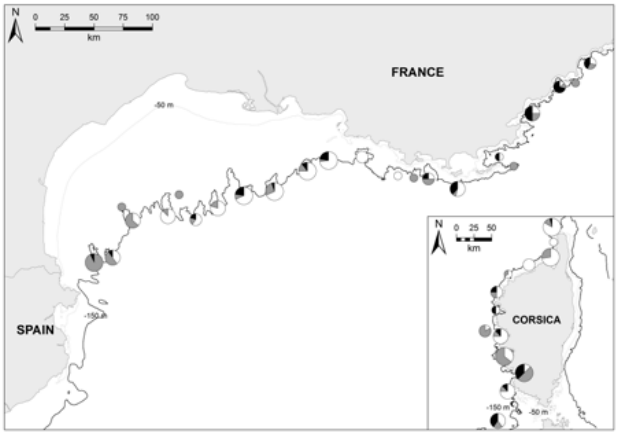

Fig. 1. Distribution map of the MedSeaCan and CorSeaCan observations of the three most frequently observed species: *Galeus melastomus* (white), *Scyliorhinus canicula* (gray) and *Etmopterus spinax* (black).

MONITORING OF SANDBAR SHARK *CARCHARHINUS PLUMBEUS* (NARDO, 1827) IN SOUTHERN AEGEAN SEA

Anil Gulsahin [1]*, Halit Filiz [1], Hasan Cerim [1] and Gokcen Bilge [1]
[1] Mugla Sitki Kocman University, Faculty of Fisheries, - agulsahin@mu.edu.tr

Abstract
Boncuk Bay in the Gökova Special Environmental Protection Area (SEPA) is a critical habitat for sandbar shark (*Carcharhinus plumbeus*) since the bay has been used as a nursery area by this species. In 2012, a study entitled "The Observation of Sandbar Sharks in Boncuk Bay in Gökova Special Environmental Protection Area" was carried out by a scientific team from Mugla Sitki Kocman University Faculty of Fisheries under the project "Strengthening the System of Marine and Coastal Protected Areas of Turkey" managed by the GDPNA and implemented by UNDP with the financial support from GEF. As a result of the observations, we encountered sandbar sharks 49 times in 105 FDOs, and totally 93 individuals were counted.

Keywords: Biodiversity, Aegean Sea

Sandbar is a coastal shark, often in shallow waters associated with sandy or muddy flats, bays, estuaries and harbours, and also further offshore, particularly on banks, near islands, flats reefs and other topographic features in open waters (Grubbs et al 2007). Boncuk Bay is the famous breeding zone of this species in the Mediterranean Sea. There are few studies on the subject [1, 2, 3]. The aims of this study listed as determine the existence and habitation of sandbar shark in the area by in situ observations, possible threats affecting shark population and provide a documentary. Sandbar shark individuals in the Gökova SEPA were observed, counted and photographed via free diving method. The study period was between 12 May and 28 September 2012. A total of 21 field studies (in May: 3 days; June: 5 days; July: 4 days; August: 5 days and September: 4 days), and 105 free diving observations (FDOs) were made. The surface seawater temperatures were measured as 20.2 ± 0.4ºC in May, 23.3 ± 1.1ºC in June, 23.5 ± 0.2ºC in July, 26.6 ± 0.3ºC in August and 24.8 ± 0.5ºC in September. We encountered sandbar sharks 49 times in 105 FDOs, and totally 93 individuals were counted. Sandbar sharks observations are decreased in end of the June increased again in early August (Figure 1).

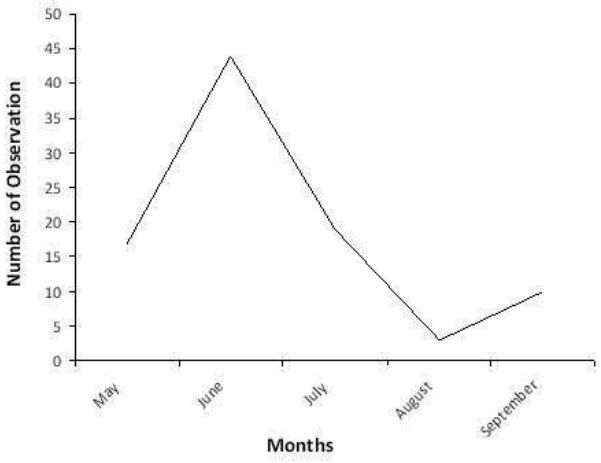

Fig. 1. Change in the number of observation by months.

The sharks are very active in the morning, most (84,3 %) observations were made in morning hours between 07:00 – 10:00 a.m (Figure 2).

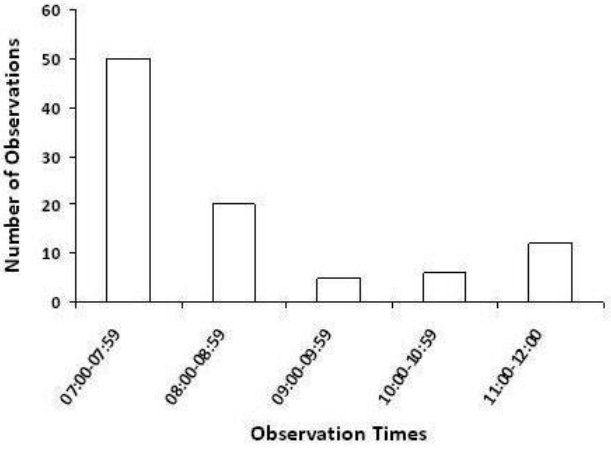

Fig. 2. Number of Sandbar Shark by observation times.

Boncuk Bay in the Gökova Special Environmental Area (SEPA), all kinds of fishing activities and boat trips in the area are prohibited. However activities that could threaten the sharks have been observed. These are ordered as follows, Illegal artisanal fishery applications were observed in protected area. From time to time, boat trips entered in the protected area to sharks for their guests. Some solid waste observed at the bottom of the area. Sailing boats discharged their bilge in open sea, but they are drifted to the Boncuk Bay via forced winds.

BY-CATCH AND DISCARDS OF ELASMOBRANCHS IN THE ARTISANAL NET FISHERY IN A CORSICAN MPA (NORTH-WESTERN MEDITERRANEAN)

L. Le Direach [1]*, P. Bonhomme [1], M. Ourgaud [2], C. Boudouresque [2] and G. Cadiou [1]
[1] GIS Posidonie - Aix Marseille University - laurence.ledireach@univ-amu.fr

Abstract
The high proportion of elasmobranchs in the discards of the artisanal fishery within and near the Scandola MPA suggests that those species do not benefit from the protection and pay a heavy tribute to gillnet and trammelnet fishing, even close to the shore.

Keywords: Elasmobranchii, Fisheries, Conservation, Coastal waters, North-Western Mediterranean

Introduction
A twelve year seasonal survey of the artisanal fishery within and near the Scandola MPA (Western Corsica, France) provided data on the catches and discards of elasmobranchs in the catches (gillnets and trammel nets). The fishing effort was concentrated near the coast in various reef habitats and *Posidonia* meadows down to 120 m coastal detritic bottoms. Fishermen targeted mainly demersal fish and the spiny lobster *Palinurus elephas*.

Material and methods
Discards of fish were evaluated onboard by recording all fishes (size and wet mass) caught by each net during 9 sampling periods (spring, summer and/or autumn), between 2001 and 2012. A minimum of 25 to 71 nets were sampled in each sampling period during about two weeks.

Results
The total fish discards were estimated at between 5 and 27% of the caught fish biomass according to the season (maximum in spring and summer). Among elasmobranch catches, discards reached 100 % of catch biomass in autumn and were never lower than 21% whatever the season. The contribution of elasmobranchs to the caught biomass was estimated at 11 to 25% whatever the season, but their mean contribution to discards was 49% and might attain 74% in summer. The composition of the caught biomass was 1/3 *Dasyatis pastinaca*, 1/3 *Raja* spp. and 1/3 of *Scyliorhinus* spp. (23%) and *Torpedo* spp. (6%).

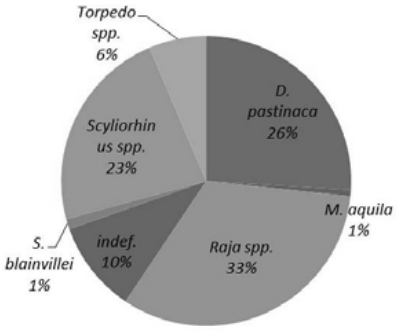

Fig. 1. Elasmobranchs caught in gillnets and trammelnets in Scandola fishery.

The ray *Myliobatis aquila* was scarce while sharks were quite rare, with less than 10 individuals observed during the total survey period. shark, namely *Etmopterus spinax*, *Galeus melastomus* and *Squalus blainvillei* were mainly encountered in spring. An unidentified species belonging to the protected genus *Squatina* has been observed only on one occasion. Unlike fishing habits in other countries, skate and ray are not targeted in the study area. However, there is now a growing interest of consumers for skate. As a result, the *Raja* species that were systematically discarded at the beginning of the study, are now kept for their wings (18% of elasmobranch discards in 2001 vs 0% in 2012). This explains why, among the elasmobranchs, the most frequently discarded species are *Scyliorhinus canicula* and *S. stellaris*, followed by *Dasyatis pastinaca* and *Torpedo* spp.

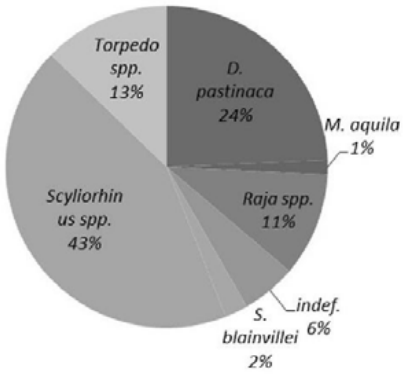

Fig. 2. Composition of elasmobranchs discards in gillnet and trammelnet fishery in Scandola MPA.

The yield in biomass of *Scyliorhinus* spp. was drastically divided by 6 in spring (188 vs 26 g/100 m respectively in 2001 and 2012). They were mainly caught by fishing nets (3.5-5 cm mesh size). The increasing use of one-wire nylon nets seemed to have enhanced catches of these species. The *Torpedo* spp. were caught by larger mesh sizes (5.5-7.5 cm) in the traditional trammel nets. The smallest mesh size (2-3 cm) used near the coast, mainly targeting red mullet (*Mullus* spp.), totalled 85 to 100% of its elasmobranch biomass discarded, which represents the highest value recorded. The highest individual mean biomass in the catches was that of *Dasyatis* spp. (3.8 kg ± 7.9 kg SD) and *Myliobatis aquila* (3.5 kg). The mean length was 47 to 58.4 cm (56.7 ± 19.8 SD) for *Raja* spp., 44.9 ± 6.4 SD for *Scyliorhinus* spp. and 40.2 ± 12.4 for *Torpedo* spp.

Discussion and conclusion
In Scandola, a few fishermen are authorized to fish in the buffer area of the MPA. Mean yields are not decreasing over time and the mean number of fishing vessels and gear recorded in the study area is relatively stable [1]. Those results must be considered as contributions to the assessment of the benefits of the protection in the area adjacent to the MPA. Nevertheless, neither the surface area of the tiny no-take zone, nor the buffer zone of the Scandola MPA, where only recreational fishing is banned, offer sufficient protection to elasmobranchs which are highly vulnerable to the artisanal gillnet and trammel net fishery, as evidenced by their dramatic decline in catches over the study period.

BEHAVIOUR OF DEEP-SEA SHARKS OBSERVED IN THE SANTA MARIA DI LEUCA COLD-WATER CORAL PROVINCE

L. Sion [1]*, F. Capezzuto [1], R. Carlucci [1], A. Carluccio [1], A. Indennidate [1], P. Maiorano [1] and G. D'Onghia [1]
[1] Department of Biology - University of Bari - letizia.sion@uniba.it

Abstract
A total of 4 shark species (*Centrophorus granulosus, Dalatias licha, Etmopterus spinax* and *Hexanchus griseus*) were observed in the Santa Maria di Leuca cold-water coral province using the baited lander MEMO during 3 video surveys carried out in 2010 and 2011. The depth examined was between 547 and 790 m. The dominant behaviour of the sharks was investigation of the bait at the foot of the lander. Ingestion of the bait was only shown in *H. griseus* and *C. granulosus*.

Keywords: Behaviour, Deep sea corals, Elasmobranchii, Ionian Sea, South-Central Mediterranean

Baited cameras on benthic landers attract deep-sea fish in order to provide information on their abundance, diversity and behaviour [1]. As part of the CoralFISH 7FP EU project and OBAMA-PRIN research funded by the Italian Government, the baited lander MEMO (Marine Environment MOnitoring system) was deployed in the Santa Maria di Leuca (SML) cold-water coral province (Central Mediterranean) in June and November 2010, and March-April 2011. MEMO consists of a stainless steel metallic frame, 2 digital cameras, a multiparametric probe, a currentmeter, an acoustic modem, and an ICT infrastructure capable of managing the entire system. A total of ten deployments between 547 and 790 m were carried out, for a total time of about 90 hours of video records. During each deployment the lander was baited with specimens of *Scomber scombrus*. The different species were identified through morphological characteristics observed in the video frames. The total number of individuals by species was counted. The behaviour was noted with respect to investigation activity, response to the bait and ingestion of the bait. During the three surveys, a total of 4 shark species were recorded: *Centrophorus granulosus*, *Dalatias licha*, *Etmopterus spinax* and *Hexanchus griseus*. *C. granulosus* and *D. licha* were only recorded during one deployment. The former was seen to be attracted by the bait, to investigate and to feed on it; the latter was also observedto be attracted by the bait and investigating on it but without feeding on it (Fig. 1). *Etmopterus spinax* was recorded two times showing attraction to the bait without feeding activity in one deployment and an indifferent behaviour in another deployment. *Hexanchus griseus* were observed 8 times. Although all specimens were seen to be attracted by the bait with an investigation behaviour at the foot of the lander, only three attacked and ingested the bait and only one attacked and removed the bait from the plate of the lander without ingesting it (Fig. 2). During one deployment *H. griseus* was also observed to interact with *Paromola cuvieri* near to the bait [2]. The present results show that the dominant behaviour of deep-sea sharks observed in the SML coral province was investigation of the bait at the foot of the lander. Differently from the observations reported in the Eastern Mediterranean for *E. spinax* [3] and *H. griseus* [4], the bait was not always consumed by the arriving individuals. These could be explained by the fact that it is unlikely that scavenging activity is an important feeding pattern for any of the species observed [4].

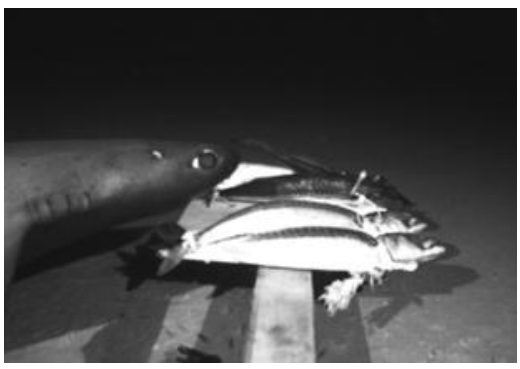

Fig. 1. Digital frame showing *Dalathias licha* in the SML coral province.

Fig. 2. Digital frame showing *Hexanchus griseus* in the SML coral province.

FIRST RECORDS OF THE LITTLE SLEEPER SHARK, *SOMNIOSUS ROSTRATUS*, IN MALTESE FISHERIES' LANDINGS

Adriana Vella [1]*, Noel Vella [1] and Elizabeth Dent [2]
[1] University of Malta - adriana.vella@um.edu.mt
[2] University of Bath

Abstract
In 2011, two little sleeper sharks, *Somniosus rostratus*, were captured from the Central Mediterranean, making them the first two records of this shark species landed in the Maltese Islands. These records fall within the outer most eastern distribution range of the species

Keywords: Elasmobranchii, Fisheries, South-Central Mediterranean

Introduction
The little sleeper shark, *Somniosus rostratus* (Risso, 1826), is a deep-sea shark living in a depth range of 180m to 2220m, with a geographic distribution is limited to the Northeast Atlantic Ocean and the Mediterranean Sea [1,2,3], with absent to very rare occurrence in the Eastern Mediterranean basin [4, 5]. In 2009, it has been evaluated as Data Deficient by IUCN, due to its rarity possibly related to a natural low populationdensity and lack of records within scientific surveys [6, 7]. In the Mediterranean Sea, *Somniosus rostratus*, as being evaluated as Least Concern [8], as it occurs below the depth of many demersal fisheries, while the restricted fishing activities below 1000m in the Mediterranean offering protection to this deep-sea species. Nonetheless, this species is still vulnerable at shallower parts of its depth range, whereas the lack of scientific knowledge on the species and its small geographical distribution range make any data available on this species valuable.

Methods
As part of ongoing fisheries and conservation research and monitoring by the Conservation Biology Research Group of the University of Malta, since 2002, through the conduction of regular fish-market surveys. Detailed records of the landings are taken, including morphometric data of elasmobranch species. Any species found to be landed for the first time by local fisheries are collected for further investigation. This paper presents one such record, where two specimens of Somniosus rostratus were landed as by-catch on long-lines. Identification of these specimen was carried out in the Conservation Biology Research Lab. and undertaken on the basis of their morphological characters [2,9], namely body proportions, teeth and number of turns in the spiracle valve. Morphometric data were measured to the nearest mm or g for length or weight as indicated by FAO [4,5].

Results and Discussion
In June, 2011, two specimens of *Somniosus rostratus*, were landed at the Maltese fisheries. These two specimens represent the first two landing records of such species amongst the species landed in the Maltese Islands. They were caught together as by-catch on long-lines off the Northeast of Malta. They were identified on the basis of their morphological characters [9][2]. These two specimens were both females having a total length of 935mm and 1036mm (Figure 1) respectively. The smaller specimen was an immature female with a gonosomatic index [(GW/TW)*100] of 0.5, while a gonosomatic index of 19.2 was noted for the second specimen. Additionally the second specimen had expanded and round uteri full of yolk. The hepatosomatic index [(LW/TW)*100] was 12.4 and 9.7 respectively, indicating a large liver in both specimens, as expected in sub-adult and adult shark specimens [10].

Fig. 1. Specimen of *Somniosus rostratus* landed at the Fish market of the Maltese Islands in 2011.

These first-time fisheries records of *Somniosus rostratus* landed in Malta indicate that mature and near mature individuals of this species occur in the Central-Southern Mediterranean Sea. As this species is found to inhabit deep waters over 1000m in depth, the presence of mature individuals in relatively shallower waters may indicate important reproductive grounds. The presence of mature females of this species in shallower waters has also been reported in Spain [1]. So *Somniosus rostratus* females may seek shallower waters as females of several other species of sharks do. In so doing they become vulnerable to fishing activities undertaken in shallower waters.

FEEDING HABITS OF SYMPATRIC DEMERSAL CHONDRICHTHYES

M. Albo-Puigserver [1]*, J. Navarro [1], M. Coll [1], R. Sáez [1] and I. Palomera [1]
[1] Institut de Ciències del Mar, ICM-CSIC, P.Marítim de la Barceloneta 37-49, 08003 Barcelona, Spain. - albo@icm.csic.es

Abstract

In the present work we describe the feeding habits of three coexisting chondrichthyans (*Galeus melastomus, Etmopterus spinax* and *Chimaera monstrosa*)in the Gulf of Lyon (North-Western Mediterranean Sea) during the summer 2011 at mean depths of 489 m. To examine their diet and potential interspecific differences, we combined two methodologies: the analysis of stomach content and isotopic mixing models. Our results showed clearly trophic segregation between *C. monstrosa* and the other two species, revealing the higher trophic position for this species.

Keywords: Demersal, Diet, Stable isotopes, Competition, Gulf of Lyon

Introduction Species that overlap niches lead to ecological divergence or competitive exclusion [1]. In marine ecosystems, segregation in feeding habits has been largely described as a common mechanism to allow the coexistence of several competing marine predators [2]. However, little is known for chondrichthyans, which play a pivotal role on the structure of marine food webs worldwide [3]. Here, we examine the feeding ecology of three abundant demersal chondrichthyans coexisting in the Mediterranean; *G. melastomus*, *E. spinax*, and *C. monstrosa*. To determine their diet, we combined stomach content analyses (SCA) and stable isotopic analysis (SIA).

Material and methods

SCA and SIA values were determined on mature *G. melastomus* (n= 34, body length = 22.73±1.89 cm), immature *E. spinax* (n= 36, body length = 12.83±2.59 cm) and mature *C. monstrosa* (n= 24, body length = 23.03±2.47 cm) sampled in the Gulf of Lyon (North-Western Mediterranean Sea) during the summer 2011. Because diet did not differ between sexes in the three species (PERMANOVA tests, all $p>0.05$,), we only compared the SCA and SIA values at species level. With SCA results, we estimated the Index of Relative Importance (%IRI) of each prey group. SIAR isotopic mixing models were used to determine the diet with SIA values [4]. Interspecific differences in %IRI, $\delta^{15}N$ and $\delta^{13}C$ were tested by using PERMANOVA tests.

Results and Discussion

Although SCA showed some discrepancies with SIA, both approaches revealed clearly trophic segregation between species (Fig. 1 and 2). *C. monstrosa* occupies a separate isotopic niche space, showing higher $\delta^{15}N$ and $\delta^{13}C$ values than *E. spinax* and *G. melastomus* ($p<0.001$; Fig. 1).

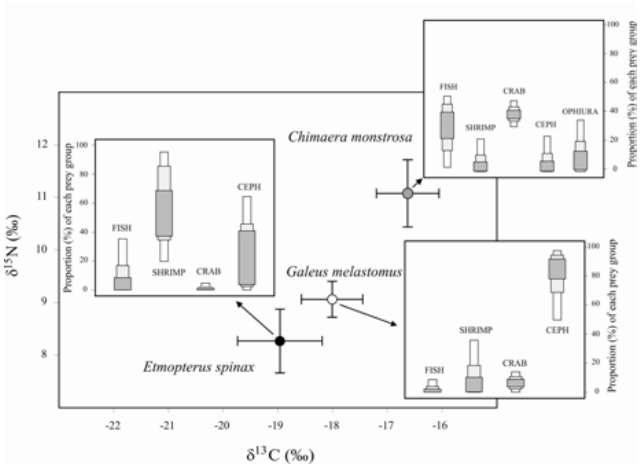

Fig. 1. Values of $\delta^{15}N$ and $\delta^{13}C$ (mean ± sd) of *Galeus melastomus*, *Etmopterus spinax* and *Chimaera monstrosa* and results of SIAR model (95%, 75% and 50% credibility intervals) showing estimated prey contributions to the diet of each species (CEPH = cephalopod).

The principal prey in the diet of *E. spinax* was the shrimps (SIAR output= 56 % and %IRI= 45%), *G. melastomus* showed a diet mainly composed of cephalopods (77% and 47%) and the diet of *C. monstrosa* was mainly composed of crabs (39% and 96.98%). *E. spinax* and *G. melastomus* have similar trophic levels, while *C. monstrosa* has a higher trophic level. Differences between methods may be due to the period of trophic information that integrates the SIA is broader than the information obtained from the SCA results [5]. In conclusion, the present study indicated that although there was a degree of overlap in some prey group, the three taxa segregate their trophic habits despite living in sympatry.

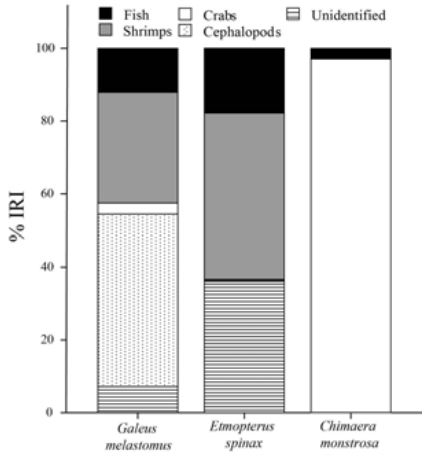

Fig. 2. Diet composition of *Galeus melastomus*, *Etmopterus spinax* and *Chimaera monstrosa* from the Gulf of Lyon (NW Mediterranean), expressed as percentage of the index of relative importance (%IRI).

Abstract

The diet of mostly juveniles of *Isurus oxyrinchus* and *Prionace glauca* is strongly dominated by teleosts (mainly *Scomberesox saurus*) and cephalopods (mainly *Histioteuthis* sp.), respectively.

Keywords: Diet, Elasmobranchii, Teleostei, Cephalopods, Gulf of Cadiz

Introduction

The shortfin mako *Isurus oxyrinchus* and the blue shark *Prionace glauca* are the elasmobranch species most affected by the sea surface longliners. These pelagic species have a slow growth rate and low fecundity [1] and are located in the highest level of the marine food web. They compete for the same alimentary sources with species which are the main target species of commercial fisheries, the swordfish *Xiphias gladius* and the tuna *Thunnus* spp. This study analysed the diet of the above mentioned elasmobranchs through the stomach contents of individuals captured by longliners from Vigo, Spain.

Tab. 1. Prey found in stomachs of the analysed species. For the meaning of %O and %N, see text.

Materials and methods

The study area was located between the Azores Archipelago and the Iberian Peninsula (15º-35º W and 30º-45º N). 82 shortfin makos and 54 blue sharks were studied between March and October 2012. Most individuals (respectively 95% and 82%) were juveniles, according to the size at sexual maturity [1, 2]. The identification (to the species or a higher taxon level) of the prey was carried out through the analysis of the vertebrae (teleosts and cetaceans) and the beak characteristics (cephalopods) [3, 4]. Frequency of occurrence (%O) is the percentage of non-empty stomachs containing a type of prey. Percent number (%N) is the percentage of individuals of a given prey versus the overall number of prey within non-empty stomachs.

Results and discussion

The number of stomachs containing prey was 51 (out of 82) and 23 (out of 54) for *I. oxyrinchus* and *P. glauca*, respectively. The diet of *I. oxyrinchus* is essentially (85%) based on teleosts (Table 1). More than 90% of individuals of teleost prey belonged to one species, *Scomberesox saurus*. In addition, remains of a loggerhead turtle *Caretta caretta* and several cetaceans were present. Literature data are in agreement with our results, but report a conspicuously higher diversity of teleost prey [e.g. 5]. As far as *P. glauca* is concerned, cephalopods represent the main prey (~87%), mostly consisting of *Histioteuthis* sp. Teleosts (mainly *Scomber scombrus*) and cetaceans were also consumed. Our results confirm some literature data [6], but strongly contrast with other data which report a mainly teleost diet [e.g. 7].

EGG-CASES OF *GALEUS MELASTOMUS* (CHONDRICHTHYES, SCYLIORHINIDAE) IN SARDINIAN WATERS

Serenella Cabiddu [1]*, Giulia Atzori [1], Marco Mereu [1] and Francesco Palmas [1]
[1] University of Cagliari - cabiddus@unica.it

Abstract
In this paper some morpho-biometric aspects of *Galeus melastomus* egg cases in Sardinian waters were analysed. The egg case had a rounded vase-like shape and did not have tendrils. The mean length without posterior horns was 4.2 mm and mean width was 1.6 mm. Egg cases from Sardinian waters were smaller than those from Atlantic and other Mediterranean areas.

Keywords: Elasmobranchii, South-Western Mediterranean, Biometrics

Introduction
The blackmouth catshark, *Galeus melastomus* Rafinesque, 1810, a common deep-water bottom-dwelling shark, is distributed in the eastern Atlantic Ocean and in the whole Mediterranean Sea, where it is found from depths of 55 to 1750 m [1]. It is an oviparous species and leys its eggs in a protective egg case. Descriptions of egg cases in Mediterranean Sea are given by few authors [2,3,4,5,7], then the aim of this paper is to analyse some morpho-biometric aspects of egg cases in the Sardinian waters.

Materials and Methods
The total lengh of each egg-bearing female was measured (cm) and the egg cases were removed from the oviducts of fresh specimens, weighted (fresh weight in grams), described and measured (mean±SD; cm). The egg case length (ECL) was used as an independent variable for proportional dimensions of other egg case structures [6] (Fig. 1).

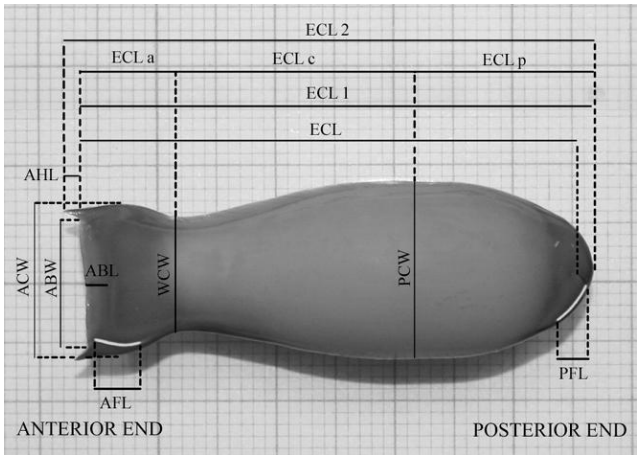

Fig. 1. Egg case measurements of *Galeus melastomus*.

Length of egg-bearing females was correlated with the egg-cases number, ECL and PCW.

Results and Discussion
A total of 41 egg cases (from 1 to 4 in each specimen) were found in 16 egg-bearing females between 45.1 and 52.7 cm of total length (49.1±2.0). The egg case had a rounded vase-like shape and did not have tendrils on either the anterior or posterior end. The surface was smooth in appearance and minute longitudinal ridges were visible running the length of both faces. Two white respiratory fissures on each side (one anterior and one posterior) were present. The egg case color changed from honey-brown to dark-brown related to stage of development. The length without horns (ECL) ranged from 35.9 to 43.8 mm (40.2±1.8), ECL1 ranged from 37.5 to 45.0 mm (41.9±1.6) and ECL2 ranged from 39.5 to 46.7 mm (43.9±1.8). The mean posterior case width (PCW) ranged from 14.4 to 7.4 mm (16.2±0.9) (40.2% ECL) and the posterior length was 17.1±1.2 mm (ECLa). Waist width (WCW) ranged from 8.9 to 12.8 mm (11.7±0.9) (29% ECL) and the anterior length was 17.5±1.5 mm (ECLb). The anterior egg case width (ACW) ranged from 11.0 to 13.4 mm (12.4±0.6) (30.8% ECL) and the central length was 7.5±0.7 mm (ECLc). Egg case height (CHI) ranged from 8.3 to 11.8 mm (9.9±0.8) (24.7% ECL). Anterior border was straight with two horns (AHL=2,1±0.4 mm). The anterior border width (ABW) was 9.7±0.6 mm and the anterior border length (ABL) was 1.5 mm. Posterior end showed two little horns in close proximity with one other. Anterior and posterior respiratory fissures length was 5.5 mm (AFL) and 4.1 mm (PFL) respectively. Fresh weight ranged from 1.6 to 3.6 g (2.2±0.5). Egg case seemed to develop proportionately and there was no relationship between the number and dimension with the size of females. Finally, dimensions of egg cases changed in relation to geographical area according to other authors [4]. Egg cases from Sardinian specimens were smaller than those from other Mediterranean areas and much smaller than those from Atlantic (Tab. 1).

Tab. 1. Measurements recorded in egg cases of *Galeus melastomus* from different areas (ECL1 and PCW in this study).

ECOLOGIE DE *LEPIDOPUS CAUDATUS* (EUPHRASEN, 1788) DANS LE BASSIN ALGÉRIEN

Farid Hemida [1]*, Habiba Benrabah [1] and Christian Capapé [2]
[1] ENSSMAL - hemidafarid@yahoo.fr
[2] Université de Montpellier II

Abstract
Le sabre argenté, ou sebta dans la région d'Alger, porte le nom scientifique de *Lepidopus caudatus* (Euphrasen, 1788). L'étude de la distribution de *Lepidopus caudatus* a été réalisée à partir des données obtenues au cours de la campagne effectuée par le navire océanographique Thalassa (ISTPM, 1982) sur toute la côte algérienne. Les résultats obtenus sont relatifs aux répartitions géographique et bathymétrique. De plus, l'étude du peuplement caractéristique de *Lepidopus caudatus* a mis en évidence les espèces qui lui sont étroitement associées.

Keywords: Fish behaviour, Teleostei, Algerian Basin

Introduction
Le sabre argenté *Lepidopus caudatus* (Euphrasen, 1788) est un poisson osseux, appartenant à la famille des Trichiuridae. Il est capturé accidentellement, bien qu'évité soigneusement par les patrons de pêche. Les captures, qui pouvaient atteindre 1500kg par coup de chalut, sont rejetées en mer. Très comestible, vendu dans des pays des rives nord et sud de la Méditerranée, le sabre demeure étrangement absent des étals des marchés algériens. La pêche proprement dite de ce poisson n'existe pas, ce qui explique l'absence de toute étude sur les côtes algériennes.

Méthodes d'étude
La campagne Thalassa s'est déroulée d'Ouest en Est [1] :182 stations de chalutage ont été réalisées entre 15 et 820m de profondeur. Sept secteurs géographiques ont été prospectés: Béni-Saf et Arzew à l'Ouest; Bou-Ismail et Zemmouri au Centre; Jijel, Skikda et Annaba à l'Est. Deux indices ont permis l'analyse des répartitions horizontale et verticale: la fréquence relative (Fr) et le rendement R ou abondance relative (Ar). Les stations en dehors de la gamme de prospection ne sont pas considérées [2]. Les fréquences relatives (Fr) correspondent au nombre de stations ayant ramené l'espèce. Le peuplement, défini selon [3], caractéristique du sabre argenté a été analysé en calculant pour chacune des espèces de rang (i) son abondance relative (xi) et sa fréquence relative (yi). Les espèces très caractéristiques (très fréquentes et très abondantes) sont mises en évidence sur un diagramme a quatre cadrans [2] .

Résultats et discussion
L'espèce étudiée est présente le long de la côte algérienne avec des variations selon la région considérée. Le sabre argenté est très fréquent à l'est et très abondant au centre de la côte algérienne (tableau 1). Ce dernier se capture au chalut sur des fonds compris entre 80m et 600m. La tranche de profondeur la plus productive (figure 1) se situe entre 200 et 400m. Deux espèces sont étroitement associées à *Lepidopus caudatus*: *Micromesistius poutassou* (Gadidae) et *Parapenaeus longirostris* (Crevette, Penaeidae). D'autres espèces lui sont également liées, mais à un degré moindre: *Phycis blennoides*, *Merluccius merluccius* (Gadidae) et *Plesionika heterocarpus* (Crevette, Pandalidae). Le sabre argenté, poisson dont la chair est très fine et très appréciable n'est pas connu de la population algérienne. On gagnerait à le cibler préférentiellement pour, d'une part alléger la pression de pêche sur les espèces commercialisées et d'autre part fournir un aliment protéique abondant, commercialisable pour peu qu'on l'y habitue aux consommateurs de la région.

Abstract
Females maturity stages of the *Dipturus oxyrinchus* reproductive tract were analyzed and confirmed by an histological analysis. In particular, the oviducal gland microstructure was studied with several histological staining techniques in order to better understand the nature of secretions produced by its different zones throughout the reproductive maturation.

Keywords: Elasmobranchii, Reproduction, Life cycles, North-Western Mediterranean

Introduction Reproductive processes of Chondrichthyans are complex and till now their information are scarce. Knowledge of the gametogenesis and the development and maturation of secondary reproductive organs as the oviducal gland, is vital for understanding the reproductive biology of a species. For this reason, the aim of this paper is to describe the reproductive tracts development and gametogenesis in the longnosed skate *Dipturus oxyrinchus* (Linnaeus, 1758), a benthic species distributed in Mediterranean and in the Eastern Atlantic on sandy and muddy bottoms from 90 to 900 m in depth [1, 2].

Materials and Methods Longnosed skates samples were collected during experimental trawl surveys and during commercial hauls performed on bottoms off Sardinian waters (Central-Western Mediterranean Sea). Maturity stages were assigned using a maturity scale proposed in the ICES WKMSEL report (2010) [3]. Oviducal glands width was recorded in millimeters. Transverse and sagittal sections of ovaries and oviducal glands respectively, were fixed in 5% buffered formaldehyde, dehydrated, embedded in a synthetic resin (GMA) and sectioned (3.5 µm). Then, the ovary sections were stained with Harrys haematoxylin and eosin (H&E), instead sections of oviducal gland with either H&E and combined periodic acid-Schiff (PAS) and alcian blue (AB) to investigate the chemical nature of secretions.

Results Female longnosed skates have two ovaries, each located on the distal surface of the epigonal organ and containing developing follicles distributed on its surface. As in all other skates, each oviduct opens into an oviducal gland (OG). A complete macroscopic and histological description of the various maturity stages has been performed (Tab.1).

Tab. 1. Macroscopical and microscopical description of females maturity stages of *Dipturus oxyrinchus*.

Maturity stage	Macroscopic description	Microscopic description
1 Immature	Small and whitish ovary with undistinguishable ovarian follicles. Oviducal gland (OG) slightly visible (1.4-7.4 mm).	Vascularized epigonal organ. Primordial (>150 µm) and primary (>300 µm) follicles are present. OG not yet differentiated.
2 Developing	Ovary enlarged with follicles of different sizes (0.8-2.90 mm). OG in developing (5.7-34.3 mm).	Previtellogenic follicles appear (>1000 µm) with lipidic drops and complex follicular epithelium. OG with uniform *lamellae*. Serous and mucous glands distinguishable.
3A Spawning Capable	Enlarged yolk follicles of different sizes (3.1-28.7 mm). OG fully developed (45.5-52 mm).	Vitellogenic follicles (>4000 µm) surrounded by the thick *zona pellucida* and basement membrane are present. All OG zones are visible (club, papillary, baffle, terminal) with secretions present in the tubules.
3B Actively Spawning	Similar to stage 3A, however with the presence of egg capsules in the uterus.	Postovulatory follicles can be present. OG tubules full of secretion materials.
4A Regressing	Ovaries shrunken with follicles of different sizes (1.23-10.68 mm). OG completely formed (29.2-61 mm).	Follicles in all stages. Postovulatory and atretic follicles, in which basal lamina appear collapsed, are present. OG with the four zones visible with secretions in tubules.
4B Regenerating	Small follicles similar to stage 2 (1.4-5.36 mm). OG developed, reduced respect to stages 3, but, in general, larger than stage 2 (23.5-34.5 mm).	Like to Stage 2, there are follicles of different sizes. OG with tubules and *lamellae* are evident. Secretions are scarce respect to other stages.

Discussion
The main structure of the reproductive tract of D. oxyrinchus is shared by all rajid species as well as by oviparous sharks. In our study, the maturation of ovaries seems to be similar to all Rajidae species as described for the thornback ray *Raja clavata* [4]. The macroscopic observations for each maturity stage have been always confirmed by histological analysis. The main morphology and functionality features of the OG are comparable with almost all Chondrichthyans [5, 6]. Indeed, it was possible to discern histologically the four zones that it is composed (club, papillary, baffle and terminal). The development of OG throughout the reproductive maturation reflected the changes in size and chemical nature of secretions of secretory tubules. Histological staining techniques allowed to recognize that gland tubules begin to produce starting from the developing stage (mucins in the club, papillary and terminal zones). In spawning capable and actively spawning stages the secretory tubules were enlarged subsequently to the increase in size and number of the secretory granules. In regressing females the secretory activity was abundant yet, whereas in the regenerating specimens there was a lower affinity for dyes, due to a reduction of secretion materials produced.

DIET OF COMMON STINGRAY, *DASYATIS PASTINACA* (LINNAEUS, 1758) IN THE GOLF OF GABÈS (SOUTH-CENTRAL MEDITERRANEAN)

Abdesselem Saadaoui [1]*, Bechir Saidi [1] and Mohamed Nejmeddine Bradai [1]
[1] Institut National des Sciences et Technologies de la Mer - saadaouiabdesselem@live.fr

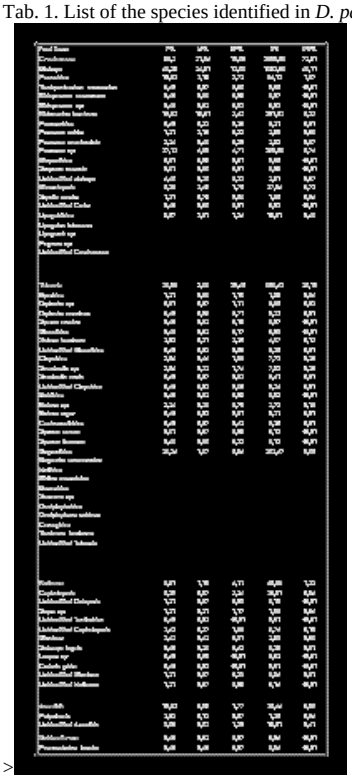
Abstract
The diet and feeding habits of the common stingray, *Dasyatis pastinaca*, in the Gulf of Gabès were studied from examination of 314 Stomach contents. Crustaceans were the most important prey component in the diet of *D. pastinaca* (%IRI =72, 91).Teleosts were second in importance (IRI%=25, 18). Changes in diet were observed and related to size of specimens.

Keywords: Diet, Gulf of Gabes, South-Central Mediterranean

Introduction
The bibliographic research highlighted a lack of aggregate knowledge on the biology of elasmobranchs in many parts of the Mediterranean [1]. The purpose of the present study was to provide a description quantitative of the diet and was to investigate feeding habits of common stingray, *Dasyatis pastinaca*, caught in Gulf of Gabès (Central Mediterranean).

Material and Methods
In order to study the diet and feeding habits of common stingray, a total of 314 specimens with a disc width (DW) between 12.7 and 70.0 cm were caught between June 2011 and January 2012 in the Gulf of Gabès. In the laboratory, stomach contents was analyzed using the percentage frequency of occurrence (F %), numerical percentage (N %), percentage by weight (W %), the index of relative importance (IRI), and percent of IRI (IRI %) for each prey type [2].

Tab. 1. List of the species identified in *D. pastinaca stomach* contents.



>

Results
Of the 314 stomach contents of *Dasyatis pastinaca* examined, 266 are full (83, 37%) and 48 are empty (16, 27%). Prey items was identified in stomachs belong five major groups: Crustaceans, Teleosts, Molluscs, Annelida and Echinoderms (Table1). Crustaceans were the dominant prey items (IRI%= 72, 91), followed by Teleosts (IRI%=25, 18). Molluscs, annelid and echinoderms were occasional preys. Changes in diet were observed and related to size of specimens. With increasing size, crustaceans decreased in importance, whereas teleosts and molluscs increased.

Discussion
The results indicate that *D. pastinaca* fed on benthic and demersal preys, and reveals that crustaceans are the most frequent prey. The present study provides broad support for the description of this species as a broad spectrum predator [3]. The composition of the diet of the common stingray changed with increasing size; crustaceans decreased in importance, whereas teleosts and molluscs became more dominants. Dietary shifts with size observed in this study, have been described for this species in another geographical area in Mediterranean Sea [4].

Abstract
Management of MPSs requires scientific perspective and knowledge. Multidisciplinary investigations may provide information on connectivity, that is an important issue for management of biodiversity. In this work we aim i) to use a simplified mathematical model to describe the possible time required to travel from the Corsica Channel to the Ligurian sea; ii) to show evidences of long distance dispersal of *Posidonia oceanica* seeds that may supply local populations in Eastern Liguria.

Keywords: Biodiversity, Ligurian Sea, Marine parks, Posidonia, Models

The establishment of effective MPAs networks in a modern perspective must be based on solid scientific knowledge and properly managed as EC pointed out through CoCoNet project. Multidisciplinary approach may describe the connectivity between nearby MPAs. This topic is fundamental because it explain the supply of MPAs with key biodiversity-building species, e.g. *Posidonia oceanica*. An example of coupled approach is reported. Monterosso al Mare meadow is within the MPA of 5 Terre (North Eastern Ligurian Sea). Stranded fruits and seeds have been recorded on local beach after massive fruiting of 1992, 1993 and 2004 [1]. Local supply has been considered as the major source for these fruits. However, *Lepas* spp. juv. (3-5 mm long) were found attached to the base of the fruits of some inflorescences (Figure 1).

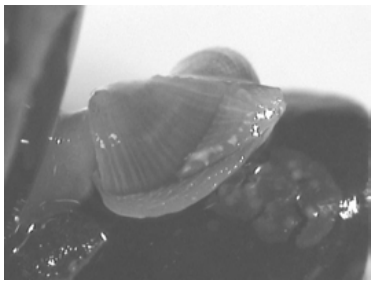

Fig. 1. A 5 mm long young specimen of *Lepas* sp. on a *P. oceanica* fruit.

This supports the hypothesis of long-distance supply as Lepas is a offshore species, so the possibility that floating fruits came from southern meadows of Corsica and Livorno (Tuscany) has been investigated by oceanographic modelling. The major large scale feature of the water dynamic in the surface layers of the Ligurian Sea is a cyclonic circulation active all year round, more intense in winter than in summer [2]. Southern waters to the Ligurian Sea occur in two main currents running along each side of Northern Corsica (Figure 2a).
A Lagrangian model forced by 10 years climatological data has been applied to study dispersion of passive tracers by simulating a high number of particles [3]. Laboratory experiments show that 1.7% of stranded fruits sunk after 9 days in a box with seawater. At least 12 days were necessary to the majority of fruits to show signs of corruption and loss of floatation. This period is in agreement with the growth of Lepad juveniles that reach 5 mm size in about 15 days. In the numerical experiment, 1000 particles were released in the Corsica channel (42.5°N, 9.625°E) corresponding to the main flow of the Tyrrhenian current (1996-2005).
The model showed that the percentage of particles that reach the Ligurian Coast (particles crossing the 44°N are considered stranded in Liguria) were 3% in 30 days. When particles were released from the closest meadow of Livorno the percentage reaching Liguria was about 10%.

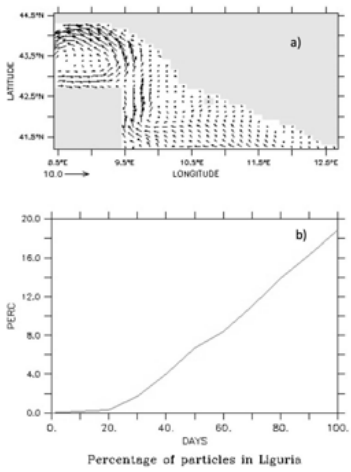

Fig. 2. a) Currents from Corsica to Liguria from circulation model, b) expected time for transport of particles from Corsica to Liguria.

A small part of the seeds found stranded in Monterosso (East Liguria) was from offshore and our coupled experiments suggest that connectivity is possible from the South. Times of transport are consistent with physical connection between the MPA of Monterosso al mare meadow and southern ones [1,4]. Coupling physical and ecological data provides unique and useful information to understand biodiversity patterns and functioning in MPAs [5]. This integrate knowledge is necessary for proper managements and a full comprehension of variability of currents gets as critical as ecological patterns to describe connectivity.

Abstract
Genetic studies of octocoral populations in the Mediterranean Sea have revealed a pattern of strong and short distance genetic structure without apparent deep genetic break. In order to better understand such structuring we provide here an analysis of connectivity in the North-Western Mediterranean for two species: the red coral *Corallium rubrum*, and the red gorgonian *Paramuricea clavata*. We compare the results obtained by different methods aimed at estimating recent or long term components of gene flow. The results are discussed in the light of the biological characteristics of these species, of their evolutionary history and of the potential limits of the methods used.

Keywords: Genetics, Gulf of Lyon, Cnidaria

The management and conservation of natural populations need to take into account gene flow levels as indicators of recolonisation abilities and population connectivity. Population genetic studies of octocorals in the Mediterranean Sea have evidenced unexpected patterns of genetic structuring for species with a larval stage: microsatellite data have shown short to significant genetic differentiation at medium to short distance for the red coral *Corallium rubrum*, and the red gorgonian *Paramuricea clavata* ([1], [2], [3], [4], [5], [6],). Significant differences have also been observed between depths in the same site (e.g. between 20 and 40 m for the red coral; [6]). These significant differences have been mainly interpreted as the consequence of reduced mean dispersal abilities. Nevertheless a phylogeographic comparison between the most distant locations did not evidence any deep phylogeographic break for the red coral. This does not support long term isolation even through well-known genetic barriers such as the Almeria – Oran front ([1]). The sampling scheme may also have impacted the observed structure between distant locations ([1]). Moreover F_{ST} values and significance do not rely only on dispersal levels but also on effective size and population history (e.g. [7]) and real estimates of dispersal (i.e. not only F_{ST}) are still lacking for these species. We analyze here microsatellite data from *C. rubrum* and *P. clavata* in order to assess in a comparative way dispersal estimates in the North-Western Mediterranean Sea. The comparison will be done between these two species in the same area in order to look for some potential shared limits to gene flow. We will analyze populations from three distant regions: Marseille, Catalonia and Corsica, with an analysis between regions and between populations inside regions. These regions have been identified as different genetic clusters based on microsatellite data ([6]). This may reflect the impact of several non-exclusive phenomena: hydrographic barriers, lack of suitable habitats between regions, distance effect in a isolation by distance framework. A more precise study of connectivity is then required in this context. A regional analysis of connectivity will also be performed, with a focus on the Marseille area: in this region the populations of these species are separated in two main areas, South and North of the city which might correspond to different genetic groups as well ([6]). A connectivity analysis is interesting here both for understanding population dynamics and evolution but also for management purposes. Finally the question of gene flow between depths in each area will be discussed. It will shed light on the interaction between migration and local selective pressures. A methodological comparison will be done between different approaches for dispersal estimates in order to try to separate the short and long term components of gene flow. The first category of methods used here is assignment approaches which allow the detection of migrant individuals: it then deals with short-term / contemporary connectivity. This is useful in order to evaluate current recolonisation abilities of these species. The second category of methods relies on models dedicated to the estimation of long term migration rates and effective population sizes. This will give some insights in the evolutionary history of these species and their interaction with environmental heterogeneities and fluctuations.

FURTHER INSIGHTS ON THE GENETIC STRUCTURE AND CONNECTIVITY IN *OCTOPUS VULGARIS* (MOLLUSCA, CEPHALOPODA) INFERRED BY MITOCHONDRIAL COI SEQUENCES

Abstract
The genetic variability of the COI gene was studied in the common octopus, *Octopus vulgaris* Cuvier, 1797. A total of 222 individuals from 7 sampling sites were analysed with the aim of elucidating patterns of genetic variation along the coasts of Sardinia (Western Mediterranean). A total of 17 different haplotypes were identified with four principal haplotypes recorded in all locations. The pairwise Fst and AMOVA revealed a high gene flow and the lack of significant genetic differentiation among populations. All COI sequences were compared with those available in GenBank for the species; the results obtained show a high sequence divergence among *O. vulgaris* from different geographic locations and emphasize the need for more detailed phylogeographic and/or taxonomic studies to exclude the presence of cryptic species.

Keywords: Genetics, South-Western Mediterranean, Systematics, Cephalopods, Fisheries

Octopus vulgaris is of great interest as a commercial species and therefore under pressure of intense fishing activity. Taxonomic problems regarding this species, whose status as a true cosmopolitan species or as a species complex is uncertain, are known to exist [1]. The aim of the present study was to use mitochondrial COI gene to determine the genetic structure and connectivity in *O. vulgaris* populations along the coast of Sardinia (Western Mediterranean). HCO-LCO primer pair [1] was used to amplify a region of the mitochondrial COI gene. A total of 222 specimens were analysed from 7 populations collected off the Sardinian coast. Additional sequences for all the species of genus Octopus were obtained from GenBank for comparison. All sequences were aligned and analysed with MEGA 5.1 and ARLEQUIN 3.5. Unbranched median joining networks were created in Haplotype Viewer to visualize the divergence between haplotypes. A 628 bp fragment of COI from 222 individuals yielded 17 haplotypes that differed for at a total of 16 sites (10 parsimony informative sites including 4 non-synonymous changes), the average number of nucleotide differences was 2.89. The mean genetic distance, calculated with the Tamura model was 0,008 (range 0,00163-0,01675). Four haplotypes were the most common (shared by 73, 55, 49, 25 individuals, respectively) and were found at all locations; the remaining haplotypes were found in 1-4 individuals (Fig 1). Two pairwise Fst were significant (CSA-SUP, CSA-CFE), but not after FDR correction. The analysis of AMOVA failed to identify significant genetic differentiation (overall Fst=0.00634, NS), with most of the total variation (99.4%) due to intrapopulation differences.

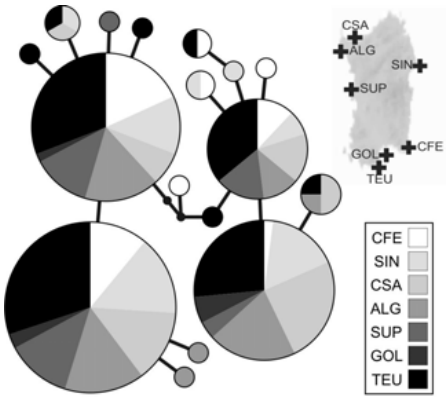

Fig. 1. Haplotype network of COI sequences of *O. vulgaris* from Sardinia, pie charts are drawn proportionally to the number of sequences.

Sardinian haplotypes were compared with homologous sequences archived in GenBank from Octopus vulgaris [1-4 and references therein] (Fig 2).In the final alignment of 508 bp, the most widespread Sardinian haplotypes were found to be shared with individuals from France, Spain, Turkey, Galicia, Senegal, South Africa and Saint Paul Islands. Some *O. vulgaris* sequences from Turkey (haplotypes 2, 3, 8, 9 in Fig 2) Japan and China (haplotypes 29-32 in Fig 2) resulted to be highly divergent from all the others. The results obtained show a high sequence divergence among *O. vulgaris* from different geographic locations and emphasize the need for more detailed phylogeographic and/or taxonomic studies to exclude/confirm the presence of cryptic species. Such information could give important insights in an evolutionary and fishery management perspective.

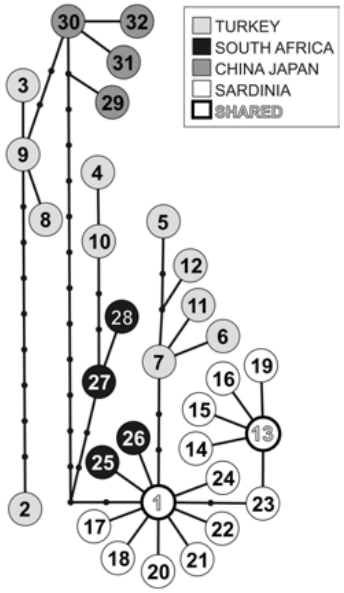

Fig. 2. Network of COI haplotypes of *O. vulgaris* from Sardinia compared with those from otained from GenBank sequences. Numbers within circles referes to the haplotype number.

PLANCTONIC LARVAE DO NOT INVOLVE GENE FLOW IN THE EDIBLE SEA URCHIN *PARACENTROTUS LIVIDUS*

Gwilherm Penant [1], Didier Aurelle [1], Jean-Pierre Féral [1] and Anne Chenuil [1]*

Abstract
Previous studies reported genetic differentiation between the Atlantic Ocean and the Mediterranean Sea, and between the Adriatic and other regions but no structure within basins. We completed these data with new mitochondrial and nuclear sequences and reanalyzed them. We found within-basin and within-region differentiation with each genetic marker, which was unexpected given the long planktonic larval phase. The easternmost population, from Lebanon, appeared strongly differentiated from other populations. A differentiation of the same magnitude was found for the northernmost population, Galway. Among basins, gene flow appeared unidirectional, from the Atlantic to the Mediterranean Sea. Atlantic and Mediterranean basins were estimated to have started diverging between 270 and 370 thousand years ago.

Keywords: Echinodermata, Conservation, Biogeography, South Adriatic Sea, North-Western Mediterranean

P. lividus is found from the Canary Islands and Mauritania to Ireland in the Atlantic Ocean, and throughout the entire Mediterranean Sea. Phylogeography and population genetics approaches using DNA markers are recent in *P. lividus* andonly based onmitochondrial DNA. They evidenced discontinuities between major ocean basins (i.e. between the Mediterranean and the Atlantic: Duran *et al.* 2004, Calderón *et al.* 2008, Maltagliati *et al*. 2010; between the Mediterranean and the Adriatic: Maltagliati *et al.* 2010). Within basins, a spatial genetic structure was observed with the COI marker along the Mediterranean Spanish coast (Calderón *et al.* 2012).

Nevertheless, this structure was not observed all years, was not consistent among all populations, and disappeared when cohorts were pooled. At a local scale Iuri *et al.* (2007) did not evidence any genetic structure in the region of Naples. For temporal comparisons, differentiation among cohorts was demonstrated using the bindin gene (Calderon & Turon 2010), appeared occasionally with COI (Calderón *et al.* 2012) and was not observed with microsatellites (Calderon *et al.* 2009).

One potential limitation of previous studies could be the use of a single locus for most of them. We reanalyzed the data from the three published large-scale studies (Duran *et al*. 2004, Calderon *et al*. 2008, Maltagliati *et al*. 2010) and combined them with new mitochondrial (COI) and nuclear (calpain EPIC) datasets. Both distance-based and frequency-based metrics were used for two reasons: (i) to compare new data with previous ones and (ii) because the frequency-based metric, not used in previous phylogeographic studies, appeared more appropriate to detect subtle genetic differentiation caused by relatively recent and contemporary processes, where migration-drift dominate over mutation.

We paid special attention to differentiation among populations within major geographical groups (i.e. Atlantic basin, Mediterranean basin and Adriatic basin), because increasing knowledge at this scale appeared essential for the protection of this exploited species. We characterized the direction and intensity of gene flow between the main groups of populations, using a coalescence analysis of isolation with migration processes to improve our knowledge on the evolutionary history of this species.

We revealed substantial genetic structure within basins, for the first time for this species, with each marker (Fig. 1) and unidirectional dispersal (gene flow) from the Atlantic to the Mediterranean compatible with sea surface currents. We estimated the beginning of the Atlantic Mediterranean divergence to be about 270-370 thousand years ago.

CONNECTIVITY OF POPULATIONS OF *APOGON IMBERBIS* IN BAY OF MARSEILLE

Delphine Muths [1], Pierre-Alexandre Rastorgueff [2] and Pierre Chevaldonné [2]*
[1] Aix-Marseille University, Mediterranean Institute of Oceanography (M I O), 13288, Marseille, Cedex 9, France
[2] UMR CNRS 7263, IMBE, Aix-Marseille University, Station Marine d'Endoume, Rue de la Batterie des Lions, 13007 Marseille - pierre.chevaldonne@imbe.fr

Abstract
La structure génétique d'*Apogon imberbis* est explorée sur 200 poissons échantillonnés entre Carry-le-Rouet et La Ciotat, à 6 loci microsatellite et pour un fragment du gène mitochondrial. Les premiers résultats ne confirment pas l'hypothèse selon laquelle les caractéristiques biologiques de cette espèce laissaient supposer un niveau de structure conséquent en rade de Marseille qui aurait pû permettre de discuter les différentes hypothèses quant aux voies de colonisation des récifs du Prado.

Keywords: Genetics, North-Western Mediterranean, Fishes, Artificial reefs

L'un des objectifs du présent projet est d'apporter des éléments de réponse à la question suivante: d'où proviennent les colonisateurs des récifs artificiels du Prado? Au vu des connaissances accumulées sur certaines espèces, couplées à l'approche modélisatrice des courants déjà effectuée sur le site des récifs [1], l'hypothèse principale est que la colonisation des récifs se ferait essentiellement en provenance de la Côte Bleue et de l'intérieur de la baie de Marseille. Cette hypothèse est-t-elle vérifiée? Quelle proportion d'individus pourrait à l'inverse provenir des Calanques Sud? Un certain nombre d'espèce sont susceptibles de coloniser ces récifs artificiels et de nombreuses y sont déjà installées. Beaucoup de ces espèces ont des capacités de dispersion importantes, qui rendent impossible l'identification de l'origine des individus s'installant sur ces récifs. A l'inverse, certains organismes, particulièrement sédentaires et ne disposant pas de phase de développement très dispersive lors de leur cycle de vie, sont supposés présenter des niveaux de structure génétique conséquents qui permettraient de déterminer l'origine des colonisateurs des récifs. En l'état actuel des connaissances, les mysidacés du genre *Hemimysis*, vivant dans les communautés de roches ombragées ou de grottes, sont les seuls organismes de la région qui sont suffisamment caractérisés sur le plan génétique [2 ;3] pour pouvoir déterminer la provenance des colonisateurs des récifs. Or le recrutement de mysidacés n'est encore que rarement observé sur les récifs. L'idée est donc de s'intéresser à une autre espèce, inféodée aux mêmes habitats que les mysidacés, présentant également une dispersion supposée faible, donc un niveau de structure génétique similaire, mais qui est déjà observée en nombre sur le récif. C'est le cas du poisson sciaphile *Apogon imberbis*, vivant dans les entrées de grottes et dans les failles, et présentant une reproduction particulière puisque la fécondation est pseudo-interne et que le mâle incube les œufs pendant une semaine avant la libération des jeunes. L'objectif premier du projet est donc d'acquérir des données sur la structure génétique d'*Apogon imberbis* dans la baie de Marseille. Cette espèce présente-elle le même niveau de structure que les mysidacés ? Les patrons de structure sont-ils congruents entre les espèces ? Dans un second temps, les informations sur la structure génétique de cette espèce doivent permettre de mieux cerner les voies de colonisation des récifs du Prado. L'analyse des 200 poissons échantillonnés entre Carry-le-Rouet et La Ciotat (Figure 1), ainsi qu'une dizaine d'échantillons plus distants (Monaco), est réalisée à 6 loci microsatellite [4] et pour un fragment du gène mitochondrial. Les premiers résultats microsatellites montrent un certain niveau de structure entre les populations d'*A. imberbis* au nord et au sud de la baie de Marseille, l'analyse en clustering identifiant deux groupes génétiques distincts, ce qui semble cohérent avec la structure observée chez les Mysidacés. Les données mitochondriales ne révèlent aucune structure significative. Les niveaux de structure observés ne semblent pas assez élevés pour permettre de discuter les différentes hypothèses quant à la colonisation des récifs. Le génotypage des individus avec 2 marqueurs microsatellite supplémentaires est en cours et permettra sans doute d'affiner ces résultats.

Abstract
The most part of the stations included in the CoCoNET project sampling plane have been previously investigated by the multinet BIONESS from bottom (sampling depth max: 800m) to surface, in October 2000 and April-May 2001. In both periods, higher values of zooplankton abundances and biomass were detected along the Italian than Albanian coasts. Zooplankton was mostly constituted by holoplankton in both seasons; in spring, the contribution of meroplankton increased with higher values along Albanian coasts, mainly due to bivalve and polychaete larvae. *Clausocalanus furcatus* and *Temora stylifera* adults and copepodites accounted for the main part of autumnal copepod assemblage whereas *Paracalanus parvus* and *Acartia clausi* for the spring one. Shannon diversity index reached the peak (3.14) in autumn along the Albanian coast at 20-40m.

Keywords: Zooplankton , South Adriatic Sea, Biodiversity, Pelagic, Coastal waters

The Adriatic Sea is a semi-enclosed and elongated basin, stretching roughly SE to NW for 800km from the Straits of Otranto to the Gulf of Venice. Conversely to the Northern basin, the Central and Southern ones are characterized by general oligotrophic condition [1]. Zooplankton assemblage oscillations are strongly affected by hydrographical and hydrodynamic conditions of the basins, with characteristic temporal and spatial patterns [2], [3]. But little is known about zooplankton vertical structure, below 50m depth probably due to the sampling depth which has never included any deeper community. The main aim of the present study is to provide detailed information on the zooplankton spatial and temporal community structure sampled by the electronic multinet BIONESS in order to set up and better finalize the WP3 and WP11 task actions in the CoCoNET project. In the framework of INTERREG Italy-Albania project 2000-2001, a total of 111 and 142 zooplankton samples were collected in autumn and spring, respectively, in a network of stations shown in figure 1.

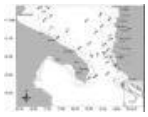

Fig. 1. Study area: sampling stations in autumn (circles) and spring (triangles)

Samples were taken by the electronic multinet BIONESS, equipped with ten 230μm mesh nets, a flowmeter for filtered water volume cubic meter estimates and a multiparameter probe system in order to measure physico-chemical factors. In October, temperature and salinity showed increasing surface trends from Italian (T = 19.8 °C, S ~ 37.6) to Albanian (T = 22°C, S ~ 38.7) coasts, determined by less salt water masses from Northern Adriatic Sea. In April, the horizontal salinity pattern exhibited two frontal systems along Italian and Albanian coasts, with a cyclonic gyre in the central part of the study area. On average, the Italian side was involved by colder and less salt waters. Zooplankton abundances and biomass were higher on the Italian (490.7±711.7ind.m^{-3}, 2.38±1.0mgm^{-3}; 358.4±711.7ind.m^{-3}, 8.28±13.5mgm^{-3} , in autumn and spring, respectively) than Albanian coasts (154.0±58.5 ind.m^{-3} , 2.38±0.96 mg m^{-3}; 118.4±43.0 ind.m^{-3}, 4.3±1.9 mg m^{-3}, in autumn and spring, respectively). In autumn, the peak abundance (6312.7ind.m^{-3}) was detected at 40-20m depth layer at the station 87 and the minimum (0.8 ind.m^{-3}) at 80-60m interval at the station 13, whereas the spring maximum (2728.0ind.m^{-3}) was recorded at 20-0m layer at the station 62 and the minimum (0.7ind.m^{-3}), at 300-200m at the station 52, respectively comparable to those measured in the same season by Miloslavic et al. [4]. Holoplankton accounted for the main part of the zooplankton in both seasons; in spring, meroplankton percentage increased with higher values along Albanian coasts (Fig. 2),

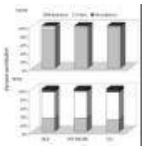

Fig. 2. Fall and spring percent contributions of holoplankton, meroplankton and other zooplanktonic forms to total abundances along Albanian, Italian coasts and in offshore waters.

mostly due to bivalve and polychaete larvae. Copepods constituted the dominant group in autumn (80.5%) and spring (58.9%), followed by chaetognaths (4.4%) and ostracods (3.8%), in fall, by salps (18.9%) and invertebrate larvae (4.1%), in spring. Autumnal copepod assemblage, constituted by 87 species (40 and 44 on the Italian and Albanian side), was dominated by few neritic species, such as *Clausocalanus furcatus* and *Temora stylifera* (adults and copepodites) accounting for about 26% of the total copepod abundances, which characterize the typical autumnal association in coastal, neritic and epipelagic waters of most of the Mediterranean regions [2]. Spring copepod population was represented by 68 species (43 and 56 on the Italian and Albanian sides, respectively). *Paracalanus parvus* and *Acartia clausi* dominated the spring assemblage in agreement with findings reported for this area ([2], [4]). Spatial and temporal diversity patterns of copepod assemblage oscillated within ranges slightly higher than that previously reported in this area [4], probably due to the greater sampling depth, with slightly higher values in autumn than in spring and along the Albanian (mean: 2.4 and 2.3, respectively in autumn and spring) than Italian coasts (2.0 and 2.2, respectively), with an absolute maximum of 3.1 at 40-20m layer at the station 42.

A PRIORI IDENTIFICATION OF CONSERVATION UNITS USING LARVAL DISPERSAL SIMULATIONS IN THE GULF OF LIONS (NW MED SEA)

Katell Guizien [1]*, Mokrane Belharet [2], Charlotte Moritz [2] and Jean-Marc Guarini [2]
[1] CNRS - LECOB - guizien@obs-banyuls.fr
[2] UPMC - LECOB

Abstract
Numerical simulations of larval dispersal from a sedentary marine species combined with a population dynamics model showed that some unprotected areas of the Gulf of Lions (Narbonne to Agde and the Camargue) are the best locations for maximizing biodiversity persistence within a reasonable no-take reserve size (10 to 20 kms, [1]). When larval transfer at the regional scale was accounted for in a metapopulation model, the resilience of soft-bottom species increased by a factor 5 and enabled a wide regional distribution of the species. Yet, the latter does not reflect the spatial structure of vulnerability imprinted by connectivity.

Keywords: Conservation, Circulation models, Larvae, Gulf of Lyon

The Strategic Plan for Biodiversity 2011-2020 formulated a conservation objective of 10 % of coastal and marine areas by 2020. Such an objective clearly imposes a scientific basis for designing new Marine Protected Areas (MPAs) to sustain biodiversity and ecosystem services inside and outside the protected area [2]. Most marine sedentary species exhibit a planktonic larval phase during which offspring are transported and dispersed more or less passively by the flow due to limited motility ability compared to horizontal flow speed [3]. Ocean modelling works well for hindcasting realistic coastal circulation [4] and provides a comprehensive description of current variability useful for improving dispersal distribution and population connectivity estimates. Without overlooking the ultimate role of species' interaction to shape local diversity, ensuring marine sedentary species' self-persistence within MPAs would require that the design accounts for a dispersion period during reproduction [5].

Methods
Dispersal's role in conservation of polychaete populations which dominate the Gulf of Lion's muddy sands communities [6] was studied considering generic passive species (neutrally buoyant, no locomotion behaviour) with most frequent PLDs from 3 to 5 weeks. Simulations of Lagrangian dispersal of larvae released in the center of thirty-two spawning patches spanning from the 10 to 30 m isobaths along the Gulf of Lions coastline were carried using the three-dimensional currents and turbulent kinetic energy computed at a resolution of 750 m x 750 m for two years (2004 and 2006, [1][7]).
Connectivity matrices containing (1) local retention rates in each patch and (2) transfer exchange between distant patches were build from these Lagrangian larval dispersal simulations for 20 spawning periods lasting 10 days. Redistribution of offspring after yearly reproduction was described by these connectivity matrices in a discrete metapopulation model. The metapopulation model was modified from [8] to account for carrying capacity limit. Demographic parameters in the metapopulation model (propagule production rate, recruitment success and survival rate) were taken spatially uniform, disregarding the variability in organic matter content between 10 and 30 m water depth along the Gulf of Lions [6]. Survival rate was only varied according to species life expectancy. Minimum recruitement success required to ensure species persistence at both local or regional scale was then seeked for and taken as a measure of species resilience.

Results and Discussion
The spatial structure of local larval retention along the Gulf of Lions imprinted a large variability in recruitment successes required for local persistence of species along the Gulf of Lions coastline. In particular, the highest recruitment success (100 %) would not be sufficient for species local persistence in the Eastern and Western part of the Gulf of Lions. Connectivity between distant patches reduced recruitment success required for regional species persistence by a factor five whatever the species life expectancy. This increase of species resilience by connectivity, together with the spatial structure of local retention, in the Gulf of Lions reflects the recurrence of alternate transport to the East and to the West at time scales ranging from day to weeks in the central part of the Gulf of Lions [3].
Minimum recruitment success required for species persistence (would it be local whatever the location, or regional with connectivity) decayed exponentially when species life expectancy increased. When connectivity was kept constant every year, the relative spatial distribution of abundances of a two-year living species mirrored the cumulated import rates in recruitment patches. Thus, the spatial distribution of a species do not inform on locations important for species regional persistence (sources). When connectivity was set stochastically every year, the relative spatial distribution of the same species were on average more uniform along the Gulf of Lions. Groups of populations which were essential for species regional persistence were identified in the central part of the Gulf of Lions after removing sequentially some sites from the metapopulation. It demonstrates connectivity alone can imprint a spatial structure to species vulnerability. Yet, any factors affecting species demographic parameters, even when it applies uniformly at the regional scale, can blur the spatial structure of vulnerability due to connectivity.
In summary, extension of protection measures should target the central part of the Gulf of Lions where hydrodynamics favor a high local retention and efficient larval exchange for species regional persistence. More generally, the present study stress that marine protection spatial planning should account for not only species biological traits but also hydrodynamics.

BIOSORPTION OF METHYLENE BLUE BY A BROWN ALGAE

Yeliz Ozudogru Cirik [1]*, Ilknur Ak [1] and Tolga Göksan [1]
[1] COMU Faculty of Marine Sciences and Technology
Terzioglu Campus Canakkale - yelizozudogru@hotmail.com

Abstract

Petalonia fascia, a brown alga, was used as a biosorbent to remove methylene blue (MB) from aqueous solutions. In this study, pH, contact time and initial metal concentration of MB were studied. Langmuir and Freundlich isotherm models were also investigated. The optimum pH value was 7 and the adsorption reached equilibrium at 50 min. According to Langmuir's model data, the maximum adsorption capacity (q_m) was 28.50 mgg^{-1}. Results showed that *Petalonia fascia* was effectively used as an alternative low cost biosorbent to remove MB from aqueous solutions. <\/div>

Keywords: Adsorption, Dardanelles, Algae

Introduction

Industrial wastes are one of the main sources of water pollution [1]. The wastes resulting from dye manufacturing are toxic and can cause serious environmental problems [2], so the removal of dyes from wastewater is important. Dyes are mainly used in textiles, plastics, tanneries, pharmaceuticals, leather, packed food, pulp and paper, paint and electroplating industries. Methylene blue (MB) is an organic and common type of colorant to dye cotton, wool, silk and many other materials. However, the use of MB can cause serious health problems [1,2,3]. In recent years, many low cost materials and techniques have been tested for the adsorption of dyes [4]. From these techniques, biosorption has been suggested as an alternative method due to its efficiency [5,6] and algae have been found to be a potential biosorbent [7]. *Petalonia fascia* (O.F.Müller) Kuntze is a brown marine macroalgae growing on stones and shells. In this study, removal of MB from aqueous solutions by *P. fascia* was studied.

Material and Methods

Petalonia fascia was collected from Canakkale Kepez area. The biomass was washed to remove some impurities and dried in an oven at 60°C until constant weight was reached. Dried biomass was ground and sieved. All the chemicals used in the study were analytical grade (Merck). For biosorption experiments, stock methylene blue (MB) solution (1000 mgL^{-1}) was used and five concentrations (5-10-20-50-100 mgL^{-1}) were prepared from stock solution using distilled water. As for pH and contact time trials, MB concentration was kept constant at 10 mgL^{-1}. The pH adjustments were performed by using 0.1 M HCl or NaOH. The MB concentrations in solutions were determined by spectrophotometer. 100 mg of each biosorbent was placed in a 50 mL Falcon tube and treated with 10 mL of MB solution. The Falcon tubes were shaken at 250 rpm at room temperature for 120 min, then samples were centrifuged at 3000 rpm and supernatants were measured by the spectrophotometer. The % removal of MB concentration was calculated according to Kousha et al. [4].

Results and Discussion

Effect of pH on the adsorption of MB

The % removals of MB in different pH values (3, 5, 7, 9) were given in Figure 1a. Accordingly, removal rates slightly increased between pH 3-9 (96.39% - 97.86%). These results were similar with the findings of the other studies [1, 3].

Effect of the contact time on the adsorption of MB

The amount of MB concentration q_t (mgg^{-1}) was calculated according to Cirik et al. [8]. Effect of time on biosorption by *P. fascia* was given in Figure 1b. Figure 1b shows that the maximum adsorption capacity was found to be 0.981 mgg^{-1} and adsorption reached equilibrium after 50 min.

Tab. 1. A comparison of Langmuir and Freundlich isotherm models for MB by *P. fascia*.

Langmuir isotherm			Freundlich isotherm		
q_m (mgg^{-1})	a_L	R_L^2	n_f	K_f (mgg^{-1})	R_F^2
28.50	0.185	0.715	1.106	4.316	0.981

Adsorption Isotherms

The equilibrium data were analyzed with Langmuir and Freundlich isotherms. The adsorbed amount in *P. fascia* showed positive correlation with the concentration of MB solution. The maximum adsorption capacity (q_m)was 28.50 mgg^{-1}. In this study, the Freundlich isotherm model (R^2= 0.981) showed a better fit than the Langmuir isotherm model (R^2= 0.715) (Table 1). In our study, *P. fascia* had a greater q_m value than the other adsorbents [3,9,10] and it could be used as an alternative low-cost material for MB adsorption.

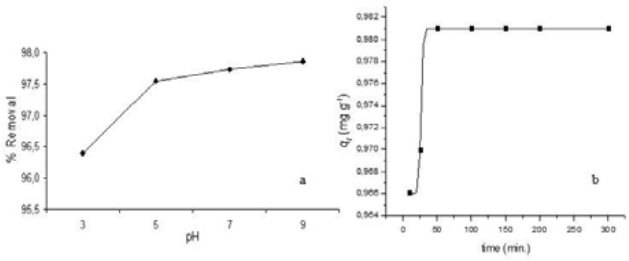

Fig. 1. Effect of pH (a) and contact time (b) on MB adsorption by *P. fascia.*

INTRODUCING CONNECTIVITY IN MARINE PROTECTED AREAS MODELLING, A REMAINING CHALLENGE

Serge Planes [1]*
[1] CNRS - USR3278 - CRIOBE Université de Perpignan - planes@univ-perp.fr

Abstract
The success of marine protected areas in conserving fishing resources and protecting marine biodiversity relies strongly on how well they meet their planned management goals. Among these goals, clearly the concept of enhancing the fecundity of commercially harvested populations with the expectation of increasing local recruitment and furthermore augmenting local fishery yields is on the top list. However, proving local improvement of fisheries, require knowledge of connectivity and capability of local self-recruitment. Very few works have been done regarding this question and we collected data that demonstrated some trends together with some recent work on progress.

Keywords: Fisheries, Conservation, Life cycles, Marine parks, Mediterranean Ridge

Introduction – Networks of no-take marine protected areas (MPAs) have been widely recommended for both biodiversity protection and managing fisheries and an increasing number of networks have been planned or implemented (1). However, to promote population persistence, protected areas must simultaneously be self-sustaining and linked to other protected areas to promote recovery from local extinctions. Most marine animals produce tiny larvae with pelagic durations ranging from days to months. Prevailing oceanographic currents may transport these propagules over large distances to form demographically "open" populations that are linked by larval dispersal. However the spatial scale over which marine populations are connected by larval dispersal continues to generate controversy, due to lack of empirical data on how far larvae travel.

State of knowledge – Numerous works have been dedicated to better understanding of connectivity, and here, we describe two case studies, base on new genetic approaches (e.i. parentage) that illustrate some recent finding and their implications into management priorities. The first piece of empirical data comes from a work on clownfish (*Amphiprion percula*) in tropical seas that demonstrated that approximately 40% of larvae settling in an island MPA (Papua New-Guniea) were derived from parents resident in the reserve (Figure 1) (2).

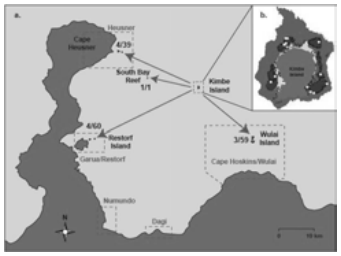

Fig. 1. Larval dispersal of orange clownfish from Kimbe Island to other designated marine reserves in western Kimbe Bay. *(A)* Proportion of recently settled juveniles at each of four locations that were progeny of Kimbe Island clownfish. Red boxes: proposed reserve boundaries (6). *(B)* Location of adult orange clownfish that produced larvae that successfully dispersed and settled on anemones away from Kimbe Island (white dots).

The work also located juveniles spawned by island residents that had dispersed as far as 35km to other proposed MPAs. These dispersers accounted for up to 10% of recruitment in the adjacent MPAs. These findings suggest that MPA networks can function to sustain resident populations both by local replenishment and through larval dispersal from other reserves. The second piece of work applied some genetic parentage analyses to measured larval dispersal from a single, managed spawning aggregation of squaretail coral grouper (*Plectropomus areolatus*) and determined its contribution to fisheries replenishment within five community up to 33 km from the aggregation (Manus Island, Papua New Guinea) (3). Within the community tenure area containing the aggregation, 17- 25% of juveniles were produced by the aggregation. In four adjacent tenure areas, 6- 17% of juveniles were from the aggregation. Larval dispersal kernels predict that 50% of larvae settled within 14 km of the aggregation (Figure 2). These results strongly suggest that both local and cooperative management actions can provide fisheries benefits to communities over small spatial scales.

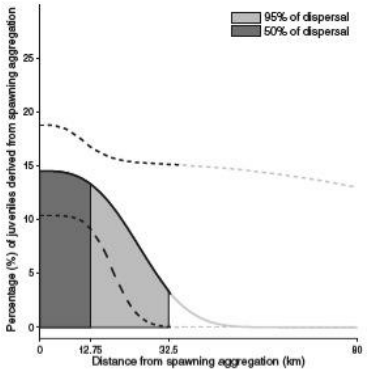

Fig. 2. Dispersal kernel based on the Ribbens function. The graph shows the relationship between proportion of juveniles from each of 66 sampled reefs that was assigned via parentage analysis to adults from the sampled spawning aggregation (*y*-axis) and reef distance from the aggregation (*x*-axis). Each data point corresponds to a reef. Solid black line: maximum likelihood fit of the function to these data, with vertical lines demarcating the distances within which 50% and 95% of successful dispersal is expected to occur. Dotted lines: minimum and maximum dispersal generated by parameters within the 90% confidence region of the best-fit parameters.

What next – None of these types of works were applied in the case of the Mediterranean Sea, however some genetic results are emphasizing local genetic differentiation suggesting some restriction in dispersal. Adding the fact that there is no reason that the retention processes will not operated in the case of the Mediterranean Sea, further work deployed in the Adriatic and the Black Sea within the COCONET project should provide insights for future plan for the Mediterranean Sea.

Abstract
Coupling Lagrangian simulation with genetic analyses, we investigated oceanographic and genetic connectivity among six locations of the Adriatic Sea for the European green crab (*Carcinus aestuarii*). Results reveal the role of circulation in determining the observed biogeographic pattern, which reflects a oceanographic subdivision of the Adriatic Sea into three sub-basins.

Keywords: North Adriatic Sea, Central Adriatic Sea, South Adriatic Sea, Biogeography, Circulation models

Introduction Identifying the spatiotemporal scale of connectivity among populations is crucial to understand the factors driving population dynamics, dispersal patterns and gene flow in marine species [1]. Coupled physical-biological models (CPBMs) are increasingly used to investigate mechanisms of larval dispersal and to contrast alternative hypotheses by simulation [2]. Integrating the outputs of CPBMs with population genetic models can provide new insights of verifying model predictions [3]. In this work, we investigated larval dispersal patterns of *Carcinus aestuarii* in the Adriatic Sea by coupling Lagrangian simulations (incorporating early-life-history traits) with a genetic marker analysis and comparing the connectivity matrices resulting from the two approaches. The aim of the work was to study the role of Adriatic Sea currents in determining retention and spillover patterns and their consequences on the genetic structure of the local European green crab populations.

Materials and methods
Genetic analyses were conducted on samples, collected in 2006, 2007 and 2008 from six sites along the Italian Adriatic coast (Marano, Venezia, Goro, Ravenna, Foggia, and Lecce), with an additional sample from the Ionian Sea (Taranto). Total genomic DNA was extracted using a salting-out protocol [4] and individuals (N=381) were genotyped at eleven polymorphic microsatellite loci. Population pairwise F_{ST} were determined with GENETIX, using 10000 permutations for all comparisons. Genetic divergence between populations was analyzed also using the AMOVA approach [5] to define groups of lagoon populations, which are geographically and genetically homogeneous and maximally differentiated from each other. Lagrangian simulations, limited to the Adriatic basin, were performed using daily average circulation fields produced by the Adriatic Forecasting System (AREG model [6]). 1000 larvae were released from each of the 6 sites according to a Gaussian distribution during the spawning season (every autumn, new and full moon [7]) in 2006, 2007 and 2008. Particles were tracked for 35 days (the average pelagic larval duration [7]) and their diel vertical migration was described as in [8]. For each site, connectivity with the others was calculated as the percentage of larvae whose final position fell within a 10-km-radius buffer from the destination site.

Results
Genetic data showed the existence of weak but significant genetic differentiation between samples (overall F_{ST} = 0.002; 95% CI = 0.000–0.004, p<0.01). Pairwise F_{ST} ranged from -0.001 to 0.005 and three values significant at the 5% level were found suggesting some genetic structure among samples (Table 1). Accordingly, AMOVA analysis identified 3 significantly differentiated groups of samples inside the Adriatic (F_{CT} = 0.002, p<0.01), the first including Marano, Venezia, Goro and Ravenna samples, the second including the Foggia sample and the third one represented by the Lecce and Taranto samples.

Table 2 shows the connectivity matrices obtained with the CPBM for the 3 years analyzed. In accordance with the results of the genetic analysis, Lagrangian simulations confirm the existence of a stronger connection among the four northern sites, which, in contrast, are isolated from the other two. The southernmost location (Lecce) is characterized by strong retention and occasional input from Foggia, confirming the observed genetic distance between these two populations.

Conclusion A coupled oceanographic-genetic analysis allowed us to derive potential dispersal patterns of *C. aestuarii* in the Adriatic Sea and, at the same time, to elucidate the genetic consequences of larval dispersal. Genetic analyses revealed the existence of weak but significant differentiation, apparently reflecting a oceanographic subdivision of the Adriatic Sea in three sub-basins. However, when dealing with such subtle differences the challenge is to discriminate between minor but real population structure and artifacts due to noise related to sampling errors [9].

AN ASSESSMENT OF HABITAT CONNECTIVITY AMONG CORALLIGENOUS AGGREGATIONS

E. Fakiris [1], E. Tzanatos [2]*, G. Papatheodorou [1], C. Koutsikopoulos [2] and G. Ferentinos [1]
[1] University of Patras, Department of Geology
[2] University of Patras, Department of Biology - tzanatos@upatras.gr

Abstract
Using data from the mapping of coralligène habitat in the Cyclades archipelago in 2007 we demonstrate a new simple methodology to assess habitat connectivity among the aggregations mapped. This methodology uses topological relations between individual coralligène aggregations to estimate the probability of an organism that leaves one (core) to encounter others. The results are discussed with regard to their management implications and potential method improvements.

Keywords: Mapping, Conservation, Aegean Sea

Introduction
In the Mediterranean, coralligène communities constitute the second most important "hot spot" for species diversity [1]. In order to protect coralligenous habitats, the formations significance as potential MPAs should be assessed. An important aspect for conserving marine metapopulations is the estimation of the probability to exchange individuals among patches of habitat (like coralligène), known as connectivity [2]. The aim of this work is to estimate connectivity among coralligène aggregations.

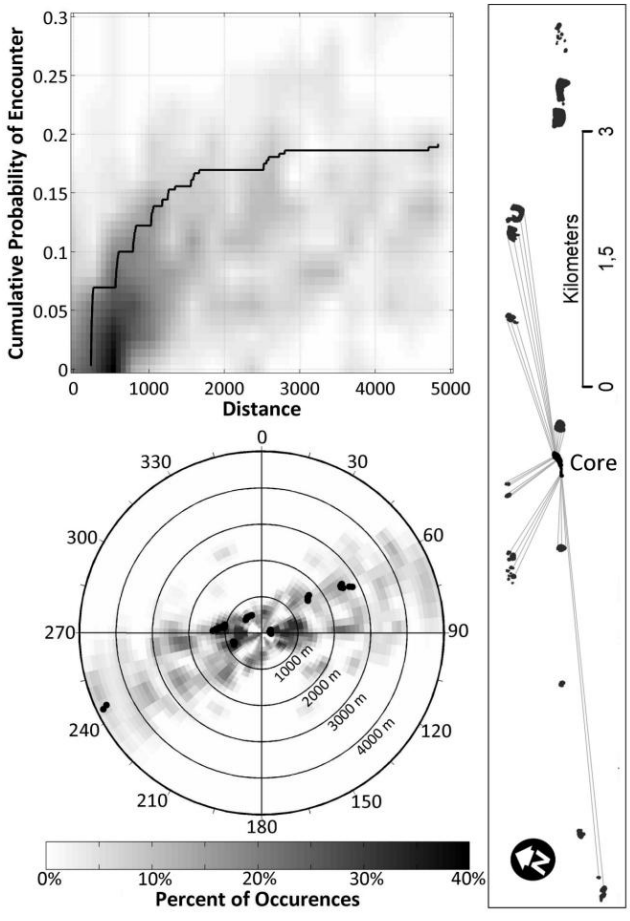

Fig. 1. Right: Spatial distribution example of coralligène aggregations surrounding a "core" one. Radial lines: directions of aggregations encountered. Top: Cumulative probability of encountering aggregations by movement distance. Bottom: Polar distribution of aggregations (black dots) surrounding the "core" (axes origin). Grey shaded areas: percentage of total number of co-occurring aggregations.

Methodology
A coralligène mapping survey was conducted in the Cyclades archipelagos (Aegean Sea) in 2007 on board the R/V FILIA using a dual frequency (100-500 kHz) Side Scan Sonar and a MKII Benthos ROV. Positional data were provided by GPS (accuracy: ~5-10m) and records mosaicking resulted to a pixel size of 1x1m. The outlines of evidently individual aggregations were manually digitized as Regions Of Interest and subjected to geometrical and acoustical analysis through the TargAn software [3]. Connectivity among the 48 aggregations mapped was defined as the total probability of an organism leaving a core aggregation to encounter others while moving across arbitrary directions and up to a maximum distance. It was estimated by summing the number of radial directions across which other aggregations were met, divided by 360^o.

Results
The evaluation led to the flagging of aggregations with high topological connectivity as potential MPAs. The most usual distances among neighbouring aggregations were estimated at 300-700m. High (20-30%) connectivity was found for less than 10% of the analyzed aggregations, corresponding to distances of 3.5-4.5 km covered. For any given aggregation, within one km of distance aggregations were encountered towards any direction, but for higher distances aggregations were mainly encountered in the orientations: 60-90^o and 220-270^o (Fig. 1). Considering the fact that in the areas mapped the isobaths had a general East-West (90^o-270^o) orientation, connectivity seems to be enhanced along that direction. This confirms the importance of current direction (which tends to follow the isobaths) for the distribution of coralligène formations, a finding very significant for the dispersal of planktonic organisms. Connectivity, as identified here, was correlated with depth and slope, indicating that the aggregations with high connectivity tended to be those at low depth ($r=-0.552$, $\alpha=0.05$, $p<0.001$) and high slope ($r=0.512$, $\alpha=0.05$, $p<0.01$).

Discussion
The quantification of individuals moving between patches of ocean seascapes remains a challenge [4]. Here we assessed connectivity as a product of the distance between aggregations and the cumulative arc covered by neighbouring aggregations, without referring to a specific organism. Hence, a promising next step would be to estimate the probability of model organisms moving among aggregations examining cases of active movement (e.g. fish migration) and passive diffusion (e.g. larval dispersal). Assessing connectivity in conjunction with the consideration of habitat quality through acoustical and geometrical analysis of sonar images [3] could lead to an improved tool for the evaluation of habitat suitability, using elements such as density, area and rugosity.

COMPARATIVE STUDY OF THE *OPHIODERMA LONGICAUDA* SPECIES COMPLEX: DIVERGENT PATTERNS OF CONNECTIVITY AND ADAPTATION BETWEEN BROODING AND BROADCASTING LINEAGES.

Alexandra Weber [1]* and Anne Chenuil [1]
[1] UMR 7263 IMBE Station Marine d'Endoume - alexandra.weber@imbe.fr

Abstract
We compared the connectivity patterns of the brittle star species complex *Ophioderma longicauda*. The broadcast spawning lineages L1-L5-L6 displayed low genetic structure, whereas the brooding lineages L2-L3-L4 displayed very high genetic structure, even at a geographic scale of 1 km. This study demonstrated the importance of life history traits such as dispersal ability in connectivity levels.

Keywords: Echinodermata, Life cycles, Genetics, North-Eastern Mediterranean, North-Western Mediterranean

Studying connectivity in marine invertebrates is essential for implementing conservation strategies and to answer evolutionary questions about local adaptation. Closely related sympatric species with divergent life history traits represent excellent model species to infer the role of life history traits in connectivity because they display the same ecology, thus the differences in connectivity should only rely on their dispersal characteristics. The brittle star species complex *Ophioderma longicauda* is composed of three brooding (L2-L3-L4) and three broadcast spawning (L1-L5-L6) lineages occurring differently in the Atlantic and the Mediterranean [1]. To improve the phylogeography which was until now based on 127 individuals, we sampled 702 new individuals across its distribution range.

As the species status of lineages was unclear, we compared the reproductive cycles of the sympatric brooding lineage L3 and the broadcasting lineage L1 during the month of May 2012. We found that the lineages L1 and L3 were truly separated species because in addition to displaying different reproductive strategies (brooding vs lecitotrophic larva), they also displayed pre-zygotic isolation as lineage L3 reproduced in May whereas lineage L1 reproduced in July.

Regarding the differential distribution of lineages L1 and L3 in the eastern basin, we wanted to test whether the brooding species L3 was better adapted to the environmental conditions of the eastern basin (higher temperatures and salinity, oligotrophy) than the species L1. We conducted a thermotolerance experiment in Marseille, with L1 individuals from Marseille and Crete, and L3 individuals from Crete. We tested 3 temperatures (17°C, 26°C and 30°C) during 3 months. We observed that the lineage L1 resisted well at 17°C and 26°C, but displayed high mortalities at 30°C, whereas the L3 individuals did not display any differences among the three tested temperatures, suggesting a higher tolerance to the elevated temperatures for the species L3, potentially explaining their high abundance in the eastern Mediterranean.

829 individuals were analyzed for two genetic markers; the COI (mitochondrial) and the intron i51 (nuclear). Lineage L1 displayed low genetic structure as the majority of Φ_{ST} comparisons were non-significant and the haplotype network showed that all dominant haplotypes were shared among the Atlantic and the three Mediterranean basins (Figure 1). Nevertheless, L1 displayed genetic structure as F_{ST} comparisons were all significant (values ranging between 0.019-0.125). The i51 data displayed also low genetic structure, as the majority of F_{ST} comparisons were non-significant. The low number of samples for L5 and L6 did not allow population comparisons, but the haplotype networks suggested that there was also little genetic structure for those two lineages.

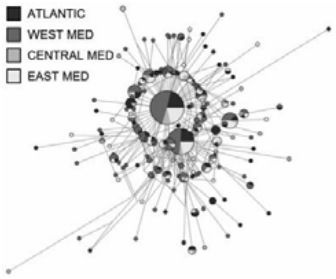

Fig. 1. COI haplotype network of *Ophioderma longicauda* broadcast spawning lineage L1, based on 509 individuals collected in the Atlantic and in the Mediterranean.

In contrast, the genetic structure observed for the lineages L2-L3-L4 was very high, since all F_{ST} and the majority of Φ_{ST} comparisons were significant (F_{ST} values ranging from 0.102 to 0.627) and the haplotype networks displayed high correlation with geography (Figure 2). The increased number of data suggested that lineages L3 and L4 were actually a single deeply structured mitochondrial lineage (which may be several species however) occurring in central and eastern Mediterranean. The i51 marker was monomorphic for all three lineages, indicating a loss of genetic diversity that occurred most probably at the apparition of brooding. Our data showed dramatic differences in genetic structure between closely related species differing almost only from their dispersal abilities, pointing out the strong influence of life history traits on connectivity.

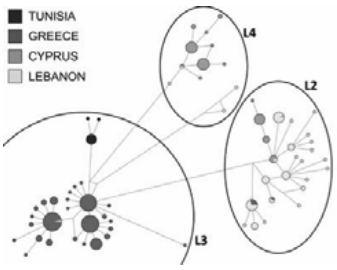

Fig. 2. COI haplotype network of *Ophioderma longicauda* brooding lineages L2-L3-L4, based on 298 individuals collected in central and eastern Mediterranean.

Abstract
Posidonia oceanica is a Mediterranean seagrass. Highly sensitive to environmental changes, it is used as an indicator of coastal water quality. Upper limits (0 to -15 m) of *P. oceanica* beds were mapped from historical (1920) and present aerial pictures. The comparison shows that upper limits are essentially stable (85 %) and regression (13 %) are mainly due to coastal artificialisation (65 %).

Keywords: Posidonia, North-Western Mediterranean, Coastal management, Global change

Introduction

Posidonia oceanica is a Mediterranean seagrass. The submarine meadows constituted by *P. oceanica* have important ecological (nursery, spawning, feeding, oxygenation) and economical roles (coast protection and sediment trapping). Highly sensitive to environmental changes, it is used as an indicator of coastal water quality [1]. Lots of papers mention local regressions of *P. oceanica* meadows in link with anthropogenic pressures [2,3] but a few ones consider large spatial and/or temporal scales [4-6].

Our comparative study considers the evolution of *P. oceanica* beds upper limits between 0 and -15 m at the scale of Provence Alpes Côte d'Azur, a French region. Knowing how slow *P. oceanica grows* (3-4 cm / year) [7], we expect majoritary stable limits. However, we expect high regressions around the most artificialized areas.

Materials and methods

The upper limits are mapped using historical (1922) and present (2012) aerial pictures. Spatial changes occurred for *P. oceanica* beds limits during these 90 years are analyzed in terms of concordance (stable upper limits), positive discordance (progression) or negative discordance (regression). Considering coastal development (harbour, buildings, aquaculture, pipes, etc) maps, we try to link the regressions with direct (physical holding) or indirect impact of development.

Results and discussion

The comparison shows that upper limits are essentially stable (85 % = 1021 ha) while regressions count for 13 % (6584 ha) and progression 1.1 % (83 ha). Recruitment (patches with concentric colonization) was clearly observed essentially next to Cavalaire-sur-mer. Regressions are mainly due to coastal artificialisation (48.7 % =21.4 % of direct impact + 27.3 % of indirect impact, see Figure 1) but 44 % remain with undetermined origins using pictures (several factors or the water body mass quality could be involved).

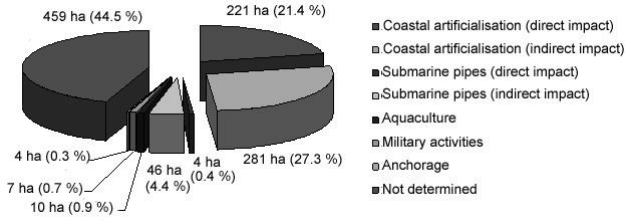

Fig. 1. Origins of *Posidonia oceanica* regression between 0 and – 15 m in Provence Alpes Côtes d'Azur region (France) between 1924 and 2012.

Anchorage causes 4.4 % of regression but is underestimated for three reasons. First, regressions around harbour areas are associated to harbour indirect impacts, anchorage impacts are hard to observe using aerial pictures and the bathymetric zone 0-15m is far less used for anchorage than 15-30 m where destruction can be locally massive.

The project is going on and we are now mapping the lower limits especially regression from dead matte observations. Until the summer the entire map will be available and used for the creation of "DONIA", a smartphone application helping boats to anchor outside of meadows. Reducing anchorage impacts on *P. oceanica* is the objective of this application based on 0-40 m maps and presently in development.

INTENSIVE FRUCTIFICATION OF *POSIDONIA OCEANICA* (L.) DEL. ON THE COAST OF MONTENEGRO (SOUTH-EAST ADRIATIC SEA)

Vesna Macic [1]*
[1] Institute of marine biology - vmacic@ibmk.org

Abstract
Meadows of seagrass *P. oceanica* were monitored on 3 locations in Montenegro (Adriatic Sea). Basic phenological parameters and meadow density are indicating good state of the meadows. On all locations fructification was observed in May 2012, but very intensive was on two locations: cape Platamuni (30%) and Jaz (28%) while on location cape Ratac fructification was only 4%. By reporting of these events we will contribute to the evaluation of the state of marine ecosystems and consequences induced by the climate change.

Keywords: Phanerogams, Monitoring, South Adriatic Sea, Global change

Introduction
Importance of *Posidonia oceanica* (L.) Del. is very well known and this seagrass is listed as a protected species under several international conventions, it is marked as priority habitat in EU Habitat Directive [1] and it is protected by national legislation in Montenegro [2]. Monitoring of *P. oceanica* meadows was performed in order to be able to apply adequate management measures (as a part of a larger marine biodiversity monitoring project financially supported by Public enterprise Morsko dobro).

Material and Methods
The present study was carried out at 3 locations in Montenegro (South East Adriatic Sea): Jaz (18°49' 21.57"E 42°16' 36.22"N), Cape Platamuni (18°46' 56.44"E 42°16' 03.11"N) and Cape Ratac (19°03' 59.41"E 42°07' 18.30"N). *P. oceanica* meadow observations and samplings were performed by SCUBA diving in May 2012. Meadow density was recorded in situ by counting the number of leaf shoots present inside a square frame (40 x 40 cm in 5 replicate measurements), at a depth of 10 m. The rate of fructification was estimated within each quadrate, from the percentage of the shoots that had fruits. In order to examine phenological parameters, 10 orthotropic shoots were collected at a depth of 10 m.

Results and Discussion
The density of surveyed meadows varied from 388 to 404 shoots/m^2. Mean values for measured phenological parameters for all 3 locations, were similar (Fig. 1.), with almost identical LAI values for cape Platamuni and cape Ratac, while LAI values for location Jaz were slightly lower. All this parameters are indicating good state of the meadows [3], but furthmore very interesting was the intensive fructification. On all 3 locations fructification was observed in May 2012, but furthermore, very intensive was on two locations: cape Platamuni (30%) and Jaz (28%) while on location cape Ratac fructification was only 4%. Length of inflorescence peduncle was also as LAI the smallest at location cape Ratac and simillar for other two locations (Fig. 1). The number of mature fruits per inflorescence on collected shoots was from 1 to 3 and their length were 2.54 ± 0,32cm. So intensive fructification was expected because of the previously reported intensive flowering observed in November 2011 on locations cape Platamuni and Jaz [4]. But, on the coast of Montenegro in last 15 years flowering and fructification of *P. oceanica* has been reported only sporadically. It is truth that observation efforts increased in several last years, but so intensive flowering and fructification, together with huge biomass of reproductive material floating and accumulated on the beaches in the middle June 2012. couldn't pass unobserved if happened in at least previous 15 years. Because of all this, intensive flowering on the end of 2011 and fructification in the 2012 on the coast of Montenegro could be considered as unike in last 15 years. The multiple observations of intensive and widespread flowering events in the Mediterranean Sea, especially after warm summers have provided evidence that flowering could be induced by high seawater temperature [5]. By reporting of these events we will contribute to the evaluation of the state of marine ecosystems and consequences induced probably by the climate change.

CYCLIC FLUCTUATIONS OF BLUE WHITING (*MICROMESISTIUS POUTASSOU*) OVER 1950- 2011 IN THE NW MEDITERRANEAN

Paloma Martín [1]*, Francesc Maynou [1], Laura Recasens [1] and Ana Sabatés [1]
[1] Institut de Ciències del Mar, ICM-CSIC. - paloma@icm.csic.es

Abstract
Landings of blue whiting fluctuated with a periodicity of 6 to 8 years in the NW Mediterranean over the period 1950 -2011, independently of fishing effort. We show that these fluctuations are correlated with the winter Western Mediterranean oscillation index (WeMOi), but not with other major climatic modes, such as the North Atlantic Oscillation (NAO). In addition, recruitment is shown to be correlated with winter SST. We conclude that years with cold winters enhance recruitment in blue whiting, which appears as a strong year class in the catches in the following year.

Keywords: Fisheries, Fishes, Recruitment, North-Western Mediterranean

Introduction
Blue whiting is one of the species with highest landings off the northern Catalan coast (between 750 and 2500 annual tones in the last decade). It is fished exclusively by bottom trawl. Cyclic fluctuations in blue whiting landings have been observed since the mid XX century. These fluctuations cannot be explained by changes in trawl fishing effort, which in the last 70 years has undergone marked changes. Thus, other alternatives, in addition to fishing effort, are explored to unveil the underlying conditions which would explain the landings variability i.e. the species link to environmental conditions and intrinsic response to changes in abundance.

Material and Methods
Data and data source: Blue whiting landings 1950-2011 (from literature 1950-1961 and official statistics 1962-2011); length frequency during high (1988-1989) and low (2009-2011) landings periods ([1], [2]); recruitment and SSB data (1994-2011; [2]). Installed engine power 1971-2011, an approximate measure of trawl fishing effort, was examined to compare with the evolution of landings (data source: official statistics). Since landings consist mainly of ≥1 year old individuals, which coincide with the age at-first-maturity, landings were taken as a proxy for SSB. The environmental variables considered were: SST (data source: L'Estartit meteorological station); winter (December to March) Western Mediterranean oscillation index (WeMOi; www.ub.es/gc/menu.htm); and winter NAO index (www.cru.uea.ac.uk/~timo/projpages/nao_update.htm). The linear trend was removed from SST and landings data series. Data were analyzed through lagged cross- correlation, with 0, 1 and 2 years lags, and wavelet periodogram ([3]).

Results
Blue whiting landings showed a number of cycles over 1950-2011 with different periodicities, of around 8 years at the beginning (1950-1980) and shorter at present, of around 6 years (Fig.1). The years of high volume of landings coincided with high fisheries production in the winter months, while in the periods of low landings, these were distributed all along the year. Furthermore, the number of age classes was higher in the years of high landings (up to 3-4 age classes); and, with low fisheries production, landings were concentrated on age classes 1 and 2. Significant correlations ($p<0.05$) were found for recruits (class 0) and winter (December- January) SST (negative), and between landings and winter WeMOi (positive) with time lags of 0 and 1 year.

Discussion
Positive WeMOi phases, which correspond to low sea surface temperature, strong northerly winds and low precipitation ([4],[5]) are linked to high landings, with time lags of 0 and 1 year. In addition, low temperatures during the winter months (December to January), at the beginning of the reproduction period, result in good recruitment. The environmental conditions during positive WeMOi phases enhance intense winter convection events north of the study area (Gulf of Lions; [6]). Fluctuations in the intensity of this phenomenon have been related to interannual variations in primary production ([7]). These environmental conditions are likely to enhance survival of the early life stages during the winter months resulting in one strong cohort, which will be exploited the following years.

THE EFFECT OF LIGHT INTENSITY ON THE INVASIVE ALGAE *CAULERPA RACEMOSA* IN FOURNI ISLAND, AEGEAN SEA, GREECE

Sarah Bartle [1], Scott Hayward [2] and Hazel Thornton [1]*

Abstract
Caulerpa racemosa is found predominantly in the Mediterranean Sea as an invasive algal species. Its presence has been seen to negatively impact native biodiversity and cause homogenisation of the environment. *C. racemosa* has a high degree of morphological plasticity and this study aimed to further current knowledge of the impact of light intensity on the growth morphology and abundance of this species around Fourni island complex, NE Aegean Sea.

Keywords: Aegean Sea, Alien species, Algae

Introduction
The green macroalgae, *Caulerpa racemosa* var. *cylindracea*, is an invasive species native to Australia that has rapidly spread across the Mediterranean since 1926 [1]. *C. racemosa* colonises a variety of substrata, and its dominating presence has been found to alter indigenous flora and fauna biodiversity [2]. It is thought that the algae's extensive morphological plasticity has contributed to its invasive success [1]. The aim of this study is to determine the effect of light intensity on the abundance and growth morphology of *C. racemosa* populations at littoral ecosystems of Fourni island complex, NE Aegean Sea, Greece to aid design of efficient control strategies for this invasive species.

Materials and methods
Data was collected in July and August 2012 at four different habitats types with differing light regimes, where *C. racemosa* was present. Each habitat was termed the following: shallow; data collected at 1m(±0.1m) depth, deep; data collected at 5m(±0.5m) depth, wall; data collected at 1m(±0.1m) depth from quadrats placed perpendicular to the sea floor on a rock wall, cave; data collected at 1m(±0.1m) depth inside a shallow open air cave-like habitat. Light intensity at each habitat type was recorded over a 72 hour period using an underwater datalogger. *C. racemosa* abundance was measured by photographic quadrat analysis using 30cmx30cm quadrats [5]. Percentage abundance was calculated per habitat using photo-Quad computer software [3]. Scrapings were collected at the deep and shallow habitat and morphological measurements concerning the stolen, fronds, ramuli and rhizomes were measured in the lab. One-way ANOVA was performed to analyse the abundance of *C. racemosa* data. Students T-test and Mann-Whitney U were performed to determine significance of variance between morphological measurements.

Results and discussion
Percentage abundance of *C. racemosa* was significantly different between habitats ($p<0.0001$) and greatest abundance was observed in the shallow habitat where light intensity was greater (Fig. 1), presumably due to increased photosynthetic rate. Morphological measurements demonstrated total stolen length ($p=0.04$, N=6); diameter of ramuli ($p=0.002$, N=157) and number of rhizomes ($p<0.005$, N=6) were significantly greater in the shallow habitat, creating a compact morphology allowing concentrated growth under favourable conditions. It is suggested that *C. racemosa* in low light intensity adopted an elongate growth form to increase surface area and escape unfavourable conditions. Stolen diameter and colouration of *C. racemosa* were not uniform across quadrat samples leading to the proposal that they are involved in reproductive stress strategies that occur under low light intensity [1].

Conclusion
This study confirmed that in the Aegean Sea, the invasive algae *C. racemosa* is sensitive to light intensity, and alters its growth, biomass production and morphology accordingly. The significant morphological differences followed the predictions made in light of the 'forager growth hypothesis' proposed by de Kroon and Knops [4]; where elongate morphs dominate low light habitats and compact morphs dominate high light habitats. Furthering the knowledge on this species may aid with accurately predicting the potential impacts an invasion may have in novel environments.

FUNCTIONAL DIVERSITY OF FEEDING MECHANISMS IN INFRALITTORAL COBBLE BEDS IN MALTESE HARBOURS AND NON-HARBOURS

Juan J. Bonello [1]*, Joseph A. Borg [1], Julian Evans [2] and Patrick J. Schembri [1]

Abstract
Cobble beds from Maltese harbour and non-harbour sites were characterised in terms of the functional diversity of feeding mechanisms. Given the nature of these two environments, differences in the overall feeding modalities of the respective species assemblages were expected; however, Maltese harbour and non-harbour sites were not very different in the frequency of the different categories of feeding traits. 'Suspension feeding' occurred in high frequencies in both harbours and non-harbours but harbours were distinguished from non-harbours by a higher frequency of 'deposit feeding'.

Keywords: Biodiversity, Coastal systems, Coastal waters, Infralittoral, Sicily Channel

Introduction
Functional characteristics are assumed to reflect adaptations to dominant environmental factors in a habitat. As a result, non-taxonomic aggregations of taxa into biological/ecological (i.e. behavioural, physiological and life history) categories might be an effective way of investigating mechanisms affecting species distributions and ecosystem function [1].

Cobble beds are intermediate between the epibiota of hard substrata and the infauna of soft sediments since they include elements from both habitats. Few studies have been made on Mediterranean cobble habitats and their ecology is practically unknown. In this study, the functional diversity of feeding mechanisms of cobble bed biotic assemblages from harbour and non-harbour sites was compared.

Material and Methods
Infralittoral cobble beds from four harbour sites (Tigné, Manoel Island A and B and Ta' Xbiex) and five non-harbour sites (Mgarr ix-Xini, Ix-Xatt l-Ahmar, Hondoq Bay, Wied ix-Xoqqa and Fomm ir-Rih Bay) were sampled. Four replicate 0.1m^2 core samples were collected from each bed. The cobble layer was removed from the corer and transported to the laboratory. The water depth and the thickness of each cobble bed were recorded.

In the laboratory, fauna retained by a 0.5-mm mesh were identified to the lowest possible taxon. Each species was assigned to one of six functional traits: 'suspension feeding' (using specialised entrapment mechanisms to capture suspended particles), 'deposit feeding' (feeding on particulate organic matter from the substratum), 'grazing' (feeding on sessile organisms attached to the substratum), 'macropredation' (capturing and killing non-microscopic organisms), 'deposit feeding/grazing', and 'multifunctional feeding' (having three or more different feeding mechanisms). This categorisation was used to generate a taxon X functional trait matrix. By multiplying trait category scores by species abundances and summing across all constituent species, a station X functional trait matrix was obtained. The matrix was normalised in terms of replicate percentage, where the total of each replicate was 100%. Statistical analyses were carried out using PRIMER v6 (Plymouth Routines In Multivariate Ecological Research, PRIMER-E Ltd.).

Results and Discussion
'Suspension feeding' was the dominant mechanism at all sites with three exceptions: Manoel Island B and Wied ix-Xoqqa where 'multifunctional feeding' was the dominant trait, and Manoel Island A, where 'deposit feeding' was dominant (Tab. 1). Harbours were distinguished from non-harbours by a higher frequency of 'deposit feeding', while non-harbours had a comparatively higher frequency of 'macropredation'.

Generally, Maltese harbour and non-harbour sites were not very different in the frequency distribution of functional traits, and 'suspension feeding' had similar frequencies in the two environments, against expectations [2]. Maltese harbours are characterised by higher turbidity levels than non-harbour sites [3], but the present results suggest that the degree of anthropogenic activity may not be high enough to significantly affect the frequency of the dominant feeding mode. Non-harbour sites differed from harbour sites by having a higher frequency of 'macropredation', mainly due to predatory polychaetes, such as species of Aphroditidae and Nephtyidae.

Tab. 1. Percentage mean (±SD) frequency of feeding traits within the nine sites.

	Suspension feeding	Deposit feeding	Grazing	Deposit feeding / Grazing	Macropredation	Multifunctional feeding
Ta' Xbiex	44.7 (5.3)	20.1 (5.6)	3.82 (2.7)	17.7 (6.6)	0.7 (0.8)	13.1 (5.2)
Tigné	45.1 (19.6)	16.0 (12.0)	5.5 (1.5)	20.3 (8.9)	1.4 (0.1)	11.7 (4.9)
Manoel Island B	16.3 (3.9)	33.4 (8.9)	8.6 (1.8)	3.8 (1.2)	1.0 (0.5)	36.8 (10.4)
Manoel Island A	31.9 (12.8)	37.9 (13.8)	4.3 (0.9)	5.4 (1.5)	1.0 (0.6)	19.6 (6.6)
Mġarr ix-Xini	47.4 (11.7)	9.5 (4.2)	8.0 (1.2)	18.6 (5.8)	2.1 (1.0)	14.3 (4.6)
Fomm ir-Riħ	41.5 (21.9)	20.8 (16.2)	4.5 (5.1)	17.8 (10.9)	3.1 (0.8)	12.2 (6.6)
Ħondoq	50.8 (20.4)	14.2 (9.8)	5.2 (3.8)	1.4 (0.6)	3.0 (2.9)	25.4 (12.9)
Xatt l-Aħmar	47.7 (29.2)	16.9 (11.7)	2.1(0.4)	3.4 (1.8)	15.9 (21.9)	14.1 (8.0)
Wied ix-Xoqqa	32.2 (7.4)	20.3 (3.7)	6.2 (3.0)	7.3 (3.2)	1.6 (1.1)	32.4 (5.5)

The structure of the cobble bed itself will impose limitations on the representation of certain functional groups. For instance, cobbles cannot support a high frequency of grazers, compared with other habitats such as algal forests, since cobbles only support turf species, therefore limiting opportunities for grazing.

No significant correlation between the abiotic factors measured (water depth, thickness of cobble layer and cobble granulometry) and the frequency of the different feeding mechanisms observed within harbours and non-harbours was found (BIO-ENV procedure). This suggests that factors other than those considered in the present study influence the distribution of traits.

Abstract
Current classification systems of marine habitats in the Mediterranean are based on homogeneous categories. However, the natural benthos is not homogeneous and there is a need to explicitly recognize and quantify the extent of habitat edges, the unique conditions and resources they offer, and the unique animal communities they support. We predicted that species seek edge habitats due to their predation mode or their ability to exploit more varied resources. We found a significant heterogeneity effect: edge habitats have higher fish abundance, species richness, and diversity than homogenous habitats. Species more abundant at edges have diets with significantly higher taxon diversity. Edge seeking species result in unique fish assemblages. Management of fish biodiversity should recognize the conservation value of edge habitats.

Keywords: Fish behaviour, Predation, Demersal, Coastal waters, North Adriatic Sea

Introduction
A large body of demersal-fish studies spanning the globe indicates that fish distribution is influenced primarily by habitat variability and differential habitat use. Habitat transitions and the resulting edge habitats may offer unique environments and resources that specifically attract edge seeking species and thus unique fish assemblages. Living on the edge of two habitats may result in reduced competition, give opportunity for specially adaptated predation modes, and offer more varied food resources. By matching life history and functional traits of species and guilds with the unique features at edges, one can predict which types of demersal fish are likely to prefer them. We predicted that (i) it is edge-seeking species that make fish assemblages at edges unique rather than random fish movement, (ii) species more abundant at edges are those that exploit a higher diversity of food taxa, and (iii) wait-chase predators seek out edges where they can await prey in the more complex of the source habitats followed by a burst chase into the more open adjacent source habitats. We further made predictions about other functional groups: cryptobenthic and ambush predators seek homogeneous habitats while highly mobile predators and planctivores not closely associated with the benthos display no preference.

Methods
Our sampling method was lure-assisted visual-census (1). We performed a total of 13806 random field transects at 135 outer coast study sites in Croatia, between May and October of each year from 2009 – 2012, spanning the N-S and E-W range of the Croatian Coast including 18 islands and five MPAs. We tested hypotheses on the effect of habitat use on resouce use with published data (2). The null hypothesis that the mean of a response variable (abundance of each individual species, and total abundance, total diversity, total richness) was the same in homogeneous and heterogeneous habitats was tested with a Wilcoxon signed-rank test. The null hypothesis that the mean number of unique food taxa per species is the same in homogeneous and heterogeneous habitats was tested with one-factor ANOVAs.

Results
A total of 158000 individual fish were detected and identified. They belonged to 82 identified species and 16 less specific taxonomic levels. Each observed fish was matched with one of the five homogeneous or their derived 40 heterogeneous habitat types. Our data demonstrate high habitat heterogeneity. Of all random transects, 30% intersected habitat edges. Highest values for abundance, richness, and diversity were never recorded in source but always in derived heterogeneous habitat. Edges associated with rock, sand, and *Posidonia* seagrass habitats contained significantly higher fish abundance, species richness, and diversity than homogenous habitats and the edge effect is not based on the random movements of fish originating from multiple adjacent source habitats. Significantly higher numbers of ambush predator species (14 > 1) and cryptobenthic taxa (24 > 4) were more abundant in homogeneous habitats than in heterogeneous habitats. Significantly higher numbers of wait-chase predator species (10 > 1) were more abundant in heterogeneous habitats (edges) than homogeneous habitats. We foound that 63% of the edge seeking species use the wait-chase predation mode. Species that are significantly and overall more abundant in heterogeneous habitats feed on significantly higher numbers of unique food taxa than taxa significantly and overall more abundant in homogeneous habitats. Efforts to understand and conserve the marine environment would benefit from a program of explicit recognition and quantification of habitat edges and their impacts on the faunal community (3).

LENGTH-WEIGHT RELATIONSHIPS OF MESOPELAGIC FISHES IN THE NORTH-WESTERN MEDITERRANEAN

M. Pilar Olivar [1]*, Balbina Molí [1] and Ainhoa Bernal [1]
[1] Institut de Ciències del Mar (CSIC) - polivar@icm.csic.es

Abstract
In the present study we analysed the length-weight relationships of the most common and abundant mesopelagic fishes of the northwestern Mediterranean: 11 Myctophidae, 1 Gonostomatidae, 1 Phosichthyidae and 1 Sternoptichydae. Data of fish length and weight were fitted to a power function, and estimations of the fitted equation parameters were given as background information for subsequent studies on body condition. The slope estimation was taken as indicative of the relative increase in weight in relation to growth in length. The small fish Cyclothone braueri has a lower allometric coefficient with significant negative value, than that corresponding to larger species such as myctophids (some of them showing positive allometric growth).

Keywords: Fishes, Growth, North-Western Mediterranean

The largest biomasses of the open ocean have been attributed to meso and bathypelagic fishes that occur together with small crustaceans, cephalopods and a few other invertebrates. The most common and abundant mesopelagic fishes in the western Mediterranean are lanternfish of the family Myctophidae and bristlemouth of family Gonostomatidae (1, 2). The diversity of these groups of species in the Mediterranean Sea is lower than in open oceans and the maximum sizes tend to be smaller than those reported for the same species in the Atlantic. They constitute a key component of the food web in oceanic waters, being commonly cited as prey for larger marine inhabitants (e. g. commercial pelagic fishes, cetaceans, marine birds). In the present study the body length- weight relationships of the most common and frequent mesopelagic fishes in the north-western Mediterranean were analysed. Information regarding to allometry in fish has been indicated as an important issue to approach body condition (3, 4); however related data are not always complete and lacks for many species, particularly for those inhabiting the water column, which are less frequently sampled in routine surveys. Information related to this issue has been already presented for some meso and bathypelagic species of the central Mediterranean (5). Mesopelagic fishes studied here were collected during winter (December 2009) and summer (July 2010) off Mallorca Island by means of different midwater trawls towed in the epipelagic layers (up to 80 m), the 400 m deep scattering layer (DSL) and benthic boundary layer (50 m above the bottom, BBL). After collection and identification on board, fishes were preserved in formalin 5%. Measures of fish length and weight were taken in the laboratory (length to the nearest mm and weight to the nearest mg). Weight and length data were fitted to a potential equation $W=aSL^b$, where W is the weight in mg, SL is the standard length in mm, *a* is the intercept and *b* the allometric coefficient. Fitting was performed after log transformation of data, and results are given as 95% confidence intervals (95%CI). Values of *b* significantly different from 3 indicated that growth in weight is relatively faster than that in length (positive allometry $b>3$) or lower (negative allometry $b<3$). Mathematically the values of the intercept, *a*, indicated the expected weight at SL 1 mm. As generally found in many other fish species, the obtained length-weight relationships for mesopelagic fishes in the present study as well, as in those from the central Mediterranean (5), fit a potential function with a coefficient of nearly 3 and correlation coefficients always close to 1 (Table 1). Significantly positive allometric relationships were observed for several myctophid species, i.e. *Benthosema glaciale, Ceratoscopelus maderensis, Diaphus holti, Lampanyctus crocodilus, L. pusillus, Lobianchia dofleini, Notoscopelus elongatus* and *Symbolophorus veranyi*. Significant negative allometry was only observed for the gonostomatid *Cyclothone braueri*, indicating a relatively slower growth in weight than in length across development. Therefore, this species/*C. braueri* tends to have a pronounced slender body shape in contrast to those species with positive allometry, such as myctophids. Differences in body shape could be related to the different behaviour of myctophids, characterized by performing extensive diel migrations from near the bottom to the epipelagic layers, whereas *Cyclothone braueri*, do not perform such migrations (1,2). Robust bodies with higher muscular and osteological development must contribute in the vertical migration, while the more attenuated shape of *Cyclothone braueri* reflects a less energetic demanding behaviour.

Tab. 1. Parameters of the allometric relationship between body length (SL mm) and weight (mg) for the most common and abundant mesopelagic fishes occurring in the upper 400 m of the water column in the western Mediterranean. a: intercept, b: slope (allometric coefficient), 95%CI: 95% confidence interval, n: number of individuals measured, r: correlation coefficient. Significant positive or negative allometry is marked in bold, black and grey, respectively.

MATRIX MODEL OF GREEN ABALONE *HALIOTIS FULGENS*: IMPLICATION FOR CONSERVATION

Marisa Rossetto [1]* and Giulio A. De Leo [2]
[1] Politecnico di Milano - marisa.rossetto@nemo.unipr.it
[2] Hopkins Marine Station of Stanford University

Abstract
Demographic models are essential tools to explore alternative conservation and management strategies for exploited populations. We developed a size-based model for the marine mollusk green abalone *H. fulgens* that incorporates quantitative information on its life-history traits, including size-dependent fecundity and mortality. Analysis of the matrix model suggests that green abalone populations have very slow population growth rates and long expected recovery time (~15 years). Elasticity analysis indicates that protecting large, highly fecund individuals can be among the most effective ways to recover depleted populations.

Keywords: North-Central Mediterranean, Models, Mollusca, Conservation

Introduction Population models incorporating quantitative information on vital rates are powerful tools for analyzing the dynamic of age or size-structure populations and can contribute to species' protection by orienting conservation effort on the life stages expected to have the greatest influence on population growth [1]. Abalones (*Haliotis* spp.) are long-lived, slow-growing marine mollusks whose natural populations have undergone dramatic declines all over the world. Overfishing, ocean warming, and the spread of disease represent the major threats for abalone populations [2]. Native populations of green abalone *H. fulgens* have collapsed all along the California peninsula since the 1970s [4], and in USA, green abalone has been identified as 'species of concern' in 2004. Size-based matrix model are considered particularly appropriate to describe the dynamic of *Haliotis* spp., as many demographic traits of abalone are known to scale with body size [5]. Elasticity analyses of such models can guide management and conservation of endangered abalone populations by revealing the relative importance of the different life stages for population rate of increase.

Methods We developed a matrix model for green abalone consisting of ten size classes of 25 mm width, from 0 to 250 mm SL, of the form $\mathbf{n}(t+1)=\mathbf{A}\mathbf{n}(t)$, with $\mathbf{n}(t)$ being the vector of population densities in each stage at time t and $\mathbf{A}$ being the population projection matrix. The model incorporated size-dependent mortality [6], size-dependent fertilities and sexual maturation [7] and plasticity in body growth. We used the projection matrix $\mathbf{A}$ to analytically compute the maximum finite rate of population increase λ, the theoretical doubling time T, the stable stage distribution w and the reproductive value v. Elasticity analysis, indicative of the relative influence of each matrix elements on population rate of increase λ, was computed as in [9].

Results Computation on the green abalone matrix model provided a maximum finite rate of population increase λ equal to 1.05. The value of λ suggests that this species should recovery slowly, at a yearly rate of 5%. This corresponds to a theoretical doubling time (i.e. number of years for the population to double its initial density) of 15 years. The first size class, corresponding to individuals of one year old, largely dominated the stable stage distribution w representing more that the 90% of the stage distribution. Reproductive value v increased exponentially with size. The four largest size classes, between 175 and 250 mm SL, contribute altogether to the 80% of the reproductive value. The elasticity analysis indicates that the larger size class contributes the most to the population growth (Fig 1).

Discussion The low value of population rate of increase (λ =1.05) obtained for *H. fulgens* is reasonable given that abalones are long-living and slow growing animals. Population recovery for green this species is expected to occur on a long time scale, more than one decade. Similar results have been obtained for other abalone species, such as H. *corrugata* in California [10]. Matrix analysis shows that large abalones (above 175 mm SL) in the final stages of the stable population have more than three quarters of the reproductive potential, highlighting the importance of big, mature individuals to the overall egg production. Elasticity analysis indicates that the largest individuals have the greatest influence on the population growth rate, suggesting that conservation efforts aimed at protecting the large abalones may be successful in promoting population recovery. Marine reserves, such as those established in the region [11], are known to successfully protect larger individuals and can be hence a desirable option to be implemented to conserve endangered abalone populations.

Abstract
In order to develop a bioenergetic model and obtain the adequate data on energy allocation to growth and reproduction, samples of two small pelagic fishes (anchovy, *Engraulis encrasicolus* and sardine, *Sardina pilchardus*) were collected off the Catalan Sea to study their annual cycle in the context of Dynamic Energy Budget theory. Seasonal lipid content (% of wet weight, W_W) was determined in both species as well as the energy density (E_D, kJ g^{-1} W_W) of individuals from summer and winter by direct calorimetry. Sardine has higher lipid content than anchovy and both species present their maximum in spring. The E_D values obtained are 4,48 - 4,61 kJ·g^{-1} W_W for anchovy and 4,74 - 4,97 kJ·g^{-1} W_W for sardine. The present study provides for the first time energetic data from direct analysis in this region.

Keywords: Pelagic, Fishes, Models, North-Western Mediterranean

Introduction
Bioenergetic models can yield important information on the life cycle dynamics of the involved species. For *E. encrasicolus*, different models have already been implemented to distinct populations, e.g., Black Sea [1], Bay of Biscay [2] and northern Aegean Sea [3]. Due to the fact that the interaction between growth and reproduction is one of the most important trade-offs in fish, our aim is to obtain the required data to develop bioenergetics models for anchovy, *E. encrasicolus* and sardine, *S. pilchardus* detailing the energy allocation to growth and reproduction during an annual cycle. Here we present the first analysis to reach the data to implement these models: seasonal lipid content of muscle and energy density of individuals in the Catalan Sea.

Material and methods
Individuals of anchovy (total length (TL): 6,4 to 16,2 cm) and sardine (TL: 8,8 to 19,6 cm) were collected monthly off the Catalan Sea, from April 2012 to March 2013. For this study individuals of both sexes and different TL classes were selected and grouped seasonally. Fulton's condition factor (CF= W_W /TL^3) was determined on each fish and averaged in each group. Total lipid of both species was extracted from dorsal muscle according to the Folch method [4]. Finally, the lipids were weighed and expressed as % of W_W. The energy content was measured on individual fishes from summer (anchovy spawning season) and winter (sardine spawning season) by direct calorimetry by means of a Parr 6725 Semimicro Oxygen Bomb Calorimeter. Individuals were oven-dried at 70ºC to constant mass (24 to 48h). After determining their dry weight, they were mixed to obtain a homogenized powder of each individual. The E_D was determined in two samples (150 to 200 mg) from each individual.

Results and Discussion
The average of lipid content was calculated (fig. 1.) and, as expected, the values were higher in sardine, being more obvious in spring, when the maximum lipid content was recorded in both species (Sardine*:* 2,035% and anchovy 0,98%). Seasonal variation was also higher in sardine as well as the variance between individuals. Sardine fat content varies widely with season [5], as anchovy feeds during their spawning season [6], fact that could explain the fairly seasonal variation of lipid content in this species. According to the CF (fig. 1.), the maximum of lipid content in spring could be explained by an increase of feeding activity. More studies, as fat composition, are needed to better understand the seasonal changes in lipid content and their relationship with the energy reserves of the animal.
The E_D doesn't differ between summer and winter, nor between anchovy and sardine, even it seems to be fairly higher in sardine (tab. 1.). The values in E_D observed for anchovy (4,48 - 4,61 kJ·g^{-1} W_W) are similar to those observed in the Adriatic Sea [7] (3,34 – 5,6 kJ·g^{-1} W_W), whereas they are lower than the values of the anchovy in the Bay of Biscay [6] (6,04 – 8,44 kJ·g^{-1} W_W). More calorimetric determinations are needed, mainly at the begining of the spawning seasons (spring for anchovy and autumn for sardine) in order to infer the possible energy storage before the peak of spawning. Further calorimetric determinations on gonad and liver will provide us with adequate data to infer energy allocation to growth and reproduction during the annual cycle.

ENERGY STRATEGIES OF *CALANUS* POPULATIONS FROM THE BLACK, MARMARA AND IONIAN SEAS

Leonid Svetlichny [1]* and Elena Hubareva [1]
[1] Institute of Biology of the Southern Seas - lsvetlichny@mail.ru

Abstract
Body size, oil sac volume, molting patterns and respiration rate were studied in copepods *Calanus euxinus* inhabiting the Black Sea and penetrating into the Marmara Sea, and mother species *Calanus helgolandicus* living in the Ionian Sea. Our laboratory and field data suggested more effective energy strategy of *C. euxinus* in the Black Sea due to metabolic effects of low salinity and temperature and ontogenetic phase shifts of metabolic rates in preadults and adults experienced recurrent hypoxia during diel vertical migrations.

Keywords: Copepoda, Physiology, Black Sea, Marmara Sea, Ionian Sea

In relatively warm, high-saline (38 psu) and oxygenated waters of the Mediterranean and Marmara Seas *Calanus* do not undertake diel vertical migrations [1, 2] whilst in cold brackish Black Sea late copepodite stages of *C. euxinus* migrate daily to deep oxygen minimum zone (OMZ) with constant temperature of 6–8°C [5] which results in nearly 8-fold decrease in their total metabolism [3]. Nevertheless, late copepodite stages of *C. euxinus* from the mesotrophic regions of the Black Sea are larger than those of the Mediterranean *C. helgolandicus* and can accumulate as high lipid reserves as *C .finmarchicus* from high-productive seas of the North Atlantic Ocean [4]. To explain this phenomenon, we conducted comparative studies of ontogenetic changes in body size, oil sac volume, molting patterns and respiration rate of *C. euxinus* collected in the Black Sea (BS), Marmara Sea (MS) and Ionian (IS) Sea, and also of the BS *C. euxinus* reared in the laboratory in the oxygenated water at high temperature (18°C) and salinity (38 psu). Morphological and physiological parameters were determined in *Calanus* individuals from all studied regions using the same methods described in [4]. Values are means ± SD.

It was shown that:

1) Diameter of eggs and body length of nauplii and earlier copepodites in *C. euxinus* and *C. helgolandicus* did not differ significantly. However, starting from copepodite stage IV, the divergence of prosome length began to increase in the individuals from different *Calanus* populations and resulted in 25 % increase of prosome length in females from the BS in comparison with the MS and IS.

2) Oil sac volume in *C. euxinus* preadults and adults from the BS was 6-8-fold higher than that in the same developmental stages from the MS and IS.

3) Intermolts dominated among copepodite stage V in the MS and IS whilst in the BS postmolts prevailed all year round indicating an increase in duration of this molting phase.

4) At the same experimental temperature (20°C) both total and basal metabolism in *C. euxinus* females collected in deep regions of the BS were 1.5-2 times lower than those in *C. euxinus* from warm (15°C), high-saline (38 psu) and oxygenated water of the MS, in *C. helgolandicus* from the IS and in the BS *C. euxinus* females reared in the laboratory from eggs at 18°C and 38 psu (Fig 1 A). Such metabolic shift was observed only in *Calanus* late development stages (Fig 1 B).

We hypothesize that due to the Black Sea environmental conditions (low salinity and temperature), *C. euxinus* can reduce energy losses and increase the duration of all developmental stages, whereas long-term recurrent hypoxia facilitates additional decrease in basal metabolic level and an increase in duration and efficiency of lipid accumulation in late copepodite stages migrating to OMZ.

A MECHANISTIC CARBON INTAKE MODEL OF*OIKOPLEURA DIOICA*.

Maxime Vaugeois [1]*, François Carlotti [1] and Frédéric Diaz [1]
[1] Aix Marseille Université, CNRS/INSU, IRD, Mediterranean Institute of Oceanography (MIO), UM 110, 13288 Marseille ; Université de Toulon, CNRS/INSU, IRD, Mediterranean Institute of Oceanography (MIO), UM 110, 83957 La Garde - maxime.vaugeois@univ-amu.fr

Abstract
A mechanistic physiological model of the appendicularian *Oïkopleura dioïca* representing three feeding processes (filtration, ingestion and assimilation) has been built to better understand the ecology of these organisms. Specifically, the model is used to investigate the buffer abilities of the house and the gut. The mathematical formulations of the three feeding processes are based on laboratory experiment observations from the literature. The simulations evidence that environmental food depletion is not immediately experienced by the organism, but it occurs after a lag time due to the house and gut buffer abilities. The duration of those lag times depends on the environmental food concentration before the depletion period.

Keywords: Models, Zooplankton , Tunicata, North-Western Mediterranean

In pelagic ecosystems, appendicularians are thought to play a significant role both on the carbon cycle and on the ecosystem structuration [1]. Two features lead to such statement: first, appendicularians are circumglobal distributed organisms and among the dominant mesozooplankton group in many marine ecosystems [2] ; secondly, their specific biology allows them to occupy a unique ecological niche in the ecosystem food web. This specific biology is linked to their feeding process. Actually, appendicularians live inside a self-produced structure called "the house" within which the environmental particles are trapped by the filtration process [3]. This structure enables appendicularians to feed on a large prey size spectrum (from 0.2 to 30 µm [4]) but it often needs to be replaced (up to 27 houses per day at 23 °C [5]). This leads to the production of a large amount of detritic organic matter, besides an already high fecal pellet production (more than 700 per day [6]).

The model reproduces the physiological dynamics of the feeding processes of *Oikopleura dioica*, a main species in the north-western Mediterranean Sea. Other models of this organism exist but the model constructed here has many innovative aspects. It takes into account the house formation dynamics, the food storage capacity of the house and the gut throughput dynamics. Consequently, it is able to simulate the house and gut content dynamics (figure 1). At constant environmental food concentration and temperature, the house carbon content dynamic exhibits oscillations related to the house renewal process. During each cycle, the carbon content of the house rapidly increases up to a value that depends on the environmental food concentration. The fecal pellets production process also leads to observe an oscillating dynamic for the gut carbon content, with a frequency which depends on the environmental food concentration.

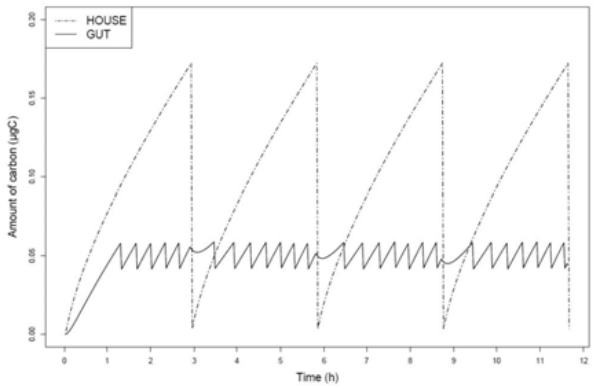

Fig. 1. House (dashed line) and gut (continous line) content dynamic during four house cycle with fixed environmental food concentration (100 µg of carbon per liter) and body weight of the organism (1 µg of carbon).

Different simulations with fluctuating food concentrations were run to highlight the food storage abilities of the house and the gut. The house and the gut allow appendicularians to survive short-term low food conditions, as their content do not immediatly drop to zero when a food depletion occurs. Thus, houses constitute a kind of external storage of non-assimilated food that can be seen as a substitute of a low level reserve inside the organism. When the house content is low, the gut content of the organism starts to be impacted as the assimilation process in consequence. We can estimate that the environmental food depletion is experienced by the organism only when its energy intake flux (here assimilation flux) is impacted. Thus, appendicularians experience environmental food depletion after a lag time duration that mainly depends on the environmental food concentration experienced before the food depletion. For one organism which experienced a food concentration condition of 100 µg C/l before the food depletion, this lag time is at least 30 minutes and can reach more than 2 hours, depending on when the food depletion occurs along the house lifespan.

In pelagic plankton models, the mesozooplankton group is most of time representative of copepods because they are the most abundant mesozooplankton organisms found along the year. Appendicularians are often second or third in terms of abundance [2] and are then not taken into account, whereas they present a different biology and ecology from the copepods. This individual-based model will be used, in future work, to constrain the processes and parameters of an appendicularian population module in a coupled biogeochemical-hydrodynamic model of the north-western Mediterranean Sea. It will allow the study of the appendicularian impact on the carbon export, and also on the structuration of the plankton community.

JELLYFISH CONNECTIONS IN THE WESTERN MEDITERRANEAN SEA

L. Berline [1]*, M. Lilley [1], F. Lombard [1], B. Zakardjian [2] and N. Daly Yahia [3]
[1] Laboratoire d'Océanographie de Villefranche - berline@obs-vlfr.fr

[3] Faculté des Sciences de Bizerte

Abstract

In the Mediterranean Sea, blooms of stinging jellyfish *Pelagia noctiluca* have occurred more frequently since 2000 (Bernard et al 2011), but their origins remain unclear. For this long-lived species, one persistent difficulty in understanding these blooms is to identify whether they are caused by local or regional processes. Here we try to understand the role of oceanic transport in redistributing existing jellyfish populations at regional and basin scale, using lagrangian particle tracking experiments mimicking jellyfish trajectories using high and medium resolution model velocity outputs.

Keywords: Cnidaria, North-Western Mediterranean, Models, Vertical migration

In the Ligurian Sea, presence of *P, noctiluca* onshore is erratic (Bernard et al 2011) while observations show a rather constant abundance offshore over a year (Ferraris et al 2012). Particle tracking simulation show that onshore presence is strongly influenced by coastline geometry, both upstream and downstream. During the year, onshore presence and therefore the probability of stranding is a function of the distance to the coast of the prominent alongshore Northern Current and of wind bursts to a lesser extent (Fig 1 and Berline et al 2013).

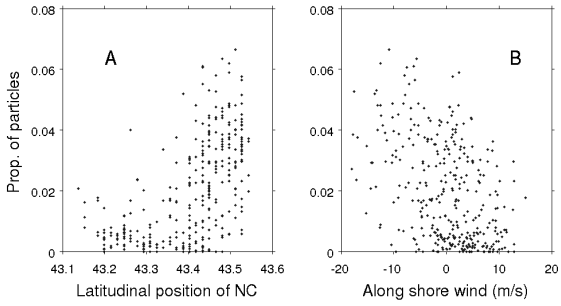

Fig. 1. Cross-shore connectivity for year 2001 as a function of (A) Northern Current latitude at longitude 7.23°E and (B) alongshore wind at location 7.5°E, 43.5°N (positive alongshore wind is blowing from the SW).

During bloom periods ('Pelagia years' sensu Goy et al 1989), reports suggest a widespread occurrence of *P. noctiluca* at a large spatial scale. Simulations including the Gulf of Lion suggest that the observed onshore distribution results from interactions between the Northern current and the diel migration behaviour (Fig. 2). The shelf of the Gulf of Lions is mostly avoided by *P. noctliuca* while Ligurian and Catalan coast are directly impacted.

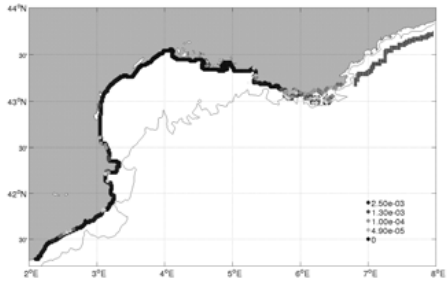

Fig. 2. Average abundance of jellyfish particle in the Littoral Zone simulated for July-August 2007, expressed as a ratio of total seeded particles.

At the scale of the Western Mediterranean basin, simulations allow quantifying transport time and mapping the most probable stranding zones. Coupled with progress in our knowledge of the biology of *P. noctiluca*, these results provide the basis for a better understanding of spatial and temporal fluctuations of jellyfish.

DISTRIBUTION OF GELATINOUS MACROZOOPLANKTON IN THE BLACK SEA OF TURKEY (SINOP REGION)

Zekiye Birinci Ozdemir [1]*, Yakup Erdem [1] and Levent Bat [1]
[1] Sinop University, Fisheries Faculty - zekiyebirinci@hotmail.com

Abstract
The distribution, abundance and biomass of gelatinous macrozooplankton (*Aurelia aurita, Mnemiopsis leidyi, Beroe ovata* and *Pleubrachia pileus*) were determined between January 2008 and December 2008 in the southern Black Sea (Sinop Region). In the vertical, the amount of gelatinous organism was no significant statistically among stations (p> 0.05: Anova). Seasonal differences have been observed in biomass and abundance of species. Maximum gelatinous macrozooplankton abundance and biomass were calculated 44.17 n.m^{-2} (September) and 180.83 g.m^{-2} (April) respectively.

Keywords: Black Sea, Cnidaria, Ctenophora, Biomass

Intoduction Gelatinous macrozooplankton important effects on their pelagic ecosystems. They consume zooplankton groups and the eggs - larvae of fish considered in the ecosystem of Black Sea [1,2,3]. Gelatinous macrozooplankton is considered to be one of the effects in changes in the Black Sea fisheries. Therefore determined of its distribution, abundance and biomass is one of the most important points ascertain of role in ecosystem.

Material and methods

The present study was carried out to determine gelatinous macrozooplankton structure in the Sinop Region of Black Sea. Vertical sampling made using plankton nets (50 cm diameter mouth opening and 210 mm mesh size). Samples were collected monthly from three stations (St.A: 50 m, St.B: 65 m, St.C: 25 m) between January 2008-December 2008.

Result and Discussion

The maximum abundance and biomass of average gelatinous macrozooplankton was obtained 44.17 n.m^{-2} in September and 180.83 g.m^{-2} in April. Itsabundance increased in the summer and early autumn, however biomass values were increase at the beginning of winter and spring. Minimum abundance and biomass of average gelatinous zooplankton were found 5 n.m^{-2} and 5.67 n.m^{-2} in December (fig 1).

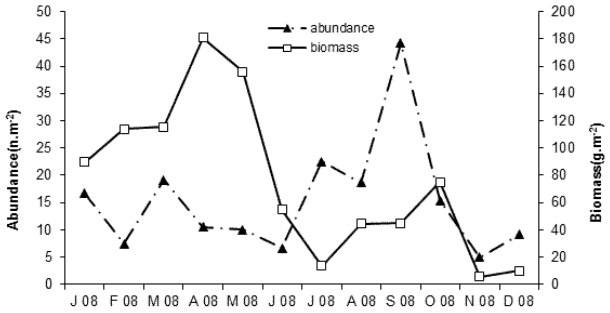

Fig. 1. Distribution of total gelatinous macrozooplankton of Sinop region, in 2008

In the study in the same region between 2002 and 2006, the most abundant and biomass of gelatinous macrozooplankton were obtained on May 2005 with 120 n.m^{-2} and March 2003 with 1073.5 g.m^{-2}. The high abundance values were determined as 42.5 n.m^{-2} on September 2002, as 91.25 n.m^{-2} on July 2003, as 108.33 n.m^{-2} on July 2004 and as 95 n.m^{-2} on May 2006. High biomass values were achieved at 230 g.m^{-2} on May 2002, 111.3 g.m^{-2} on March 2004, 447.75 g.m^{-2} on May 2005 and 393.33 g.m^{-2} on July 2006, respectively [4,5,6]. Gelatinous species composition showed varied by monthly. Growth A. aurita biomass was showed in spring and late winter. Its higest value was determined 16.67n.m^{-2} in March and 124.17g.m^{-2} in April. M. leidyi abundance was increased summer. Maximum value was in August as 51 n.m^{-2}, however maximum biomass was determined 82.5 g.m^{-2} in January. Higher P. pileus values were recorded in the winter and autumn months. Its maximum abundance and biomass was 11.67 n.m^{-2} in September and 7.14 g.m^{-2} in January. B. ovata was found just 3 months (October, November and December). Maximum abundance and biomass was 2.5 n.m^{-2} in December and 17.29 g.m^{-2} in September (fig 2).

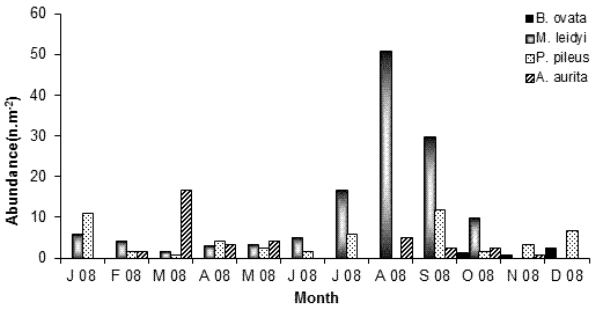

Fig. 2. Abundance and biomass of gelatinous macrozooplankton species of Sinop region in 2008

In terms of annual abundance, M. leidyi was the dominant group (52%) in 2008, then the following species was P. pileus with 27%. Analyzed the distribution of biomass of the species A. aurita had the highest share value of 53%, the next species was M. leidyi with 41%. In both abundance and biomass B. ovata was found to have a very low. Compared toprevious years, A. aurita was the dominant group in 2002, whereas P. pileus was the highest abundance group in 2004, 2005 and 2006 [4,5,6]. The percentage of M. leidyi decreased from 2002 to 2006, whereas it was increased in this study.

POPULATION DYNAMIC OF *AURELIA AURITA* IN BIZERTE COASTAL AREA (SOUTH-WESTERN MEDITERRANEAN) BETWEEN 2012 AND 2013

Sonia K. M. Gueroun [1]*, Rihab Saidi [1] and Mohamed N. Daly Yahia [1]
[1] Faculté des Sciences de Bizerte - sgueroun@yahoo.fr

Abstract
Abundance and growth of *Aurelia aurita* were studied from February 2012 to March 2013 in Bizerte area. In 2013, *A.aurita* population displayed recorded the highest abundance with a mean of 1.2 ± 0.7 ind.³ while in 2012 it exhibited the highest bell diameters with a mean of 9.1 ± 0.4 cm. The specific growth rate was higher in 2013 (k = 1.04 d^{-1}) than in 2012 (k = 0.01 d^{-1}) due to the smaller initial size of medusae population.

Keywords: Medusae, Population Dynamics, Growth, South-Western Mediterranean

Introduction
The jelly moon, *Aurelia aurita*, is undoubtedly the most studied medusae in the world probably due to its worldwide distribution and high abundance. Dynamic occurrence of this scyphozoan has been reported from many parts of the world [1, 2]; however it remains scarce in western Mediterranean where only two publications referred to *A.aurita* population dynamic [3,4].

Material and methods
The occurrences of *Aurelia aurita* was investigated with a bimonthly frequency from February 2012 to March 2013 in Bizerte area (Tunisia, South-Western Mediterranean): bay (37°17'09.23"N, 09°53'91,1"E) channel (37°16'10.8"N, 09°52'42,7"E) and lagoon (37°12'20.15"N, 09° 50'53,56"E). *A. aurita* abundances were calculated from *in situ* counting, oblique macroplankton net hauls (700µm mesh size) and vertical WP2 net hauls (200µm mesh size). In order to characterize the size structure of *A. Aurita* population , specimens were collected with a scoop net from the surface and the bells diameter were then measured. The average specific growth rate (k, d^{-1}), for February-March 2012 and 2013 periods, was calculated according to the folloxing equation: $K = 1/T \times (W_{March}/W_{February})$, (W: wet weigh, T: time in days) [1]. Medusae dry weight (W) were calculated from the equation: $W = 0.00173D^{2.82}$ (D: bell diameter)[2].

Results
In 2012, *A. aurita* abundance averaged 0.5 ± 0.3 ind.m^{-3} whereas in 2013, it averaged 1.2 ± 0.7 ind.m^{-3}. The medusae were more abundant in the lagoon than in the channel and the bay (Fig 1-A).

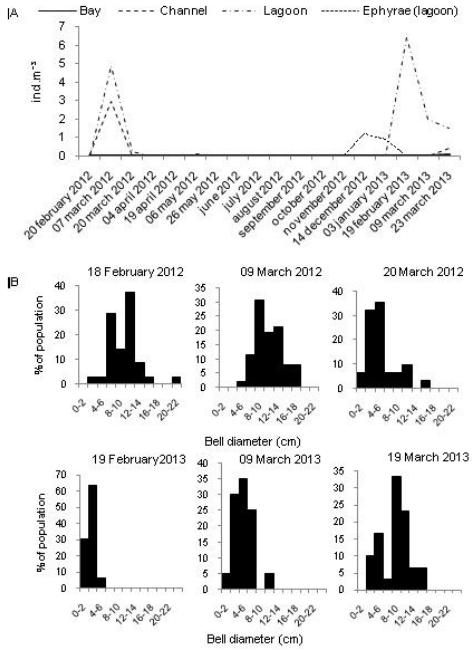

Fig. 1. *A. aurita* abundance (A) and growth (B) in Bizerte area between 2012 and 2013.

The ephyrae were only recorded in the lagoon. Bell diameters of *A. aurita* populations averaged 9.1± 0.4 cm in 2012 and 5.3 ± 0.4 cm in 2013 (Fig 1-B), and exhibited an average specific growth rate of 0.01d^{-1} and 1.04 d^{-1}, respectively. *A. aurita* populations are constituted of a succession of five cohorts in 2012, and two cohorts in 2013.

Discussion
Early appearance, high abundance and ephyrae presence of *A. Aurita* in Bizerte lagoon suggest that it originates from the lagoon as in Thau. Polyps colonies probably find refuge, food and substratum necessary to its development [3]. For the population in 2013, ephyrae were released from benthic polyps between December 2012 and January 2013. Nevertheless, for the population in 2012, as more cohorts and medusae with a bigger size bells were observed, ephyrae release might have occured earlier than December 2011. Strobilation may be affected by many factors, such as temperature and food supply [5,6]. The growth rate was highest in 2013 because of the smaller initial size of medusae population in February compared to 2012. The increase of the growth rate over the period of rapid growth of the young medusae were reported in the literature nevertheless few is known about the rate growth limitation. The low growth rate in 2013 may be limited by the level or the type of the available food [1]. All observations,i.e. the bell diameter, the number of cohort composing the population, and the specific growth rate of medusae, suggest that the *A. aurita* population was younger in February-March 2013 than in 2012.

MONITORING THE ABUNDANCE OF JELLYFISH OFF THE COAST OF VALENCIA (SPAIN) DURING THE SUMMER PERIOD (2009-2012)

Juan Eduardo Guillén Nieto [1]*, David Gras Olivares [1], Joaquín Martínez Vidal [1] and Alejandro Triviño Pérez [1]
[1] Instituto de Ecología Litoral - j.guillen@ecologialitoral.com

Abstract
The present work studies the abundance and species composition of jellyfish on the beaches of Valencia (Spain), comparing surface seawater temperature, chlorophyll *a* production, and wind conditions in the summer seasons of 2009-2012. Although the causes that can motivate jellyfish abundance are many and difficult to establish, we have detected two different periods: 2009-10 and 2011-12. In the first period, we observe high abundances of jellyfish, coinciding with periods of low seawater temperatures in spring, high levels of chlorophyll a, and a limited role of calm winds. By contrast, in 2011-12, the temperature in spring months was higher, the concentration of chlorophyll a lower, the percentage of calms higher, and finally jellyfish abundances were lower than those observed in the period 2009-10.

Keywords: Coastal waters, South-Western Mediterranean, Medusae, Zooplankton

Introduction. The presence of jellyfish is a common phenomenon, and that sometimes can become massive. The main factors that may influence the amount of jellyfish along the coast, are: i) the frequency of certain winds and ocean currents ii) the water temperature and the number of hours of sunlight throughout the day (both essential to trigger reproductive phenomena in most planktonic species), and iii) the eutrophication, which can promote the growth of plankton biomass and, therefore, greater availability of food resources for jellyfish (Garcia-Comas *et al*., 2011; Sabatés *et al*., 2010). The purpose of this paper is to help understand the relationship between physical and chemical factors, and marine ecological and the presence of jellyfish off the coast of Valencia, trying to obtain long time series of results, in order to meet potential cycles in the arrival of these jellyfish.

Material and Methods. Since 2009 is carried out monitoring on the presence of jellyfish along the coast, based on observation from boat observer notices, and records of lifesaving services of the municipalities participating in the campaign. In parallel tracks on the surface temperature (taken by multiparameter probe), the concentration of chlorophyll *a* total in a total of 20 stations spread over the Valencian coast, and notes on the wind conditions obtained from the meteorological station network.

Results. Figure 1a shows the variations between the number of observations of jellyfish records between the summers of 2009-2012. This figure shows how the observed quantities of jellyfish in the summers of 2009 and 2010 (823 and 1048 records respectively) was higher than those of 2011 and 2012 (577 and 164 respectively). The largest number of records of jellyfish is between July and August, with the increased presence of species *Pelagia noctiluca*, and *Rhizostoma pulmo*. Subsequently, in September and October, the species dominates is *Cotylorhiza tuberculata*. Occasionally (2010), during the months of April and May, there are specimens of *Chrysaora hysoscella*, and less frequently, of *Physalia physalis*, associated currents from the Strait of Gibraltar. Other species have been observed, like *Olindas phosphorica* in relatively confined areas, and also, since 2008, *Carybdea marsupialis*. In the summer seasons with lower abundance of jellyfish (2011-12), the dominant specie was *C. tuberculata*. In the coast of the Valencian Region, the arrival of jellyfish off the coast, could be associate with winds from the E, which favors the presence of Pelagia noctiluca and *R. pulmo* while the presence of an uncommon jellyfish *P. physalis* and *C. hysoscella*, could be related to winds from the S, SW. The parameters studied lead us make a clear difference between the summers of 2009-10, when increase abundance jellyfish, and the subsequent period of 2011-12, with lower observed jellyfish records. Thus, the surface temperature of the seawater was colder in the months of May in 2009-10 (mean 20.02 +1.35° C) compared to the average observed in the next two years (22.33 +0, 45° C), with statistically significant differences ($p = 0.01$) (Fig. 1B). Chlorophyll *a* levels were higher in the case of the period 2009-10, along the lines of that cold winters can cause increased production planktonic (Estrada et al., 1989), also with significant differences (p=0,01; 2,51 µg/l in 2009-10, compared to 1,69 µg/ in and 2010-11). In relation to wind regimes, differences were also observed between the two periods, in the summer seasons of 2011-12 calm prevailed (27.42% of days, compared with 9.45% in 2009-10).

Conclusions. In the present work it has been found a period of great abundance of jellyfish in 2009-10, when surface temperature seawater observed is lower in spring and the concentrations of chlorophyll a are higher, which could result in increased plankton production. The predominance of calm winds, can also be a relevant factor in the number of observations of jellyfish in the area. This study highlights the potential role of seawater temperature, concentration of chlorophyll *a*, and wind conditions, as factors that may influence the unequal abundance jellyfish off the coast ofValencia. Without detriment to ocean currents, climate change, changes in the food chain, overfishing, etc.

SEASONAL DISTRIBUTION OF SCYPHOZOA (CNIDARIA) AND CTENOPHORA SPECIES IN GÖKOVA BAY, MUGLA, TURKEY

Nurçin Gülsahin [1]* and Ahmet N. Tarkan [1]
[1] Mugla Sitki Kocman University, Faculty of Fisheries - ngulsahin@mu.edu.tr

Abstract
In this study, seasonal distribution of the gelatinous organisms Scyphozoa (Cnidaria) and Ctenophora species was determined in Gökova Bay which has been one of the most important fishing area in Turkey. Sampling of the study was done between September 2011-October 2012 at 10 stations in the bay. Two Scyphozoa species- *Aurelia aurita, Cotylorhiza tuberculata* and three Ctenophora species- *Mnemiopsis leidyi, Beroe ovata, Cestum veneris* were observed in Gökova Bay. Especially, it was found that *C.tuberculata* reached high abundances in summer and autumn months. *M.leidyi* and *B.ovata* were showed high abundances on stated months.

Keywords: Ctenophora, Medusae, Gokova Bay

Gelatinous organisms are important ecologically because they are consume on zooplankton, have wide distribution and also complex life cycle [1]. The seasonal bloom of jellyfish medusae is a characteristic of many marine environments, but there is also a great interannual variability in the abundance of medusae [2]. In this study, seasonal distribution of Scyphozoa and Ctenophora species was determined in Gökova Bay, Mugla, Turkey. Gökova Bay, whose total area of 52000 hectares, is located in the connection zone of Aegean Sea and the Mediterranean and has been declared as "private environment protection zone-PEPZ" since 1989. It is one of the protected eight marine areas in Turkey [3]. Previously, there was not done a comprehensive study about gelatinous organisms in the area. This study was done between September 2011-October 2012 monthly at 10 stations in Gökova Bay. Regular shoreline surveys were carried out in the study area with a boat during each month for sampling Scyphozoa species. All observations were made from the front part of the boat and jellyfish were counted in 2 m width and 2 m depth from both sides of the boat. Ctenophora was sampled horizontally at all stations by a 200µm WP-2 net. Also, scuba diving was used for counting and sampling of Scyphozoa and Ctenophora species. Data were additionally converted to numbers of individuals per 100 m^3. Only *C. andromeda* which lives upside-down on the sea floor was counted and calculated to numbers of individuals per 100 m^2. Moreover, temperature, salinity and dissolved oxygen values of all stations were measured monthly by YSI multiprobe system.

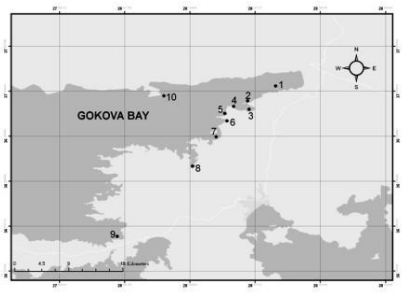

Fig. 1. Gökova Bay and sampling stations.

During the study period minimum surface water temperature was 15ºC in January at station 8; maximum temperature was 29,06ºC in July at station 4. Mean temperature value of the study period was 21,12 ºC, mean meaured salinity was 37,96 ‰. Minimum water salinity was 27,13‰ in October at station 10, maximum salinity was 39,78 ‰ in June at station 3. The mean value of the dissolved oxygen (DO) of the study period was measured 7,35 mg/l and minimum DO was 5,25 mg/l (at station 10) in September, maximum DO was 9,43 mg/l (at station 8) in April. *Aurelia aurita* was observed only in May and September at station 6 and had low abundance. Medusae *Cotylorhiza tuberculata* was found all the months of the study except December, January, February, March, April and May. *M. leidyi* and *B. ovata* also showed high amounts and aggregated in stations2,5,6,7,8 and 10. Also, *Cassiopea andromeda* was found in the bay from April to December and had mean abundance 33,5 ind./100m².

Tab. 1. Monthly abundance values (individual/100m^3) of the Scyphozoa and Ctenophora species in Gökova Bay.

	Aurelia aurita	*Cotylorhiza tuberculata*	*Mnemiopsis leidyi*	*Beroe ovata*	*Cestum veneris*

Aug.12	-	130	91	52	-
Sep.12	2	93	140	117	17
Oct.12	-	45	526	67	4

It was found that *C.tuberculata* which is native spacies of Gökova Bay reached high abundances in summer and autumn months. *M.leidyi* and *B.ovata* were showed high abundances in certain months (Table 1). The enter of Gökova Bay is quite wide so the bay is effected from Aegean open water system and has high potential of waves and currents. The current coming from the open water enters to Gökova Bay from the north, turns and gets out through mid-line of the bay [4]. The species coming from the open water could settle in the bay under optimum conditions. Also, there are many small bays in Gökova Bay which show oligotrophic character. Jellyfish were drifted to the small bays and increased their numbers in there. Sea water temperature of Gökova Bay showed typical Mediterranean Sea characteristic that mean value of temperature was not below 15°C in the bay. Therefore, the bay is suitable environment for Scyphozoa and Ctenophora species for the purposes of temperature.

RECENT CHANGES IN THE NORTHERN ADRIATIC HYDROMEDUSAN FAUNA

D. Lucic [1]*, M. Miloslavic [1], B. Gangai [1], I. Onofri [1] and I. Ivancic [2]
[1] University of Dubrovnik Institute for Marine and Coastal Research - davor.lucic@unidu.hr
[2] Center for Marine Research, Ruder Boškovic Institute

Abstract
Previous investigations of the northern Adriatic observed the changes in the hydromedusan fauna that demonstrate one aspect of the long-term consequences in marine ecosystem: decreased biodiversity. Following concern about substantial changes in these area, in this study we present the comparative results of the composition and abundance of hydromedusan fauna of northern Adriatic, pointing to the possibility of species repopulating recent years. During 2009-2011 we found considerably higher number of species and higher abundances in comparison with the results for the last 5 decades.

Keywords: Biodiversity, Cnidaria, North Adriatic Sea

Introduction
There is long tradition of marine plankton research of the northern Adriatic and its ecosystem is regarded as typically neritic. During the last 50 years ecological changes were already noted in the northern Adriatic, and many species disappeared from this zone [1]. Among the first described plankton species of the northern Adriatic were hydromedusae that at the beginning of 20th centaury they were rated to 42 species: 35 meroplanktonic and 7 holoplanktonic [2]. Low oxygen saturation near bottom and hypersaturation near the surface demonstrated new established trend from 1955 onwards, and it has been hypothesized that meroplanktonic hydromedusae could indicate early phase of hypoxic events [3]. The changes observed in the hydromedusan fauna demonstrate one aspect of the long-term consequences in marine ecosystem: decreased biodiversity [4]. Following concern about substantial changes in the northern Adriatic, in this study we present the comparative results of the composition and abundance of hydromedusan fauna of northern Adriatic, pointing to the possibility of species repopulating recent years.

Methods
Plankton was sampled monthly by bottom-to-surface vertical tows with 0.20 mm (WP2) Nansen mesh plankton net at four stations: two in the western part of the northern Adriatic (44,9^{0}N, 12,8'E; 44,7^{0}N, 12,7'E), and two in the eastern part (45,0^{0}N, 13,3'E; 45,4^{0}N, 13,4'E). Presented data are results of investigations during three study periods: the first from 1999-2002, second from 2003-2007 and the third from 2009-2011.

Results and Discussion
Our results clearly showed that the number of species and their abundance increase from the first to the third investigated period (Table 1). Thus, during 2009-2011 we found 16 anthomedusa and 8 leptomedusa that is considerably higher number of species than the findings of Benovic et al. ([3], [4]). We assume that some species were introduced by input currents in the northern Adriatic, which is confirmed by the increasing density of trachymedusa, but abundances of some species were several times higher than in previous records ([3], [4]). Although the abundance of hydrozoan species vary during their life cycles [5], our high mean and maximum values of this metagenetic specimens could indicate the possibility of establishing stable populations in the area. These changes are consistent with the recent changes in the plankton composition and abundance, probably caused by a climatic forcing and recognized oligotrophication of the entire northern Adriatic ([6], [7]). Our results confirm previous suggestions of Benovic et al. ([3], [4]) that hydromedusae may be used as indicators of changes in marine shallow ecosystems.

Abstract
Extensive blooms of gelatinous macrozooplankton species have occurred in recent decades in Mediterranean waters. We conducted a literature review of the impacts of blooms on the ecosystem services provided by the Mediterranean Sea and on the consequent welfare losses and highlight gaps and further research needs. The results of a case study focused on the estimation of the economic losses suffered by Northern Adriatic fishermen are also summarized and explained.

Keywords: Blooms, Ecosystem services, Economic valuation, Fisheries, North Adriatic Sea

1. Introduction
Extensive blooms of gelatinous macrozooplankton species have occurred in recent decades in Mediterranean waters [1]; [2]; [3]; [4]. We conducted a literature review of the impacts of blooms on the ecosystem services provided by the Mediterranean Sea and on the consequent welfare losses and highlight gaps and further research needs. The results of a case study focused on the estimation of the economic losses suffered by Northern Adriatic (NA) fishermen are also summarized and explained.

2. The impacts of blooms on the ecosystem services of the Mediterranean Sea: A review
According to the literature reviewed, blooms affect a number of the ecosystem services provided by the Mediterranean Sea. These include provisioning services (e.g. biomass production; provision of seawater for cooling systems of coastal power plants) and regulating services (e.g. maintenance of food webs' structure and function). The impairment of ecosystem services by blooms leads to the loss of welfare benefits. Very few estimates of the welfare losses due to blooms were retrieved, suggesting the need for more economic valuation studies in the Mediterranean region.

Tab. 1. Welfare benefits affected by jellyfish blooms by species.

Benefit affected	Energy production	Catch/production of marine living resources	Recreation	Human health
Species				
Aurelia aurita		√		
Cotylorhiza tuberculata			√	
Pelagia noctiluca		√	√	√
Rhizostoma pulmo		√		
Ropilema nomadica	√	√	√	√
Mnemiopsis leidyi		√		

3. Gaps and further research needs
Based on the results of the literature review, we suggest a number of different economic techniques, which can be used for the economic valuation of the welfare losses caused by blooms. They range from market analysis to revealed and stated preference techniques [5]. An example of the use of economic techniques is presented in Section 4 below.

4. Northern Adriatic fisheries' losses: A case study
We conducted a survey of fishermen in the city of Chioggia (Italy), focusing on fishermen's perceptions about jellyfish blooms in the NA Sea and investigating how blooms interfere with with fishing operations. The study provides evidence that jellyfish blooms interfere with fishing operations in several ways and affect different fishing segments.

Tab. 2. Frequency of reports of interferences of jellyfish with fishing operations by fishing system practiced.

	Mid-water trawling (%)	Otter trawling (%)	Small scale fishing (%)
Return to port	0.0	37.5	0.0
Change of fishing grounds	100.0	93.8	0.0
Clogging of fishing gear	100.0	93.8	57.1
Breakage of fishing gear	100.0	75.0	42.9
Additional catch sorting time	100.0	87.5	85.7
Reduction in fish catches	100.0	93.8	71.4
Jellyfish stings	50.0	43.8	42.9

The study also provides evidence that NA fishermen suffer considerable economic damage because of jellyfish interferences. We estimated economic losses deriving from reduction in catches and from additional fuel costs due to changes of fishing grounds. The former could amount to as much as € 8.2 per year for the mid-water- and otter trawling segments, if no additional hauls were performed to mitigate losses. Additional fuel costs were conservatively estimated and could represent an annual increase in fuel costs of 3% per vessel for the same fishing segments mentioned above.

SPATIAL-TEMPORAL DIRECTED GRAPHS FOR MODELING THE DISPERSION OF PLANKTON IN THE MEDITERRANEAN SEA

B. Petelin [1]*, I. Kononenko [2], M. Kukar [2], V. Malacic [1] and A. Malej [1]

Abstract
In this work a new methodology is proposed for predicting dispersion of biological species. The methodology uses multi-level spatial-temporal association rules and directed graphs. The latter are the basis of Markov models which help us predict the spatial distribution of species, depending on previous observations. We applied the methodology on results of the Mediterranean Ocean Forecasting System (MFS) model and available observations of the jellyfish *Pelagia noctiluca* (Cnidaria: Scyphozoa). The model results are promising for further prediction of plankton dispersal.

Keywords: Cnidaria, Population Dynamics, Circulation models, South-Western Mediterranean

We developed a new methodology [1] which upgrades the Lagrangian tracking of fluid parcels analysis and consists of several phases. First we calculate a vast number of Lagrangian trajectories within velocity fields of a numerical model. Second, we subdivide the model domain into smaller sea areas and search for spatial-temporal association rules that denote the probability of the transition of parcels from one area to another in a specified time interval (see Fig. 1). Third, from the resulting association rules we construct multi-level directed graphs which cover the whole domain and represent a basis for modeling the dispersion of biological species using the Markov processes. The above methodology is described in detail in [1].

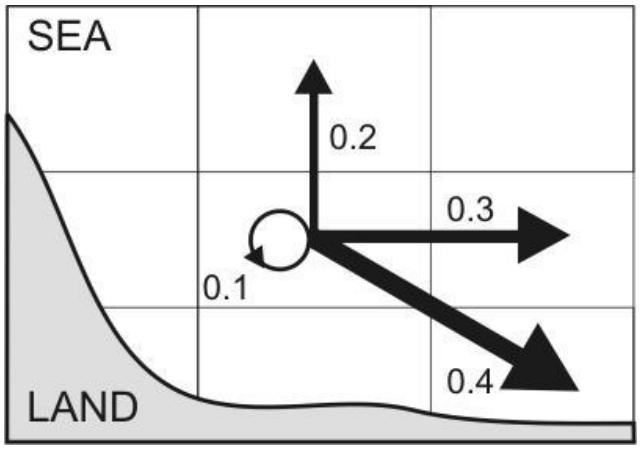

Fig. 1. Spatial–temporal association rules used in the proposed methodology. The arrows show the transitions of particles from the selected area to the surrounding areas.

The methodology was applied on the surface velocity fields of the numerical model Mediterranean Ocean Forecasting System (MFS) [2]. We generated 156 directed graphs that cover monthly transitions of parcels in the period 1999-2011. Each directed graph has an associated transition matrix of a non-homogenous Markov process. Graph nodes (sea areas) represent the states, and the elements of the matrix denote the probabilities of movements of particles (biological species) between the areas. We can obtain the long term probabilities of movements by multiplying the matrices sequentially in time. For modeling the spread of biological species, we have chosen the jellyfish mauve stinger (*Pelagia noctiluca*, Scyphozoa). This jellyfish forms recurrent blooms in the Mediterranean and eastern Atlantic [3] with considerable effects on tourism and coastal industry. Its life cycle is characterized by the absence of benthic polyp and its holoplanktonic life cycle enables mauve stinger to occupy offshore water niches in addition to coastal environments. Our past study showed low genetic differentiation of *Pelagia noctiluca* over a large spatial scale (Mediterranean Sea and Eastern Atlantic) indicating that its populations are demographically open and have considerable dispersal capabilities [4]. As an example for the spread of mauve stinger in the Mediterranean Fig. 2 shows, after six months of dispersal, the hypothetical distribution (in %) of *Pelagia noctiluca (Scyphozoa)*, which was observed in the Alboran Sea in April 2008. A further upgrade of this application with new observations will improve the predictability of jellyfish spread with the model.

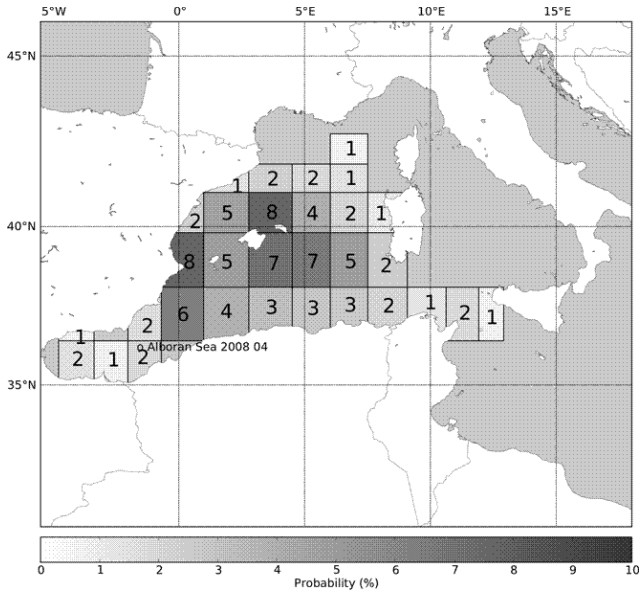

Fig. 2. The hypothetical distribution (in %) of *Pelagia noctiluca*, which was initially observed in the Alboran Sea in April 2008, after six months. The rectangles represent the nodes of the multilevel directed graph. The small circle represents the location of the observation of jellyfish in the Alboran Sea in April 2008, the color saturation and the numbers in the nodes show the percentage of jellyfish which are distributed in different areas after six months.

Abstract
A comprehensive analysis of the facts associated to the Portuguese Man-of-War swarms events in year 2010 was performed. All the *Physalia* sightings during several years and the climatic/oceanographic conditions have been analyzed. Finally, a virtual experiment of the drifting of the individuals using a hydrodynamical model, consisting of a ROMS based numerical simulation forced with realistic winds (ASCAT) and heat fluxes from ERA-Iterim, together with an Individual Based Model (IBM) simulations was performed. The results showed small differences in the overall estimated arrival of *Physalia* between the model experiment and the real observations.

Keywords: Alboran Sea, Gulf of Cadiz, Gibraltar Strait, Medusae

The Portuguese Man-of-War, *Physalia physalis*, is armed with a singularly potent toxin [1] [2]. The major protein of the venom is *physalitoxin*, which is a hemolysin [3]. This is contained in nematocyst, which chemical characterization [4], collagenase activity [5] and cloning and functional expression of the cnidocytes [6] had been described. The nematocysts venom of *P. physalis* is lethal to animals and humans [2]. The envenomation syndromes on humans of *P. physalis* are extent [1]. As fatal reactions: toxin-induced immediate cardiac arrest and delayed renal failure; as systematic reactions: toxin-induced, Irukandji reaction and respiratory acidosis; as local reactions: toxin-induced to skin, mucosa and cornea, recurrent reactions up to tour episodes, distant site reactions and local lymphadenopathy; as chronic reactions: contractions, vascular spasm and mononeuritis; as post-epidode dermatitis: granuloma annulare. In this study, the occurrence of the Portuguese Man-of-War in the NE Atlantic and Mediterranean Sea have been compiled from 2005 to 2011 from different sources: media, national and regional agencies and Jellywatch Program data base (http://jellywatch.org/) (Fig. 1).

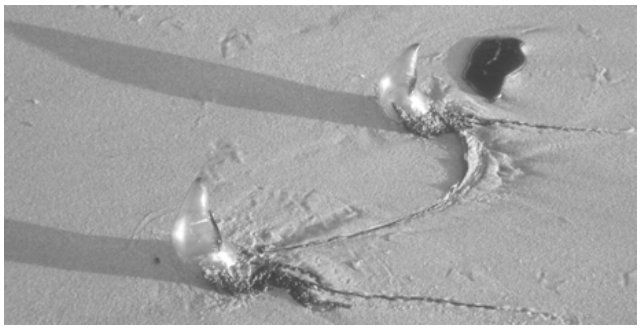

Fig. 1. Two stranded colonies of *Physalia physalis* in the beach of Camposoto (Gulf of Cadiz) on February 5th 2009.

The year 2010 registered an unusual record of *Physalia* sightings along the Mediterranean Sea and (at Atlantic and Mediterranean coastlines) and Canary Islands (North East Atlantic). This was an outstanding year in the frequency of occurrences, but also in the total number of colonies arrived (> 100,000 colonies), compared to 2009 and 2011 that they were less than 60 colonies (Fig. 2). Therefore, the climatic/oceanographic conditions have been analyzed of that particularly year, which pointed out to be one year of stronger westerlies winds in the NE Atlantic basin compared to the time series from 1979. Also, the winter 2009-2010 had one of the most negative North Atlantic Oscillation index (-4.64) measured during the almost 150-year record. A virtual experiment of the drifting of the individuals was performed using a hydrodynamical model. This consisted of a ROMS based numerical simulation forced with realistic winds (ASCAT) and heat fluxes from ERA-Iterim, together with an Individual Based Model (IBM) simulations. The oceanic population of *P. physalis* started to appear stranded on the beach on February 22nd 2010. Then the observations on the coast occurred from West to East advancing towards the Mediterranean, passing the Strait of Gibraltar and to the far East of the Alboran Sea. The beaching timing observed is highly correlated to the simulated ($r=0.81$, $p<0.001$, $n= 18$). The results showed small differences in the overall estimated arrival of *Physalia* between the model experiment and the real observations.

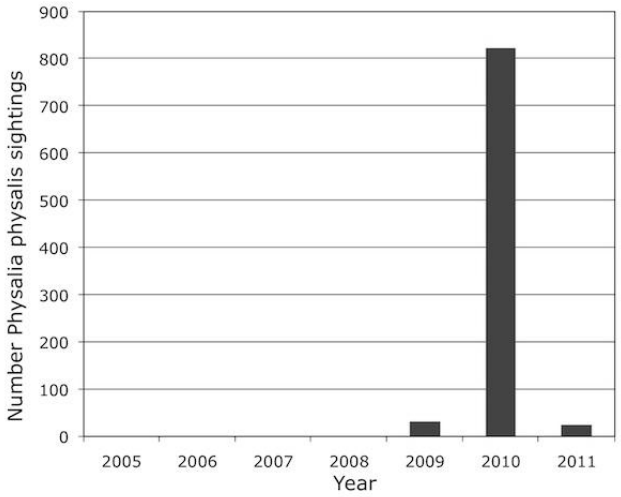

Fig. 2. Total number of *Physalia physalis* sightings at both adjacent basins of the Gibraltar Strait during seven consecutive years (2005-2011).

REVIEW OF APPENDICULARIAN BIODIVERSITY IN THE ADRIATIC

Rade Garic [1]* and Mirna Batistic [1]
[1] Institute for Marine and Coastal Research University of Dubrovnik - rade.garic@unidu.hr

Abstract
Until 2007 continuous monitoring of appendicularians in the Adriatic was not conducted except few isolated annual series. Since 2007 eleven appendicularian species were recorded in the Adriatic for the first time while three species recorded in previous investigations were not found. Due to infrequent sampling of appendicularians it is hard to determine if this sudden increase of species number is the result of prior inadequate samplings or if it is related to hydroclimatic changes. Here we try to assess status of newly recorded appendicularian species in the Adriatic by using their population dynamics and by revising historical samples.

Keywords: Biodiversity, South Adriatic Sea, Zooplankton , Tunicata

Introduction

In the last 20 years an increase of biodiversity is recorded in many gelatinous zooplankton groups in the Adriatic [1] while appendicularians were not investigated. The last basin-scale investigation of appendicularians was conducted from 1974 to 1976, more than 30 years ago [2], while yearly cycles were investigated in 1989/1990 and 1996/1997 in coastal South Adriatic [3,4] and from 1999 to 2002 in the North Adriatic.

In 2009 species *F. aequatorialis* was recorded in open waters off Albania [5] and a new species to science *Fritillaria ragusina* [6] was described from samples collected in the open Adriatic waters in 2008. Here we present a review of the status of Adriatic appendicularian biodiversity with nine new appendicularian records for the Adriatic. We also try to assess which species were possibly overlooked in previous investigations and which could be promising candidates for indicator species of different water masses.

Materials and methods

From 2007 onwards appendicularians were sampled bimonthly on 4 stations from the coast to the open sea along transect from 42°38'N, 18°02'E to 42° 20'N, 17°43'E. A 100 m deep costal station off Dubrovnik was sampled twice per month. All stations were sampled using Nansen closing nets with 53-µm, 200-µm and 250-µm mesh. A limited number of historical samples from 1974-1976, 1987 and 1996 was examined for possibly overlooked species.

Results and discussion

From 2007 onwards we recorded nine more species in addition to *F. aequatorialis* and *F. ragusina* in the Adriatric for the first time: *Oikopleura villafrancae, Folia gracilis, Appendicularia tregouboffi, Fritillaria formica tuberculata, F. formica digitata, F. charybdae, F. lucifer, Tectillaria fertilis* and *Kowalevskia oceanica*.

Based on presence of species in historical samples and their abundance patterns in recent samples six species were overlooked in previous investigations: *Oikopleura villafrancae, Folia gracilis, Fritillaria ragusina, F. formica digitata, Appendicularia tregouboffi* and *Kowalevskia oceanica*. During the revision of historical samples from 1970s, *O. villafrancae* was regularly found in deep sea samples. This species was probably overlooked in earlier investigations due to its poor preservation in net tows and typical depth of occurence of more than 300 m.Species *Folia gracilis, Fritillaria ragusina, Appendicularia tregouboffi* are open sea species which are found in 53-µm mesh net, but rarely in 200/250-µm mesh nets. These species were also found in historical open sea samples taken with 53-µm mesh net in 1980s suggesting that they were probably overlooked due to inadequate sampling techniques. Species *Fritillaria formica digitata* and *Kowalevskia oceanica* were found in samples from 1990s. Species *K. oceanica* was probably overlooked because of its similarity to *K. tenuis* while species of *F. formica* group were never determined to the *formica* or *tuberculata* species level in previous investigations. The declining abundance pattern is registered in species *K. oceanica* and *F. formica digitata* from 2007 onwards suggesting that they migh have interrmittent occurence in the Adriatic, possibly related to entering currents. Similar declining patttern from 2007 onwards is also found in species *F. aequatorialis* and *O. intermedia*. Species *F. aequatorialis* hasn't been found in examined samples from years prior to 2007, while species *O. intermedia* is regarded as accidental Adriatic species [2]. Species *O. intermedia* was recorded in late 1970s but never afterwards, until 2007. This species likely also belongs to species with intermittent occurence in the Adriatic and future investigations might confirm the same for species *F. aequatorialis*. Species *Fritillaria formica tuberculata* was found in many samples throughout the years and should be regarded as common member of Adriatic appendicularian fauna.

Species *T. fertilis* and *F. charybdae* are rare species even in the Mediterranean and their presence might indicate influence of Atlantic waters on deep layers. In September 2011 a single specimen of recently described *Fritillaria lucifer* [7] was found in the tow from 300 m to the surface. This is first finding of this species since its description from Monterey Bay (Pacific Ocean). The pecularity of this isolated specimen was presence of two ovaries while holotipic individuals caught in pristine condition had only one ovary (Fig. 1).

Three appendicularian species have not been found since 1970s in the Adriatic: *Oikopleura rufescens*, *Megalocercus abyssorum* and *Fritillaria fagei*. These species are probably extinct from the Adriatic.

Even though the majority of newly recorded species were overlooked in previous investigations, there are notable changes in appendicularian species composition in the Adriatic. This corrensponds to recorded changes in other gelatinous zooplankton groups [1]. Future investigations will determine the value of species with intermittent occurence as indicator species of different circulation regimes in the Adriatic.

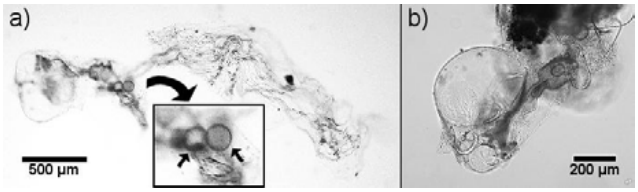

Fig. 1. *Fritillaria lucifer*. a) The whole animal with enlarged detail showing two ovaries; b) lateral view of the anterior part of trunk.

Abstract
Phytoplankton communities were studied in the Biguglia lagoon between May 2012 and March 2013. A massive invasion of *Mnemiopsis leidyi* occurred during the same period. We discuss the potential interactions between ctenophores and phytoplankton.

Keywords: Blooms, Chlorophyll-A, Ctenophora, Lagoons, Corsica Trough

Mnemiopsis leidyi (Agassiz, 1865; Ctenophora) is a species accidentally introduced in the Mediterranean Sea since 1990 [1]. It was found in a lagoon environment for the first time in 2005 (Berre lagoon, France; Bonnet, Com. Pers.). *M. leidyi* is not strictly carnivorous, but it may also eat the micro- and nanoplankton, which constitute important sources of nitrogen for its growth [2].

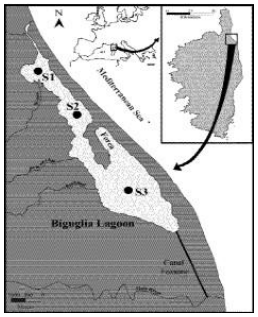

Fig. 1. Biguglia lagoon and sampling stations

M. leidyi appeared sporadically in August 2011 within Biguglia lagoon (Corsica, France,Fig.1). This brackish and shallow lagoon (average depth 1.5 m) is a confined ecosystem disturbed by a growing eutrophication since the eighties [3]. Phytoplankton communities were studied in three stations of the Biguglia lagoon between May 2012 and March 2013. A massive invasion of *Mnemiopsis leidyi* occurred during the same period. This study aims at pointing out the interactions between *M. leidyi* and phytoplankton communities. *M. leidyi* developed from August 2012 to February 2013 in the Biguglia lagoon with a maximum biomass in November 2012. During this period, salinity and temperature varied between 7-25 psu and 7-28°C, respectively. Subsurface Chl *a* concentrations measured with a FluoroProbe (BBE) ranged from 1.4 to 25.5 µg.L-1. Highest Chl *a* values were observed in November 2012 in all stations (Fig.2). Dinoflagellates were abundant all year round but a shift between Chlorophytes and Cryptophytes occurred in Oct-Nov. 2012 (Fig.2). Microscopic observations of phytoplankton communities revealed a codominance of *Gymnodinium sanguineum* and *Prorocentrum minimum* at that time. Both species are essential for the development of the larval stage of *M. leidyi* [4] and may have contributed to their expansion in the Biguglia lagoon in 2012.Conversely, this expansion also disturbed the phytoplankton communities'structure. In particular, the classical pico-nanoplankton summer bloom [4] has not been observed, in phase with literature indications [5]. However, there was an increase in biomass at each station (Oct-Nov.). Documenting key processes that influence ctenophore survival during early developmental stages may provide relevant insights to better understand the initiation and maintenance conditions of the *M. leidyi* adults' blooms commonly observed in coastal waters [4].

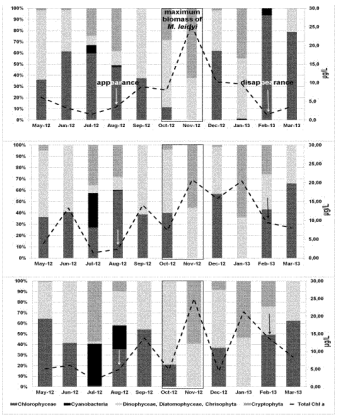

Fig. 2. Monthly fluctuations of the main phytoplankton groups and Chl. *a* with BBE FluoroProbefor each station.

In particular, it is important to improve our knowledge on the different growth stages of *M. leidyi*, their sizes and trophic behaviors. In the Biguglia lagoon and elsewhere, the study of this invasive species becomes essential to better understand the impacts of *M. leidyi* blooms on phytoplankton communities.

PEUPLEMENTS MACROZOOPLANCTONIQUES DES ÎLES HABIBAS (MER ALBORAN): BIODIVERSITÉ ET COMPOSITION

Aziz Hafferssas [1]* and Yacine G. E. Khames [1]
[1] Faculté des Sciences Biologiques, USTHB, Algérie - ahafferssas@usthb.dz

Abstract
Le zooplancton des cents premiers mètres de l'archipel des Habibas a été échantillonné pendant le printemps 2012. Quatre radiales représentatifs des différentes structures hydrologiques (système oligotrophe côtier d'origine Atlantique et zone productive de type frontale) ont été étudiées. Une trentaine d'espèces macrozooplanctoniques ont été dénombrées. La distribution des peuplements montre d'étroites liaisons avec les structures hydrologiques. Les fortes abondances et biomasses sont localisées au sein de la zone frontale. Les espèces peuvent rencontrer des conditions trophiques favorables à leur développement. Au contraire, les peuplements sont faiblement concentrés au niveau de l'écosystème oligotrophe où la couche superficielle y concentre de faibles biomasses phytoplanctoniques (moins de 1 mg.m^{-3}).

Keywords: Biodiversity, Alboran Sea, Zooplankton

Matériel et méthodes
L'échantillonnage a été fait autour des îles Habibas. Cette île est située à proximité d'un front géostrophique dénommé Alméria- Oran. Celui ci est une conséquence du passage du courant atlantique et son affrontement avec les eaux méditerranéennes (Davies & al., 1993). Pour cette étude, douze stations de prélèvements ont été choisies (Figure 1).
Les échantillons zooplanctoniques ont été prélevés sur la couche d'eau épipélagique (0-200 mètres). Six stations (1.1, 1.2, 1.2, 2.1, 2.2, 2.3) sont situées au sein de l'écosystème oligotrophe côtier (R3 et R4) d'origine atlantique (Chl a surface < 1 mg.m^{-3}) et six stations (3.1, 3.2, 3.3, 4.1, 4.2, 4.3) sont localisées dans la zone de forte productivité biologique de type frontale (Chl *a* surface > 1 mg.m^{-3}) (R3 et R4). Le zooplancton a été échantillonné par des traits verticaux. Le filet utilisé est le Working Party 2 dont le tissu filtrant est en Nylon-Nytal de 200 µm de vide de maille.

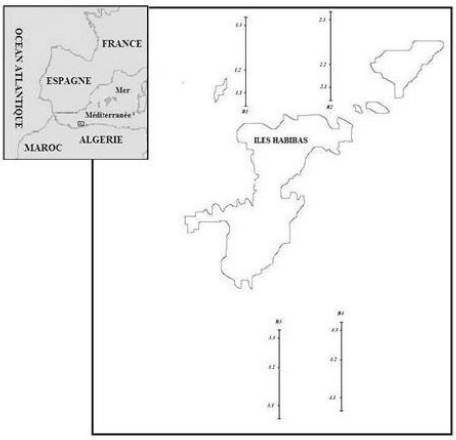

Fig. 1. Stations de prélèvements zooplanctoniques autours des îles Habibas.

Résultats.
La zone étudiée, héberge 26 taxons macrozooplanctoniques (Tableau 1). La faune appartient à divers phylums. Au sein des stations proches de la zone productive, de type frontale, les abondances totales sont supérieures à 100 individus.m^{-3}. Néanmoins au sein de l'écosystème oligotrophe côtier, les abondances totales sont nettement au dessous de 50 individus.m^{-3}.L'organisation trophique au sein de la zone frontale, est nettement dominée par les prédateurs: Ils représentent plus de 60 % de l'abondance totale. Au contraire, les filtreurs ne représentent qu'un faible pourcentage (moins de 40 %). En revanche, ce comportement trophique est dominant au niveau de la zone productive (plus de 70 %). Au sein de la zone oligotrophe, les valeurs pondérales sont faibles. Elles oscillent entre un minima de 1.60 mg.m^{-3} à un maxima de 3.52 mg.m^{-3}. Sur le front, les valeurs sont supérieures à 5 mg.m^{-3}. Une très faible variabilité est notée entre les six stations liées aux radiales 3 et 4. La faune macrozooplanctonique hébergée par les deux écosystèmes liés à l'archipel des habibas de est composée de 26 taxons. Celles-ci se répartissent sur trois phylums (Tunicata, Cnidaria et Chaetognatha), 17 genres et 11 familles. Ceux-ci ont été déjà collectés dans d'autres régions du bassin méditerranéen (Daly Yahia & *al.*, 2004). Les niveaux des abondances et des biomasses macrozooplanctoniques varient en relation avec les structures hydrologiques. Les fortes concentrations ont été localisées au asein de la zone productive. Le caractère oligotrophe de la faune est surtout signalé au sein de la zone oligotrophe côtière; les peuplements caractérisent des eaux faiblement productives (Chl *a* < 1 mg.m^{-3}). La zone d'influence du front Alméria - Oran semblerait réduite. Contrairement au front liguro-provençal, aucune incidence n'a été relevée sur les radiales côtières la zone étudiée. L'écosystème frontal représente une particularité au sein des côtes algériennes. Celle ci est corroborée par les données physiques et biologiques (Raimbault & *al.*, 1993). La forte productivité biologique (Chl *a* au niveau de la subsurface > 1 mg.m^{-3}) favorise l'accroissement des abondances zooplanctoniques où les filtreurs sont dominants.

Abstract
The massive outburst of jelly organisms on the Spanish coast is a phenomenon with relevant implications at the socio-economic level. The aim of this study is to combine the abundance variability of these organisms with the physical and oceanographic forcing. The interannual variations of gelatinous plankton by different sources of data at regional scale (Alboran and Balearic Sea) are analyzed since 2007. Also, at local scale daily observations of abundance of jellyfish were estimated since 2011 in a fixed station offshore the Alicante coast. Remote sensing data are analyzed to characterize which are the time windows of increased proliferation of gelatinous plankton and their connection with the physical environment.

Keywords: Alboran Sea, North-Western Mediterranean, South-Western Mediterranean, Medusae

The worldwide concern about the massive proliferation of marine gelatinous zooplankton in the last decades has resulted in extensive recent work [1]. However, there is still no agreement about the underlying cause for their occurrence. Several hypotheses have been tested, thus the processes involved are not always mutually exclusive. Eutrophication, over-fishing, species introduction and climate change, are some of the proposed explanations [2].

Given the magnitude of ecological and socio-economic consequences of jellyfish outbreaks in the Mediterranean Sea, the understanding of mechanisms driving them is of great importance for the prediction of future scenarios. The identification and location of the target species as well as the gathering of relevant data seems a first valuable step through population dynamics and ecological modelling.

The aim of this study is to combine the abundance variability of these organisms with the physical and oceanographic forcing. The interannual variations of gelatinous plankton by different sources of data at regional scale (Alboran and Balearic Sea) are analyzed since 2007 (fig. 1).

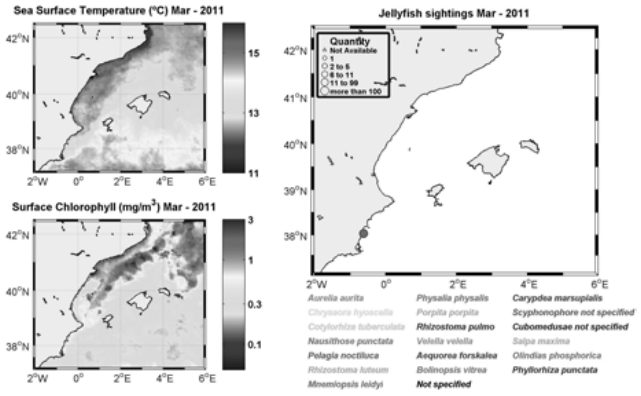

Fig. 1. Mean remote sensing sea surface temperature and surface chlorophyll and jellyfish sightings during March 2011 in the Balearic Sea.

Also, at local scale daily observations of abundance of jellyfish were estimated since 2011 in a fixed station (38º 25.200' N, 00º 20.850' W) sited near by a marine culture of fish floating cages, 1.87 miles offshore the Alicante coast (fig. 2). The number of species identified in this station was a four: *Chrysaora hyoscella*, *Cotylorhiza tuberculata*, *Pelagia noctiluca* and *Physalia physalis*. The specie most frequent and also most abundant was, in both years sampled, *Pelagia noctiluca*.

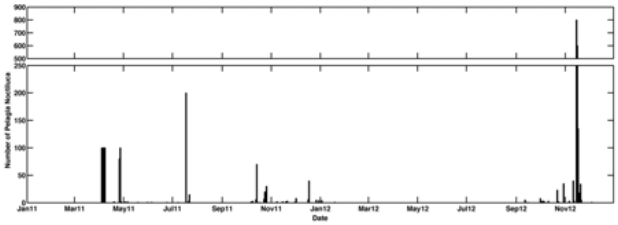

Fig. 2. Daily abundance variability of *Pelagia noctiluca* 1.87 miles offshore the Alicante coast, Spain, during 2001 and 2012. The exact location is observed in the map of fig.1 with a dot.

Remote sensing data are analyzed to characterize which are the time windows of increased proliferation of gelatinous plankton and their connection with the physical environment.

Abstract

The predator ctenophore *Mnemiopsis leidyi* is a globally invasive species that was introduced in the seas around Europe and its expansion in new areas continue. *M.leidyi* has a wide environmental tolerance and could establish in contrasting ecosystems. We analyze variability of its morpho- physiological features, genetic diversity, patterns of spatial and temporal population dynamics in the Black, Azov, Caspian, Baltic, several areas of the Mediterranean seas as a response on different conditions (salinity, temperature, prey concentration). We conclude that environmental conditions determined its morpho-physiological features in its phenological variability range. This study may provide understanding evolutionary processes of invasive species in contrasting ecosystems.

Keywords: Alien species, Ctenophora, Black Sea, North-Eastern Mediterranean, North-Western Mediterranean

The predatory ctenophore *Mnemiopsis leidyi*(A.Agassiz, 1865) is a globally invasive species, "super" invader, native for the northern and southern America. It was first introduced into the Black Sea in early 1980s. From the Black Sea, it spread north to the Sea of Azov, south to the Sea of Marmara and to the Aegean Sea (Shiganova et al., 2001). It was brought in the Caspian Sea in 1999 (Shiganova et al., 2004).In 2009 it was recorded along the coastal areas of eastern and western Mediterranean (Galil et al., 2009; Boero et al., 2009; Fuentes et al., 2009 ; Shiganova & Malej, 2009). In 2006 its outbreak was recorded along the north-western European coast (Javidpour et al., 2006). In 2009 it was found in the coastal area of Australia and in the Indian Ocean (Costello et al., 2012). *M.leidyi* expansions in new areas still continue. Therefore this invader need to be detailed studied in comparative aspects in all recipient areas. *M.leidyi* has a wide environmental tolerance and high ecological plasticity and could establish in contrasting environmental conditions both marine and brackish ecosystems. The goal of the review is a comparative analysis of the variability of *M. leidyi* morphological, ecophysiological features, genetic population diversity ; patterns of spatial and temporal population dynamics in the Black, Azov, Caspian, Baltic seas, several areas of the Mediterranean as a response on different environmental conditions (salinity, temperature, productivity, prey concentration), anthropogenic factors and climate change effect; assessment of *M. leidyi* impact on trophic web of brackish and marine ecosystems in the seas of Eurasia; sensitivity assessment of ecosystems for invasion of *M.leidyi* and for invaders in general. We analyze the variability of morphological features of *M.leidyi* in different environments and conclude that environmental conditions determined its morphological features in its possible range of phenological variability. Earlier three species of genus Mnemiopsis were described on the base of these features (Mayer, 1912). We use data of genetic analysis based on analyses of investigated sequence variation in the nuclear ribosomal Internal Transcribed Spacer (ITS) region of the ctenophore *M. leidyi* that has provided understanding of its invasion history including dynamics of new areas' colonization and population sources (Ghabooli et al., 2011). We analyse *M.leidyi* physiological features in different environments that determine life cycle, which include metabolic and feeding rates, reproduction time and duration, fecundity, growth and size, pattern of distribution and finally predation rates on zooplankton. We analyze the interannual variability, individual and population *M.leidyi* size, spatial distribution and seasonal time of its spreading from the main area of distribution to adjacent areas and seas: from the Black Sea to the adjacent seas, from the Southern Caspian to the North that are controled by surface water temperature, especially by minimal winter and spring SST, and wind direction, which are modified mostly by global scale atmospheric patterns. *M.leidyi* effects on the European seas ecosystems are different. The strongest impact was recorded in the productive and disturbed Black, Azov and Caspian Seas, where it had cascading effect at all levels of ecosystems both bottom up and top down. During last years some temporal effect was observed in the Baltic Sea and coastal areas of the eastern and western Mediterranean. But effects depend on population size, which is controled by current environmental and biotic conditions and climate forcing. The comprehensive assessment of this globally invasive species may provide understanding evolutionary processes of invasive species, patterns of population dynamics of invaders in different contrasting ecosystems and their sensitivity for invasions.

GELATINOUS ZOOPLANKTON IN THE BAY OF MARSEILLES - POTENTIAL CONTROL OF THE FISH POPULATION OVER THE ARTIFICIAL REEFS?

Delphine Thibault-Botha [1]*, Melanie Santo [1] and Megane Neauport [1]
[1] Aix-Marseille Universite Institut Mediterraneen d'Oceanologie - delphine.botha@univ-amu.fr

Abstract
Gelatinous zooplankton play important roles in coastal seas, competing with fish for food items and eating fish eggs and larvae. Despite this, they have been understudied in many ecosystem, especially in coastal marine ecosystems. In the framework of the colonization of the artificial reef, strong population of gelatinous zooplankton could limit the extension of the recruitment of fish over the reef, due to their strong feeding capacities. Gelatinous zooplankton both the carnivorous (siphonophores and jellyfish) and the filter feeders (salps, doliolids, appendicularians) have been collected over the Artifical reef area since 2010 on a bi-weekly base and show large seasonal variations.

Keywords: Biodiversity, Coastal systems, Zooplankton , Gulf of Lyon

Introduction Gelatinous zooplankton has been observed for a very long time along the coast of the Northwestern Mediterranean Sea. Nevertheless information are lacking on this group of organisms which play important roles in the structuring and functioning of the pelagic ecosystem The Northwestern Mediterranean Sea hydrodynamics is largely dominated by the North Current but also through strong southwards winds and inputs of freshwater through several small rivers and a larger contribution from the Rhone River. Artificial reef structures were placed in the Bay of Marseilles in 2008 and colonization by encrusting, benthic and pelagic species has been followed since then. Gelatinous zooplankton are part of the pelagic ecosystem and could regulate the population of fish around the reefs.

Material and methods Bi-weekly sampling has been conducted since 2010 in order to study the plankton composition found over the artificial reef. CTD cast were performed at a station located roughly in the mid-section of the reef area. Chlorophyll was measured at the surface and bottom of the water column. Mesozooplankton was collecting using vertical WP2 net. Nansen Net for gelatinous zooplankton mounted with 700um mesh size was towed from the bottom (~30m) and the surface, as well as horizontally at the surface at ~1 knot. Zooplankton collected was then preserved in formalin buffered solution until further taxonomic analysis. Gelatinous zooplankton were identified down to species when possible. Fish egg and larvae were also counted.

Results and discussion Over the 3 year period, temperature (figure 1) and salinity (not shown) displayed large inter-annual variations

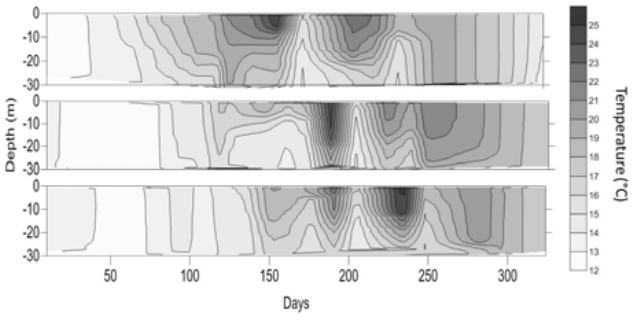

Fig. 1. In situ temperature profiles in 2010 (top), 2011 (middle) and 2012 (bottom) over the artificial reef

with a lag in the beginning of the warming season from 2010 to 2012 of about 2 months. Clear upwelling events as well as seasonal stratification are reported in all three years during the summertime. 2012 was also characterized by warmer waters in autumn. Fluorescence signal (Figure 2) displayed also strong inter-annual variation with spring 2012 displaying highest values. Low and rather homogenous values are reported through the rest of the year.

Gelatinous zooplankton as well as fish eggs/larvae were more abundant in surface nets than in vertical nets. This is partly due to the larger volume of water sampled but as well as by the aggregation of these pelagic organisms in the surface layer (hyponeuston; Della Croce, 1962). Gelatinous zooplankton both the predatory type and the filter feeders were observed through the year in variable abundance over the artificial reef area.

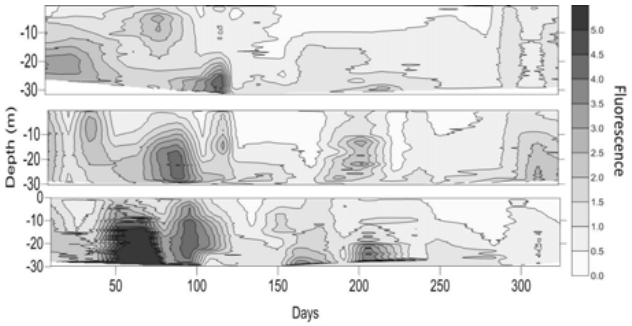

Fig. 2. *In situ* fluorescence profiles in 2010 (top), 2011 (middle) and 2012 (bottom) over the artificial reef

Predatory organisms were represented by siphonophores, medusa and chaetognathes. Salps, doliolids and appendicularians were the most abundant gelatinous filter feeders. Siphonophores were overall the most abundant type, contributing up to 100% of the gelatinous population and were presented by the following species : *Chelophyes appendiculata, Eudoxoïdes spiralis, Muggiaea atlantica, Muggiaea kochi, Lensia subtilis, Lensia fowleri, Lensia conoidea, Lensia subtiloides, Lensia subtilis, Lensia multicristata, Abylopsis tetragona,* and *Abylopsis eschscholtzi*. Both polygastric and eudoxid forms were found. Medusae were at time abundant and presented by *Obelia* sp., *Eutonina scintillans, Echoeilota ventricularis, Rhopalonema velatum, Eutima gracilis, Podocoryne borealis, Sminthea erygaster, Solmundella bitentaculata, Persa incolorata* and *Arctopodema ampla*. No clear pattern have been observed. Filter feeders showed large aggregates in spring and autumn. Salps were represented by both blastozooid and oozoids individuals of *Thalia democratica*. *Doliolum denticulatum* and *Doliolum nationalis* were the two species of doliolid reported. Appendicularian were mainly members of *Oïkopleura fusiformis, Oïkopleura longicauda* and *Oïkopleura dioïca*. Large jellyfish such as *Velella velella* and *Pelagia noctiluca* were seldom sampled by our net. Little information being available on the population of gelatinous zooplankton of the Bay of Marseille (Arfi et al., 1982), impact of the artificial reef structure and mainly on the establishment of several fish population remains unknown. Comparison with the SOMLIT station slightly off shore located at the entrance of the bay of Marseille allowed some spatial comparison. Gelatinous zooplankton assemblage appeared similar with matching temporal variations. Nevertheless fish eggs and larvae were more important over the reef area.

THE ROLE OF NEWLY FOUND MUCIN (Q-MUCIN) OF JELLYFISHES IN THEIR PHYSIOLOGY AND ECOLOGY.

Abstract
The role of novel mucin (Q-mucin) recently found in jellyfish bodies are investigated based on the physiology and ecology of jellyfishes. Although no direct evidence has been obtained, we speculate that Q-mucin are used as a mediating molecule in its biomineralization process, that is, collecting calcium to be used in the nervous and muscle systems from sea water. With this consideration, "Jellyfish explosion" can partly be understood by the change in the mineral environment of oceans.

Keywords: Calcium, Chemical analysis, Medusae, Biotechnologies, Extra-Mediterranean regions

In 2005, we discovered a novel mucin (qniumucin: Q-mucin)[1,2] from many kinds of jellyfishes, which is a group of highly polymerized glycoproteins composed of a single peptide main chain and blanched random glycochains connected to the peptide via an *O*-glycoside bond. Generally, mucins are involved in mucus of various animals, however, Q-mucins is not found in the mucus of jellyfishes but seems to be a content of extracellular matrices (ECMs) of their body. The chemical structure of Q-mucin is extremely simple as solved our series of studies[1-4] which shows a sharp contrast to conventional mucins extracted from various domestic animals.

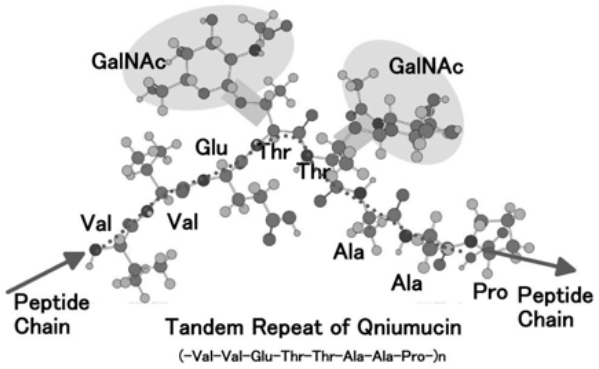

Fig. 1. Possible structure of a single tandem repeat part of jellyfish mucin (qniumucin: Q-mucin). The main peptide chain has a sequence of 8 amino acids -Val-Val-Glu-Thr-Thr-Ala-Ala-Pro-. Two monosaccharides (N-acetyl galactosamine: GalNAc or its derivatives) are connected to two the central Thrs. This sequence repeats several tens times to form a high polymer. Since GalNAc also has various anionic groups, (phosphate, phosphonate, and sulfate) Q-mucin has a function of ion exchange resins.

Fig. 1 shows a possible structure of Q-mucin of its single repeating part. The long peptide part has a simple repeating structure with a unit sequence of 8 amino acids, -Val-Val-Glu-Thr-Thr-Ala-Ala-Pro- and glycochains a simple monosaccharide which is GalNAc, or its derivatives having anionic groups such as phosphonate ($-O-PO_2^--CH_2-CH_2-NH_2$), phosphate ($-O-PO_2^{2-}$), and sulfate ($-O-SO_3^-$) (this one is not confirmed yet). However, no sialic acids are involved in the glycan chains deferent from any higher animals. Since no mucins can be synthesized by any methods, Q-mucin has a chance to be a useful and well-defined material as a chemical substance. Jellyfish wastes accumulated on gulfs can be used as the source of Q-mucin.

Based on the consideration of its chemical structure, we recently studied the original function of Q-mucin in jellyfishes and obtained some knowledge about their physiology and ecology. Jellyfish seems to employ Q-mucin as a mediating material to capture useful minerals from sea water. The above-mentioned anionic groups in the glycan chains have a tendency to collect various doubly or more charged metal cations with a large binding equilibrium constant, e.g. with Mg^{2+}, Ca^{2+}, Sr^{2+}, Cu^{2+}, and Cd^{2+}. In other words, Q-mucin has a function of ion-exchange resins. This property is rather uncontrolled (random) but the mineral composition of sea water is stable in all over the oceans. Therefore, each jellyfish can safely collect calcium and other nessesary minerals with a very simple mechanism to maintain their life. For example, dilute (<5 ppm) Cu^{2+} and Cd^{2+} are toxic for jellyfish and without the stimmulation of Ca^{2+} it loses the motions. We suspect that a jellyfish moves its body to stir the surrounding sea water and capture the minerals effectively by Q-mucin, especially for calcium needed for its muscle and nervous systems, i.e. biomineralization process similar to other sea creatures.

In the long history of development, jellyfish is the first animal which acquired a sophisticated and dynamic muscle and nervous systems. It seems to want to use calcium dynamically but only has small gravity stones for the storage of calcium instead of the bone system in the higher animals. Although almost all the researches on biomineralization of jellyfishes published previously only investigate the final production of gravity stones, now we focus on the mediating materials, Q-mucin, and would like to discuss their chemical knietics that collect mineral cations from sea water where they are involved with relatively low concentrations.

We suppose that the causes of "Jellyfish Explosion" can be related to the change in mineral environment of our oceans especially for calcium concentrations. For example, concrete structures affect the near-coast environment and similar mass occurrence of shells is frequency found. In our study, now we have indirect evidence only, but some discussion about ecology of jellyfish may be possible.

ISOTOPIC TISSUE FRACTIONATION AT BIVALVE *PINNA NOBILIS*, A NON-INVASIVE APPROACH

Carme Alomar [1]*, Salud Deudero [1] and Maite Vázquez-Luis [1]
[1] Instituto Español de Oceanografía Centre Oceanogràfic de les Balears - c.alomar@ba.ieo.es

Abstract
Carbon and nitrogen isotopic values of muscle and mantle in Mediterranean endemic bivalve *Pinna nobilis* individuals have been analyzed to study tissue fractionation. Muscle tissue is enriched in both $\delta^{13}C$ and $\delta^{15}N$ compared to mantle on average 1.11 ‰ and 0.71 ‰, respectively. Analyses of mantle tissue do not involve sacrifice of individuals and are therefore proposed as a conservation tool in the study of *P. nobilis*.

Keywords: Bio-indicators, Bivalves, Conservation, Balearic Islands

Introduction- *Pinna nobilis* is one of the largest bivalves in the world [1] and endemic to the Mediterranean. Populations have been reduced due to direct and indirect impacts [2]. As a consequence, it has been listed as a Mediterranean endangered species (92/43/EEC). Previous studies have suggested muscle as the most appropriate for stable isotopes analyses [3]. The aim of this study was to analyze mantle and muscle tissues of *P. nobilis* at three different localities to i) study fractioning between tissues, ii) study isotopic differences among localities and iii) propose sampling of mantle instead of muscle to study the trophic ecology of the fan mussel. Results will allow comparison of muscle and mantle tissue in order to provide a non-invasive technique for sampling vulnerable fan mussel.

Materials and Methods-The study was carried out at 3 sampling sites: Cabrera, Es Freus and Andratx, Balearic Islands (Western Mediterranean). Individuals of *P. nobilis* were collected under licence from the Government for research purposes by experienced scuba divers in February 2013. For each *P. nobilis* individual, muscle and mantle tissues were obtained. Stable isotopes of $\delta^{13}C$ and $\delta^{15}N$ were analyzed following standard procedures [4]. A multivariate analyses of variance PERMANOVA tested significant spatial differences among sites and tissues.

Results- For all localities, muscle tissue were enriched in $\delta^{13}C$ and $\delta^{15}N$ compared to mantle tissue (Fig. 1). Values of $\delta^{13}C$ were highest at Andratx and lowest at Es Freus. Values of $\delta^{15}N$ were highest at Andratx and lowest at Cabrera (Fig. 1). Both $\delta^{13}C$ and $\delta^{15}N$ isotopic signatures of *P. nobilis* showed significant differences for locality (Lo) (PERMANOVA, Lo, $\delta^{13}C$, $p < 0.001$ and Lo, $\delta^{15}N$, $p < 0.001$, Fig 2.) and tissue (Ti) (PERMANOVA, Ti, $\delta^{13}C$, $p < 0.001$ and Ti, $\delta^{15}N$, $p < 0.001$, Fig 2). Only the interaction between tissue and locality for $\delta^{15}N$ showed significant differences (PERMANOVA, Lo x Ti, $\delta^{15}N$, $p < 0.05$, Fig 2).

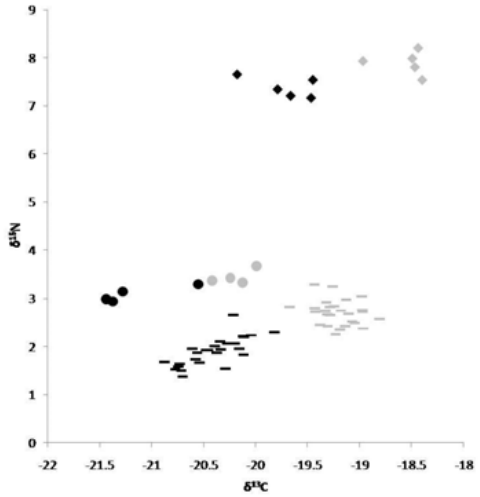

Fig. 1. Individual values of $\delta^{13}C$ and $\delta^{15}N$ for *P. nobilis* at Andratx ♦, Cabrera – and Es Freu •. Mantle is represented in black and muscle in grey.

Discussion-The present study shows significant differences between tissues and localities. Muscle is enriched compared to mantle of the same individual. Both tissues are nitrogen enriched in localities which receive higher anthropogenic pressure, Andratx. Mantle has shown to follow the same isotopic pattern as muscle. Studying mantle in place of muscle does not involve scarifying individuals and minimizes the sampling impact on the existing populations contributing to the conservation of this endangered specie.

ANNUAL CYCLE OF ^{13}C AND ^{15}N STABLE ISOTOPE SIGNATURES OF ADDUCTOR MUSCLE AT THE BIVALVE *PINNA NOBILIS*

Carme Alomar [1]*, Salud Deudero [1] and Maite Vázquez-Luis [1]
[1] Instituto Español de Oceanografía Centre Oceanogràfic de les Balears - c.alomar@ba.ieo.es

Abstract
Pinna nobilis are efficient filter feeders bivalves and provide evidence of surrounding conditions. Individuals of a Marine Protected Area (MPA) have been sampled and isotopic values of $\delta^{13}C$ and $\delta^{15}N$ have been analyzed to study the annual cycle of the fan mussel in non-eutrophic waters. Values obtained in summer months are higher indicating the need to consider temporal shifts in stable isotope linked with trophic resources availability.

Keywords: Bivalves, Coastal systems, Trophic relations, Balearic Islands

Introduction-Organism assimilate both carbon and nitrogen derived compounds from their food sources [1] giving isotopic signals which reflect surrounding water conditions. Isotopic values of $\delta^{15}N$ quantitatively asses trophic level, whereas values of $\delta^{13}C$ indicate relative contributions to the diet of different potential primary sources, giving evidence of inshore versus offshore food intake [2].Environmental differences such as light intensity and nutrient concentrations, species composition and geographic variability affect $\delta^{13}C$ and $\delta^{15}N$ values of primary producers in a region [3].Therefore, isotopic analysis is an effective method to study food webs [4].The aim was to study the annual cycle of the filter feeder *P. nobilis* at a MPA with stable isotope analyses of $\delta^{13}C$ and $\delta^{15}N$ and to contribute with new isotopic values to the existing library of such data.

Materials and Methods-The study was carried out at Cabrera, a MPA in the Balearic Islands (Western Mediterranean). Between five and ten individuals were monthly collected under licence from the Government for research purpose by experienced scuba divers from April 2011 to March 2012. Stable isotopes of $\delta^{13}C$ and $\delta^{15}N$ in muscle tissue of *P. nobilis* were analyzed following standard procedures [5]. A multivariate analyses of variance PERMANOVA tested significant spatial differences among months and season.

Results-Values of $\delta^{13}C$ were highest in August (-18.83 ± 0.00 ‰) and lowest in April and March (-19.81 ± 0.02 ‰ and -19.81 ± 0.00 ‰) (Fig.1). Values of $\delta^{15}N$ were highest in May (3.37 ± 0.00 ‰) and lowest in March (2.54 ± 0.00 ‰) (Fig. 2). Both isotopes showed significant differences between months (PERMANOVA, $P < 0.001$). Values of $\delta^{13}C$ and $\delta^{15}N$ were highest in summer, -19.16 ± 0.00 ‰ and 3.11 ± 0.00 ‰, respectively, and there were significant differences between seasons (PERMANOVA, $P < 0.001$).

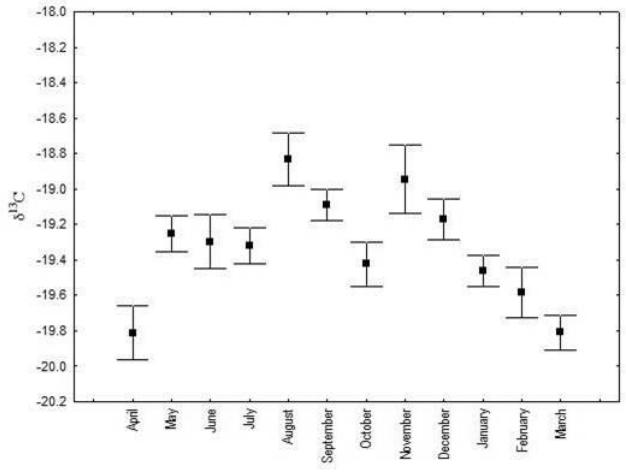

Fig. 1. Monthly mean ± Standard Error of isotopic signatures of $\delta^{13}C$ at muscle of *Pinna nobilis* in Cabrera.

Discussion-The fan mussel shows variation in isotopic composition of muscle among months and summer months are enriched in carbon and nitrogen. This variation suggests a change in inhabiting conditions and diet. The study contributes with new data and obtained results agree with available data from the literature for the same specie and sampling area.

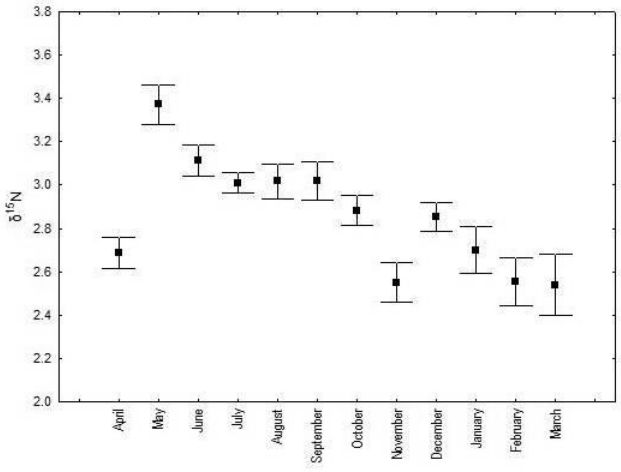

Fig. 2. Monthly mean ± Standard Error of isotopic signatures of $\delta^{15}N$ at muscle of *Pinna nobilis* in Cabrera.

[3] MARUM

Abstract
Vulnerable Marine Ecosystems (VME) in the deep Mediterranean Sea have been identified as consisting of communities of Scleractinia (*Lophelia pertusa* and *Madrepora oculata)*, Pennatulacea (*Funiculina quadrangularis)* and Alcyonacea (*Isidella elongata*). This study deals with video data recorded in the heads of French Mediterranean continental canyons.

Keywords: Biodiversity, Bathyal, Canyons, North-Western Mediterranean

Introduction
Adverse impacts to Vulnerable Marine Ecosystems (VME) in the deep sea have now become an international concern since the United Nation called on governments and Regional Fishery Management Organisations to prevent them. The biggest constraint in protecting VMEs are the uncertainties in the distribution and abundance of VME indicator species, and similar uncertainties in the link between fishing intensity and significant adverse impacts. The pressures on natural marine resources and the demand for marine ecological services are considered excessive and have led to the establishment of the European Marine Strategy Framework Directive (MSFD). This study was performed in the framework of the initial assessment of the bathyal benthic ecosystems in the French continental canyons of the Mediterranean Sea.

Method
Quantitative observations were extracted from 101 video films recorded during the MEDSEACAN cruise in 2009 (Aamp/Comex) [1]. Qualitative information was extracted from four other cruises (two Marum/Comex cruises in 2009 and 2011 and two Ifremer cruises in 1995 and 2010) to support the previous observations in the Cassidaigne and Lacaze-Duthiers canyons. All the species, fishing impacts and litter recognized in the video films recorded from 180 to 700 m depth were mapped by GIS. Abundances and distributions of benthic fishing resources (marketable fishes, Aristeidae, Octopodidae), Vulnerable Marine Species, trawling scars and litter were calculated and compared between 17 canyons and the open slope between the Stoechades and Toulon canyons.

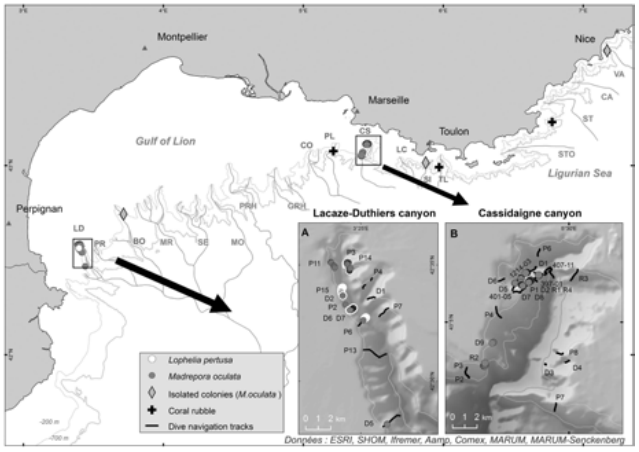

Fig. 1. Distribution map of frame-building scleractinian cold-water coral communities. **A**: Zoom in the Lacaze-Duthiers canyon. **B**: Zoom in the Cassidaigne canyon.

Results and discussion
Lacaze-Duthiers and Cassidaigne canyons revealed the highest density and largest colony sizes of scleractinian cold-water corals, which distribution was mapped in detail (Fig. 1). Funiculina quadrangularis was rarely observed, essentially in the Marti canyon and, I. elongata was abundant in three canyons (Bourcart, Marti, Petit-Rhône). The alcyonacean Callogorgia verticillata, observed in high abundance in the Bourcart canyon and in less abundance in several other canyons, is proposed as a Vulnerable Marine Species. Our studies on anthropogenic impacts show that litter was present in all of the canyons, however, higher abundances were found in the Ligurian Sea, where the heads of the canyons are closer to the coast. Seafloor disturbance due to benthic fishing was observed to be mainly due to trawling in the Gulf of Lion and to long lines in the Ligurian Sea where rocky substrates are present. The bauxite red mud residue expelled in the Cassidaigne canyon was seen to prevent fauna from settling at the bottom of the canyon and it covered much of the flanks [2].

QUANTIFICATION OF ANTHROPOGENIC PRESSURES ON MARINE ECOSYSTEMS OF THE GULF OF TUNIS

Slim Gana [1]* and Khaoula Souissi [1]
[1] SAROST Marine Engineering and Geosciences Division - slim.GANA@sarost-group.com

Abstract
In the framework of the EU-funded PERSEUS[1] project, we quantify the impacts of anthropogenic pressures on Gulf of Tunis marine ecosystems. The first step of the methodology required by the MSFD's [2] principles is "the initial assessment of the environmental state", with the view to achieve the main objective "Good Environmental Status (GES)" by 2020. Practically, we used a standard methodology developed by Halpern et *al*. [1]; [2] based on expert survey to determine the cumulative impact index of anthropogenic pressures on marine ecosystems in the Gulf of Tunis.

Keywords: Mapping, Gulf of Tunis, Coastal management

Introduction
In order to achieve the Good Environmental Status in a given area, it is first necessary to identify threats on marine ecosystems. The Gulf of Tunis is chosen as one of the study areas in the case of the European project "PERSEUS" to implement the MSFD's principles. This Gulf is concerned by different anthropogenic pressures threatening its ecosystems. The quantification of threats impact on marine ecosystems is important for coastal management and for determination of remedial measures. In this work, we are focusing on the first step of the MSFD's methodology which is "the initial assessment of the environmental state"

Methods
First, a geo-database describing the different threats and the most important coastal ecosystems in the Gulf of Tunis was prepared. Second, we determined the weighted average vulnerability score through an expert survey by considering 5 vulnerability ranks: spatial scale, frequency, functional impacts, resistance and resilience [1]. We included another rank that determines the level of "certainty" in the survey response. The weighted average vulnerability score was calculated following the following steps: for each threat-ecosystem combination, we rescaled "scale" and "resistance" (multiplied by 4/6 and 4/3, respectively); each weighted value of 5 vulnerability ranks was multiplied by the certainty value; the sum of these weighted values for each vulnerability measure was divided by the sum of the certainty values to obtain the weighted-average vulnerability score for each threat-ecosystem. Then, cumulative impact index is calculated using the following formula for each cell :

$$I_c = \sum_{i=1}^{n} \sum_{j=1}^{m} D_i \times \mu_{ij} \times E_j$$

Where: $\mathbf{D_i}$: log transformed and normalized value of an anthropogenic pressure at location "i", $\mathbf{E_j}$: is the absence or the presence of an ecosystem "j" in each cell ((0=absence) or (1=presence)), $\boldsymbol{\mu_{ij}}$: is the weighted vulnerability score (0 to 4), **n**: number of anthropogenic pressures identified in the Gulf of Tunis, **m**: number of ecosystems identified in the Gulf of Tunis. Finally we implemented the database using a GIS for mapping the cumulative impact index.

Results
The Gulf of Tunis is threatened by several pressure types (Rivers discharges, wastewater discharges, maritime traffic, industries and tourism) which threaten its marine ecosystems by inducing different impact levels. The most important pressure loads is located around the Bay of Tunis (Fig 1).

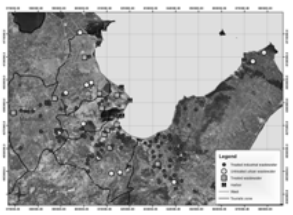

Fig. 1. Anthropogenic pressures in the Gulf of Tunis

The cumulative impact index of these pressures allows the quantification of threats to determine the environmental state in the area and help decision-making for a sustainable management of the marine environment to achieve "the Good Environmental State (GES)". Anthropogenic pressures in the Gulf of Tunis induce different cumulative impact levels depending to the considered ecosystems. The Bay of Tunis is the most threatened area of the Gulf because it is the recipient of the most important pressure loads (Fig 2).

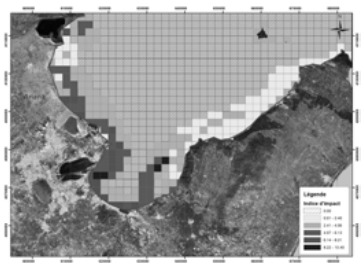

Fig. 2. Cumulative Impact Index in the Gulf of Tunis

The eastern part of the Gulf is less impacted than the western one because of the low volume of existing pressures in this area (from Korbous to Ras At Tib). The determination of the weighted average vulnerability score shows that the most important vulnerability scores are assigned to the seagrass (*Posidonia oceanica*, *Caulerpa prolifera* and *Cymodocea nodosa* meadows) against trawling, dredging and disposal of dredge spoil. In addition, the result can be different in dependence to the ecosystems considered in the study.

BOTTOM TRAWL DISCARDING PRACTICES IN THERMAIKOS GULF (NORTH AEGEAN SEA): PRELIMINARY RESULTS

Xaralambos Apostolidis [1], Paraskevi K Karachle [2]* and Christos D Maravelias [2]
[1] Aristotle University of Thessaloniki, School of Biology, Department of Zoology, Laboratory of Ichthyology, Box 134, 54124, Thessaloniki, Greece
[2] Hellenic Centre for Marine Research, 46.7 km Athens Sounio ave., P.O. Box 712, 19013 Anavyssos Attiki, Greece - pkarachle@hcmr.gr

Abstract
Preliminary results on the discards of trawlers in Thermaikos Gulf are presented. Higher rates of discarding (52.3% on average) than previously reported in Greek waters were recorded. The percentage of individuals under the minimum landing size of the most prevalent commercial and discarded species ranged between 6.7% (*Citharus linguatula*) and 93.6% (*Trachurus mediterraneus*). Results indicated depletion of fish stocks due to high fishing effort and an increase of more resilient and less vulnerable to overfishing species, mainly Cephalopoda and Crustacea.

Keywords: Aegean Sea, Trawl surveys

Introduction Discarding, a common practice in most fisheries, has important implications for the ecosystem and fisheries economy [1, 2]. The process of discarding is very variable in nature, especially in the Mediterranean multispecies fisheries context [3]. Among different fishing methods, bottom trawling produces proportionally more discards [4]. Herein we describe and analyze discards in relation to landings of bottom trawl fishing in Thermaikos Gulf, NW Aegean Sea. These data are important information, since catch data are not available after 2008 in Greece.

Materials and methods Sampling was conducted on a monthly basis (November 2012 - March 2013), in Thermaikos Gulf. Four commercial trawlers, of approximately the same horsepower and length, were used (40mm squared mesh size cod end). Catches, after sorting by crew members into landings and discards, were identified to the lowest possible taxonomic level (hereafter species) and weighed. Additionally, the number of discarded individuals per species was recorded. Random subsamples of 30 individuals of discarded commercial species were measured to the nearest millimeter (mm) of total, carapace and mantle length for fish, Decapoda and Cephalopoda, respectively.

Results and Discussion In total, catches of 27 hauls were sampled during 12 one-day fishing trips. Overall, 96 species were recorded in the catches (60 fishes, 9 decapods, 6 cephalopods and 21 other invertebrate species). Landings composed mainly of *Mullus barbatus* (22.4%), *Sepia* spp. (10.0%), *Squilla mantis* (8.2%), *Melicertus kerathurus* (7.7%), *Parapenaeus longirostris* (7.45%), *Eledone* spp. (6.9%) and *Lophius* spp. (6.1%). Discards were dominated by the blue-leg swim crab *Liocarcinus depurator* both in terms of weight and number of individuals (Fig. 1a, b).

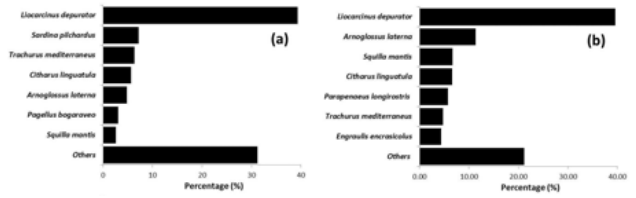

Fig. 1. Most prevalent discarded species in terms of biomass (a) and number of individuals (b).

With respect to commercial species that were discarded, *Citharus linguatula*, *P. longirostris*, *S. mantis*, *Trachurus mediterraneus*, *Engraulis encrasicolus* and *Sardina pilchardus* were the most abundant. Length frequency distributions of the four first species were skewed toward small sizes (Fig. 2). In the contrary, length frequency distributions of *E. encrasicolus* and *S. pilchardus* presented a bimodal pattern (Fig. 2). The latter is most probably a result of the fact that these species were totally discarded and thus not sorted. The positive skewed distributions of the rest of the species are indicative of size based selection during sorting by the crew. The number of individuals discarded and under the minimum landing size (MLS) differed between these species. In particular, 6.7%, 34.7%, 93.6%, 42.7% and 34.7% of the individuals discarded were below the MLS for *C. linguatula* (MLS = 80mm), *P. longirostris* (MLS = 20mm), *T. mediterraneus* (MLS = 150mm), *E. encrasicolus* (MLS = 90mm) and *S. pilchardus* (MLS = 110mm) respectively. No MLS has been set for *S. mantis*.

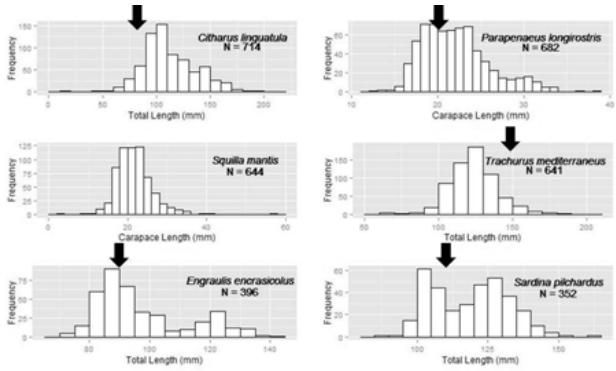

Fig. 2. Length frequency distributions of the six more abundant commercial and discarded species. Black arrows indicate minimum landing size.

Invertebrates' biomass in both landings and discards (52.5% and 53.5% respectively) was higher compared to fish. Haul specific discarding ratio (discards/landings) was on average 52.3%, while discarded fish were on average 23.5% of catches. These values are higher compared to results of similar studies performed in Greek waters [2, 5]. All above facts indicate depletion of fish stocks due to high unselective fishing effort and an increase of more resilient and less vulnerable to overfishing species.

The research leading to these results has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement no 289192.

RADIOACTIVITY CONCENTRATIONS IN INDIGENOUS AND TRANSPLANTED MUSSEL (*MYTILUS GALLOPROVINCIALIS*) OF TURKISH SEA COAST

Ö. Kiliç [1]*, M. Belivermis [1], F. Gözel [1], Y. Çotuk [1] and S. Topçuoglu [1]
[1] Istanbul University Faculty of Science, Department of Biology - kilic_onder@yahoo.com

Abstract
In the present study, radioactivity concentrations (^{137}Cs, ^{40}K, ^{226}Ra, ^{228}Ra, ^{210}Po and ^{210}Pb) were determined in indigenous mussels (*Mytilus galloprovincialis)* collected in Bosphorus, Black Sea, Marmara Sea and Aegean Sea coast of Turkey. Since *M. galloprovincialis* is not available, mussel cages were employed in Levantine Sea coast . The average activity concentrations of ^{137}Cs, ^{40}K, ^{226}Ra, ^{228}Ra, ^{210}Po and ^{210}Pb were found to be 0.71 ± 0.13, 469 ± 24, 0.94 ± 0.07, 1.0 ± 0.11, 121.9 ± 4.2 and 10.9 ± 0.9 Bq kg^{-1} in dry weight (d.w.), respectively. The average of ^{210}Po/^{210}Pb ratio was found to be 13.9. All found activity concentrations were compared with levels of similar studies carried out in Mediterranean coast.

Keywords: Radionuclides, Monitoring, Aegean Sea, Black Sea, Marmara Sea

Introduction
Mytilus galloprovincialis is commonly used for determination of contaminant levels such as radionuclides, trace metals and organic contaminants in marine environment [1-4]. Natural radionuclides are the main source of radioactivity in the marine environment. In addition, artificial radionuclides which released into atmosphere due to nuclear weapon tests and nuclear power plants (NPP) accident such as Chernobyl NPP accident, contribute to existing radioactivity in the marine environment. Some studies were locally carried out for determination of radioactivity concentrations by using various samples in Turkish Sea coast [1,2,4], however, radionuclide levels were not determined in all coast of Turkey in the same period of year by using same bioindicator species. Therefore, this is the first comprehensive study related with determination of radionuclide levels in Turkish coast.

Materials and Methods
The mussel samples (*M. galloprovincialis*) were collected at 20 stations in May 2012 from Turkish coast (8.333 km) (Figure). Due to high seawater temperature *M. galloprovincialis* is not available in Levantine Sea and south coasts of Aegean Sea. Therefore, mussel cages were employed in this area for 4 stations during 6 months (from October to May 2012). After all collected mussel samples were transported to laboratory, the samples with a shell length 4-6 cm were cleaned any external material, their soft tissues were dissected and then dried at 85 ^{0}C to constant weight and homogenized. Activity concentrations of ^{210}Po and ^{210}Pb in soft tissue of mussels were measured using silicon surface barrier detectors connected to multi-channel analyzer alpha spectrometer. Activity concentrations of ^{137}Cs, ^{40}K, ^{226}Ra and ^{228}Ra were measured by using gamma ray spectrometer with HPGe detector.

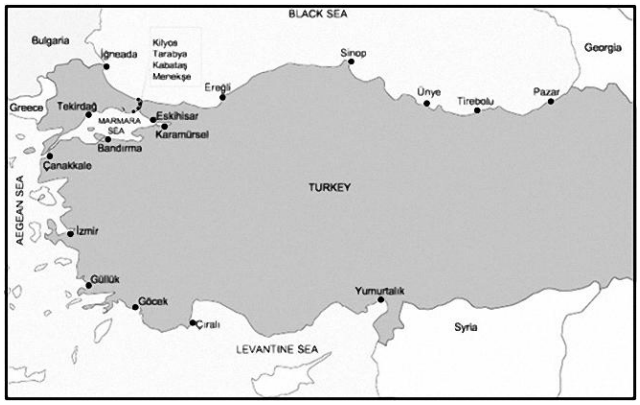

Fig. 1. Passive and active biomonitoring locations

Results and Discussion
It is seen that the activity concentrations of ^{137}Cs were found in very low levels (MDA< - 1.37 Bq kg^{-1} d.w.) in all stations. These results are consistent with levels (0.3-1.9 and 0.86–2.43 Bq kg^{-1}) of previous studies [3,4]. Thebault et al. (2008) determined activity concentrations of ^{137}Cs in the range of 0.01-1.50 Bq kg^{-1} w.w. (wet weight) by using *M. galloprovincialis* in Mediterranean Sea including Turkish coast [5]. In the current study, activity concentrations of ^{137}Cs (0.09-0.31 Bq kg^{-1} w.w.) were found at lower levels, when it was compared with those of aforementioned study [5]. Although ^{40}K was found to be high activity concentrations (391-592 Bq kg^{-1}), ^{226}Ra and ^{228}Ra activities (MDA< - 1.26 and MDA< - 1.68) were found to be low since both of radionuclides are not accumulated in the soft tissues. Activity concentrations of ^{210}Po (26.3-279.6) were found much higher than those of ^{210}Pb (4-23) since ^{210}Pb is not accumulated in soft tissues. The average of ^{210}Po/^{210}Pb ratio (13.9) was found to be similar those of ^{210}Po/^{210}Pb ratio (12.1) which was has been found by some authors [2]. The activity ranges of ^{210}Po and ^{210}Pb were lower than the levels (52-1344, 6-167; 518-2254, 21.5-258.8; 53-1960, 5-135, respectively) of previous studies [2,6,7]. When activity concentrations of studied radionuclides compared with levels of literature, it is seen that radioactivity concentrations are consistent with levels in the present study.

Abstract
In this study, it was aimed to examine the relationship among chl-*a*, oceanographic parameters such as temperature, salinity (ppt), pH, dissolved oxygen (DO), electrical conductivity (mS/cm) and Total nitrogen (TN), Total Phosporus (TP), Ammonia-nitrogen (NH_4) and Silicate (SiO_2) between October 2010 and December 2011 in Izmit Bay. Samples were taken once per a month (October 2010- December 2011) in the surface waters (inner and outer bay of the Izmit- Marmara Sea). NO_2, NO_3, NH_3, PO_4 and SiO_2 concentrations were determined spectrophotometrically. The lowest and highest concentrations TN, PO_4-P, SiO_4-Si and chl-*a* were 0.01-0.79 mg/L, 0.03- 0.21 mg/L and 0.72- 14.82 mg/L, respectively. Mean atomic ratio of N/P was lower than the Redfield ratio of 16 for ocean phytoplankton expect July and August 2011, and N was the limiting nutrient.

Keywords: Marmara Sea, Nutrients, Phytoplankton, Chlorophyll-A

Nutrients are essential components of marine life. The most important inorganic nutrients, with respect to euthrophication, are phosphate, total of nitrite, nitrate and slicon. Although most of the nutrients are present in sufficient concentration, lack of them limit growth of phytoplankton. On the other hand their abundance can be cause bloom condition. Izmit Bay is located at the eastern end of the Marmara Sea. It has approximately 45 km long and 1.8-9 km width. The bay is separated into three sections which are known as western, central and eastern. These sections are connected each other with shallow and narrow passages (Balkis 2003). Sea water quality of Izmit Bay is under pressure of heavy industrial and domestic discharges. Treated or untreated industrial and domestic wastes discharges into the Izmit bay and it is necessary to monitor nutrient concentrations in the region. Thus, in this study it is aimed to examine monthly nutrients changes with oceanographic conditions in the surface waters of the Izmit Bay (Fig. 1).

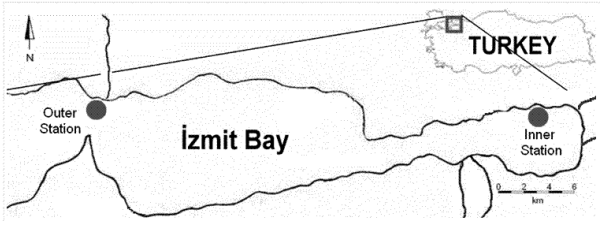

Fig. 1. Sampling stations in the Izmit Bay

Samples were taken once a month (from October 2010 to December 2011) in the surface waters (inner and Outer Bay) of the Izmit Bay (Fig. 1). Nitrite (NO_2), nitrate (NO_3), ammonium (NH_3) phosphate (PO_4) and silica (SiO_2) concentrations were determined spectrophotometrically. Also spectrophotometric techniques were used for determination of Chl-*a* (µg/L). Dissolved Oxygen (mg/L), Temperature (°C), pH, Electrical Conductivity (mS/cm) and Salinity (ppt) were determined by Hydrolab DS-5 Data Sonda. These data were given as average value in the table 1. The ratio between nitrogen and phosphorus varied between 0.15-61.46. Based on the present results, N/P ratio has reached its maximum levels in summer months (i.e. June 2011 and July 2011). Mean atomic ratio of N/P was lower than the Redfield ratio(i.e.16:1) for ocean phytoplankton (except July and August 2011) and nitrogen is assumed the limiting factor. The best N/Si/P ratio for phytoplankton health is about 15/15/1 (Friligos 1981). Thus, lower level Si/P ratio were observed during the sampling period. Maximum concentrations of nitrate + nitrite, phosphate and silicate were determined during winter season because of the low consumption by phytoplankton. The highest Chl-a concentration was measured in winter season in the inner bay possibly related with the nutrient abundance dependent phytoplankton increase. However it is known that Chl-a distribution is depends on other hydro-chemical conditions (e.i. temperature, light conditions, salinity).

1: outer bay, 2: inner bay

Since 1950's increasing industry and a growth of human population resulted in a dramatic increase of contaminant discharge to the Izmit Bay. Although treatment plants established in the region substantial level of discharges remain untreated and presents results reveal that nutrient input to the surface waters of the bay is still effective on the conditions that can be stimulate plankton bloom. Following experiments should be composed to understand ecosystem structure and determine recent changes . Long-term monitoring studies in the Izmit Bay are necessary for better understanding in nutrient cycle and plankton distributions.

CLIMATE CHANGE IMPACTS ON PRIMARY PRODUCTION AND ECONOMICALLY IMPORTANT FISH STOCKS IN THE BLACK SEA

Selin Kucukavsar [1]*, Aysen Yilmaz [2] and Hakan Ercan [3]

[3] METU-ESS/Deparment of Economics, Ankara-TURKEY

Abstract
Present study deals with the determination of the relationship between climate change and primary production and to understand how economically important fish stocks have been influenced by the variations in primary production in the Black Sea for 1970-2010 period.

Keywords: Primary production, Fisheries, Economic valuation, Global change, Black Sea

Introduction
The Black Sea is very sensitive to environmental changes, anthropogenic impact, and climate forcing. Hydro-meteorological and biochemical data records showed that robust climatic signature at inter-annual to inter-decadal time scales is evident. A general warming trend was observed in the annual mean Sea Surface Temperature (SST) by a continuous rise at the rate of 0.25 ^{o}C with in the last 100 years even though a strong cooling phase in 1992–1993 years were observed [1]. Unfavorable phytoplankton growth is especially reflected at higher trophic levels in the form of their reduced stocks after 1995 since the warming trends were more drastic. SST increase was recorded as 0.96 ^{o}C in the Black Sea for the 1982-2008 period [2]. Similarly, SST data examined for the period of 1958 and 2005 in the North Sea showed shifts in the ecosystem such as unfavorable primary production and decreased cod recruitment during the 1980's due to increased SST [3]. Strong relationship between NAO and SST is clearly evident and these climatic driven changes in the Black Sea are also related with the NAO index [1].

Methodology
Long term (40 years) data available through in situ measurements of lower trophic level ecosystem parameters (METU-Institute of Marine Sciences) and satellite data provided by Goddard Earth Sciences Data and Information Services Center-NASA are evaluated, whereas the data on meteorological parameters and biodiversity change/fish stocks are collected from Turkish State Meteorological Service and Ministry of Food, Agriculture and Livestock respectively. Regression analysis was performed to investigate the relationship between the above parameters and to propose sustainable management strategies, economic and policy tools for Turkish fishery sector for the coming 20 years.

Results and Discussion
One of the main concerns regarding the marine environment is reduced primary productivity and consequently decreased fisheries production due to global warming. The general trends in SST and the Total Catch in the Western Black Sea for the last 40 years has been presented in Figure 1.

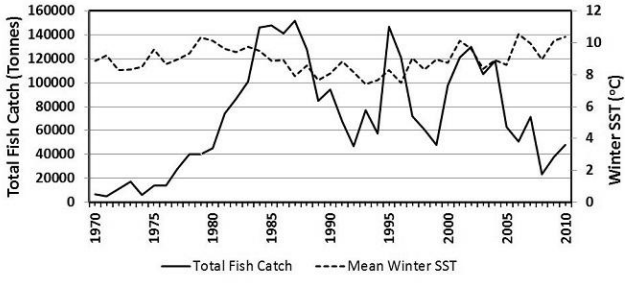

Fig. 1. Total Fish Catch and Sea Surface Temperature (SST) in the Western Black Sea

The eutrophication period after 1970 (intensified after 1980) caused increase in primary production and the related higher trophic level production including fish production. The sharp decrease in the fish catch in the late 1980s was due to the invasion test of a ctenophore, *M. leidyi* which reached very high biomass level (> 1 kg/m2) in 1989. This caused devastation in the regular food chain of the entire Black sea and a sharp decline in the total catch (especially the anchovy catch) observed in 1990s and the introduction of *B. ovata* in 1997, a predator of *M. leidyi*, helped the ecosystem to recover till the beginning of 2000 [4]. The increasing trend in the total fish catch just after irregular cooling period (1992-1993) was separately and clearly defined within this catastrophic ecosystem change. Total fish catch in the Black Sea has declined intensively after 2000 due to increase in the SST which was proved by Mann-Kendall trend (p value=0.0001; α=0.05). Potential consequences of SST increase on the bottom up nutrient flux processes were the main cause for the decrease in the primary production and ultimate fish catch. Figure 2. shows the changes in chlorophyll-a concentrations with respect to changes in SST. Finally, decrease in the profits of fisheries sector was shown using the present data and appropriate models/projections were performed for the coming two decades.

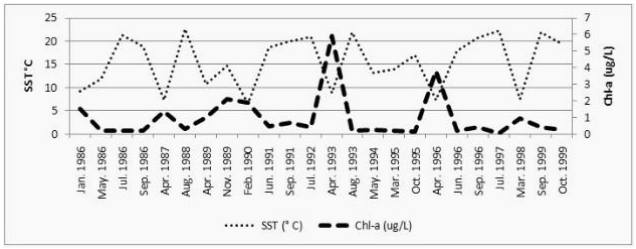

Fig. 2. Western Black Sea Chlorophyll-a in situ measurements and corresponding Sea Surface Temperatures

Abstract
In the Gulf of Lion, a pluridisciplinary project (COSTAS) combining ecology and biogeochemistry of contaminant aims at understanding the trophic transfer of contaminant, including ^{210}Po, a natural radionuclide which induces the highest internal radioactive dose in fishes. Based on ^{210}Po concentrations and δ^{15}N measurement on seawater, SPM, five size classes of plankton, anchovy and sardine, we demonstrated for the first time the biomagnification of ^{210}Po among sardine and anchovy foodweb.

Keywords: Gulf of Lyon, Food webs, Bio-accumulation, Radionuclides, Plankton

Introduction The COSTAS project aims at understanding the trophic transfer of metallic and organic contaminants through seawater, phytoplankton, zooplankton, sardine and anchovy populations in the Gulf of Lion (NW Mediterranean Sea). Its originality is to combine the ecology of the trophic web with the biogeochemistry of organic and metallic contaminants. Here we present the evidence of ^{210}Po (natural radionuclide from ^{238}U decay chain) trophic transfer in the foodweb of these fishes in the Gulf of Lion.

Material and method Seawater, SPM and plankton were sampled in May 2010 and February 2011 in the Gulf of Lion at different sampling sites from east to west. Seawater was pumped at the Chl-*a* maximum and filtered through a 0.45µm filter for SPM analysis. Small plankton organisms were sampled by pumping seawater at the Chl-a maximum followed by onboard filtration through 200µm, 60µm and 6µm mesh size plankton nets. Two small plankton size fractions were retained [6-60µm] and [60-200µm]. A trawling system (200µm mesh) was used to get larger plankton organisms. Plankton was collected during 30 min and sieved onboard through three different meshes: 2000µm, 1000µm, 500µm and 200µm to get four large plankton fractions: [200-500µm], [500-1000µm], [1000-2000µm] and [>2000µm]. ^{210}Po and δ^{15}N analysis and measurement were performed at the CEREGE and MIO laboratories.

Results and discussion A strong spatial structuring of sites based on ^{210}Po concentrations was evidenced by hierarchical clustering, both in spring (May 2010) and winter (February 2011). In May, ^{210}Po concentrations presented values significantly different according to size : the highest concentrations were recorded in SPM and the [6-60µm] fraction, and the lowest value in the dissolved phase and the largest size fraction [>2000µm], while ^{210}Po concentrations did not differ significantly among plankton fractions from [60-200µm] to [1000-2000µm]. In February, 210Po concentrations presented homogenous values in particulate matter and plankton fractions in the Gulf of Lion. However, higher ^{210}Po concentrations were observed for each period in the eastern part (Figure 1).

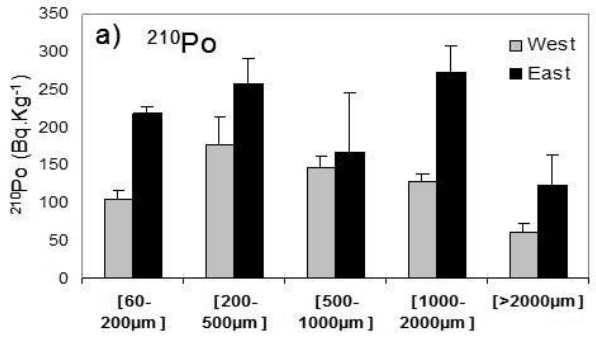

Fig. 1. Figure 1: Mean (+ SE) concentrations of ^{210}Po in the different size fractions of plankton in the East and West parts of the Gulf of Lions

^{210}Po concentrations in both species decreased in the following order: liver~gonads>fish remains>muscles. Concentrations were significantly different between species, with higher concentrations measured in anchovy (tissues and whole fishes, t-tests, $P<0.01$ for all tissues). In May, δ^{15}N was significantly lower in the largest size class [>2000µm], while in February, highest δ^{15}N was measured in the [1000-2000µm] fraction and the lowest in the [60-200µm] fraction. Like ^{210}Po, δ^{15}N was higher in the East than in the West part of the Gulf of Lion for each period Significant positive linear relationships were observed between Log^{210}Po (y) and Logδ^{15}N (x) in plankton size fractions in May ($y = 1.809x + 1.192$, $R^2 = 0.85$, $P<0.001$) and February ($y = 0.636x + 2.147$, $R^2 = 0.59$, $P<0.01$). However, the slope and accuracy of the relationships were higher in spring than in winter. For investigating a possible biomagnification of ^{210}Po in the food webs of sardine and anchovy, ^{210}Po and δ^{15}N values in a whole fish were used[1], along with mean concentrations in plankton fractions from the two sampling dates. Then, a similar significant positive linear relationship between Log^{210}Po and Logδ^{15}N was observed from plankton to the two zooplanktivorous fish species (Figure 2). This relationship demonstrates the biomagnification of ^{210}Po along the food webs of these zooplanktivorous fishes, related to the trophic level (δ^{15}N) of organisms. Such relation is shown here for the first time along the complete foodweb structure.

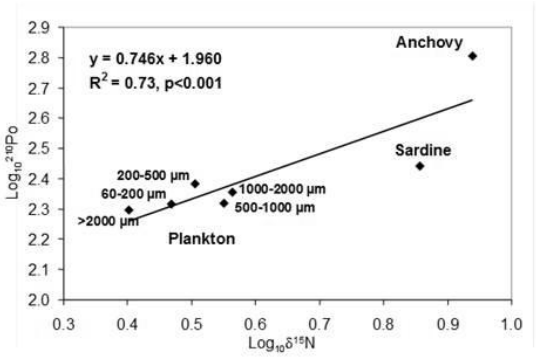

Fig. 2. Figure 2: Biomagnification of ^{210}Po in the food webs of two small pelagic zooplanktivorous fishes, *Sardina pilchardus* (sardine) and *Engraulis encrasicolus* (anchovy) in the Gulf of Lions.

POPULATION DYNAMICS, BIOLOGY AND STATE OF EXPLOITATION OF THE NORWAY LOBSTER (*NEPHROPS NORVEGICUS*) IN THE BALEARIC ISLANDS

Beatriz Guijarro [1]*, Natalia González [1], Vanessa Rubio [1] and Enric Massutí [1]
[1] Instituto Español de Oceanografía. C.O. Baleares - beatriz@ba.ieo.es

Abstract
The Norway lobster (*Nephrops norvegicus*) is the target species of the deep-water bottom trawl fishery carried out in the upper slope (250-500 m) off Mallorca (Balearic Islands). This study aims to analyse the trends in its catches per unit of effort, as well as its population dynamics and biological parameters, and to assess its state of exploitation. Biological information has been calculated for this species in this area for the first time and used as input parameters for the stock assessment. The current fishing mortality is higher than the reference point $F_{0.1}$, which indicates that the stock is subjected to overfishing.

Keywords: Decapoda, Population Dynamics, Stock assessment, Growth, Balearic Islands

The Norway lobster (*Nephrops norvegicus*) is one of the main fishing resources of the deep-water bottom trawl fleet from the Balearic Islands, representing up to 7% in biomass and 10% in economic value from all the deep-water crustaceans landed [1]. Although landings from this species showed a negative trend between 1986 and 1995 [2], an improvement in its state of exploitation, using indicators, has been detected [3]. Even though it is the main target species from the upper slope, between 250 and 500 m depth, no previous studies have been carried out on its biology in the area, with a lack of information for parameters such as growth curve, length-weight relationship or maturity ogive.

The objectives of this study were: (i) to analyse the annual, seasonal and geographical trends of the catches per unit of effort of *N. norvegicus* from the bottom trawl fleet off Mallorca; (ii) to analyse the population dynamics of this species and calculate its growth parameters; (iii) to analyse the reproductive biology (spawning period, maturity ogive, fecundity) and other biological traits such as condition index and length-weight relationship and (iv) to assess the state of exploitation of the species using traditional assessment methods. Data were obtained from different sources: (i) official landings from the bottom trawl fleet; (ii) monthly sampling on-board trawlers; (iii) annual bottom-trawl surveys; and (iv) on-board and in-laboratory individual biological sampling. Annual, seasonal and geographical trends were analysed by Generalized Additive Models and the state of exploitation was analysed by Extended Survivor Analysis (XSA) and Yield per Recruit (Y/R) analysis.

Data analysed from the commercial fleet covered years between 2000 and 2011 and from the scientific surveys from 2001 to 2011. Biological sampling was performed seasonally between 2010 and 2012 and annually between 2001 and 2011. Annual landings from the bottom trawl fleet off Mallorca oscillate between 5 and 32 tons, with an average size of approximately 36 mm carapace length (CL, Figure 1). Length-weight relationship showed a positive allometry (b= 3.4) and length at first maturity for females was established at 37 mm CL. The Von Bertalanffy growth function parameters were estimated as L_∞= and k= 0.126, showing a slow-growth performance.

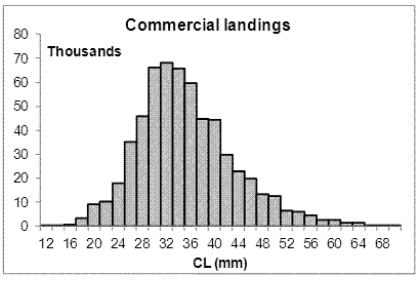

Fig. 1. Size frequency distribution of *N. norvegicus* from the bottom trawl commercial landings (average 2002-2011).

XSA showed a quite stable population during the years analysed (Figure 2a), with its total abundance around 10.5 million individuals, recruitment abundance around 5.5 million individuals, total biomass around 95 t and spawning stock biomass around 46 tons. Fishing mortality was estimated between 0.3 and 0.6, with a current value of 0.45 (average of the last three years). Y/R (Figure 2b) showed this current fishing mortality higher than the reference point $F_{0.1}$ (0.13), which indicates that the stock is subjected to overfishing.

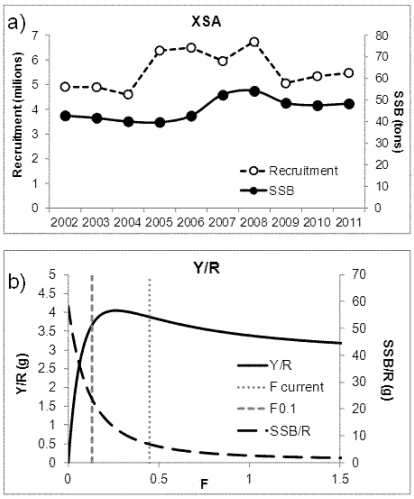

Fig. 2. Results from the Extended Survivor Analysis (XSA, a) for *N. norvegicus* showing the recruitment abundance and spawning stock biomass (SSB) and from the Yield per Recruit analysis (Y/R, b), showing the current F (0.45) and the reference $F_{0.1}$ (0.13).

ETUDE PRELIMINAIRE DE LA STRUCTURE DES PEUPLEMENTS DE FORAMINIFERES DU GOLFE DE TUNIS

Samia Khabouchi [1]* and Atf Azzouna [1]
[1] université de Tunis El Manar: Fac. Sciences - khab.sami@yahoo.fr

Abstract
The structure of Foraminifera from the Gulf of Tunis revealed large differences between the various environmental factors between the stations studied. Water quality, dissolved oxygen, salinity and granulometry are limiting factors. The Foraminifera responded to different abiotic stess by a special change in their specific composition and the appearance of morphological abnormality of their tests, therefore they are used as bio-indicator of pollution. Keywords: Foraminifera, bio-indicator, diversity, Gulf of Tunis.

Keywords: Bio-indicators, Gulf of Tunis

Introduction
Le Golfe de Tunis, à cause de sa côte la plus urbanisée de la Tunisie, est le siège d'une forte pression anthropique. Ce qui nécessite un suivi et une attention particulière à sa biodiversité. Les Foraminifères sont de bons indicateurs des changements de l'environnement pour multiples raisons dont: (i) un cycle de vie trés court (1 à 3 mois en moyenne, 1an maximum, [4]), (ii) des préférendums écologiques spécifiques à chaque espèce [3], (iii) une grande diversité qui fait partie majoritairement de la méiofaune, (iv) une réaction rapide au stress environnemental comme les variations de l'oxygène dissous, du pH, de la température, de la salinité, de la granulométrie et de la qualité de l'eau. Dans le présent travail, et en se basant sur les facteurs cités ci-dessus, la structure des peuplemens des Foraminifères est comparée entre cinq stations du Golfe de Tunis afin d'évaluer la réponse de ces protistes au variations des différents paramètres et de tirer l'attention sur l'état actuel des stations prospectées.

Matériel et Méthodes
L'échantillonnage est réalisé entre janvier 2010 et juillet 2011, à partir des cinq stations suivantes du Golfe de Tunis: Sidi Rayes, BorjCedria, Radès, la Goulette et la Marsa. Deux types de carottes de 2cm de diamètre et de 6 et 10cm de hauteur sont enfoncées à un mètre de profondeur, retirées délicatement et bouchées des deux cotés. Au laboratoire, le tri des espèces s'est fait par des pinces trés fines et effilées. Les échantillons triés ont été conservés surtout à sec. Les différents mesures sont effectuées à l'aide d'un multiparamètre; la classification granulométrique est celle de Lansonneur, 1977. [2]

Résultats et Discussion
Les cinq stations prospectées sont toutes polluées sauf celle de Sidi Rayes. Cette dernière est la moins riche en espèces avec une richesse spécifique Rs=18. La fréquence (fi) est très variable oscillant entre: espèces rares (0.05< fi<1%) et très fréquentes (1< fi < 5%). Les facteurs abiotiques de cette station, mis à part la qualité des eaux, sont comparables à ceux de la station de Borj Cedria(tab 1) ; mais, la diversité spécifique est totalement différente entre les deux. Ce qui permet de suggérer que la qualité des eaux est un facteur majeur dans la vie des Foraminifères. La Goulette, qui est une station très polluée, à forte conductivité (36.04) et à faible teneur en oxygène dissous (71%) est la station la plus riche en espèces (34 espèces). Les espèces trés rares (0.05% < fi) -*Lagena sp*1 *et Lagena sp* 2- sont typiques de cette station. *Rosalina bradyi* est une espèce trés fréquente et spécifique des eaux polluées. La taille et la couleur du test d'une même espèce varie considérablement d'une station à une autre, du plus petit et souvent foncé en milieu pollué au plus grand et clair en milieu propre; il s'agit d'une adaptation aux conditions de stress: les Foraminifères réduisent leur taille pour s'adapter au type de sédiment où ils vivent et pour diminuer la consommation d'oxygène réduite en milieu pollué. L'étude granulométrique montrent que : (*)certaines espèces n'ont pas de préférence granulométrique comme *Qinqueloculina* et *Elphipium* qui se rencontrent du sable très grossier à très fin (les stades juvéniles), ainsi que les *Ammonia* avec une légère préférence pour le sable moyen à grossier, (*)la plupart des espèces préfèrent le sable moyen à fin particulièrement *Rosalina*, (*)le sable très fin ne contient que les stades juvéniles, (*)la granulométrie agit sur la croissance du test des espèces (tab 2).

Tab. 1. Données écologiques des stations étudiées

Station	Température (°C)	pH	Oxygène dissous (%)	Conductivité PPM	Salinité (g/l)	qualité des eaux
la Marsa	19.6	8.45	72.2	34.780	34.78	polluée
la Goulette	19.3	8.4	71	36.040	36.04	très polluée
Radès	20.3	8.29	74	35.360	35.360	très polluée
Borj Cedria	19	8.35	71	34.140	34.140	polluée
Sidi Errayès	23	8.35	71	34.100	34.1	propre

Tab. 2. Répartition des genres de Foraminifères selon le type de sédiment

	Sable trés grossier	Sable grossier	Sable moyen	Sable fin	Sable trés fin
LA MARSA	----	*Ammonia*	Reste des espèces	*Rosalina* *Ammonia*	Stade juvénile
LA GOULETTE	----	*Quinqueloculina sp* +++ *Ammonia*	*Ammonia* *Triloculina* *Elphidium*	*Quinqueloculina* *Ammonia* *Massilina*	Reste des espèces
RADES	*Elphidium*	*Ammonia* *Elphidium*	*Rosalina* *Ammonia* *Quinqueloculina*	*Globigerina* *Rosalina*	Espèces juvéniles : *Rosalina* *Globigérinides*
BORJ CEDRIA	-----	*Ammonia* *Elphidium* *Quinqueloculina*	*Quinqueloculina* *Elphidium* *Ammonia* *Triloculina*	*Quinqueloculina* *Ammonia*	*Ammonia*
SIDI RAYES	*Quinqueloculina*	*Ammonia* *Cornuloculina*	*Quinqueloculina* *Elphidium* *Massilina* *Ammonia*	La plupart des espèces	Stade juvénile

Conclusion
La réponse fonctionnelle des Foraminifères à des modifications soudaines du milieu est utilisée comme indicateur de pollution.

ORGANOTIN LEVELS IN MARINE ORGANISMS FROM EASTERN AEGEAN COAST (TURKEY)

F. Kucuksezgin [1]*, S. Aydin-Onen [1], L. Gonul [1], I. Pazi [1] and F. Kocak [1]
[1] Dokuz Eylul University Institute of Marine Sciences and Technology - filiz.ksezgin@deu.edu.tr

Abstract
The average concentrations of TBT ngSng^{-1} were found as 235 in fish, 116 in mussels and 635 in barnacles. All mussels sampled showed values of TBT+DBT, which were below the "tolerable average residue level (TARL)" as currently accepted. Barnacles have high potential as biomonitors for the presence of organotin in the Aegean Sea.

Keywords: Aegean Sea, Fishes, Bio-accumulation

Introduction

Since the early 1960s organotin compounds (OTs) have been used for several purposes, such as polyvinyl chloride stabilizers, fungicides and as antifouling agents in ship paints [1]. Many countries worldwide have banned the application of TBT-based paints to small vessels (<25m) and butyltins have been identified as priority hazardous substances [2]. Due to the ongoing legislative restrictions, various studies worldwide have shown a slow decline on TBT contamination [3]. There have been a few studies on the distribution of OTs in Turkish coastal areas. This study aims firstly to create a baseline regarding organotin levels in mussel, barnacle and fish tissues; secondly to gather more information on the use of selected species as biomonitors and finally to evaluate potential risks for butyl tin species contamination in seafood along the Eastern Aegean coast as sampled in 2009.

Material and Methods

In the present study, different marine species were sampled for BTs analysis in terms of their different feeding strategies. Samples were collected from the Saros, Candarli and Izmir Gulfs along the Eastern Aegean coast, during 2009. Marine biota samples were analysed according to Cassi et al. [4]. Mussel (ERM-CE477) sample was used as a control for the analytical methods.

Results and Discussion

TBT concentrations ranged between 134-368, 186-275, 157-198, 181-260, 276-327 ng Sn g^{-1} ww for *M. barbatus, D. annularis, M. merluccius, S. vulgaris, P. erythrinus*, respectively. Total BTs concentrations, and in particular the TBT, in barnacles were generally higher (396-1163ng g^{-1}ww) than those monitored in the mussel and fish species sampled along the Eastern Aegean coast. MBT was the dominant species in mussels, fish and barnacles. This may indicate that MBT is derived not only from the dominant breakdown product of TBT degradation but also from other sources, such as city sewage, industrial wastewater etc. Based on average seafood consumption for Turkey, TARL was found to be 680 ng TBT g^{-1} (279 ng Sn g^{-1}). A comparison of the results of the present study with the TARL indicated that three samples for fishes were found to exceed the TARL when only TBT is considered. Only *Solea vulgaris* samples were below the TARL if both the sum of TBT+DBT and TBT were considered. For mussel samples, whole values were below the TARL, thus confirming that this group is the one posing no risk for consumers. But, in contrast all barnacle samples exceeded the approved TARL.

Conclusion

Tolerable Average Residue Levels of TBT+DBT based on the average weight of 60 kg exceeded in 50% of the fish sampled. The levels of organotin compounds derived seafood in the Eastern Aegean Coast of Turkey constitute “a risk to humans” as presently defined. Although bivalves are the most commonly used organisms as biomonitors, this study showed that barnacle *A. amphitrite* may be considered among the most sensitive organisms for biomonitoring programs due to their high accumulation capacity for absorbing BT compounds from their surroundings.

PINNA NOBILIS AND EPIPHYTIC FORAMINIFERA AS POTENTIAL BIOINDICATORS OF HEAVY METAL POLLUTION IN BALEARIC ISLANDS (WESTERN MEDITERRANEAN)

M. Morató Trobat [1]*, A. Khokhlova [2], S. Deudero [1], G. Mateu-Vicens [2], M. Vázquez-Luis [1] and J. Campillo [3]
[1] Centro Oceanográfico de Baleares-IEO - merce.morato@ba.ieo.es
[2] Cátedra "Guillem Colom Casasnovas", Universidad de las Islas Baleares
[3] Centro Oceanográfico de Murcia-IEO

Abstract
Metal (Cd, Cu, Hg, Pb, and Zn) concentrations and percentage of deformed foraminifera were measured in soft tissues of *P. nobilis* and sediment samples, respectively, in order to assess pollution levels in Baleraric Islands.
Analyses of Cabrera and Mallorca indicated that heavy metal concentrations were generally higher in the majority of samples, specially in Santa Maria bay (Cabrera, MPA), where high percentages of deformed shells (up to 26 %) and high values of metal pollution index (38.171 mg/Kg) were found.

Keywords: Balearic Islands, Bio-indicators, Bivalves, Foraminifera, Metals

Introduction
Heavy metals are an special group of contaminants, being the most common environmental pollutants and can be either adsorbed onto sediments or accumulated in benthic organisms, sometimes to toxic levels [1].
Pinna nobilis L., 1758 is a fan mussel endemic to the Mediterranean Sea and is considered the biggest bivalve mollusc of this area. It is common within the seagrass meadows of *P. oceanica*,is a long-lived species, benthic filter and easy to find at the seabottom. Foraminifera are protozoans with an external skeleton (shell), forming one of the most conspicuous groups in the epiphytic community of the *P. oceanica*. Foraminifers are very abundant in all marine environments, they have relatively short life-cycles and they react quickly to environmental changes at global and a local scale, are highly adapted to well-defined ranges of environmental parameters and pollution. Analysis of soft tissues of endemic bivalve *Pinna nobilis* revealed high heavy metals levels. The analysis of foraminifera assemblages revealed considerable amounts of individuals with deformed shells. These organisms are known as being significant bioindicators for monitoring seagrass meadows ecosystems, therefore their specific response to environmental changes can indicate the presence of the pollutants [2].

Materials and methods
The study area comprehends four localities from the Balearic Islands, situated in Mallorca (Andratx and Magaluf) and Cabrera (Santa Maria bay and Els Estels - only foraminifera samples). Mallorca is the biggest island of the Balearic Islands, which is located in the Western Mediterranean. The study area is located in the southern part of the island, two stations, Magaluf and Andraxt, with different degrees of anthropic impact was investigated and the other stations, Santa Maria bay and Els Estels (only foraminifera samples) were observed in Cabrera island (9 km south-east of Mallorca) which is characterise by the excellent conditions with low anthropogenic impact, and has the maximum degree of protection since 1991(LAW 14/1991).
Fourteen *P. nobilis* samples were taken in October 2011 by scuba diving and samples of foraminifera were collected over soft bottoms colonized by *P. oceanica* from May to November 2012 in the same sites. Concentrations of Cd, Cu, Pb and Zn were determined by atomic absorption spectrometry (AAS), and Hg was determined by Advanced Mercury Analyzer (AMA 254). For comparison of total metals at the sampling sites, the metal pollution index (MPI) was applied ([3]; [4]).

Results and discussion
Species identification and morphometric analyses of benthic foraminifera revealed high percentages of deformed shells, from 7% in Andratx, to the highest value in Santa Maria Bay (up to 26%) where only 1% of deformed shells in natural population can by present. Metal Pollution Index (MPI) mean concentrations in soft tissues of *P. nobilis* samples (dry weight) range from 6.22 mg/Kg in Andratx, 34.45 mg/Kg in Magaluf, and 38.17 mg/Kg in Santa Maria bay.

Higher values of heavy metals agree the highest percentages of deformed foraminifera, thus MPI and percentage of deformed foraminifera reaches the maximal value in Santa Maria bay and the minimal value in Andratx. The metal pollution index reaches the maximal value for Santa Maria Bay can be explained by the fact that the highest concentrations of three metals (Cd, Pb and Zn) out of the five considered.

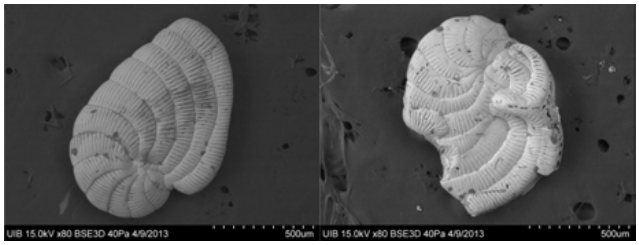

Fig. 1. Normal and deformed foraminifera *Peneroplis planatus* from Cabrera, Balearic Islands.

Conclusions
The high percentage of abnormal tests and metal pollution index indicates the presence of heavy metal pollution higher in Cabrera, marine protected area. Generally, the most effective bio-monitoring approach is to use several species representing differing trophic levels [5]. Therefore, the use of these organisms as bioindicators can be very useful in determining the health of seagrass meadows ecosystems in areas that have no obvious symptoms of degradation.
Assessing bioaccumulation is also a component of international efforts to identify and control chemicals of environmental concern, and there is a need to establish reliable procedures for estimating bioaccumulation potential from knowledge of properties of the substance.

A CHEMOTAXONOMICAL APPROACH TOWARDS SYNTHETIC INDICATORS OF MAIN PHYTOPLANKTON GROUPS IN THE CONTEXT OF MSFD

R. Casotti [1], M. Saggiomo [1]*, O. Mangoni [2], F. Margiotta [1], V. Saggiomo [1] and I. Santarpia [1]
[1] Stazione Zoologica Anton Dohrn - m.saggio@szn.it
[2] Dip. di Biologia, Università di Napoli 'Federico II', Napoli, Italia

Abstract
Chemotaxonomy of algal liposoluble pigments is proposed as a synthetic indicator of phytoplankton group composition to be used in the assessment of chlorophyll concentrations and shifts in groups composition (diatoms to flagellates) as required by the MSFD.

Keywords: Phytoplankton, Eutrophication, Tyrrhenian Sea

Introduction
In order to pursue the Good Environmental Status (GES) with the aim to reduce the negative effects of anthropogenic eutrophication, the MSFD includes several criteria to be followed, among which, for Descriptor 5 (Eutrophication), total chlorophyll concentrations and the shift in the diatom-to-flagellate ratio. Within this Descriptor, the assessment is based on the nutrient concentrations in the water column and their direct and indirect effect on Chl *a* concentration and species shift in floristic composition (e.g. diatom to flagellate ratio) used as indicators. However, the tools to reach the described criteria are not clearly defined neither agreed upon. In recent years, the chemotaxonomical approach to phytoplankton community composition is spreading. This is based on the observation that some pigments can be mainly attributed to specific algal classes and/or types and are therefore used as taxonomical markers (Mangoni *et al*., 2008). This approach allows to map the main functional groups including smaller size groups usually underestimated by microscopical counts. This works aims at analyzing the temporal dynamics of main phytoplankton groups along the water column at a fixed station in the Gulf of Naples from 2003 to 2010 as related to macro-nutrients and water column dynamics.

Materials and methods
The sampling was carried out weekly from 2003 to 2010, at LTER Station MareChiara. Sea water samples were collected from 4 to 5 depths (0, 10, 20, 40, 60 m) for the determination of nutrient and chlorophyll concentrations and HPLC liposoluble pigments. The contribution of the various functional groups to the microalgal biomass (in terms of Chl *a*) was determined by using the ChemTax software (Latasa, 2007).

Results
The sampling period was characterized by cold winters (from 2003 to 2006) and hot summers except for the winter of 2007. This was the warmest winter in the recorder period and prevented the winter-mixing that usually drives the injection of new nutrients from deeper waters. The multi-year distribution of salinity showed a strong influence of anthropogenic inputs at surface, traced by lower salinity waters. Diatoms dominated phytoplankton, representing up to 53% of the total biomass, in terms of chlorophyll and also closely matched its variability in time, with two peaks, in spring and autumn. The other major algal groups showed a large interannual variability in contribution to total phytoplankton biomass (Fig. 1a). Principal component analysis (annual average values) of phytoplankton groups as related to environmental parameters shows a close correlation between total biomass, nutrients and diatoms (Fig. 1b). In the years from 2007 to 2010 there was less variability in the biotic and abiotic properties of the water column. The distribution of phytoplankton biomass in surface was usually significantly correlated to anthropogenic inputs in terms of less saline waters. Diatoms show higher contribution in the coldest winter (2004, 2005, 2006) as related to active vertical mixing and the consequent injection of nutrients from deeper waters. These years were also characterized by an increased presence of Pelagophyceae. Chlorophytes did not show any clear correlation with any environmental variable, with a constant contribution along the years.

USING FISHERY INDICATORS FOR THE EVALUATION OF THE STATUS OF TWO COMMERCIALLY IMPORTANT DEMERSAL STOCKS IN THE CENTRAL AEGEAN

Andreas Palialexis [1] and Vassiliki Vassilopoulou [1]*
[1] Hellenic Centre for Marine Research - celia@hcmr.gr

Abstract
State and pressure indicators describing the status and the trends of two commercially important species (*Merluccius merluccius* and *Parapenaeus longirostris*) were estimated using both fishery-dependent and fishery independent data. Both species, targeted by trawl fishery in the Central Aegean Sea, account for the highest proportion of catch and annual gross income. Results revealed signs of deterioration of the two stocks for the study period (2003-2008).

Keywords: Fisheries, Aegean Sea, Demersal

The use of indicators as tools to identify changes, quantify problems and monitor the implementation of policies and regulations is developed rapidly in fisheries and ecosystem fields [1]. The importance of such indicators is highlighted through the Marine Strategy Framework Directive (MSFD 2008/56/EC) to achieve and maintain the Good Environmental Status in European Waters. In this study we quantified selected state and pressure indicators using trawl fisheries data, derived from the EU Data Collection Regulation programme, to assess the status, and study possible trends of two commercially important species – the hake (*Merluccius merluccius*) and the deep-water rose shrimp (*Parapenaeus longirostris*) - in the Central Aegean Sea.

State indicators describing key features of the populations of the two species, were quantified using data derived through fishery independent surveys (MEDITS surveys, in this case), and included: total stock biomass, and descriptors of length structure (i.e. 25% and 75% percentiles of the length distribution for small and large individuals respectively). Pressure indicators describing the intensity of fishing (i.e. the input to the fishing activity) were taken from official records and included: fleet size and effort expressed as Days-at-Sea. Pressure indicators describing catch & discards (i.e. the output of the fishing activity), were based on records made by observers on board commercial vessels, and included: catch and discards amount in weight and numbers per species, minimum, mean and maximum size of catch and discards. For comparative purposes data from both experimental and on-board surveys covered the same period i.e. 2003-2008 (except for 2007, when no data were available). All indicators were tested for significant trends by applying a simple linear regression and evaluating the significance of the slope.

The fleet size of trawlers in Greece presented a slight decline from 2003 to 2008 (336 to 323 respectively), with the majority of the vessels operating in the Aegean Sea (~90%). However, no change in Days-at-Sea has occurred across the time-series.

Deep-water rose shrimp, the top landed species in the Aegean Sea, was landed in lengths lower than the Minimum Landing Size (MLS). Regarding pressure indicators, the discard weight slightly increased over 2003-2008, with neither catch weight nor discarded fraction exhibiting any significant trend. Moreover, a significant decreasing trend appeared in the minimum catch sizes. Biomass state indicators showed also a significant decline during the study period.

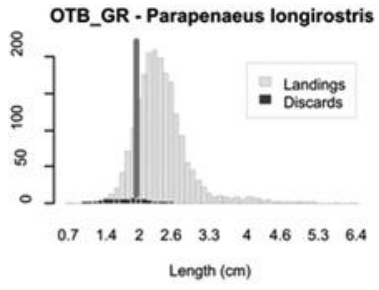

Fig. 1. Length composition of deep-water rose shrimp caught by the Greek trawlers in the Central Aegean Sea. Dark gray illustrates discards, light gray landings, and the Minimum Landing Size bar is at 2cm carapace length.

Hake was landed below the MLS and the discarded proportion consisted of the very small sized individuals. Discard weight and discard ratio of the species increased in the Aegean Sea over the 2003-2008 period. As for state indicators, the high percentile (95%) of population length distribution exhibited a significant decline, suggesting the existence of a decreasing trend in the size of larger individuals during the study period in the central Aegean Sea.

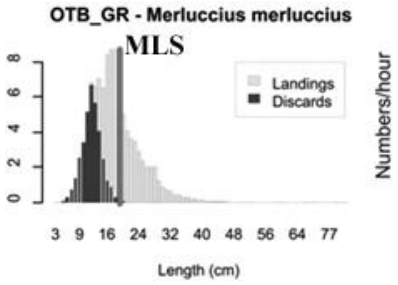

Fig. 2. Length composition of hake caught by Greek trawlers in the Central Aegean Sea. Dark gray illustrates discards, light gray landings and the Minimum Landing Size bar is at 20cm total length.

Our findings highlight the existence of signs of deterioration of the status of the two stocks over the period under study. However, the recent implementation of the EC Regulation 1967/2006 imposing a modification to the cod-end mesh opening to either 40 mm square or 50 mm diamond, as well as the banning of the operation of trawl vessels within 1.5 NM off the coast may have contributed towards improving the status of fishery resources, but this could not be confirmed due to the lack of data since 2008. Furthermore, it should be pointed out that the weak compliance of Greek fishermen to the national and EU regulations, particularly regarding the MLS [2], resulted in less discards of the two species, in cases when individuals smaller than the MLS had a market demand.

TO THE COMPLEX ESTIMATION OF BIOLOGICAL SIGNIFICANCE OF MARINE AREAS

Borys Aleksandrov [1]*, Gaina Minicheva [1] and Yuvenaliy Zaitsev [1]
[1] Institute of Biology of Southern Seas Odessa Branch, NASU - alexandrov@paco.net

Abstract
One of the key tasks of EC Water Frame Directive (2000) is the warning of degradation of aquatic ecosystems. The concept «good environment status» is offered for the determination of the grade of deviation between analyzing aquatic ecosystem and the desirable level, for this purpose 11 descriptors have been worked out. The index of biological significance of aquatic area (K_f) has similar aim. It combines the characteristics of biodiversity, water quality and anthropogenic effects in investigating area. The possibilities of this new index have been illustrated on the example of off-shore aquatic areas of the Black and Azov Seas within the limits of Ukraine.

Keywords: Conservation, Biodiversity, Black Sea

Introduction
Ukraine has the biggest coast line (1628 km, or 37%) and the largest shelf area (55750 km^2, or 57%) among all Black Sea countries. It is explained by the fact that from 33 of the wetlands of internationally importance the 19 Ramsar's sites are located in Ukraine. The largest part of marine protected areas is situated on the coastal zone of Ukraine in the Black Sea and the Sea of Azov. All of 5 marine coastal ecotones, registered in European seas, are located in the Black sea as well. Among 37 benthic biocenoses - 35 are found in Ukraine. The aim of this study is to work out the methodology of a quantitative appraisal of biological value determination of marine aquatic bodies and settings (lagoons, bays etc.) for creation of new, or expansions of existent marine protected areas.

Methodology
The complex (integrated) index of biological significance of aquatic object (K_f) has been worked out for creation of new or widening the existence of marine protected areas. It was tested on 34 aquatic areas in Ukrainian part of the Black Sea and the Sea of Azov: 13 – bays, 13 – limans (estuaries), 2 – lagoons, 2 – lakes, 1 – Delta (Danube), 1 – Island (Zmeiny), 1 – exposed shelf area (Zernov's Phyllophora Field), 1 – strait (Kerch).The ecological state of analyzing aquatic bodies and settings of Ukraine has been described from accessible literatures data from more than 100 references.

Result and Discussion
Three direct characteristics of biological significance were used in K_f: total number of Red Data Book species, total number of macrozoobentic species; total number of benthic biocoenoses. Besides, for calculation of the K_f value three characteristics of aquatic productivity that reflected the water quality in the whole have been considered: primary production of phytoplankton; primary production of benthos, that has been calculated as average value of specific surface of three dominant species of macrophytobenthos [2]; ratio of total biomass of plankton and macrozoobenthos under the square meter of sea surface. The last (seventhes) characteristic including in the equation for determination of K_f was anthropogenic effect factor (K_{AI}). The given characteristic was calculated for each investigating area by the generalized matrix of expert assessments of ecological processes in the Black Sea coastal zone. K_{AI} includes 27 – stress factors and 15 types of their possible effect on ecosystem. There are 10 kinds of anthropogenic effects with different influence on biological characteristics of aquatic ecosystems (positive or negative): 1) industry, 2) agriculture, 3) pisciculture, 4) sea transport, 5) municipal economy, 6) coast protection, 7) hydro-power engineering, 8) tourism and resorts, 9) nature conservation, 10) environmental education and environmental ethics [3]. Average significance of the K_{AI}-index reflected the influence of different types of anthropogenic effects (starting from negative effects, for example agricultural runoff and industrial wastes, up to positive one – the activity of the environmental inspections). The map "Recommendations for the establishment of new and the expansion of existing protected areas in the coastal waters of the Black and Azov Seas" has been prepared on the bases of carried out K_f value calculations [1].This work has been carried out under the financial support from the side of "Towards Coast to Coast NETworks of marine protected areas (from the shore to the high and deep sea), coupled with sea-based wind energy potential" Project.

[2] Ifremer, LEADNC

Abstract
This paper presents an innovative remote high-definition rotating unbaited video system developed by Ifremer, IRD and ADECAL (New Caledonia Economic Development Agency). This system has many advantages for observing variation of biodiversity of macrofauna and habitats under human pressure in the context of global change. It has been used to evaluate the impact of "Cap Sicié" outfall (France, Var).

Keywords: Biodiversity, Fishes, Monitoring, Coastal waters, North-Western Mediterranean

Introduction
Functional organisation and biogeography of coastal fish communities of the French Mediterranean Sea are paradoxically poorly known. Studies are essentially concentrated on Marine Protected Areas and data are rarely comparable. However observing spatial and temporal variations of marine biodiversity through non-destructive techniques is a major stake for understanding patterns of variations facing anthropogenic pressures in a context of global change. Underwater Visual Censuses (UVC) have been widely used for monitoring coastal ecosystems. Advantages and disadvantages of UVC for estimating fish abundance and diversity have been reported and discussed in many papers. Aside from UVC, different video techniques have been used for observing marine biodiversity (macrofauna and habitat) essentially during the last decade. This paper presents a remote high-definition unbaited rotating video system, called STAVIRO (for STAtion VIdéo ROtative in French), patented by Ifremer, IRD and ADECAL (New Caledonia Economic Development Agency). Advantages of STAVIRO are numerous. Non-destructive, it can be used whatever the juridical status of the study area is (in MPA for example). The presence and abundance of vagile species is less affected than by the presence of a diver. It doesn't require diver or expert staff. A large number of observations can be realized on the field within a short time. It can be implemented easily on site by technical staff following a repeatable protocol. This enables to cover large areas including many habitats, to obtain comparable data from several sites and then avoid on-site observer effects. Finally, data can be archived easily. Between 2010 and 2012, 500 observations by STAVIRO have been carried out along the French Mediterranean coast.

Materials and methods
Staviro system:

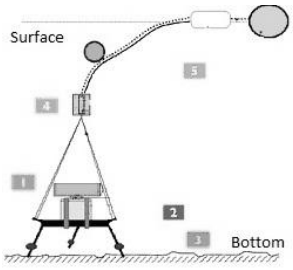

Fig. 1. Description of the Staviro system: 1) video camera housing; 2) engine housing; 3) weighted aluminium support; 4) landing camera insuring the flatness of the system 5) floating rope, intermediate buoy and surface buoy.

Figure 1 describes the STAVIRO system [1]. Rotations are programmed so that the camera housing rotates from 60° every 30 seconds. Images of three rotations are analysed by experts. Hence, six observation sectors are recorded per 360° rotation. In order to gather information about the variability of fish presence and abundance, the system are left in place 12 minutes.

Study area:
"Cap Sicié" is a cape located in the Var department in the south of France. Since the 40's, the site has been the largest waste water discharge of Toulon's urban area. In order to study the impact of the outfall on fish communities and habitats, 72 stations were randomly defined between 5 and 22m and divided into three areas: "Z1" West outfall (moderately impacted), "Z2" outfall (impacted), "Z3" East outfall (reference zone). Three campaigns have been carried out, respectively in spring, summer and autumn 2012. For each station, all fishes were identified at species level. For each species and each station, the maximum and mean abundance observed over the three rotations were calculated. Frequency and abundance density of each taxonomic family in the data set were investigated. Overall density and species richness per station were computed as synthetic metrics of biodiversity. Each metrics was modelled with respect to area, season and habitat using General Linear Models.

Results and discussion
135 observations were collected over 13 days by two persons. Good weather conditions permits the realisation of 30 stations a day. The analysis time was 45 minutes per station. 86 837 fishes were counted. 99.7% were identified at species level. 16 families, 24 genus and 37 species were identified. Species richness was found to strongly depend upon habitat. In every habitat, species richness did not significantly differ between seasons and zones.

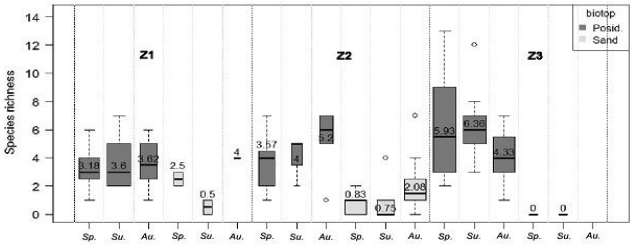

Fig. 2. Species richness per station as function of area, season and habitat. (Sp. = spring; Su. = summer; Au. = autumn).

This work has proved that STAVIRO systems are effective for observing variation of biodiversity over the time and are a good tool to design observatories of coastal macofauna and habitat variations under human pressure at the French Mediterranean coast scale. The implementation of such a monitoring network would support reporting on biodiversity status of fish communities and habitats in coastal areas for MSFD.

Ackwnowledgement
This work was supported by the Rhone-Mediterranean and Corsican Water Agency.

Abstract
In the framework of the MSFD implementation, a gap analysis of the methodological elements for environmental status assessment has been carried out within the PERSEUS FP7 project. It analyses and compares the kind of gaps reported for the eleven descriptors of Good Environmental Status by the Mediterranean Sea and Black Sea European countries.

Keywords: Biodiversity, Black Sea, North-Western Mediterranean, South-Eastern Mediterranean, Pollution

The research project PERSEUS has studied the experience of EU countries in the framework of the Marine Strategy Framework Directive (MSFD) environmental status assessment, with a view to share this knowledge with non-EU countries. Of the nine coastal EU Member States in the Mediterranean and Black Seas, information has been collected for five countries, which had published in 2012 their draft Initial Assessments and Good Environmental Status reports [1]: Cyprus, France, Greece, Romania and Spain. It has not been possible to include information from Italy, Malta and Bulgaria because their draft reports were not available. Slovenian information has not been included due to time constraints, but eventually it may be used in further steps.
Therefore, an analysis has been developed, considering all relevant information regarding the descriptors' scope, the methodologies and the data availability reported by each of the five countries at criteria and indicator level.
In order to provide a synthetic representation of the gaps underlined for each descriptor, a scoring system was introduced. Six PERSEUS partners were involved in a qualitative assessment of 8 semi-quantitative criteria, based on a matrix aiming to assess the methodological gaps per descriptor, taking into account the methodology developed by Van der Sluijs et al. (2001) [2].
The collected scores have been averaged among the six organisms and normalized (Fig. 1). They have then been aggregated to obtain a single score per descriptor (Fig. 2) and a single score per criterion. This process enables the visualization of the gap issues and aims to provide a broad comparison between descriptors. It is, however, based on expert judgment and, due to the diverse nature, content and importance of the MSFD descriptors, it should not be considered as exhaustive but rather as indicative, providing a general overview of the methodological gaps.

Gaps evaluated per descriptor

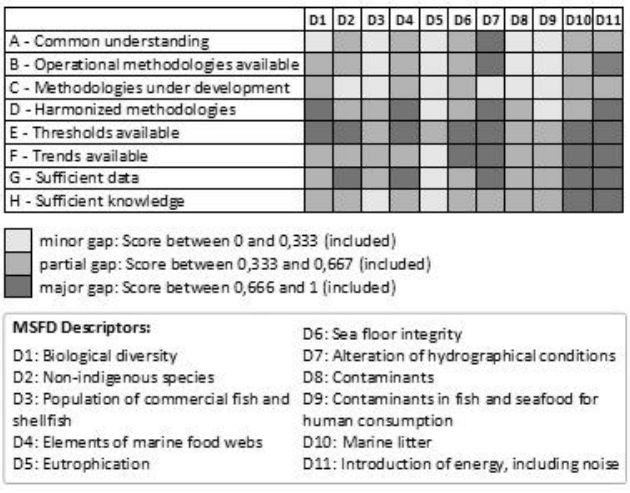

Fig. 1. Gap score composition for each descriptor

Comparison of the descriptors gap scores
The representation of the aggregated gap scores per descriptor is presented below, on the scale 0-1.

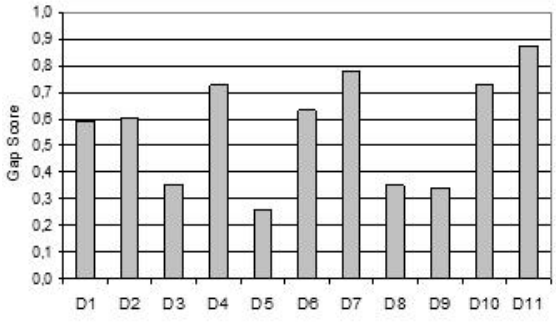

Fig. 2. Aggregated gap scores per descriptor

We notice on Fig. 2. that D11 (noise), D7 (hydrological condition) D10 (litter) and D4 (food webs) exhibit the highest gap values. D6 (seafloor integrity), D2 (NIS) and D1 (biological diversity) present also important gap scores. D3 (fisheries), D5 (eutrophication), D8 (contaminants and environment) and D9 (contaminants and human health) have lower gap scores. However, it should be noticed that even these "low gap score descriptors" still need harmonization efforts, further development and establishment of consistent regional thresholds/reference values.

Analysis of the most reported gaps
The analysis of the most reported gap, when outcomes from all descriptor were pooled together, has been produced by comparing the aggregated gap scores per criterion. The most important gap identified is the general lack of thresholds. The lack of data, the lack of harmonized methodologies, the lack of information on trends, as well as the insufficient knowledge present also high gap scores. Finally, the lack of operational methodologies, the lack of further methodological development and the lack of common understanding present lower scores.

Abstract

End-to-End (E2E) models attempt to describe in a common framework the ecosystem covering from hydrodynamics and biogeochemistry to fish and fisheries dynamics for the evaluation of the possible impacts of antropogenic and natural changes on ecosystem structure and functioning. A E2E approach has been set up for the Mediterranean and Black Sea linking biogeochemical LTL model with HTL food web models to evaluate the effectiveness of policy scenarios and to assess space variability and trends in terms of ecological indicators such as ecosystem vigor, organization and resilience.

Keywords: Ecosystem services, North-Central Mediterranean, North-Eastern Mediterranean, North-Western Mediterranean, Black Sea

Methods and approaches for assessing marine ecosystem state are increasingly requested for the evaluation of the possible impacts of antropogenic and natural changes on ecosystem structure and functions and for the evaluation of the effectivness of conservation policies. This implies the possibility of using integrated assessments tools capable of considering the cumulative effects of all major factors influencing marine ecosystem dynamics. End-to-End (E2E) models attempt to describe the ecosystem responses to main drivers (climate change, nutrient enrichment, fisheries) in a common framework, which covers from hydrodynamics and biogeochemistry to fish and fisheries dynamics [1]. The development of E2E applications in the Mediterranean Sea represents an important opportunity for setting a common framework useful for harmonization, intercomparison and generalization of results achieved at sub-basin scales, and towards the development of a pan-Mediterranean framework. This will allow to compare Mediterranean sub-regions, to evaluate the effectiveness of policy scenarios and to assess space variability and trends in terms of ecological indicators such as ecosystem vigor, organization and resilience [2], and more.

In the PERSEUS-FP7 project we focused on several regional sub-basins such as the Gulf of Lion, the Adriatic Sea, the North Aegean Sea, the Western and Eastern Black Sea, as a first step but other sub-regions (Ionian, Catalan, Tyrrenian, Sicily channel) can be easily integrated [3].

The E2E modelling approach we implemented capitalizes on already existing and state-of-the-art tools in hydrodynamic and biogeochemistry (LTL model), as well as food web models (HTL), which are linked through a methodology which enables integration of LTL and HTL sub-models with no, or minor, re-parameterization of their closure terms [4].

The integrated approach followed the processes of a) standardization of the structure of the HTL models; b) aggregation of the information of the LTL model for coupling; c) extension of HTL models to represent also the LTL processes and building the E2E model; d) correction of the trajectory of E2E model to account for different biological, temporal and spatial resolution of the integrated E2E model.

a) the standardization of the structure of the HTL models is needed because several ecological indicators are sensitive to the number and composition of functional groups used to describe a system. After considering several possibilities, including the use of the least complex structure embedding each and every subregional structure, the most complex substructure common to all regions, the use of variable structure and of dual representation of the same region, we ended up with an intermediate complexity structure specific for the Mediterranean Sea, also able to account for fisheries impacts. The aggregated structure for the HTL models includes 9 invertebrates, 12 fish and elasmobranches, seabirds and marine mammals.

b) The LTL part of the E2E models has been achieved by using a common biogeochemical plankton functional type model (OPATM-BFM, [5]) for the whole Mediteranean region. The results of the BFM model were aggregated in order to be used efficiently in the E2E modelling scheme. For example, the BFM results for different copepods (Z3 and Z4) were pooled into a single functional group (Zoo2), and microzooplankton groups (Z5 and Z6) were lumped together under another functional group. Diatoms, dinoflagellates and nanoflagellates (P1, P2 and P4) in BFM were grouped together into Phy2. Picoplankton (Phy1) and Bacteria (Bact) were represented as separate functional groups.

c) Furthermore given the current knowledge and models results, phosphorous was defined as the single limiting nutrient for the Mediterranean Sea whereas nitrogen was considered more appropriate for the Black sea (see Black Sea State of the Environment Report 2001-2006/7). The E2E model implemented in Ecopath with Ecosim (EwE) (www.ecopath.org) extended to represent LTL, was built using the information from the standardized HTL structure previously defined plus estimates of average annual fluxes between LTL compartments (including diet, nutrient consumptions, flows to and between non-living compartments) calculated by BFM for the parameterization of the lumped LTL functional groups (5 living and PO4, POP, DOP and Input PO4 non-living functional groups). Therefore, the extended E2E model, thus comprise of 37 functional groups covering 5 trophic levels, from nutrients and detritus to plankton, small, medium and large pelagics, jellyfish, marine mammals and seabirds and includes fisheries dynamics, all embedded in a 3D description of hydrodynamics and physical properties. Results of the E2E model provided the first estimates of vigor and resilience at the Mediterranean scale.

Abstract
We present two different approaches to study human pressures within the context of the Marine Strategy Framework Directive (MSFD) and further developments on Maritime Spatial Planning (MSP). The first approach considers a single driver or sector (ie., maritime transport) and its relation to multiple pressures and their relationship with descriptors from MSFD. We use data of automated identification systems (AIS) and highlight the potential applications of this new source of data. The second approach integrates multiple drivers, which results in multiple pressures, into an integrative cumulative index. The study area is the Gulf of Lyon (NW Mediterranean), as a trans-boundary case study developed in the FP7 project KnowSeas. The results obtained highlight the potential of both approaches to be used in different steps of the MSFD.

Keywords: Mapping, Conservation, Gulf of Lyon

From one driver to multiple pressures: Maritime transport plays an important role in the world trade and its economic developments. In Europe the "motorways on the sea" concept has been an important issue since the launch of the EU Transport white paper (EC 2001). An enclosed sea such as the Mediterranean is particularly vulnerable to ship-associated pressures due to a high-volume of shipping routes, long history of use, and sensitive shallow and deep-sea habitats [1]. Maritime transport is related to most of the descriptors targeted by the MSFD and associated negative pressures are more specifically related to biodiversity loss, introduction of alien species, pollution, marine litter and underwater noise [1,2,3]. We developed a system to store, manage, analyse and visualize AIS data based on open-source components (PostGIS, R). Using this information, different products may be generated [2]. We illustrate these products in the Gulf of Lyon area using an AIS dataset for the year 2012 (Figure 1).

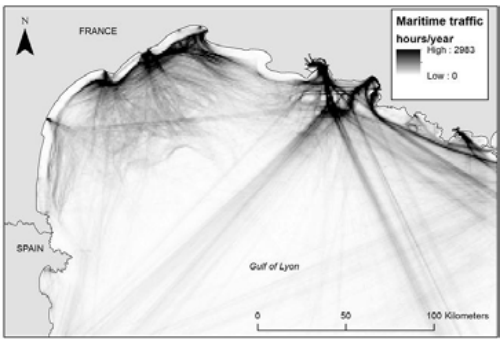

Fig. 1. Marine traffic density in the Gulf of Lions derived from AIS data

From multiple drivers to a single pressure index : The good environmental status of marine environments is conditioned by a wide set of pressures exerted by human activities. Therefore, long-term economic, environmental and social aspects have to be considered simultaneously to understand the complex network linking sea uses and environmental pressures and impacts. The acquisition of a holistic approach is essential for the management of marine areas: the identification, comparison and quantification of cumulative pressures are critical in order to understand effects on marine ecosystems [4]. We conducted a high-resolution cumulative pressure analysis based on [4]. We generated 35 pressure maps, and included 16 ecosystem types. Due to the absence of a current vulnerability matrix for the Mediterranean we used the same matrix developed at global scale [4]. The final map of the cumulative pressure index in the Gulf of Lions is presented in Figure 2.

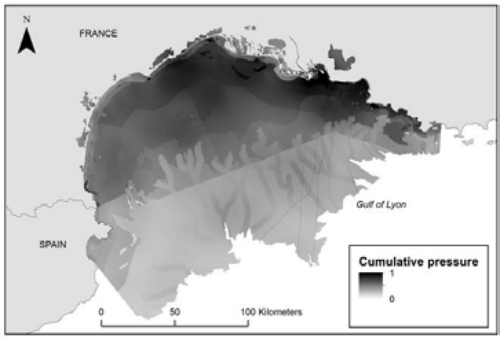

Fig. 2. Cumulative pressure index

Implications for the MSFD : Both approaches are suitable for supporting the Initial Assessment by providing quantitative data on different pressures considered in the MSFD [2]. In addition, the example of generating soundscapes from marine traffic data highlights it potential for modelling indicators of good environmental status. Finally, the information provided in this study can also be incorporated into Decision Support Systems for supporting the design of further monitoring programs and assessing plans of mitigation measures considered in the MSFD.

A METHOD BASED ON SATELLITE IMAGERY TO EVALUATE THE EUTROPHICATION AT MSFD SCALE IN THE ALBORAN SEA

J. M. Mercado [1]*, D. Cortés [1], F. Gómez [1], P. León [1], S. Putzeys [1], S. Sallés [1] and L. Yebra [1]
[1] Instituto Español de Oceanografía Centro oceanográfico de Málaga - jesus.mercado@ma.ieo.es

Abstract
A time series of chlorophyll *a* daily images provided by MODIS-Aqua from 2002 to 2010 was analysed by means of *k-means* clustering analysis in order to identify the main spatial variability patterns of nutrients and chlorophyll a in the northern Alboran Sea. Based on the output of this analysis, six areas were identified whose chlorophyll a annual cycle presented distinguishing features. Baselines of nutrients and *in situ* chlorophyll were calculated for each area and afterwards used to define the good ecological state (GES) and to evaluate their actual state.

Keywords: Eutrophication, Nutrients, Time series, Chlorophyll-A, Alboran Sea

Introduction. The eutrophication is a process driven by enrichment of water by nutrients, that could be natural, human-induced or both [1]. The anthropogenic eutrophication in the Mediterranean Sea is usually a local process that affects coastal waters; therefore its assessment at the scale of the MSFD requires identifying the hot-spots where the nutrient charge can be not explained from natural sources. This task is complicated in some marine regions because the time and spatial distribution of nutrients is inherently (i.e. naturally) patched. This is the case of the Alboran Sea where the Atlantic jet that penetrates through the Gibraltar Strait feeds two quasi permanent anticyclonic gyres which occupy the entire central part of the basin. Intensive geostrophic fronts are located at the edges of the western and eastern Alboran anticyclonic gyres. Furthermore, favourable winds induce episodically enriched water upwelling [2]. Consequently, the permanent presence of conspicuous latitudinal and longitudinal hydro-geochemical gradients is a typical feature of the Alboran Sea. In the present work, an objective method based on statistical analysis of chlorophyll *a* satellite image time series is described allowing to delimit homogenous areas with respect to their annual productivity cycle. The analysis facilitates the definition of practical baselines to the assessment of the good ecological state (GES).

Materials and Methods. The chlorophyll *a* daily images provided by MODIS-Aqua (1.1x1.1 km resolution) from 2002 to 2010 were gathered. Monthly means for each pixel were calculated (questionable pixels as indicated by L2 processing flags were excluded). A *K-means* clustering analysis was performed with the monthly means in order to group the pixels according to both relative concentration and annual cycle of satellite chlorophyll *a*. The number of groups pre-chosen was six. In parallel, a database of chlorophyll *a* and nutrients generated during multiple research surveys performed in the northern Alboran Sea was built. Data collection included registers from 1992 to 2011.

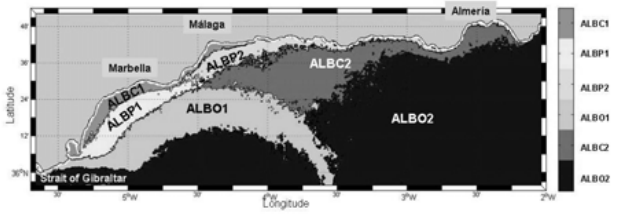

Fig. 1. Output of the *K-means* clustering analysis. The six areas identified according to their annual productivity cycles are shown.

Results and Discussion. Six homogenous productivity areas were identified (Fig. 1) which matched with the main hydrological structures: the cores of the anticiclonic gyres (ALBO2), the edges located at the north of them (ALBO1 and ALBOC2) and the upwelling coastal areas (ALBC1 and ALBP1). Baselines of nutrients and *in situ* chlorophyll *a* for each pixel group were calculated by aggregating the data according to the position of the sampling station. The assessment of the actual state in each area was performed by comparing the concentrations in the recent period (2006-2011) with the corresponding baseline (Table 1). Nitrate remained stable in 2006-2011 in comparison to the whole time series in all the areas. However, increasing trends of phosphate were obtained in ALBC1, ALBP1 and ALBP2. In contrast, there were not significant differences in chlorophyll *a* for the two periods. Consequently, primary symptoms of eutrophication were not detected in the Alboran Sea [3]. In performing the described procedure to assess the eutrophication state, it was implicitly assumed that the good ecological state (GES) was reached when there were not increasing time trends of nutrients and/or chlorophyll *a* beyond the shifts attributable to hydrological variability.

Tab. 1. Description of the data base of nitrate and in situ chlorophyll a concentrations used for determining baselines in each area delimited by the cluster analysis

Nitrate (µM)					
	n	Median	Mean	Standard deviation	Percentile 90
ALBC1	480	0.35	0.97	1.28	2.84
ALBC2	470	0.09	0.42	0.89	1.34

NEW METHODOLOGICAL APROACH IN ESTIMATION OF THE NORTHWESTERN BLACK SEA WATER BODIES' ENVIROMENTAL STATUS

Galina Minicheva [1]*, Andrey Zotov [1] and Eugeniy Sokolov [1]
[1] Institute of Biology of Southern Seas Odessa Branch, NASU - minicheva@ukr.net

Abstract
The central concept of the EU Water Framework Directive - Environmental Status (ES) reflects both the degree to which people use the water environment and the peculiarities of nature conditions in different types of marine ecosystems. It has been proposed to assess ratio between nature ecosystem capacities and artificial force using Artificial Force Index (AFI). The AFI is determined from the difference between 5 WFD's classes as the result of comparison of ES assessed on morphofunctional indicators of Macroalgae and Phytoplankton with the categories of Nature Resistance Index. Negative, zero and positive AFI values have been presented for 12 water bodies of the northwestern part of the Black Sea. Reasons, under which the ES could be lower, identical or higher than the nature capacities of an ecosystem, have been discussed.

Keywords: Phytobenthos, Phytoplankton, Black Sea

Introduction
Implementation on the National level of the EU Water Framework Directive (WFD, 2000/60/EC) and the Marine Strategy Framework Directive (MSFD,2008/56/EC) requirements and standards in all the countries of the Mediterranean-Black Seas Basin is an important condition of trans-boundary monitoring and water resources management. Ukraine has started the work to adapt the National marine ecosystems monitoring methods to the WFD key principles. It has been proposed in the paper to apply the developed in Ukraine morphofunctional indicators for macrophytes and phytoplankton, as well as Nature Resistance Index (NRI) to make expert judgement on the two constituents of Environmental Status (ES) – the nature capacity of an ecosystem and the artificial force impacting it.

Methodology
ES is the central notion on the WFD. It is used as a universal indicator to assess the «degree to which human uses of the water environment». If we use both historical and current data to assess the ES of the same ecosystem, the «altered the structure and functioning of aquatic plant and animal communities» would give us objective picture of temporal dynamics of human impact, as the nature conditions in this case will constitute relatively constant values. When we assess the ES of different types of aquatic ecosystems (coastal, shelf, estuary, bay, gulf, delta front and so on) the Biological Quality Elements (BQE) indicators contain double information: on nature capacities of the ecosystem and on the level of human impact. In this case comparison between the ES of aquatic ecosystems belonging to different types will not always unambiguously reflect human impact only. There is, for example, high probability that the state of the Black Sea Danube Delta Front will show lower ES compared to the state of the Black Sea Crimean Coast because of natural eutrophication due to river discharge and, as the result, simplification of communities and poorer biological diversity. In order to single out non-natural impact from the ES of an ecosystem we propose to use Artificial Force Index (AFI). The AFI characterizes the difference between the level of environmental processes observed in a real ecosystem including human impact and the potential level of environmental processes that could form in water bodies exceptionally under the influence of an ecosystem's natural properties. The AFI should be determined using comparative method from the difference between the WFD classes ES and NRI. For the ESC assessment we propose morphofunctional parameter as a new indicator for Macroalgae and Phytoplankton - specific surface (S/W), which is calculated according to special algorithms [1]. The S/W value is connected with the morphological structure of different aquatic vegetation life forms and reflects their environmental activity in production process. Based on the S/W, a number of new indicators are proposed to assess the ESC of benthic vegetation [2]. Use of the NRI is proposed to assess the ecosystems capacity to resist artificial force based on their natural properties. NRI is calculated as an integral value of hydrological & morphological parameters of water body bed, catchment area, geographical & climatic conditions with further reference to the WFD classification scale [3].

Result and Discussion
The first attempt of the AFI determination has been made for 12 water bodies of the northwestern part of the Black Sea. More than half of the water bodies (7) have negative AFI values, which mean that their ES is worse than nature features as the result of human pressure. The maximum negative values of the AFI (-2) were demonstrated by the Hadzhibeyskiy Liman (located within the city boundaries; sink for domestic discharges from the city with million population) and the Sukhoy Liman (with commercial port in its water area having annual cargo turnover 15 million tons). ES of the 3 water bodies correspond to the nature features of their ecosystems (AFI=0). Only 2 of the 12 Limans have demonstrated positive AFI values: the Tiligul Liman (AFI =+1) with two protected areas of regional significance along its banks and the Dofinovskiy Liman, with the lowest SC NRI category (area - 5.5 km2; average depth – 0.6 m; used to have no natural connection with the sea). At that, the highest AFI value happened to be demonstrated by the Dofinovskiy Liman (AFI = +2) as the result of successful environmental management (there is a fish farm, which has built hydro-engineering facilities and is managing water exchange with the sea). The results received entitle us to continue development of methodological approaches in assessment and comparative interpretation of ES categories of aquatic ecosystems having different natural properties. Work is executed at support Project "Towards COast to COast NETworks of marine protected areas (from the shore to the high and deep sea), coupled with sea-based wind energy potential".

Abstract
The background and the guidelines of the new marine environmental policies (e.g. MSFD) is the ecosystem global approach. Previous indicator-based strategies for ecosystems evaluation was focused on specific elements. Here we propose a global approach, based on conceptual models, to evaluate the status of 24 geolocalized pelagic and benthic marine habitats (*e.g. Posidonia oceanica* beds).

Keywords: Monitoring, North-Western Mediterranean

The EU Marine Strategy Framework Directive (MSFD 2008/56/EC) established a framework for community action in the field of marine environmental policy. The French marine environment action plan (PAMM) has crystallized the French scientific community and all stakeholders involved in marine management towards a common goal and possible improvements have been identified to optimize the next PAMM (2018-2024). The North West Mediterranean region was divided into 24 habitats, for which conceptual models were developped. As an example, the *Posidonia oceanica* ecosystem conceptual model is presented in figure 1.

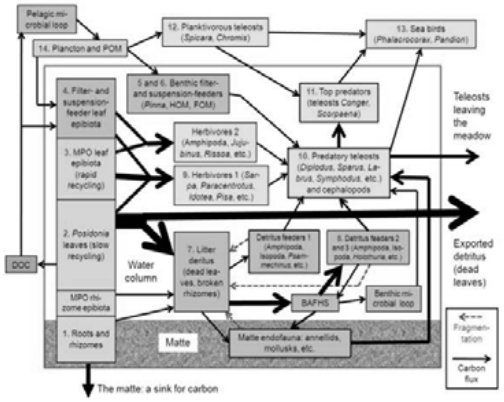

Fig. 1. Conceptual model of the functioning of the *Posidonia oceanica* ecosystem in the North Western Mediterranean Sea (C.F. Boudouresque, original figure; modified from [1])

The rationale and principle governing our ecosystem-based approach are to quantify and evaluate each compartment (functional group) of the conceptual model by means of a set of parameters, to balance their relative weight and therefore to calculate a rank for the ecological status within a given area in relation with surrounding pressures. Each parameter was evaluated by means of a semi-quantitative scale (4 through 0), from very good (4) to very low (0). Compartments were balanced, according to their relative weight in the ecosystem functioning, from 5 (higher weight) to 1 (lower weight). A final rating from 0 to 20 is calculated (highest rating for the highest ecological status). For each compartment, each value of the compartment status and each site, a Confidence Index (CI) has been proposed. The reason for the CI is (i) that data for one or several compartments may be missing or of poor quality in some sites (ii) the reliability of available data may be different between compartments and sites and (iii) it is worth driving the attention of managers and scientists on those compartments that are poorly known and which deserve further field studies. This method was applied to a variety of sites, including continental France, Corsica, Balearic Islands and Catalonia (Italie will be included), that are representative of the North Western Mediterranean subregions, as defined in the MSFD (Figure 2).

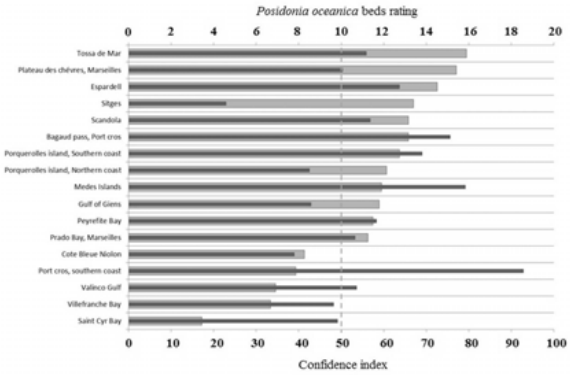

Fig. 2. Evaluation of *Posidonia oceanica* beds from 17 stations based on state rating (mark : 0-20; dark grey) and confident index (mark : 0-100; light grey)

This method allows identifying 3 situations: (1) CI < 50% and whatever the ecological rating is, we expect that knowledge or data are not sufficient enough to allow evaluating the station and we propose to strengthen research and monitoring programs on the area. (2) CI > 50% and ecological rating > 10/20, we expect that the station is in relative good status and does not need particular management measures or to undergo enhanced monitoring. (3) CI > 50% and ecological rating < 10/20, we expect that the ecosystem is not in good status and present a risk of disequilibrium. Further management and monitoring are required.

Abstract
Projections of operational biogeochemical modelling for the Mediterranean Sea are fully available within the MyOcean infrastructure and they might be a not replaceable tool for the estimate of the environmental status of a marine system, also sensu European MSFD. Still, there is an urgent need of suitable and efficient methodologies to assess models skills and reliability of the forecast products. In fact, since the specificity of biogeochemical properties, ad-hoc tools have to be developed and implemented (e.g. Relative Operating Curve, non-parametric statistics). In this work the application of different validation tools to the results of the biogeochemistry component of the Mediterranean Monitoring and Forecast Centre is presented and discussed.

Keywords: Ecosystem services, North-Western Mediterranean, Models, Monitoring

Reliable model estimates of biogeochemical and ecological properties are an urgent need for the estimate of the environmental status and the assessment of efficacy of conservation and environmental policies, also with reference to the enforcement of the European MSFD. Indeed, models can provide space interpolation, time extrapolation and estimates of hardly measurable indicators. Consequently, the assimilation of biogeochemical and ecological data in oceanographic models have been gaining increasing attention, up to the implementation of operational ecological models in GMES (now Copernicus) related services. However, assessing the validity of model results is a complex process that requires the definition of appropriate indicators, metrics, methodologies and faces with the scarcity of real-time in-situ biogeochemical data. Furthermore, biogeochemical models typically consider dozens of variables which are heavily undersampled. Biogeochemical operational forecasts of the Mediterranean Sea are available for users through the MyOcean portal [1]. The biogeochemical forecasts are provided by OPATM-BFM model [2] which is off-line coupled with the MFS general circulation model [3] and includes a 3DVAR assimilation scheme [4] of satellite chlorophyll concentrations [5]. The system runs biweekly and provides 7 days of reanalysis and 10 days of forecast of many variables (primary producers, chlorophyll, nutrients, oxygen and primary production). The set of reanalysis gives an assessment of the near past conditions of the Mediterranean marine ecosystem. Decadal reanalysis might be used for optimal analysis of long term dynamics.
The present stage of validation compares model results with daily satellite data of surface chlorophyll concentration, and with climatological seasonal in-situ profiles of chlorophyll, nutrients (nitrate, ammonium, phosphate and silicate) and oxygen. The comparison with satellite data uses both parametric statistics (as standard indicators and Taylor diagram) and non-parametric statistics (as percentiles comparison, contingency table and Relative Operating Curve -ROC-) and it is aimed to assess the skill of the forecasts in capturing the short term, mesoscale patterns of the surface chlorophyll field which are triggered by the physical processes.

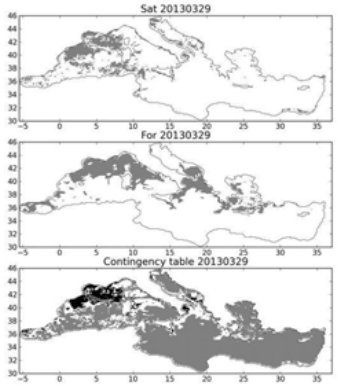

Fig. 1. Satellite (upper panel) and forecast (central panel) maps of chlorophyll concentration higher than 0.4 mg/m3 (gray) for 29/03/2013. Map of the table of contingency (lower panel): true positive predictions (black), true negative predictions (gray) and misses (white).

An example of the contingency table (from which the ROC index is estimated) is shown in Figure 1 which reports the model forecast and satellite observations for a day at the end of March 2013 and highlights the capability of the model system to reproduce the phytoplankton blooms in the North Western Mediterranean (NWM). Such blooms are trigged by vertical mixing and are vital for the productivity of the entire water column ecosystem.

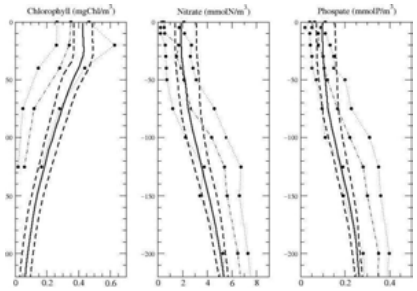

Fig. 2. Comparison of seasonal (winter) profiles of chlorophyll, nitrate and phosphate for Northern Western Mediterranean. Median and range interquartile are shown for model results (black lines) and climatological observations (dots and thin lines).

The system also reproduces fairly well the mean biogeochemical vertical structure of the column. Figure 2 shows the comparison of non-parametric statistics between modelled and seasonal climatological chlorophyll, nitrate and phosphate for the upper layer in NWM. In this case the difference between the medians of model and observation is smaller than the variability of observations, and the shape of vertical profiles are similar. however, a proper assessment of the full model output remains a challenge.

Abstract
Anthropogenic pressures are known to cause regression of the upper portion of the most important underwater coastal seascape of the Mediterranean: the *Posidonia oceanica* meadow. Evaluation of its status is part of monitoring programs, but lack of definite reference conditions hampers proper conclusions. We elaborated an innovative model to locate the region of the seafloor where the meadow upper limit should lie in natural conditions (i.e. those governed only by hydrodynamics, in absence of significant anthropogenic impact). This model was validated along the Ligurian coastline and is currently tested at Mediterranean scale.

Keywords: Coastal systems, Posidonia, North-Western Mediterranean

Introduction
The problem of sliding baselines represents a major concern for the evaluation of global change impacts on ecosystems [1]. Lack of information on pristine (or at least historical) conditions to be used as references impairs our understanding of the effects of global change on natural ecosystems and their consequences on the amount of resources a healthy ecosystem can provide. In general, reference conditions can be defined in three ways:
i) historical information, when available and reliable, which is not always the case [2];
ii) data collected in pristine areas, still scarce worldwide and often insufficiently enforced [3];
iii) modelling [4].
Here we present an innovative predictive cartographic approach able to identify the seafloor portion where the meadow upper limit should naturally lies (i.e. its reference conditions). The model was elaborated and validated along the Ligurian coastline and is currently tested in other Mediterranean areas.

Methods
The conceptual framework of this model is based on 3 essential components (Fig. 1):
i) Definition of the breaking limit position, which represents the major constrain for the landward meadow development [5]. We modelled the breaking limit (1 year return time) using the software Mike 21 SW (www.dhi-italia.it). Mike 21 SW is a spectral wind-wave model that simulates the growth, decay and transformation of wind-generated waves and swells in offshore and coastal areas.

ii) Definition of the morphodynamic domain of the beach using the surf scaling index ε [5]
In each site, the surf scaling index ε was calculated combining wave parameters with information derived from the specifically created bathymetric maps (Table 1). The following formula was employed

$$\varepsilon = a\omega^2/g \cdot tan^2\beta$$

where: a (breaker amplitude) = $H_0/2$; ω (incident wave radian energy) = $2\pi/T_0$: T_0 = period; g = acceleration of gravity; β = the slope of the beach in the surf–zone.

iii) Definition of the *P. oceanica* upper limit geometry. We coupled detailed aerial photo with thematic bionomic cartography.

Results and discussions
In GIS environment, we modelled the extent of the seafloor where the meadow should naturally lie (i.e. the reference condition), according to the breaking limit position and the morphodynamic domain of the beach. Then, we added the GIS layer over the meadow upper limit geometry. Therefore, the final output shows, on the same map, both the reference condition and the actual location of the upper limit, allowing to assess the status of the landward extent of a given *P. oceanica* meadow.

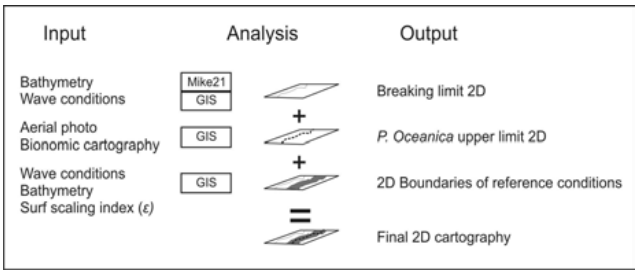

Fig. 1. Conceptual framework of the 2D model to predict the reference condition of *Posidonia oceanica* upper limit

Knowing where the upper limit of a specific meadow should naturally occur is fundamental to quantify any suspected or observed regression caused by anthropic factors. The predictive model presented in this paper allows quantifying the amount of seagrass meadow regression, thus providing the theoretical reference condition requested by the European Directives (MSFD and WFD). In conclusion, these result have important consequences for coastal zone management, as the status and the depth of the upper limit of *P. oceanica* meadows is part of current protocols for seagrass monitoring activities (Boudouresque et al. 2006; Montefalcone 2009), which need reference conditions to track their evolution under natural and anthropogenic influences.

DÉTECTION DE LA MALADIE DE L'ANNEAU BRUN CHEZ *FULVIA FRAGILIS*

Mouna Rifi [1], Monia El Bour [2] and Jamila Ben Souissi [1]*
[1] Institut National Agronomique de Tunis - jbensouissi@yahoo.com
[2] Institut National des Sciences et Technologies de la Mer

Abstract
L'étude de la coque lessepsienne invasive *Fulvia fragilis*, en provenance de la baie de Tunis et la lagune de Bizerte, a révélé la présence des symptômes caractéristiques de la maladie de l'anneau brun. Les prévalences élevées de cette maladie expliqueraient en grande partie les épisodes de raréfaction et de mortalités de ce bivalve dans les 2 sites.

Keywords: Alien species, Bivalves, Diseases, Tunisian Plateau

Introduction
Fulvia fragilis (Froskal in Niehbur, 1775), un cardiidae originaire de l'Indo Pacifique et de la mer Rouge, a été signalé pour la première fois en Tunisie dans le golfe de gabès par Passamonti en 1996 [1] et a élargi son aire de répartition géographique aux côtes les plus septentrionales à savoir la lagune de Bizerte [2] et la baie de Tunis [3]. Lors de, l'étude écobiologique de l'espèce, nous avons détecté des malformations coquillières et des dépôts de matière organique à l'intérieur de l'animal, symptômes caractéristiques de la maladie de l'anneau brun.

Matériel et Méthodes
Des échantillonnages mensuels à bimensuels de *F. fragilis* dans la baie de Tunis et la lagune de Bizerte ont été effectués, entre avril 2006 et Octobre 2007. Dans le cadre d'une étude de la reproduction de ce bivalve, un total de 4534 specimens en provenance des 2 sites a été récolté et observé. Des coupes coquillères ont été examinées au microscope éléctronique à balayage et la prévalence de cette maladie a été calculée.

Résultats
L'examen des coquilles montre des anomalies et malformations avec des dépôts de matière organique (figure 1). L'ultrastructure coquillière révèle la présence de bactéries de type gram (-) (figure 2), et le germe responsable étant *Vibrio tapetis*. Tous les symptômes de la maladie de l'anneau brun décrits dans la littérature ont été observés [4]. La prévalence de cette maladie chez les spécimens récoltés dans la baie de Tunis oscille entre 10 et 100 % avec une moyenne de 74,33% et fluctue entre 0 et 100% dans la lagune de Bizerte avec une moyenne de 50,6%. Lors de notre suivi sur le terrain plusieurs épisodes de mortalité ont été enregistrés notamment durant les périodes chaudes de l'année. L'étude de la reproduction a montré une déficience chez les spécimens pêchés à la lagune de Bizerte. Par ailleurs, un suivi de l'Indice de condition, considéré comme un indice eco physiologique pour cette coque, a révélé une déterioration métabolique plus accentué chez les specimens de la lagune de Bizerte.

Fig. 1. Des coquilles de *Fulvia fragilis* présentant des symptômes de l'anneau brun.

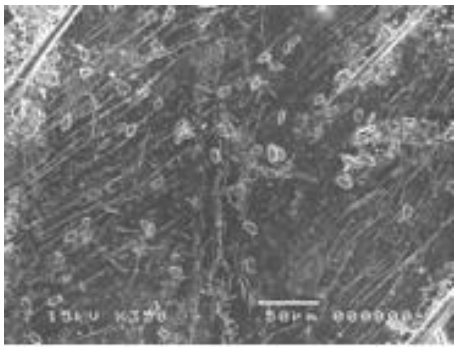

Fig. 2. Photo de la bactérie (bacille gram -) détectée au niveau de la coquille de *Fulvia fragilis.*

Discussion
La maladie de l'anneau brun a fait l'objet de plusieurs travaux de recherche [4 ; 5]. Les études ont montré que cette maladie, notamment chez *R. philippinarum*, induit un déséquilibre de la balance énergétique [5]. Certains auteurs [5] ont décrit de fortes mortalités de *R. philippinarum* suite à son infection par la maladie de l'anneau brun. En Tunisie, cette maladie a été détectée chez plusieurs espèces de bivalves. La présence de cette maladie chez *F. fragilis* expliquerait en partie les fortes mortalités estivales et la raréfaction de l'espèce. Le déséquilibre métabolique accentué observé chez les spécimens de la lagune de Bizerte serait probablement du à l'effet conjugué de la pollution intense du site et de l'infection de ce bivalve par la maladie de l'anneau brun. Les perturbations du cycle de reproduction ainsi que l'amaigrissement de l'animal ont été démontrés par l'étude histologique et le suivi de l'indice de condition que nous avons réalisés [6].

DO INVASIVE MACROALGAE INFLUENCE ASSOCIATED MOLLUSC DIVERSITY IN THE MEDITERRANEAN SEA ?

Riccardo D'Agostaro [1]*, Marco Milazzo [1] and Renato Chemello [1]
[1] Dipartimento Scienze della Terra e del Mare, University of Palermo - riccardo_dagostaro@yahoo.it

Abstract
The benthic molluscs associated to the non-indigenous red algae *Asparagopsis taxiformis* invading the Mediterranean rocky subtidal were compared with those associated to a native brown alga. The results showed a marked difference in species richness and abundance between native and non-native algal species.

Keywords: Alien species, Biodiversity, Algae, Mollusca, Tyrrhenian Sea

Introduction
The introduction and spread of non-indigenous species represent one of the main threats to biodiversity, structure and functionality of ecosystems at various scales [1]. One of such potential threat may be currently represented by the invasive macroalga *Asparagopsis taxiformis*, a non-indigenous red alga widely distributed along the west coast of Sicily (Italy). Different seaweeds do not support benthic fauna in the same way, due to several factors such as algal architecture, life cycle or presence of chemical defenses [2]. This work compares the molluscan assemblages associated with *A. taxiformis*, with those associated with *Cystoseira brachycarpa*, a brown alga typical of the shallow rocky subtidal of the SW Mediterranean, trying to quantify the potential effects caused by the invasion of *A. taxiformis* on native benthic fauna.

Material and methods
The study was carried out within the Egadi Islands MPA (Western Sicily, Central Mediterranean) on a shallow rocky platform, where *A. taxiformis* and *C. brachycarpa* share the habitat. In order to estimate the abundance and composition of the associated molluscs, in June 2011, four different habitats' types were sampled: native habitat with *C. brachycarpa* (C), non-native habitat with *A. taxiformis* (A), invaded but dominated (covering ≥70%) by native *C. brachycarpa* (mixed native habitat, MC) or dominated (covering ≥70%) by non-native *A. taxiformis* (mixed not-native habitat, MA). Ten samples for each habitat's type, represented by a single algal stem, were collected by scuba-diving. Molluscs were then sorted out, identified to species level and counted, whilst the main physical attributes of algae were calculated and used for the estimation of the architecture, the interstitial volume and the biomass [3].

Results and discussion
A total of 79 mollusc species were identified. Fifty of them were on native habitat with *C. brachycarpa* (C), 52 species were found on mixed native habitat (MC), while 23 were on mixed non-native habitat (MA), but only 21 were found on habitat exclusively dominated by *A. taxiformis* (A) (Fig.1). PERMANOVA showed significant differences in molluscan assemblage among habitats and sites ($p<0.001$). The highest dissimilarity was found between molluscan assemblages associated to MC and A (88.4%; SIMPER) and C and A (89.16%; SIMPER). The correlation between biomass of macroalgae was significantly correlated to species richness ($r_s=0.53$; $p<0.01$) and total abundance ($r_s=0.53$; $p<0.01$) of associated molluscs.
These results showed a marked difference between the molluscan assemblages associated with native and non-native habitat, furthermore an overall reduction in the number of species and abundance was associated to *A. taxiformis* due to differences in the main structural index and in the algal biomasses.

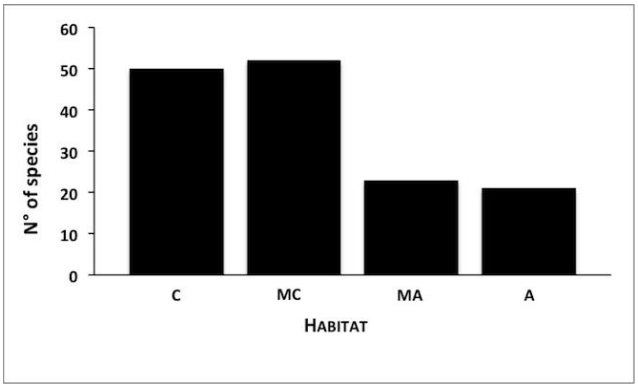

Fig. 1. Total number of species found on different habitat's types. C= Native Habitat, MC= mixed native habitat, MA= mixed non-native habitat, A= non-native habitat.

Abstract
The isotopic composition of 30 Lessepsian and 19 native fish inhabiting the littoral rocky shores of Lebanon (Eastern Mediterranean) was analysed. Wider $\delta^{15}N$ and narrower $\delta^{13}C$ ranges were identified for LES than for native species and both Multivariate and population metrics pointed to a narrower trophic niche width of these formers with respect to their native counterpart.

Keywords: Lessepsian migration, Stable isotopes, Food webs, Levantine Basin

Introduction
Stable isotope analyses (SIA) are powerful tools to investigate the ecological consequences of non-indigenous fishes on receiving ecosystems [1, 2]. They allow to estimate niche width and can be used to quantify the potential ecological effects of non-indigenous species on recipient food webs [2]. Here we use SIA, to investigate the food web of the eastern Mediterranean rocky-reef fish assemblage, after the establishment of Lessepsian immigrants (LES). Our aims were to: 1) describe the structure of the new food web and 2) compare the trophic niche of LES *vs*. native fish species, according to both the whole assemblage and the different trophic guilds established a priori.

Materials and methods
Common native fish species, together with a representative pool of Lessepsian fishes were collected in 2012 along the littoral zone of Beirut (Lebanon, Eastern Mediterranean). Portions of tissues were prepared and analysed according to standard protocol for SIA. Multivariate techniques (nMDS, PERMANOVA, PERMDISP) and standard population metrics [2] were used to compare isotopic ratios of LES and native species at community level and on trophic guilds (TG) defined a priori (benthic carnivores=BC, generalized carnivores=GC, planktivores=PL, piscivores=PI and herbivores=H).

Results
A total of 49 fish species (19 natives and 30 LES) were analysed. The nMDS plot showed the relative position of samples according to their isotopic ratios (Figure 1).

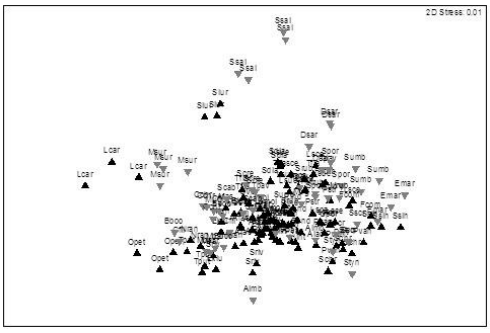

Fig. 1. NMDS plot of the isotopic ratios of C and N of LES (black) and native fish (grey).

PERMANOVA analysis revealed a significant separation between the isotopic ratios of LES *vs*. natives at both the level of the entire assemblage ($F_{1,160}$= 7.38, p<0.01) and of single trophic guilds ($F_{5,160}$= 11.28, p<0.001). In addition, PERMDISP showed significantly higher dispersion (i.e. more generalized diet) in isotopic values of natives *vs*. LES ($F_{1,159}$=15.40, p=0.002). In general, LES species showed greater $\delta^{15}N$ (higher trophic levels, NR in Table 1) and narrower $\delta^{13}C$ range (limited range of exploited resources, CR) than natives. The other population metrics (CD, SEAc, Table 1) pointed to a narrower niche width and low trophic diversity of LES compared to natives.

Tab. 1. Population metrics of LES and native species according to both the whole assemblage (All) and trophic guilds established a priori. For population metrics see details in [2].

Discussion
Here we provided the first comprehensive dataset on the isotopic composition of the most successful Lessepsian immigrants. Competition for trophic niche has been indicated as a primary force in ruling the coexistence of species of native and Lessepsian origin, often resulting in strong ecological segregation or displacement. Present findings do not support the idea of invaders as opportunistic species [3]. On the contrary, our results showed a greater trophic specialization of LES compared to natives. This pattern could be generated by some new capabilities of LES to exploit available resources with respect to native species. The particular situation of the Mediterranean, with several empty niches and lower competition among fish than in tropical reefs may favour this behavior. Further isotopic studies, targeting changes in stable isotope values along the spatial and temporal scales, will be promising to understand the applied and theoretical aspects associated with the Lessepsian bio-invasion.

LIFE HISTORY STRATEGIES OF NON-INDIGENOUS *UPENEUS PORI* AND CONFAMILIAL *MULLUS BARBATUS* IN THE NORTHEASTERN (NE) MEDITERRANEAN

Meltem Ok [1]* and Ali C. Gücü [1]
[1] Middle East Technical University, Institute of Marine Sciences, Turkey - monkseals@gmail.com

Abstract
In this study, allocation of energy and time for growth and reproduction of *M. barbatus* and *U. pori* were investigated to understand life history strategies adapted by a native and non-indigenous confamilial species based on multidisciplinary survey data collected in three successive years in the NE Mediterranean. The results indicated that the species seem to fulfill their biological activities within a short period of time when the highest productivity is reached in the area. The native fish exhibits fast growth, early maturation and short reproduction season while its counterpart spawns during two different time period (dual spawning) on the bathymetric slot (upper thermocline) that *M. barbatus* abandons during summer.

Keywords: Demersal, North-Eastern Mediterranean, Fishes, Lessepsian migration, Life cycles

Introduction
The Mediterranean Sea is in a metaphoric change mainly due to anthropogenic interferences and natural perturbations. The life history traits adopted by the native components and those successfully established are among the most important weapons in the modern Mediterranean arena. In this study, patterns in life history strategies (timing and energy allocation for growth and reproduction) of *M. barbatus* (Red mullet) and lessepsian *U. pori* (Por's goatfish) were investigated to improve ecological understanding of demersal fish assemblages of the Northeastern Mediterranean Sea.

Material and Method
The data used in the study were collected during the monthly fisheries surveys between May 2007 and May 2010 at six different depths (Figure 1) where temperature and salinity profiles at each station were measured.
The energy allocation is evaluated by i) the parameters of seasonally oscillating von Bertalanffy Growth function, ii) length at first maturity, iii) sex-ratio and size differences by sex and iv) biological indices, namely GSI, HSI and Somatic K.

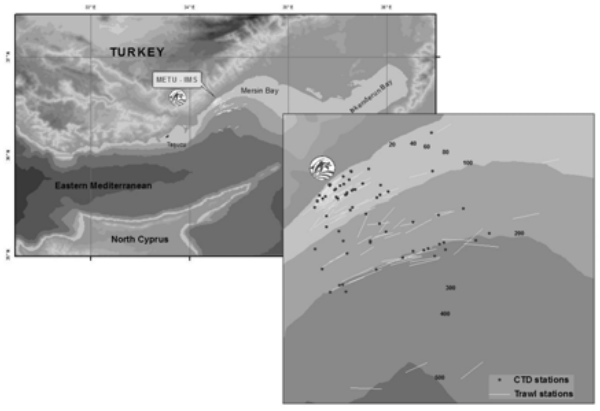

Fig. 1. The study area including bathymetry of the region as well as the position of the trawl hauls and CTD profiler. Lines show the trawl hauls while points show the CTD sampling cast performed during the study period.

Results
The parameters of seasonalized vBGF approximated based on monthly length frequencies of *M. barbatus* (n=18894) and *U. pori* (n=3577) indicated that the both species displays strong seasonality in growth (C = 0.40) while former grows faster (K = 0.56) and larger (L∞ = 26 cm) with early-summer deceleration in growth (WP=30). The latter species is smaller in size (L∞ = 20.0, K = 0.45) and slow growth state is displayed earlier than the former. The analyses indicated that both species reaches sexual maturity in the first year of life when male red mullets reaches to 11.6 cm and females reaches 12.6 cm total length on average. The length at first maturity for *U. pori* is reached at smaller total length (9.5 cm and 10.0 cm for males and females respectively). A significant difference was observed in the spawning season of *M. barbatus* and *U. pori* (Figure 2).

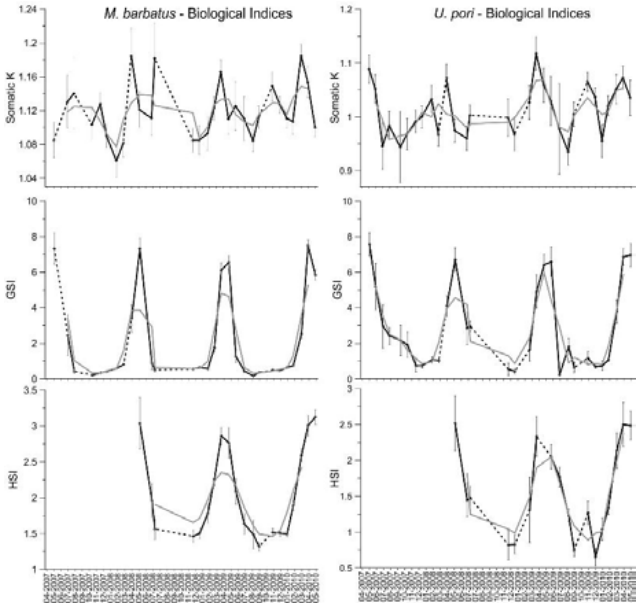

Fig. 2. Time series of calculated biological indices of *M. barbatus* and *U. pori*. Continuous grey lines are the 3x running averages.

The red mullet develops its gonads fast and spawns within a month between May and June. The data clearly showed that gonad development in *U. pori* occurs two times a year starting from late February - early July and early July to late December indicating the existence of secondary spawners within the population. As for bathymetric preference, *U. pori* almost exclusively occupied the depths shallower than 20 m depth while the native confamilial occupied deeper waters down to 220 meters. The very warm (> 27 °C) waters of the upper summer thermocline seem to limit the distribution of *M. barbatus* on the shallow littorals. *U. pori* successfully occupies this area left by the *M. barbatus* and gets the most benefits by high seasonality in growth, fast and multiple gonadal development and smaller maturation size. Golani (1994) has already reported similar niche partitioning on the bathymetric distribution axis.

VERRUCAE ON SEA-FANS: UNEXPECTED ABUNDANCE OF THE BARNACLE *CONOPEA CALCEOLA* (ELLIS) ON THE GORGONIAN *EUNICELLA SINGULARIS* (ESPER) IN THE MEDITERRANEAN SEA

Andrea Peirano [1]*, Chiara Lombardi [1], Nicolò Ponzè [2] and Silvia Cocito [1]
[1] ENEA, Marine Environment Research Centre, La Spezia, Italy - andrea.peirano@enea.it
[2] Area Marina Protetta Isole Egadi, Favignana (TP), Italy

Abstract
Colonies of the symbiotic Mediterrean gorgonian *Eunicella singularis* were found to host the warm-tropical barnacle C*onopea calceola* on rocky bottoms in the Sicily Channel. Barnacle' presence and abundance (some tens individuals per colony) is probably due to increasing seawater temperatures, this 'co-habitation' supposedly representing a strategy for *C. calceola* species' survival and a further threat for *E. singularis* in an increasingly warming Mediterranean Sea.

Keywords: Crustacea, Sicily Channel, Cnidaria, Global change, Alien species

Introduction
The barnacle *Conopea calceola* (Ellis), living on gorgonians, has been reported present, yet rare in Southern Italian coasts ([1], [2]). Records are given here on monospecific, dense stands of candelabra-like *Eunicella singularis* (Esper) hosting the barnacle, found in the Sicily Channel.

Material and methods
A biodiversity survey was carried out in May 2012 at Favignana Island (Marine Protected Area of Egadi Islands, Sicily Channel, Italy). In 13 localities, rocky bottom communities were video-surveyed along transects spanning on the whole a 0 to 60 m depth range. Video sampling (30 min per transect) was performed with a full-HD camera equipped with a wide-angle lens recording nearly 0.75 m^2 at a distance of approximately 50 cm.

Results and Discussion
A total of 570 *E. singularis* colonies were surveyed, of which 24.6 % were seen to host *C. calceola* (Tab. 1). The majority of *E. singularis* colonies living on bottoms between 15 and 30 m were characterized by tens of 'verrucae' barnacle housings (Fig. 1).

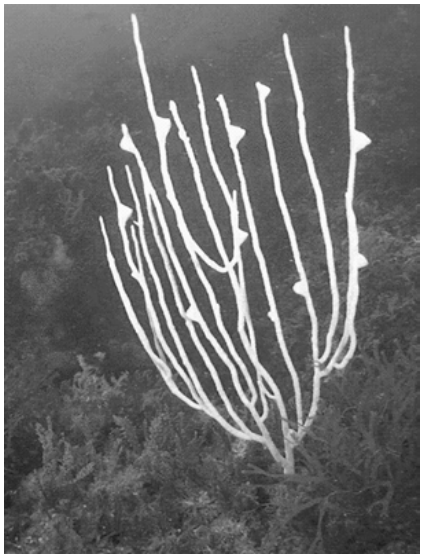

Fig. 1. Colony of *Eunicella singularis* on a flat rocky bottom at Favignana, Egadi Island, Sicily Channel (South Western Mediterranean) colonized by more than 12 individuals of the barnacle *Conopea calceola* that form visible verrucae.

By sampling a few *E. singularis* colonies, gorgonian tissue was observed to wrap *C. calceola* shell with the exception of a small opening which ensure barnacle feeding. The presence of alive individual within the shell suggested that the white gorgonian is a suitable substrate for the barnacle. Warm-tropical *C. calceola* has a wide distribution extending from the eastern Atlantic coast to the Indian Ocean, and further to the seas bordering S.E. Asia ([3]). Present occurrence and abundance of this barnacle may be compared with those of other warm-water species such as *Solidobalanus fallax* (Broch), which is found inhabiting the British sea-fan *Eunicella verrucosa* ([4]). As for *S. fallax, C. calceola* ubiquitous presence observed in the last few years is probably due to increasing seawater temperatures, favoring species widespread and making it more detectable. In light of serious threats affecting the Mediterranean white gorgonian *E. singularis* such as the extensive mortalities that occurred in the past decade ([5]), the increase in *C. calceola* abundance could signify a further problem for *E. singularis*. This 'co-habitation' may represent a strategy for *C. calceola* survival in the changing Mediterranean Sea.

FEEDING BEHAVIOUR OF INVASIVE WHELK, *RAPANA VENOSA* VALENCIENNES, 1846 FROM THE SOUTH-EASTERN BLACK SEA, TURKEY

Hacer Saglam [1]* and Ertug Düzgünes [1]
[1] Karadeniz Technical University - hacersaglam@yahoo.com

Abstract
In present study the effects of predator size, prey size, temperature and prey type on the time spent on feeding by *Rapana venosa* were studied in the laboratory conditions in the south eastern Black sea.

Keywords: Black Sea, Alien species

Introduction

The Rapa whelk is not a native species of the Black Sea and introduced from Asian waters in the 1940's and it's first reported in Turkey waters in 1960s [1]. Rapa whelk, *Rapana venosa*, characterized by strong ecological fitness due to its high fecundity, generalist feeding strategy, early sexual maturity, longevity, fast growth rate and broad tolerance to salinity, temperatures, water pollution and oxygen deficiency (Figure 1). All these factors are characteristics of a successful invader. There are no major predators of invasive adult whelk in this region and an intensive predatory impact on the mussels by Rapa whelks [2].

Fig. 1. Rapa whelk morphology

Rapa whelks are the most important component of the demersal fauna in the coastal waters of south eastern Black Sea. Rapa whelks play an important role in the food web. The results of this study are a contribution to the understanding of the role of this species within the ecosystem.
The diel feeding periodicity, gastric emptying, food consumption [3] daily consumption rates, prey preferences [4, 5] were studied on feeding of Rapa whelk up to date. The present study aims to determine feeding behaviour of *R. venosa* based on the time spent on feeding in the Black Sea, Turkey.

Material and Methods

Rapa whelk was collected using dredge on the South-eastern Black Sea at 20 m depth. Whelks were maintained in fiberglass tanks supplied with continuously flowing seawater. Adult whelks were placed in the aquaria, 30x30x30 cm, with water circulation and were fed mussel tissue or live mussels, *Mytilus galloprovincialis*. The ten experiments were conducted between July and October 1998. Feeding behaviour of whelks ranging from 61 to 89 mm in shell length was observed for 24 h for each experiment. In each experiment, each of the whelks was starved for 48 h and then presented a single meal of fresh mussel tissue (approximately 1 g). The total time spent on feeding from the start until the end of feeding on mussel tissue or live mussels was recorded for each individual. Effects of predator (Rapa whelk) size (71, 78 and 82 mm), prey size (0.97, 1.35 and 1.70 and 2.46 g), temperature (20, 23 and 26ºC) and prey type (mussel tissue and living mussel) on the time spent feeding were studied.

Results and Discussion

Rapa whelk was consumed mussels without damaging the shell of its prey in our study. The time spent on feeding by Rapa whelk decreased with increasing its size and increased with increasing prey (mussel tissue) ($P<0.05$). The time spent on feeding by predator Rapana varied with the temperature. Approximately 1 g mussel tissue was consumed in 70.6, 49.2 and 18.5 minutes at 20, 23, 26°C by adult whelks respectively. The Rapa whelk consume 14.3 g living mussel (2.42 g mussel tissue) in about 310 minutes while it consume 2.46 g mussel tissue in 160 minutes at 27-28°C. The estimated average food requirement for Rapa whelk was 1.2 (Northern Adriatic), 0.68 (South Western Atlantic) and 0.2-03 (South Eastern Black Sea) g mussel tissue per day [3, 4, 5]. These differences between studies may be due to different whelk size, temperature and prey types. The approximately 1 g mussel tissue used in our experiments is higher than daily food requirement for Rapana.

Abstract
Invasions by alien species is one of the most alarming threats that reduces biodiversity and leads to direct or indirect ecological effects on marine ecosystems. Northern Adriatic lagoons are affected by high anthropogenic impacts, which may facilitate the introduction and spreading of alien species. The sphaeromatid isopods *Paracerceis sculpta*, native to the northeast Pacific, has been found for the first time Pialassa Baiona, a brackish lagoon connected to Ravenna harbour, in 2012. Field data suggest that *P. sculpta* became a pest species, being more competitive compare to the two native sphaeromatid species inhabiting the lagoon.

Keywords: Lagoons, Alien species, Brackish water, Crustacea, North Adriatic Sea

Introduction Northern Adriatic coastal lagoons show a high rate of introduction of alien species compared with other coastal regions, becoming one of the major hot spot of invasion in the Mediterranean basin ([1], [2]). Human disturbance and the increase of vessel traffic countries is an important pathway of spreading of alien species in stressed environments ([2]). *Paracerceis sculpta* (Holmes, 1904) is one interesting examples of alien species introduced to costal lagoons. It is a sexually dimorphic sphaeromatid isopod native to the NE Pacific, from southern California to Mexico. This species has been introduced to many areas and has a world wide distribution. Maritime traffic has been assumed to be the most probable vector of spread for *P. sculpta*, which could be transported among fouling, in ballast water or associated to species of interest for aquaculture ([2]). **Material and methods** The abundance of sphaeromatid isopods was investigated in 4 areas of the Pialassa Baiona, a lagoon connected to the Ravenna harbour and located 60 nm south to Venice. Area 1 is landward and close to main human disturbance sources (sewage, thermal plants, etc.), area 2 seaward and also affected by disturbances, area 3 seaward but less subjected to disturbance and area 4 landward and far from disturbances ([3]). Specimens were collected both in the soft bottoms, by box corer in May 2012, and associated to recruitment panels, recovered every two weeks between March and October 2012. Data from previous soft bottoms surveys were also reported.

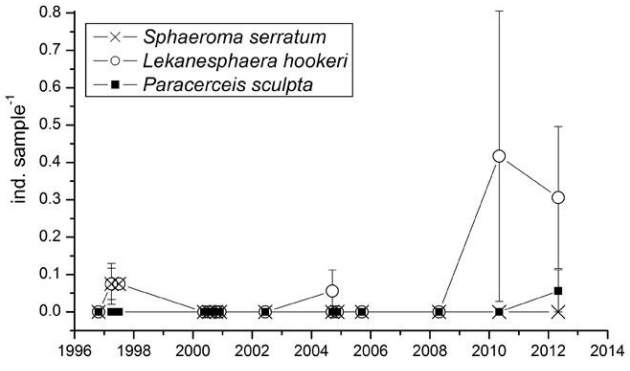

Fig. 1. Mean densities (± s.e.) of sphaeromatid isopods in benthic samples collected in the coastal lagoon Pialassa Baiona since 1996 to 2012.

Results The first record of *P. sculpta* in the northern Adriatic Sea dates back to April 1981, in the Venice lagoon ([4]), but it has never been observed in the soft bottoms of Pialassa Baiona lagoon, until May 2012 (Fig. 1).The native sphaeromatid species inhabiting the Pialassa Baiona are *Lekanesphaera hookeri* (Leach, 1814) and *Sphaeroma serratum* Fabricius, 1787. Few individuals of *P. sculpta* were found in area 2, in May, thereafter the species became more abundant, reaching 9.2 (±2.67 s.e.) ind. sample^{-1} in September in area 2, and colonising the area 3 (Fig. 2). *L. hookeri* was the most abundant species in the lagoon, even if during the investigated period its populations seem to move progressively from area 1 to 2 and then 3. **Discussion** *P. sculpta* was found in area 2, and 3, both areas are close to the sea and to the harbour entrance. This distribution suggests a recent introduction of the species into the lagoon, facilitated by maritime traffic and local human disturbances. The gradual enlargement of the colonised area and the increase in population size of this alien species suggest that it may be threatening native species. Further studies are needed to confirm that *P. sculpta* is more competitive than the native species and it has a true impact in term of loss of ecological functions.

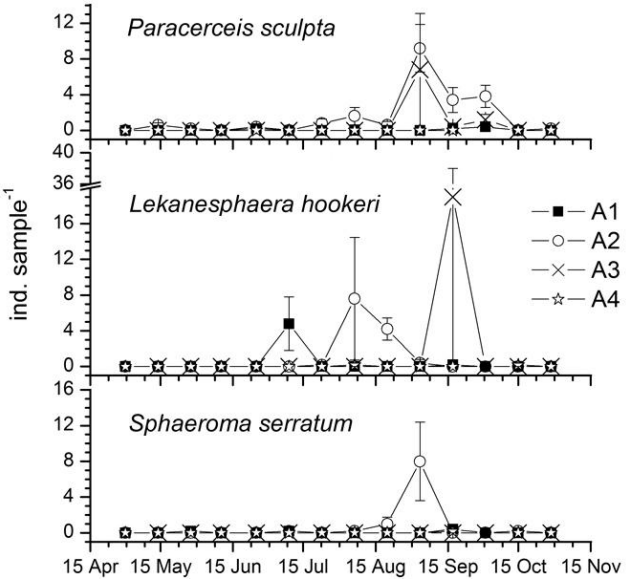

Fig. 2. Mean densities (± s.e.) of sphaeromatid isopods in recruitment panel samples in four inner areas in the Pialassa Baiona in 2012.

TRACKING CHANGES IN FISH ABUNDANCE ACROSS THE COAST OF LEBANON: A LOCAL ECOLOGICAL KNOWLEDGE STUDY

Safia Alajlan [1]*, Ernesto Azzurro [2] and Michel Bariche [1]
[1] American University of Beirut - sha55@aub.edu.lb
[2] ISPRA,Italy

Abstract
The current work aims at detecting changes encountered in fishery landings along the Lebanese coast using an LEK approach. Preliminary results mainly indicate a decrease in the abundance of native as well as invasive species having commercial importance. Furthermore, we found an increase in a number of invasive species that are considered as pests to fishermen, while others were found in high abundance despite fishing pressure.

Keywords: Alien species, Levantine Basin, Global change, Fisheries

Introduction

The eastern part of the Mediterranean Sea has been severely impacted by anthropogenic activities, such as coastal degradation, overfishing, species invasions and seawater warming (1). Local Ecological Knowledge (LEK) can be defined as the information accumulated over time by a group of local people through observation and interaction with the natural environment. LEK is emerging as a powerful, low cost, information source on natural ecosystems, complementing "traditional" scientific research (2). Gathering information from local fishermen can improve our understanding of the temporal changes occurring within the marine ecosystem, as has been shown recently for Mediterranean fish (3). Here we apply this methodology with the aim to reconstruct recent changes in fishery landings along the Lebanese coast.

Materials and Methods

Regular visits to fishing ports spread along the entire coast of Lebanon are being undertaken to interview fishermen, which were selected based on seniority (≥10 years of experience). A total of 32 fishermen from various parts of the country have been interviewed so far following a survey questionnaire. This questionnaire has been adopted from the CIESM Tropical Signals Program (http://www.ciesm.org/marine/programs), and slightly modified to accommodate the specific requirements of the Eastern Mediterranean region.

Results and Discussion

Preliminary results showed that several native fish species, such as *Mycteroperca rubra*, have decreased dramatically in size and abundance as they have been overexploited by the local fishery. Exotic species showed different patterns of abundance in the landings: The populations of some invasive species have considerably increased and this correlated with their date of invasion, especially for those of non-commercial importance (*e.g. Lagocephalus sceleratus*). However, other species (*e.g. Upeneus moluccensis*) have declined significantly, after having an initial stage of population expansion. The latter have been highly targeted because of their market value. In contrast, other species have displayed a high abundance despite significant fishing pressure (*e.g. Siganus rivulatus*). Surveying LEK from the coastal waters of Lebanon has shown encouraging preliminary results. This simple and innovative approach has open up new opportunities to detect temporal changes in fish diversity and abundance in the Levant.

Acknowledgements

This study has been conducted within the framework of the CIESM tropical signals program. We kindly acknowledge all the Lebanese fishermen who participated in the survey.

SIGANUS SPECIES IN AN ARTISANAL FISHERY IN THE EASTERN AEGEAN

A. Pennington [1], J. Shepperson [1], A. Jeffery [1], A. Miliou [1] and V. Anagnostou [1]*
[1] Archipelagos Institute of Marine Conservation - b.anagnostou1@gmail.com

Abstract
Underwater visual census (UVC) surveys, fishery landings surveys and interviews were used to assess the level of Siganus spp. invasion in Fourni island complex, NE Aegean Sea, Greece. Results showed that despite a high abundance of Siganus spp. being observed in UVC surveys, this was not translated into fisheries landings. Interview surveys identified avoidance behaviour and discarding activities by local fishermen, due to the low economic value of Siganus spp. fish in the specific region. This study provides evidence that changing public perceptions could bring both economic and ecological benefits to the local area.

Keywords: Lessepsian migration, Aegean Sea, Fisheries

Introduction
Siganus spp, are considered to be amongst the 100 worst invasive species in the Mediterranean [1], and have been shown to cause a significant impact on local ecosystems [2]. They have become established in a relatively unsaturated niche, due to a scarce number of indigenous herbivorous fish and now pose serious competition for food and habitat, to native herbivores, which are economically important species [4]. This study comments on the extent of the *Siganus* invasion, the fishermen's perceptions, and the implications for the fishery in the region of Fourni island complex, NE Aegean Sea, Greece.

Methods
Three parallel studies were conducted to obtain the relevant information:
1. Fish populations were surveyed between 31st August and 26th September 2012 over *Posidonia oceanica* meadows and rocky algal habitats using standard underwater visual census (UVC) as described by Sala *et al* [2].
2. Daily port landing surveys of the artisanal fishing fleet were conducted at the main port on Fourni, recording species and total length (cm) throughout 2012.
3. Interview based surveys of local fishermen were conducted in order to gauge perceptions of the *Siganus* spp. catch.

Results
The composition of herbivorous fish recorded in UVC surveys differed to that of the fishery landings surveys. In the UVC data, *S. luridus* accounted for 67% of all herbivorous fish observed, but it only accounted for 15% of herbivorous fish landed. In contrast, in the UVC data *Sparisoma cretense* only accounted for 24% of the herbivorous fish observed, but accounted for 83% of all herbivorous fish landed. *S. luridus* has clearly replaced the native *S. salpa* in Fournoi, as evident in both the UVC and fisheries surveys (fig 1). *S. luridus* can now be considered established on Fournoi, this is verified by the presence of both juveniles and adults at all sites (mean of 31 individuals at each site) and by the dominance in terms of biomass of *S. luridus* at three out of four sites surveyed.

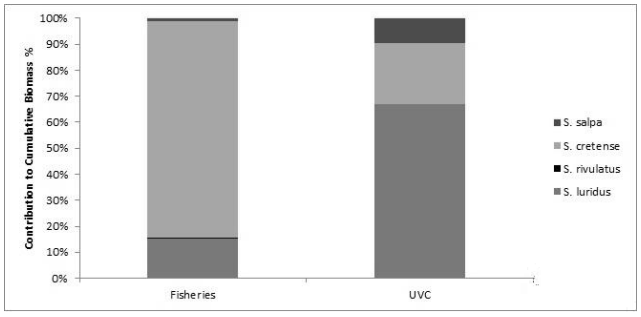

Fig. 1. The composition of herbivorous fish in UVC and fisheries surveys

The results indicate that *Siganus* luridus is the most abundant herbivorous fish species in shallow water ecosystems in Fourni, however they have not replaced *S. cretense* as the dominant herbivorous species in fishery landings. One possible explanation may be due to discarding of *Siganus* at sea, which was evident from interviews and on-board observations, due to its low commercial value in this region. Another possibility identified by the results from our surveys was that local fishermen actively avoided areas which were likely to yield high catches of *Siganus*, due to the increased labour involved in removing fish of poor value from their nets. In some areas in the Mediterranean, *S. luridus* has been successfully introduced into the market, which has shown a positive effect on the fishery [5]. In Fourni there is currently no market for the species, and fishermen doubt it would ever be profitable. However, it is worth noting that perceptions of the Fourni community have changed previously, for example, *Mullus surmullettus*, a fish now of high economic importance, was also once unpopular. Considering the abundance of *Siganus*, if consumer neophobia could be overcome, and a market established for *Siganus* in Fourni, it would have the potential to bring economic benefits to the fishery as well as ecological benefits to the ecosystem [2].

SUR LA PRESENCE DES POISSONS EXOTIQUES NOUVEAUX DE LA COTE LIBANAISE (MEDITERRANEE ORIENTALE)

Ghazi Bitar [1]*
[1] Lebanese University - Faculty of Sciences - ghbitar@ul.edu.lb

Abstract
Les poissons exotiques répertoriés de la côte libanaise comptent 42 espèces. Nous y ajoutons six espèces dont trois, sont mal connues (*Enchelycore anatina, Lagocephalus sceleratus, Torquigener flavimaculosus*) et trois sont nouvelles pour la côte libanaise (*Plotosus lineatus, Abudefduf vaigiensis, Pseudanthias squamipinnis*). Cette dernière espèce n'a jamais été encore signalée en Méditerranée.

Keywords: Alien species, Levantine Basin

Introduction Depuis l'ouverture du canal de Suez en 1869 et avec le réchauffement global, des centaines d'espèces marines ont migré de la mer Rouge vers la Méditerranée orientale, en modifiant la composition et la structure des habitats marins dans cette région et en particulier au Liban [1,2,3,4]. Dans un atlas des poissons exotiques [5], 59 espèces de poissons Indo-Pacifiques sont enregistrées dans la région méditerranéenne, mais ce nombre ne cesse d'augmenter [6].

Matériel et méthodes Depuis 1991, dans le cadre des études des communautés benthiques et ichtyologiques, nous avons prospecté systématiquement la côte libanaise en plongée. Pour faire progresser l'inventaire de la biodiversité ichtyologique et rechercher les espèces exotiques en relation avec le changement global, la reconnaissance visuelle des poissons en plongée a été complétée par des photographies sous-marines.

Etat des lieux D'après les travaux bionomiques et ichtyologiques effectués sur la côte libanaise , 42 espèces de poissons exotiques sont signalées : *Himantura uarnak, Dussumieria elopsoides, Etrumeus teres, Herklotsichthys punctatus, Saurida undosquamis, Parexocoetus mento, Tylosurus choram, Hemiramphus far, Hyporhamphus affinis, Fistularia commersonii, Atherinomorus lacunosus, Sargocentron rubrum, Platycephalus indicus, Epinephelus fasciatus, Pelates quadrilineatus, Terapon puta, Apogon nigripinnis, Sillago sihama, Alepes djedaba, Leiognathus klunzingeri, Lutjanus argentimaculatus, Upeneus moluccensis, Upeneus pori, Pomadasys stridens, Pempheris vanicolensis, Heniochus intermedius, Pomacanthus maculosus, Sphyraena chrysotaenia, Pteragogus pelycus, Oxyurichthys papuensis, Scarus ghobban, Callionymus filamentosus, Siganus luridus, Siganus rivulatus, Scomberomorus commerson, Cynoglossus sinusarabici, Stephanolepis diaspros, Ostracion cubicus, Lagocephalus lagocephalus, Lagocephalus spadiceus, Lagocephalus suezensis, Champsodon vorax.* Ici nous rapportons la présence de six espèces dont trois, signalées dans un rapport national personnel [7], mais mal connues par la communauté scientifique (*Enchelycore anatina, Lagocephalus sceleratus, Torquigener flavimaculosus*) et 3 autres nouvelles pour la côte libanaise (*Plotosus lineatus, Abudefduf vaigiensis, Pseudanthias squamipinnis*). La dernière n'est jamais signalée en Méditerranée.

Enchelycore anatina : un seul individu rencontré et photographié (14/05/2008) à l'entrée de la grotte Chak El Hatab au nord de Selaata. Puis à Ramkine (29/05/2011) et à Batroun (18/06/2011).

Lagocephalus sceleratus : Un seul individu observé à Tyr (11/09/2010) et un autre photographié dans la même zone (6/04/2011).

Torquigener flavimaculosus : rencontré et photographié à Tyr (10/092009) puis à deux reprises ensuite (11/09/2010 et 17/04/2011). Nous l'avons trouvé dans deux autres localités à Beyrouth (30/09/2010 et 23/03/2011) et à Batroun (9/07/2011 et 14/10/2011). Il est toujours observé en groupe de quelques individus.

Plotosus lineatus : un très jeune spécimen rencontré et photographié pour la première fois à Tyr (15/09/ 2012). D'après un pêcheur, ce poisson se rencontre en petit banc dans la région de Tyr.

Abudefduf vaigiensis : Cette espèce nouvelle pour le Liban a été observée et photographiée dans deux localités sur fonds rocheux entre 2 et 5 m de profondeur. Quatre individus photographiés ensemble à Khaizaran (9/08/2012) et un seul à Tyr (15/09/2012).

Pseudanthias squamipinnis : identifié par Mireille Harmelin-Vivien, ce poisson, nouveau pour le Liban et la Méditerranée, a été observé et photographié à BIEL (au sud du port de Beyrouth) par le plongeur professionnel Albert ASSAL en Mai - Juin 2000. A chaque reprise un ou deux individus ont été rencontrés.

Conclusion et perspectives A part les deux espèces de Tetraodontidae *L. sceleratus* et *T. flavimaculosus,* le fait que la première observation de ces espèces ne concerne qu'un ou un petit nombre d'individus dans peu de localités, ne permet pas de dire si elles sont bien établies au Liban. En plus de ces six espèces, sept autres ont été enregistrées depuis 2007 : *Etrumeus teres, Scarus ghobban, Ostracion cubicus, Champsodon vorax, Epinephelus fasciatus, Heniochus intermedius, Pomacanthus maculosus.* Comme le réchauffement global et l'arrivée des espèces exotiques affectent tout particulièrement le bassin levantin, le Liban est un lieu privilégié pour l'étude de la biodiversité marine dans cette région, ainsi que ses évolutions récentes. En ce sens, l'élaboration des plans d'action nationaux et régionaux afin de bien contrôler et suivre la répartition de ces espèces en relation avec le réchauffement global est une nécessité.

THE IMPACT OF INVASIVE FISH POPULATIONS ON THE EASTERN MEDITERRANEAN FOOD WEB

[3] National Center for Mariculture

Abstract
The food web in the eastern Mediterranean is heavily affected by alien fish populations. Recent studies comparing the trophic levels of soft bottom demersal alien and native fish, revealed that the weighted trophic level of the aliens is considerable higher than that of the native ones.

Keywords: Lessepsian migration, Levantine Basin, Food webs, Fishes

Introduction: The invasion of Indo-Pacific biota through the Suez Canal, combined with warming and unsustainable fisheries, have altered the biodiversity of the Eastern Mediterranean. About 100 alien tropical fish species were reported from the Levant basin, where they have been gradually replacing native species (Galil and Goren, in press).The invasion and replacement have greatly affected the infralittoral food web structure in the easternmost Mediterranean. In rocky habitats, the native herbivores are either small sized or of negligible biomass, while the two alien herbivores, *Siganus rivulatus* Forsskål, 1775 and *S. luridus* (Rüppell, 1829) comprise about one third of the fish biomass and, impacting the local macrophytes and food web (Goren and Galil 2001; Lundberg et al., 2004).
Material and Methods: The results presented in this talk are based on measurements and weights of ca. 500,000 fish collected by an otter trawl along the Israeli coast during 2008-2012.
Results and Discussion: Recent studies compared the trophic levels of alien and native fish populations on infralittoral (to depth of 40m) soft-bottom habitats along the Israeli coast. The results revealed that while the average trophic levels of native and alien fishes are similar (3.44 ± 0.55 and 3.65 ± 0.44 respectively) (data on trophic levels extracted from FISHBASE (Froese and Pauly 2013)), the weighted trophic levels are dissimilar. The native species dominated the lowest and the highest trophic levels (below 3 and above 4), whereas the aliens dominated the range of 3 to 4 (Figure 1).

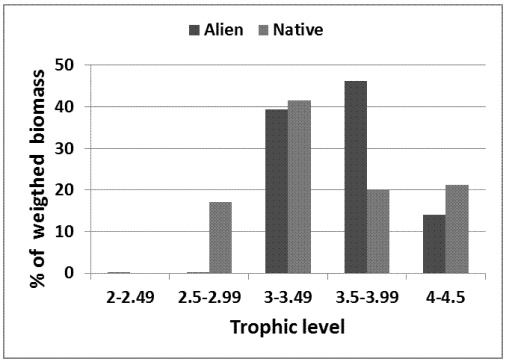

Fig. 1. A comparison of the weighed trophic levels' distribution between alien and native species (divided into five guilds).

Moreover, when the weighted fish biomass was grouped into two trophic guilds (2-3.49 and 3.5-5.0; Figure 2) the average trophic level of the alien fish was significantly higher than that of the native species. The ongoing replacement of the native species biomass by the alien fishes is expected to increase the overall weighted trophic level of the fishes and thus, may significantly affect the entire food web in the eastern Mediterranean.

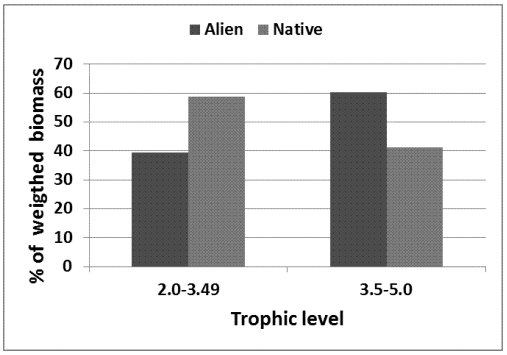

Fig. 2. A comparison of the weighed trophic levels' distribution between alien and native species (divided into two guilds).

EAST IS EAST AND WEST IS WEST – IMPLICATIONS OF BIOINVASION PATTERNS IN THE MEDITERRANEAN SEA FOR IMPLEMENTATION OF THE MSFD

Abstract
About 700 non-indigenous marine multicellular species have been recorded in the Mediterranean Sea, with many establishing viable populations. So far more non-indigenous species (NIS) were documented in the Levantine Basin than in the better surveyed western Mediterranean, and whereas most of the NIS in the eastern Mediterranean have presumably entered through the Suez Canal, shipping and massive shellfish farming are the drivers in the western Mediterranean. The implications of regionally different vectors for the implementation of the Marine Strategy Framework Directive (MSFD) mandated good environmental status concerning NIS in the Mediterranean are briefly discussed.

Keywords: Alien species, Suez Canal, South-Eastern Mediterranean, North-Western Mediterranean

Introduction
The EU's ambitious MSFD (2008/56/EC) [1], aiming to achieve good environmental status by 2020 (http://ec.europa.eu/environment/water/marine/directive_en.htm), places great emphasis on the "trends in abundance, temporal occurrence and spatial distribution in the wild of non-indigenous species … in relation to the main vectors and pathways" (http://eur-lex. europa.eu/lexUriServ). With so much at stake for regulators, scientists, and stakeholders it is important that NIS datasets used for the implementation of MSFD policy decisions are scientifically verified. This contribution aims to report updated statistics on NIS introduced in the Mediterranean Sea, with focus on the different introduction pathways between its eastern and western regions.

Material & Methods
Data were extracted from AquaNIS, a European wide information system of aquatic NIS. AquaNIS is a flexible, easily extendible structure, where new data blocks and functional modules may be included as necessary. Data is organised in four interrelated data blocks: INTRODUCTION EVENTS, SPECIES, GEOGRAPHY and IMPACTS. Data within blocks are grouped according to attributes (Biological traits, Pathways and vectors, etc.). Introduction events were updated with records until year 2012.

Results & Discussion
AquaNIS records about 700 multicellular NIS in the Mediterranean Sea, of which a great many are invasive: 111 species were recorded in 5 or more countries, and 19 hyper-invasive species were recorded in 10 or more countries. Molluscs (31%), crustaceans (18%) and bony fish (16%) make the largest contributions to the number of documented NIS in the Mediterranean and comprise more than 60% of total NIS richness in the sea. Macrophytes (11%), annelid polychaetes (11%), bryozoans and cnidarians (6%), and all other taxa (7%) complete the number of species. There are considerable differences among the peri-Mediterranean countries in the number of NIS recorded. Far more NIS have been documented in the Levantine Basin than the entire western Mediterranean: 352 multicellular NIS were reported along the 180 km long coast of Israel, whereas only 62 NIS were reported off the 1660 km long Mediterranean coast of peninsular Spain. Most of the NIS in the eastern Mediterranean have presumably entered through the Suez Canal, but are increasingly spreading to the central Mediterranean: they comprise 39%, 30% and 23% of the NIS in the Tunisia, Malta and southern Sicily, respectively. Shipping and massive shellfish farming are the main drivers in the western Mediterranean. Propagule pressure [2] is recognized as the most important factor for the invasion success of species causing impacts on biodiversity and disturbance on community structure and functions. A meta-analysis of invasiveness of species and invasibility of habitats found that propagule pressure (defined as a composite measure of the number of viable NIS individuals, genotypes and taxa, the number of discrete introduction events, their frequency and duration) was a significant predictor of both [3]. Of the three high propagule conveyances into the Mediterranean –shipping, mariculture, Suez Canal– the latter supplies the largest number of successfully established NIS in the eastern Mediterranean Sea by virtue of the magnitude, frequency, and duration of the trans-isthmian corridor invasion and the common evolutionary history of its components. Such high propagule pressure of co-evolved invaders greatly increases the risk of further invasions. The implications of enlarging the Suez Canal without erecting a barrier to the Erythraean biota is all too clear –increasing the delivery of multiple invaders, increasing the supply of deeper living taxa. The influx of thermophilic Erythraean NIS has recently invaded deeper waters, establishing an ever larger invasion bridgehead in the Mediterranean. At present only voluntary ballast water management is in effect in the Mediterranean, but the 'Ballast Water Management Convention' will enter into force within a few years. In 2011 IMO published 'Guidelines for the control and management of ships' biofouling to minimize the transfer of invasive aquatic species'. Institution of "zoosanitary precautions" by the mariculture industry have already contributed to a reduction in the numbers of mariculture-associated NIS in the past decade. When properly regulated and enforced, the number of shipping and mariculture introduced NIS will decline. However, the Mediterranean countries have yet to develop a comprehensive and effective response to the introduction of NIS through the Suez Canal. Key industry groups, governmental bodies, even regional environmental groups have poor appreciation of the magnitude of the problem. Scientific, administrative and political coordination at the regional level is urgently needed to attain the MSFD mandated good environmental status concerning NIS in the Mediterranean.

A PRELIMINARY ANALYSIS INTO THE RELATIONSHIP BETWEEN *POSIDONIA OCEANICA* MORPHOLOGY AND CAULERPA RACEMOSA

J. Shepperson [1], A. Jeffery [1], L. Taylor [2], A. Miliou [1], H. Thornton [1]* and C. Acasuso-Rivero [1]
[1] Archipelagos, Institute of Marine Conservation, P.O. 42, Pythagorio, 83103, Samos, Greece - hazel@archipelago.gr

Abstract
The present study investigates the interaction between the invasive algae *Caulerpa racemosa* and the endemic seagrass *Posidonia oceanica*, in the eastern Aegean Sea. When *C. racemosa* is present, *P.oceanica* exhibits a smaller morphology and a lower shoot density, which can be indicative of a more degraded seagrass ecosystem. This forms the preliminary analysis of a study concerning how *P.oceanica* and *C.racemosa* are impacted by their coexistence.

Keywords: Alien species, Aegean Sea, Posidonia

Introduction
The invasive species *C. racemosa var. cylindracea* can have a significant impact on its surrounding ecosystems, therefore its rapid spread in the Mediterranean gives cause for concern [1,2]. It can be found within the Mediterranean's endemic and protected *Posidonia oceanica* beds, which are regarded as one of the most valued and highly productive shallow-water ecosystems [3]. The interaction between the two species in the eastern Aegean offers the opportunity to investigate how the morphology and level of degradation of *P. oceanica* influence *C. racemosa* presence.

Methods
Three bays around the Greek Island of Fourni Korseon (eastern Aegean) were sampled between July and September 2012. All three bays are characterised by extensive Posidonia beds that suffer differing levels of C.racemosa invasion within each site. Ten metre transects were randomly placed in the P.oceania meadows, with 20 by 20cm quadrats placed randomly along the transects at pre-determined points.

A total of 110 quadrats were sampled, between depths of 1.5 – 5m. Through snorkel surveys, Posidonia meadow characteristics such as shoot density and canopy height were measured. Canopy height was determined using methods described by Short and Coles (2001) [4], where random handful of shoots were fully extended and 80% of the full height of the leaves were measured, using the sediment as the base. From each quadrat, 10% of the P.oceanica shoots were removed for morphometric analysis, to obtain measurements of shoot height, blade area, and blade density.

In addition, all C.racemosa was extracted, to determine the mass in each quadrat. A wet to dry conversion ratio was determined by drying samples of C.racemosa for 48 hours at 200°C (ratio 29:3, r-sq = 0.02). All C.racemosa samples were subjected to a constant treatment, and processed within 24 hours of extraction. A Mann-Whitney test was used to test individual P.oceanica morphology variables for differences when C.racemosa was present or absent, and a Kruskal-Wallis test used to look for differences in C.racemosa abundance between sites.

Results and Discussion
P. oceanica beds showed a significant positive correlation between canopy height and shoot density, $r(108) = 0.669$, $p<0.001$, with *C. racemosa* presence being related to this trend. When *C. racemosa* is present, *P. oceanica* exhibits a trend towards a lower shoot density and a smaller morphology (Tab. 1), which can be indicative of a degraded or stressed seagrass ecosystem [4]. *P. oceanica* shoot morphology did not differ between the three study sites, however, the abundance of *C. racemosa* was not the same at all three sites (Kruskal-Wallis, $p<0.001$). This suggests that there may be additional factors influencing the level of *C. racemosa* invasion in *P.oceanica* beds, in addition to shoot morphology.

Tab. 1. Results of Mann-Whitney test. Values from each measurement indicate mean ± standard error.

Variable	*C.racemosa* present	*C.racemosa* absent	p
Shoot Density (shoots/0.2m^2)	22.156 ±1.320	42.947 ±3.564	<0.001
Canopy height (cm)	19.264 ±0.792	30.751 ±2.219	<0.001
Number of blades per shoot	5.111 ±0.120	5.082 ±0.195	n.s.
Blade height* (cm)	11.673 ±0.428	16.766 ±1.070	p<0.001
Blade width (mm)	0.689 ±0.0103	0.722 ±0.0199	n.s.
Blade area* (cm^2)	8.245 ±0.372	12.276 ±0.920	p<0.001

This study supports findings that when *P. oceanica* is degraded, the opportunistic *C. racemosa* is able to invade more successfully, which could have further consequences on an important and already threatened ecosystem. These findings will contribute to an on-going analysis into how *C. racemosa* and *P. oceanica* growth rates are impacted by their coexistence.

ABOUT TWELVE YEARS OF PRESENCE OF THE ALIEN SPECIES *HYPNEA CORNUTA* (RHODOPHYTA, GIGARTINALES) IN THE MAR PICCOLO OF TARANTO (IONIAN SEA, SOUTHERN ITALY

Antonella Petrocelli [1], Marc Verlaque [2]*, Giuseppe Portacci [1] and Ester Cecere [1]
[1] IAMC-CNR, Taranto, Italy
[2] Mediterranean Institute of Oceanography, Marseille, France - marc.verlaque@univ-amu.fr

Abstract
Populations of the alien seaweed *Hypnea cornuta* were followed on a twelve-years period in the Mar Piccolo of Taranto. On the 13 alien macrophytes identified in the basin since the eighties, it is the only established species that showed an invasive behaviour, even though without any clear negative effect on environment, human health or socio-economical activities.

Keywords: Algae, Alien species, Lagoons, Phytobenthos, Ionian Sea

Introduction
The Mar Piccolo of Taranto, which is a Transitional Water System (TWS) under strong pressures of aquaculture and importation of seafood, is the third Mediterranean hot spot for the introduction of alien macrophytes. Most of aliens recorded in the basin come from the cold-temperate Pacific Ocean [e.g. *Undaria pinnatifida* (Harvey) Suringar, *Grateloupia turuturu* Yamada, *Codium fragile* (Suringar) Hariot subsp. *fragile*] and did not succeed to establish. Conversely the Lessepsian species *Hypnea cornuta* (Kützing) J. Agardh, which was first recorded along the Italian coasts in the Mar Piccolo in December 2000 [1], formed permanent both attached and unattached populations. Here we report the results of a twelve year monitoring of this species in the Mar Piccolo.

Materials and Methods
During a twelve-years period, *H. cornuta* was qualitatively and quantitatively monitored in two sites of the Mar Piccolo (Fig. 1). From 2000 to 2006 its occurrence and spread were qualitatively followed at the station of first observation (Battendieri). Then, from 2007 to 2010, monthly quantitative campaigns were carried out also at Cimino, where the species was first observed in October 2007. In 2011 and 2012, quantitative observations were carried out in early summer and autumn.

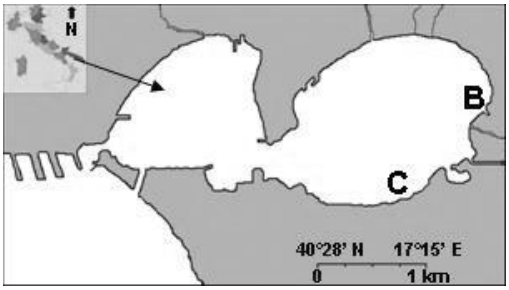

Fig. 1. Map of the Mar Piccolo of Taranto. (B) Battendieri; (C) Cimino.

Results and Discussion
From 2000-2006, the qualitative monitoring showed that *Hypnea cornuta*, firstly found as sparse thalli attached on pebbles, spread out, year after year, at Battendieri, also colonising the soft bottoms under free-living thalli. No fertile gametophyte was ever found but, both attached and free-living thalli produced stellate propagules that were observed detached on the surrounding substrates. From 2007 to 2010, quantitative observations carried out on macrophyte assemblages highlighted that *H. cornuta* was becoming a dominant species in summer-autumn, with a steady annual increase of biomass in both stations. The maximum biomass was registered at Battendieri in August 2010 (m ± sd : 971 g wet weight 0.25 m^{-2} ± 15.43). In this station, first fertile tetrasporophytes were observed in summer 2008. In the absence of fertile gametophytes, it was supposed that tetraspores were apomeiotic and give birth directly to new tetrasporophytes. In 2011 and 2012, seasonal monitoring showed a slight decrease of biomass during the two sampled months (July and November) with respect to 2010 but, in the absence of sampling in August, we cannot conclude on a possible decreasing trend of populations. On the 13 alien macrophytes listed in the Mar Piccolo since the eighties, *H. cornuta* is the only established species that showed an invasive behaviour, even though without any clear negative effect on environment, human health or socio-economical activities. Its success in this southern Mediterranean TWS agrees with its natural worldwide distribution in the warm seas.

Abstract
Here we provide a dynamic reconstruction of exotic fish occurrences in the Mediterranean Sea and report on the means in which we are tracking this phenomenon. Data were mainly extracted from published sources, resulting in a total of 2456 geo-referenced observations, from 1896 to March 2013. The database currently includes 85 Lessepsian species, 20 human mediated introductions and 44 recent immigrants from the Atlantic, holds a number of 172 fish taxa, including questionable and cryptogenic species.

Keywords: Species introduction, Fishes, North-Central Mediterranean

Introduction
The current change in the species geographical ranges is one of the most apparent signals of a changing biodiversity worldwide [1]. A spectacular example of this phenomenon is provided by the recent alterations of the Mediterranean marine biota due to the ongoing incoming of species of extra-Mediterranean origin. A major convenient division of these immigrants separates '"true"' exotic species, introduced outside their dispersal potential, from non-native organisms which have extended their distribution by natural means [2]. The former classification would include Lessepsian species entering through the Suez Canal and other human mediated introductions (for example, ballast water or aquarium escapes). The second type of immigrants is basically represented in the Mediterranean by Atlantic species, entering the Mediterranean through the Straits of Gibraltar. Here we present 'ORMEF', a new geo-referenced database, with the aim to provide 1) a dynamic reconstruction of exotic fish occurrences in the Mediterranean Sea, and 2) insights on the methods we have used to detect these species thus far.

Materials and Methods
Data were extracted from a total of 457 published sources, spanning from 1896 to 2013. Presence records were geo-referenced using ArcGIS 9.3 as Geographical Information System (GIS) (Fig. 1). Documentation of biological, ecological, taxonomic information, introduction pathways, bibliographic references and other relevant data for each species was also compiled. The database was here explored to provide synthetic information on the chronology of these sightings and on species spatial dynamics. For insights on how exotic fishes are being monitored in the Mediterranean Sea, we analyzed the whole set of records according to the country and means of detection.

Results and Discussion
The ORMEF database currently includes 2456 geo-referenced observations. Out of these, 2019 were extracted from published presence records; 377 from checklists and 60 from grey literature. Initial analyses consisted of calculations of linear rates of spread for both single species and major pathways of arrival. Spatial patterns are shown for i) Lessepsian species, ii) human mediated introductions other than Lessepsian, and iii) Atlantic species entering through Gibraltar. Professional fishing gears such as trawls and nets have traditionally been important means of recording exotic species, but the recent increasing use of underwater photographs and videos has emerged in the last few years. The uneven geographical allocation of species sightings along the various Mediterranean sectors reflects the unbalanced publishing efforts among different Mediterranean countries, with the greatest gap corresponding to some southern countries, where little published information exists.

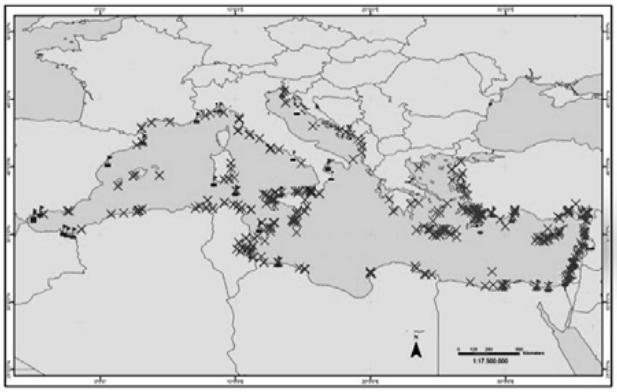

Fig. 1. ORMEF (Occurrence Records of Mediterranean Exotic Fishes) Database: Geographical distributions of documented records. First records in the Mediterranean are reported with flags, subsequent records with crosses.

Abstract
Public participation in programs aimed at biodiversity monitoring, is rapidly expanding in the Internet Era. Here we present SEAWATCHERS, a new interactive website aimed to acquire geo-referenced observations of exotic fish species at the Mediterranean scale. The system is open to volunteer-based collaborations who are passionate observers of marine life. A first phase of testing generated 47 records (in a period of 10 months), including the observation in Catalonia of Abudefduf saxatilis, a new species for the Mediterranean Sea.

Keywords: North-Central Mediterranean, Fishes

Introduction
The Mediterranean Sea is undergoing rapid biodiversity alterations and new research approaches are needed to track these changes at the basin scale. Among the reliable solutions to overcome practical difficulties in surveying large geographical ranges, community-based actions have rapidly gained scientific consensus [1]. The engagement of volunteers is also expected to have a role for Mediterranean research [2] but specific procedures for the detection of exotic species were thus far limited to the local level.

Materials and Methods
SEAWATCHERS is an interactive web site aimed to collect sightings that enthusiasts of marine life make through their activities, whether professional or recreational. In May 2012, a new specific action (at http://www.observadoresdelmar.es/projecte-9.phpto) was developed with the double aim to receive referenced observations of exotic fish species and to generate awareness on the issue of Mediterranean fish invasions. Users post their observations, usually sending a photograph, and then a team of scientific editors validate these sightings (Fig. 1). Finally, the overall occurrences are projected in an interactive map (Fig 2c). Here we report the preliminary results of a testing phase, which was concluded in March 2013.

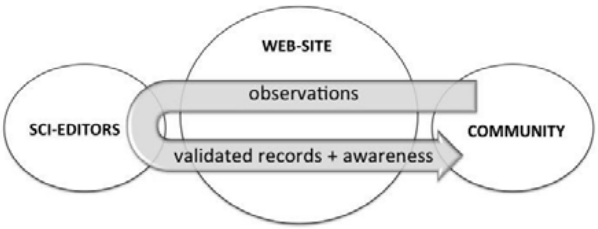

Fig. 1. SEAWATCHERS/exotic fish: Basic conceptual scheme.

Results and discussion
Overall, 47 sightings (Fig. 2c) were received during the phase of testing, for a total of 16 recorded species. Some of these observations were particularly significant, such as 3 new sightings of *Fistularia commersonii* from the Western Mediterranean and the observation of *Abudefduf saxatilis*, spotted on August 2009 along the coast of Tarragona, Spain (Lat. 41.1210º, Long. 1.3704º) at 3 m depth. This observation represents the first documented record of this Atlantic species in the Mediterranean Sea, providing a new and scientifically validated record of an exotic species in the Mediterranean. These preliminary results encouraged us to promote this system at the Mediterranean scale. Information gained through this participatory action would provide an additional, low cost resource to professional monitoring activities, while promoting awareness among its participants.

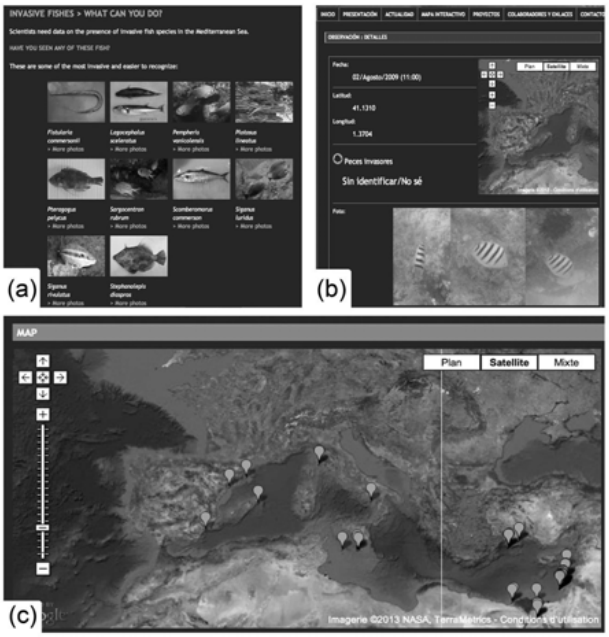

Fig. 2. Screenshots from SEAWATCHERS /exotic fish: a) Main target species; b) Submitted sighting of Abudefduf saxatilis fron the Catalan Sea; c) Geographical distribution of 47 records posted during the preliminary test phase (May 2012 - March 2013)

Acknowledgments This project has been funded by FECYT in collaboration with CLIMCARES, VECTORS, CUBOMED, EN CHANGES. We thank Joseba Santiago, who developed the web site platform and all the volunteer observers.

Abstract
Caulerpa taxifolia var. *distichophylla* is an Australian species which was introduced into the Mediterranean Sea. Finally it was reported from the Levantine coast in 2007 (Gulf of Iskenderun, SE Turkey). Since then it has expanded, covering large areas of the eastern Mediterranean. *C. taxifolia* var. *distichophylla* has not been reported in any earlier marine floras of Cyprus. We report for the first time observing *C. taxifolia* var. *distichophylla* presence on the northern Cypriot coast describing its ecological and morphological features.

Keywords: Alien species, Algae, Cyprus Basin

Introduction
The marine alga *Caulerpa taxifolia* (Vahl) C. Agardh is native to several tropical and subtropical regions of the world (Phillips and Price 2002). Seaweed invasions are a growing concern around the world (Ribera and Boudouresque 1995). One of the most famous, or infamous, of these in the past decade was the establishment of an aquarium strain of tropical green seaweed, *Caulerpa taxifolia* (Komatsu et al. 2003). Accidentally introduced into the Mediterranean Sea in 1984, the tropical alga *Caulerpa taxifolia* has spread since then, reaching the Mediterranean coast. Invasive populations of *C. taxifolia* now occur at more than 100 sites where more than 13,000 hectares have been colonized (Meinesz et al. 2001; Galil 2008). *Caulerpa taxifolia* var. *distichophylla* (Sonder) Verlaque, Huisman & Procacini was reported only from the Iskenderun Bay (Mediterranean coast of Turkey) by Cevik et al. (2007 as *Caulerpa taxifolia*) and Sicily by Jongma et al. (2013). But it has not yet been reported from the Cyprus coast since then. In the present study, we carried out morphological analyses to identify the taxon and compared with the materials obtained from Iskenderun Bay (Cevik et al. 2007).

Material and method
Specimens with stolons were hand-collected with SCUBA diving in June 2009 in the northeast coast of Northern Cyprus. The physico-chemical characteristics of the colonized area were registered during the field study by using DKK-TOA WQC 24 Instruments, Multiparameter Water Quality Checker.

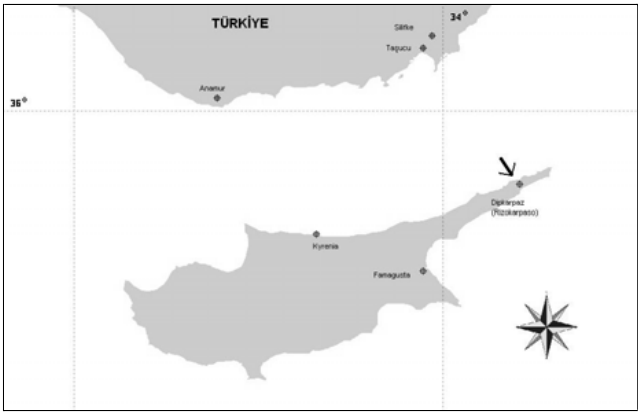

Fig. 1.
Cyprus coast-line and the sampling locality (arrowhead).

Results and Discussion
Current distribution, substratum structure and morphological variations; The colonies of *Caulerpa taxifolia* var. *distichophylla* were found at two regions in Ayios Philon Church Bay, Dip Karpaz, Northern Cyprus (35º 38' 12.52" N; 34º 22' 30.71" E). The general biotope structure (mainly depending on depth, substrata and flora communities) of the site shows a dense *Cystoseria* spp. on the rocky substrata with a very small part covered with *Posidonia oceanica* (L.) Delile. The measurements at two points showed that *C. taxifolia* var. *distichophylla* spread within the depth limits of 6-8 m. *Morphological variations and comparison of Cypriot and Iskenderun specimens;* The specimens of Caulerpa collected in the Northern Cyprus do not exhibit the usual morphology of the species. It resembles the specimens collected in Iskenderun (Cevik et al. 2007). Compared with specimens of Iskenderun and Cyprus; the Cyprus stolons are less elongated in shape and its stolons, fronds and pinnules are more or less elongate and long then the Iskenderun material. *Conclusions;* In conclusion, *C. taxifolia* has been studied extensively in the western Mediterranean, as its impact on the marine ecosystem is well admitted. It colonizes all types of sea bottoms such as; rock, sand, mud and dead *P. oceanica* meadows, and invades indigenous biocenoses, modifying the biodiversity and the ecodiversity. The present study constitutes the first report of *Caulerpa taxifolia* var. *distichophylla* along the Northern Cyprus coast. It is spreading in two different regions which are close to each other. At the site, it is found that *P. oceanica* meadows are located 100 m away, but brown algae are present in nested appearance with *C. taxifolia* var. *distichophylla*. At both regions under *C. taxifolia* var. *distichophylla* invasion, it is observed that presence of molluscs, fishes and other species continues in usual manner.

Abstract
In the last decade no less than 33 Red Sea (Lessepsian) fish species have invaded the Mediterranean, including coral-associated species; there are 19 Atlantic species and aquarium/mariculture escapees; numerous indigenous species have extended their range northwesterly in the Mediterranean. All these indicate a profound "sea change" faunal shift in the Mediterranean, due to either temperature rise or the wider, deeper Suez Canal. These processes must be monitored to study their possible impact on the future of marine biodiversity in the Mediterranean.

Keywords: Alien species, Lessepsian migration, Fishes, Mediterranean Ridge

The last decade has seen a tremendous acceleration of fish invasions into the Mediterranean. Since 2000 no less than 33 Red Sea (Lessepsian) fish species have invaded the Mediterranean (Fig 1), among them 2 species of commercial value (*Nemipterus randalli* and *Decapterus russelli*) and 5 non-commercial species (*Fistularia commersonii*, *Plotosus lineatus*, *Jaydia smithi*, *Ostorhinchus fasciatus* and *Lagocephalus sceleratus*) [1] that established large populations almost immediately upon arrival. A number of coral-associated species have migrated as well (*Pomacanthus imperator*, *P. maculatus*, *Chaetodon austriacus* and *C. larvatus*). Numerous indigenous species have extended their range north-westerly in the Mediterranean. All these indicate a profound "sea change" faunal shift in the Mediterranean. Figure 1 reveals two different species accumulation trends. Despite the growing ichthyologic study effort, the number of new Lessepsian species records per decade remained constant (6-11) from the 1950's to the end of the 20 century. The dramatic increase in Lessepsian migrant species in the last appear to be due mainly to the widening and deepening of the Suez Canal, which led to an increase in water flux in the Canal, thus allowing *propaguli* distribution and adult fish swimming freely into the Mediterranean. In the framework of Marine Strategy, the Atlantic species newly recorded in the Mediterranean have been in part recognized as a natural phenomenon; however the problem of Atlanto-Mediterranean fish species is very complex in terms of genetic units and their geographical limits. Members of CIESM exotic fish team agreed about the necessity to maintain the study of these fishes in the original CIESM approach, because a) Atlantic successful species show by their spatial and temporal distribution very clear links with ecological factors (3, 4, 5, 6); b) an oscillating balance (see below) between Lessepsian and Atlantic migrants in some critical areas such as the Sicily Strait has been observed. c) Its monitoring could open windows for the studies concerning the maintenance of Mediterranean biodiversity. The ratio of Lessepsian/Atlantic invaders shows a geographical West-East gradient, with only one Lessepsian species in the Alboran Sea and a maximum in the Levantine Sea. The shift to a prevalence of Lessepsian species occurs in the Central Mediterranean, in Greek waters, while in Italian waters the overall ratio during the last twenty years has been 4/7. In the 2013 updating of CIESM exotic fish Atlas, Atlantic species are 9 and Lessepsian 21; in Marseille, 91 Lessepsian species and a large sample of Atlantic species observed in Italian waters were figured in five categories (1), “very rare”, "rare", "prevalent", “common” and “very common” and related to the time of their appearance: among Lessepsians the latter two categories were about 1/3 of the total and appeared both a century ago and in the years 2000-2005. In Italian waters three numerical categories (5) of Atlantic successful species were found in seven cases: *Kyphosus* spp., *Sphoeroides pachygaster*, *Beryx splendens*, *Seriola fasciata*, *Psenes pellucidus*, *Seriola carpenteri*, and *Pisodonophis semicinctus*; all but the first were observed in coincidence with the twenty year period (1980-2000) characterized by high Winter NAO indexes (http://www.LFEO.COLUMBIA.EDU/NAO) (see also fig. 1). *Enchelycore anatina*, established from the Aegean to the Levantine Sea, was recently found also in the Eastern Adriatic (7) and in Italian waters, in the Ionian Sea.

FACILITATING ASSESSMENTS OF ALIEN INVASIONS IN THE MEDITERRANEAN: THE EUROPEAN ALIEN SPECIES INFORMATION NETWORK (EASIN)

S. Katsanevakis [1]*, A. L. Nunes [1], M. Trombetti [1], I. Deriu [1] and A. Cardoso [1]
[1] Joint Research Centre, Institute for Environment and Sustainability, Water Resources Unit - stelios.katsanevakis@jrc.ec.europa.eu

Abstract
The European Alien Species Information Network (EASIN) provides tools and services for the exploration of alien species information in Europe. Efficient widgets can be used for the easy creation of distribution maps of any aggregation of alien species. Herein, we investigated distribution patterns of marine alien species in the Mediterranean Sea, using EASIN tools and data from various sources. These patterns differ depending on the pathway of introduction, indicating that human activities shape alien species richness patterns and overall biodiversity patterns in a changing Mediterranean Sea.

Keywords: Alien species, Biodiversity, Lessepsian migration, Mapping, Levantine Basin

Mediterranean countries are severely affected by biological invasions, which are considered as one of the most important direct drivers of biodiversity loss [1]. A stepping stone for the assessment of biological invasions in the Mediterranean is the collection of basic information on the occurrence and spatial distribution of alien species, pathways of introduction, spread rates, life histories, biological and ecological traits. Such information is a prerequisite for the efficient prevention, early detection, rapid response, and management of biological invasions.

In the framework of CIESM, pioneering work has been conducted for alien fish, molluscs, crustaceans and macrophytes through the 'Atlas of Exotic Species in the Mediterranean' (http://www.ciesm.org/online/atlas/index.htm). Information on marine alien species in the Mediterranean can be also retrieved from a large number of other online global, European, regional, or national databases [2]. Furthermore, there is a large amount of occurrence records in the literature that is not included in any online information system.

In September 2012, the European Commission's Joint Research Centre (JRC) launched the European Alien Species Information Network (EASIN) to facilitate the exploration of existing alien species information from distributed sources and to assist the implementation of European policies on biological invasions [2, 3]. EASIN integrates and harmonizes alien species data from all available sources, and functions as a one-stop shop for such information in Europe. It provides web services and tools that allow easy exploration, visualization, and best use of alien species data [2].

Herein, as an example of the use of EASIN, we analysed the distribution patterns of marine aliens in the Mediterranean according to the pathways of introduction. Currently EASIN includes data from GBIF (Global Biodiversity Information Facility; http://www.gbif.org), GISIN (Global Invasive Species Information Network; http://www.gisin.org), REABIC (Regional Euro-Asian Biological Invasions Centre; http://www.reabic), CIESM (Mediterranean Science Commission; http://www.ciesm.org/online/atlas/index.htm), ELNAIS (Hellenic Network on Aquatic Invasive Species; https://services.ath.hcmr.gr/), and selected literature (EASIN-LIT; http://easin.jrc.ec.europa.eu/About/EASIN-Lit).

Richness of alien species introduced through the Suez Canal was higher in the eastern coastline of the Mediterranean basin and progressively decreased along the southern Turkey and Greek coastlines, while it was much lower in the western basin and the Adriatic Sea (Fig. 1). The richness distribution patterns for alien species introduced by shipping were very different, with no apparent east-west gradient; hotspot areas included the eastern Mediterranean coastline, many sites in the Aegean, northern Adriatic, the Sicily strait, and the French coast (Fig. 2). For species introduced by aquaculture (not shown here), hotspot areas included the northern Adriatic, Sicily and the French coastline. Apparently, human activities shape the distribution patterns of alien species and affect the overall biodiversity patterns in a changing Mediterranean Sea.

PATTERN OF *OCULINA PATAGONICA* OCCURRENCE ALONG THE IBERIAN PENINSULA COASTLINE: A FIRST STEP TO UNDERSTAND THE FACTORS AFFECTING ITS INVASION DYNAMICS

Eduard Serrano [1]*, Rafel Coma [1] and Ribes Marta [2]
[1] Centre d'Estudis Avançats de Blanes (CEAB-CSIC) Institut de Ciències del Mar (ICM-CSIC) - eserrano@ceab.csic.es

Abstract
The zooxanthellate coral *Oculina patagonica* can drive a compositional shift in Mediterranean shallow water benthic communities. We examined occurrence of the species on natural rocky reefs along the Iberian Peninsula coastline. Although the species was found on 70% of the explored locations, the distribution of the species exhibited a core area in the SE Iberian Peninsula, and progressively decreased to the northeast and to the southwest. This marked pattern of occurence in a coastline encompassing a 3°C temperature gradient provides an opportunity to determine the main factors that affect the *O. patagonica* invasive dynamics in the Mediterranean Sea.

Keywords: Alien species, South-Western Mediterranean, North-Western Mediterranean, Biogeography, Temperature

Macroalgae dominate Mediterranean shallow water assemblages, whilst corals are extremely rare. However, climate change and the introduction of alien species are currently affecting the structure and dynamics of marine ecosystems worldwide. In this sense, a persistent phase shift from macroalgal to alien coral dominance has already been reported at a particular location in the Mediterranean Sea [1]. *Oculina patagonica* is an alien, non-lessepsian scleractinian zooxanthellate coral that presumably originated from the southwest Atlantic and was first recorded in the Mediterranean Sea in 1966 (Gulf of Genoa, [2]). The most abundant populations of this coral in the Mediterranean have been recorded in the coast of the Iberian Peninsula ([3], [4], [1]), where the species was already found to occur in the 1970s (along ~300 km of the southeast region of the Iberian Peninsula, [5]). Over the last decade, a large increase in abundance of the species has been documented in several locations in this area ([4], [1]). In parallel, the coral has been found in several new areas throughout the Mediterranean, suggesting that *O. patagonica* is spreading geographically ([6]). This spreading has been demonstrated in the northern Iberian Peninsula and in the Aegean Sea ([7], [8]). In this study, we examined occurrence of the species on natural rocky reefs along the Mediterranean coast of the Iberian Peninsula. Five regions, each encompassing ~200 km of coastline, were sampled along the Iberian Peninsula from southeast to northeast over the period 2008-2010. Occurrence of the coral was examined on 12 to 29 natural rocky reefs within each region (Fig. 1). Occurrence of the species on each location was determined by means of the detailed exploration of 1500 m^2 of the sea floor using SCUBA, between 0 and 10 m depth. A total of 90 randomly selected rocky reefs were examined for the presence of the scleractinian coral *O. patagonica*.

The species was observed to occur in about 70% of the explored locations (n = 64). However, occurrence of the species exhibited a marked pattern of variation along the Iberian coastline (Fig. 2, Chi-square, $p<0,05$). The species was present on most of the locations in zones 2, 3 and 4 (presence in 100, 95 and 83% of the locations, respectively) and, in contrast, the species was present in about half of the examined locations in zones 1 and 5 (presence in 50 and 45% of the locations, respectively). Recent data on occurrence of the species on the northernmost part of this coastline (zone 6 from [7]) has been included in Figure 2 to provide a complete view of the occurrence of the species along the Mediterranean coast of the Iberian Peninsula. The northward spread of the species in Zone 6 has been related to the availability of open space, sea warming and its effect on extending the growth period of the species, and the particular biological features of the coral *O. patagonica* [7]. The regions examined in this study encompasses a temperature gradient of 3 ºC, which corresponds to the range of predicted increases in ocean temperature for the Mediterranean by 2070-2099, [9]). Therefore, the marked pattern of variation in occurrence of the coral *O. patagonica* along the Iberian coastline provides a good opportunity to determine the effect of the main factors that contribute to the population dynamics of the alien coral *O. patagonica* in the Mediterranean Sea.

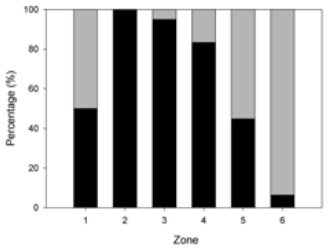

Fig. 1. Proportion of locations with *Oculina patagonica* occurrence for the six regions distinguished along the coastline of the Mediterranean Iberian peninsula **.** The proportion of locations in which *O. patagonica* was found are represented by black bars. The proportion of locations in which *O. patagonica* was not found are represented by grey bars. Data from zone 6 was obtained from [7].

FIRST RECORD OF STRIPED EEL CATFISH *PLOTOSUS LINEATUS* (THUNBERG, 1787) FROM EGYPTIAN WATERS OF THE MEDITERRANEAN

Tarek Temraz [1]* and Jamila Ben Souissi [2]
[1] Marine Science Department- Suez Canal University - ttemraz@yahoo.com
[2] National Institute of agronomy Tunisia

Abstract
On October 2012, the lessepsian migrant *Plotosus lineatus* was captured offshore Damietta coast (Egypt, Eastern Mediterranean sea). This represents the first record of this species along the Egyptian waters.

Keywords: Lessepsian migration, South-Eastern Mediterranean, Suez Canal

Introduction: The Suez Canal is an artificial sea-level water way running south to north across the Suez Isthmus to connect the Red Sea with the Mediterranean. The canal was opened for navigation on 17th of November 1869 and was closed five times; the last time was the longest one as it lasted for eight years. The canal was reopened on 5th of June 1975. The canal encompasses various benthic habitats. At Port Said and surroundings the soil is mainly of silt and clay (drifted from the Nile estuary this formation extend bout 40km south wards to Kantara. The middle part between Kantara and Kabrit consists of fine and coarse sand, while the southern region composed of dispersed rocky layers entrapping soft sediment and sea grass beds in between [1]. Science the opening of the Suez Canal the migration of species between the two ends was questioned and the Northward migration process named "Lessepsian migration" [2] The striped eel catfish *Plotosus lineatus* was first recorded in the Mediterranean [3]. Since then it was rapidly becoming a dominant component of the benthic biota of the Levant [4]. During annual environmental monitoring program off Damietta coast at (N 31° 30.50' 20" E 31° 43' 43.20") (Figure, 1).

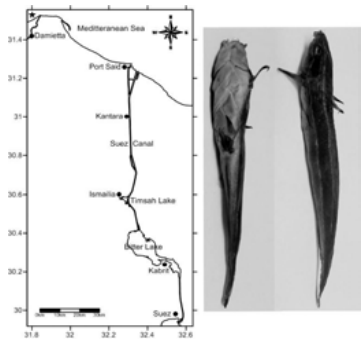

Fig. 1. Sampling location and specimen photo

Sampling of benthic habitat resulted in catching 7 specimens of *Plotosus lineatus*. The survey was conducted on muddy substrate. The stinging catfish was newly introduced to the Egyptian Mediterranean waters were local fishermen name it (Shelan) similar to the name of small Nile catfish.

Description of the specimens: The specimens' dorsal color was dark brown with 2 whitish lateral strips originating from the snout, the ventral surface whitish to creamy with pale brown dendritic organ. The fins have darker borderline. Four pairs of barbels; one nasal and one maxillary barbels extend slightly beyond the posterior borders of eye. The inner pair of mental barbels is shorter than the outer pair. The upper jaw overhanging with pointed teeth while the lower jaw has conical ones anteriorly and molar like posteriorly. Smooth (no scales) elongated body with broad head and laterally compressed after anus. The specimens weight varied from 4.836 - 6.983 g, total length 112 to137 mm, head length 22-26,snout length 4.2- 4.4, eye diameter 4.5-4.7, caudal fin 4.4 -4.7, first dorsal fin height 12.5 -13.1, first dorsal fin base 7.6 -7.9, second dorsal fin height 3.1-3.3, second dorsal fin length71-75, pectoral fin length 7.9 -8.2, pectoral fin base 3.9- 4.1, anal fin height 2.4-2.6, anal fin length 65.3 – 69.1. The count of spines and rays; first dorsal fin with one serrate spine and four rays, second dorsal fin with 78- 86 rays, pectoral rays 10-11, pelvic rays11-12, and anal rays 63-68.

Discussion: *Plotosus lineatus* widespread over the coral reef ecosystems in Indian Ocean, Western Pacific and East Africa [5]. Recently in 2006 it was recorded among the 100 worst invasive species in the Mediterranean [6] and recorded in the seventy nine Lessepsian migrant fish species up to 2010 [7]. As a migrant species it was recorded in the Red Sea and represents the only member of the family plotosidae [8], very early record in late 1800s took place in Gulf of Suez [9]. While it was recorded in southern Suez Canal in the early 1930s [10] no range of extension along the canal was recorded. The majority of the Red Sea migrants spread along the Israeli coast and consequently among the Levant littoral as a result of the permanent alongshore anti-clockwise current. As this species showed euryhaline capacities [1] the Bitter lakes didn't pose a barrier for migration across the Suez Canal and it was reported to cause injury to swimmers and beach users at Kabrit (personal communications). The abundance of the striped catfish along the northern region of the Suez Canal was relatively recent 4 to 5 years ago. On the other hand the migration is more likely related to availability of suitable food source, substrate composition and environmental conditions as well as lack of predators and competitors for space and food. Further studies are needed to indicate the reasons for the *Plototus lineatus* delay in migration to the Mediterranean (140 Years) and to indicate whether the proliferation along Damietta coast is as a result of the spreading along the Israeli coast or from recent dominance along the Northern region of the Suez Canal. Furthermore, this may suggest a role for Suez canal as earlier monitoring stations for potential migrants to the Mediterranean.

UPDATING OF THE CIESM WEBSITE - ATLAS OF EXOTIC SPECIES IN THE MEDITERRANEAN: MACROPHYTES

Marc Verlaque [1]* and Charles F. Boudouresque [2]
[1] Mediterranean Institute of Oceanography (MIO), Aix-Marseille Université, France - marc.verlaque@univ-amu.fr
[2] Mediterranean Institute of Oceanography (MIO), Aix-Marseille Université, France

Abstract
An update of the CIESM website of exotic macrophytes introduced into the Mediterranean Sea is proposed. A list of 19 new exotic taxa has been drawn up, and among them 7 invasive or potentially invasive taxa. Overall, 129 taxa of exotic macrophytes have been recorded in the Mediterranean Sea.

Keywords: Alien species, Algae, Ionian Sea, North-Eastern Mediterranean, North Adriatic Sea

Introduction
The Mediterranean distribution of 110 exotic marine macrophytes is presented on the CIESM website (1). To highlight any recent change in the flow of species introductions and to identify any exotic macrophyte likely to significantly change the composition and functioning of Mediterranean assemblages, we analysed the inventories of exotic species and publications on this subject available since 2009 (2-5).

Materials and Methods
For each species, we considered: D: the date of introduction (ante- or post-2009), R: the native region, Distr.: the Mediterranean distribution, V: the putative vector(s)/pathway(s) of introduction and S: the status in the recipient area(s), i.e. Casual if only one record, or Established, if several records in space and/or in time. A given species can have several putative vectors/pathways of introduction.

Tab. 1. Addition to the CIESM website (1). Abbreviations: <: ante-2009, >: post-2009; Atl.: Atlantic; IndoPac.: Indo-Pacific; C: Casual; E : Established.

Species	Date	Region	Distribution	Vector/Pathway	Status
OCHROBIONTA					
Ascophyllum nodosum	>	Atl.	Central Basin	Shellfish	C
Chrysonephos lewisii	<	Atl.	Western Basin	Shipping	E
Microspongium globosum	<	Atl.	Eastern Basin	Shipping	C
Microspongium tenuissimum	<	Atl.	Western Basin	Shellfish	C
Padina antillarum	<	IndoPac.	Eastern Basin	Suez Canal	C
RHODOBIONTA					
Gracilaria vermiculophylla	<	IndoPac.	Adriatic Sea	Shellfish	E
Grateloupia minima	<	Atl.	Western/Central Basins	Shellfish	E
Hypnea anastomosans	<	IndoPac.	Eastern Basin-Israel	Suez Canal	E
Hypnea flexicaulis	>	IndoPac.	Adriatic Sea	Shellfish	E
Lomentaria flaccida	<	IndoPac.	Western Basin	Shellfish	C
Palisada maris-rubri	<	IndoPac.	Western/Central Basins	Suez Canal	E
Solieria sp.	>	IndoPac.	Western Basin	Shellfish	E
CHLOROBIONTA					
Batophora sp.	<	Atl.	Central Basin	Shipping	E
Cladophora hutchinsioides	<	IndoPac.	Western Basin	Shellfish	C
Caulerpa taxifolia var *distichophylla*	<	IndoPac.	Eastern/Central Basins	Aquarium	E
Codium arabicum	<	IndoPac.	Eastern Basin	Suez Canal	E
Codium parvulum	<	IndoPac.	Eastern Basin	Suez Canal	E
Ulva californica	>	IndoPac.	Adriatic Sea	Shipping	C
Uronema marinum	<	IndoPac.	Western basin /Adriatic	Shipping	E

Results and Discussion
A total of 19 taxa (7 Chlorobionta, 7 Rhodobionta and 5 Ochrobionta) have been listed (Table I) but only 4 of them, namely *Ascophyllum nodosum*, *Hypnea flexicaulis*, *Solieria* sp. and *Ulva californica*, were reported after 2009, attesting the apparent absence of recent increase in the rate of species introduction. The major putative vector/pathway of recent introductions is shellfish transfer (9 taxa), mainly in the aquaculture sites of the North-Western Basin and the Northern Adriatic Sea, followed by the Suez Canal (5 taxa), mainly in the Eastern and Central Basins, shipping (5 taxa), and the aquarium trade (1 taxa). The major donor region is the Indo-Pacific Ocean (13 taxa), in relation with the two major vectors/pathways of introduction, followed by the Atlantic Ocean (6 taxa). The majority of taxa are established (12 established versus 7 casual), and 7 are invasive, namely *Caulerpa taxifolia* var. *distichophylla*, *Chrysonephos lewisii*, *Codium arabicum*, *C. parvulum* and *Gracilaria vermiculophylla*, or potentially invasive, namely *Solieria* sp. and *Ulva californica*. However, we must not forget that the apparent absence of recent increase in the introduction rate can be merely an artefact due to the weakness or the unbalanced effort of investigations in certain regions. The species introductions through shellfish transfers have been thoroughly studied in the North-Western Basin and the Adriatic Sea but the small Lessepsian migrants remain poorly known. It is the same situation for the exotic marine flora of the southern Mediterranean coasts. An in-depth study of the marine flora of the Middle-East and the North Africa would probably increase the number of exotic macrophytes occurring in the Mediterranean Sea and the proportion of Indo-Pacific species arriving in the Mediterranean Sea through the Suez Canal. However, the possibility that the number of introduced macrophytes is reaching a plateau cannot be excluded as suggested by (6). Overall 129 taxa of exotic macrophytes were recorded in the Mediterranean Sea.

ACTIVITÉS AQUACOLES ET INSTALLATIONS D'ESPÈCES INVASIVES (TUNISIE)

jeanne Zaouali [1]* and Jamila Ben Souissi [1]
[1] INAT Institut National Agronomique de Tunisie - jeanne.zaouali@planet.tn

Abstract
La récente accélération des activités aquacoles offshore en Tunisie avec la présence de cages flottantes disséminées tout au long du littoral oriental ne s'est pas faite sans de rapides retentissements sur les biocénoses autochtones marquées par l'installation d'un nombre important de NIS d'origine érythréenne.

Keywords: Biogeography, Gulf of Gabes

Matériel et méthodes
L'étude du fouling des filets et des infrastructures des cages d'élevage de loups et daurades royales (23 sociétés actives en 2012) et de grossissement du thon rouge (5 sociétés) installées depuis la région de Beni Khiar (cap Bon- Tunisie septentrionale) jusqu'à Zarzis (frontière tuniso -libyenne), a permis de mettre en évidence, d'une part, la présence d' espèces érythréennes jusqu'alors non répertoriées en Méditerranée et, d'autre part, de mesurer la progression spatio temporelle d'espèces invasives déjà acclimatées dans les eaux du sud du bassin oriental (notamment dans les eaux libyennes).

Résultats
Les observations faites tout au long de la côte ont ainsi montré l'installation d'espèces nouvelles jusqu'alors non répertoriées dans les eaux méditerranéennes.
Des mollusques gastéropodes typiquement représentatifs des biocénoses de mer Rouge tels :
Neritea sanguinolenta Menke,1829 avec 2 morphotypes distincts, Zenetos et all., 2003 (1) - bicolore blanc et noir à la Chebba (zone nord du golfe de Gabès - fouling des infrastructures des cages, 6 individus juvéniles, taille moyenne dans la plus grande largeur= 12 mm et rouge vif à Hergla -Sahel soussien – fouling des cages, 3 juvéniles de taille moyenne de 8 mm).

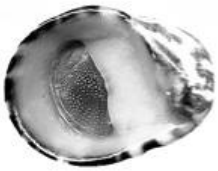

Fig. 1. *Neritea sanguinolenta*- Mencke, 1829 -morphototype noir et blanc - la Chebba (Tunisie)

Morula (Morula) aspera (Lamarck, 1816) Mastaller, 1978 (2), Clarmont et all., 2013 (3) zone sud du golfe de Gabès, fouling des infrastructures des cages, 2 juvéniles de taille moyenne de 8 mm. *Gibberulus gibberulus albus* Linnaeus, 1758- la Chebba, prairie d'*Halophila stipulacea*, un individu de 39 mm de hauteur - (Gab Alla, 2001 (3).

Fig. 2. *Morula (Morula) aspera* (Lamarck, 1816)- Zarzis (Tunisie)

La remontée d'espèces, identifiées en 2007 au niveau de la grande Syrte, Tripoli, Zaouali et all., 2007 (5 et 6). apu par ailleurs être mise en évidence. Ces espèces, elles aussi représentatives de biocénoses érythréennes sont le décapode *Grapsus granulosus* H. Milne Edwards, 1853 (omniprésence au niveau des cages jusqu'à la péninsule du Cap Bon) et le polyplacophore *Acanthopleura gemmata* (Blainville, 1825) - 1 individu de 35 mm de longueur - fouling des infrastructures des cages proches du port de Zarzis.

Discussion
Pour conclure, la présence d'espèces érythréennes non signalées dans la partie septentrionale du bassin oriental méditerranéen peut être considérée comme caractéristique de ses côtes méridionales. Ces néo peuplements montreraient, qu'en dehors de l'injection de propagules allochtones liées à l'introduction volontaire d'espèces malacologiques non indigènes qui ne peuvent, a priori, être retenus dans le cas présent, il peut exister un autre effet pervers des activités de l'aquaculture marine. C'est ainsi, que dans le cas des espèces citées, les colonisations observées ne sont pas à imputer directement à des transferts volontaires de mollusques. Elles pourraient, par contre, être mises en relation avec les installations de centaines de cages flottantes ayant nécessité le transport, notamment par mer, d'une importante quantité de matériel (infrastructures des cages, gros engins de manutention et filets en tous genres, souvent de 2ème main et d'origine les plus variées). L'efficacité de ces installations de biocénoses originales puisqu'elles n'ont, actuellement, pas d'équivalents en Méditerranée orientale septentrionale est, par ailleurs, potentialisée par le corollaire en zone sèche, des effets du réchauffement climatique global, qui est une forte augmentation de la salinité des eaux côtières caractérisant la portion sud du bassin oriental.

Remerciements: Avec tous nos remerciements à Mr Roland Houart (Institut royal des sciences naturelles de Belgique) pour ses précieuses indications concernant la faune malacologique.

HABITAT USE, MOVEMENT AND SIGHTINGS OF MONK SEALS IN CROATIA BETWEEN 2010 AND 2012-2013

L. Bundone [1]*, J. Antolovic [2], E. Coppola [3], S. Zalac [2], M. Hervat [2], N. Antolovic [2] and E. Molinaroli [1]
[1] Ca' Foscari University, Dip DAIS, Venice - luigibundone@tiscali.it
[2] Grupa Sredozemna Medvjedica, Zagreb
[3] Gruppo Foca Monaca, Rome

Abstract
Sightings of Mediterranean monk seal (*Monachus monachus*) have been recorded and verified from the whole Croatia since 2000. This paper reviews some of the activities carried out *in situ* and seals sightings between 2010 and the first month of 2013. The preliminary results clearly show the importance to conduct further investigations in the Istrian region and Cres Island, to be extended as well to the entire Croatian coastline, in order to understand the actual population consistency.

Keywords: Conservation, Monitoring, North Adriatic Sea, Central Adriatic Sea

Introduction
Scattered sightings of the Critically Endangered Mediterranean monk seal (*Monachus monachus*) have been reported along the entire Croatian coastline in the last two decades. About 180 sightings were gathered and verified by the Grupa Sredozemna Medvjedica-GSM (Croatia), in collaboration with the Gruppo Foca Monaca-GFM (Italy), during the years 2000-2009. Since 2005, a considerable amount of these encounters have been recorded, with a certain frequency, along the Istrian Peninsula (North-Western Croatia). Following these encounters, the GSM and the GFM have started a series of activities in 2008 to monitor the area concerned and to organize local and national sensitization campaigns for the protection of the monk seal. Thanks to the positive effects of increased public awareness on this matter, from 2009 a more consistent record of data collection has become attainable, including a great number of images taken in the Istrian region and Cres Island areas. Apart from collecting and verifying sightings data and direct monitoring, short surveys were carried out with the intent to comprehend the species habitat availability and use of the region.

Materials and Methods
A total of 130 verified encounters were reported, directly recorded, stored and analyzed from 2010 to 2012 including the first couple of months of 2013. The data were classified into 3 categories according to the information that can be deduced from them:
1-Sightings with photos or videos that allow photoidentification of specimen/s;
2-Sightings with photos or videos that do not allow photoidentification of specimen/s;
3-Sightings with no photos or videos but with reliable evalution (through direct interviews).
All the images collected came from the area of Cres Island and the Istrian Peninsula. The first category of sightings yielded the photoidentification of an adult female, following the methodology of Samaranch & González [1] and Forcada & Aguilar [2]. Although these analyses do not enable any other specimens clear detection, nevertheless they have made it possible to determine the home range extents of the aforementioned female: spreading from the Eastern Cres coast to Pula (about 130-150 km of coastline). This statement is in accordance with the data on the movement of the species [3] and habitat use [4] from other areas of the Mediterranean. In January 2011, after prior experimental pilot projects, a video-monitoring system (Vivotek IP 8332) was installed by GFM-GSM in the cave of Mala Kolombarica (southern part of the Kamenjak peninsula, Istria), allowing a continuative screening coverage of the internal beach. This is an active cave frequently used by the specimen that we were able to identify; the interior of the cave is easily accessible from the water and might not display ideal conditions for active use by seals during the summer months, due to anthropic presence in the highest tourist periods.
Even though, a large amount of collected images depicts the same specimen, a minor number of these, particularly the ones belonging to relatively more remote areas, were not clear enough to conduct any further identification. In addition, some of the overall sightings cannot be ascribed to a single individual, when taking into account the position and the time of the records. Particularly the ones coming from Southern Croatia, since distances and time to cover them far exceeded the natural known ability of the species of about 12-40 km/day [3].

Discussion and Conclusion
This work reviews data from occasional encounters of monk seal specimens and short self funded monitoring campaigns. Thus the results cannot be considered exhaustive of the monk seal actual population status in Croatia but represent a preliminary enquiry of a more consistent reasonable reality. The sightings reflect the position of the witness and its/their behaviour rather than the seals. Apart from the direct monitoring surveys most of the data belongs from tourists or people in recreational time, meanwhile few of them come outside the holiday seasons and or human settlement areas, rarely from places with scarce human presence and occurrence. Taking a look back at the images, from 2005 onwards, it is evident that at least an adult female has been frequenting the Istrian region since then. Moreover, comparing directly the data from Southern Croatia and the Istrian-Cres ones, it is evident that they cannot be ascribed to the same specimen with the current knowledge on the species movements. From our study it appears that the country coastline might hold two different nuclei of seals from the northern and southern coast, but the information is unsubstantial to define the real numbers of individuals and the eventual specimens inter-exchange. The adult female identified in the area between Pula and Cres has shown a pattern of coastal use that reflects habitat utilization and preferences explainable as an actual home range. This behaviour is a sufficient forethought to support a more thorough study of the region in order to ascertain the presence of other specimens, breeding caves and eventual births. Further investigations and a more detailed and systematic analysis of habitat availability is required in order to have a much better understanding of the real consistency of monk seal population along the entire Croatian coastline.

Abstract
A collaborative programme for monitoring cetacean has been established in the Mediterranean Sea based on ferries as platform. Outputs of the programme are a baseline for long term – large scale data on cetacean distribution and relative abundance. Results from data collected in the PELAGOS Sanctuary show how this work can help to manage these species.

Keywords: Monitoring, Cetacea, North-Western Mediterranean, Conservation

Introduction
Because threats can have impacts on cetacean population size or distribution, long term population monitoring is needed to early detection of any significant change that require a (re)definition of conservation efforts. The characteristics of the species and their habitats, the costs (affecting the repeatability and spatial extent of the surveys) and standardized protocol are the main parameters affecting the success of monitoring programmes. A collaborative programme for monitoring cetacean has been established in the Mediterranean Sea since 2007. More than 10 scientific bodies work along sampled routes using ferries as platform of research. Within the programme, a synoptic large-scale cetacean systematic monitoring program has been realized within the PELAGOS Sanctuary in 2010, funded by PELAGOS France through the GIS3M.

Materials and Methods
In 2011 /2012 MMO embarked on 4 lines covering the PELAGOS Sanctuary. To collect data the standardized line transect method were applied along fixed routes from the command deck of the ferry. The frequency of sampling was based on a regular design throughout the year (February 2011-April 2012) on lines Toulon-Ajaccio (TA) and Livorno-Bastia (LB) and weekly from June to September on the two other lines, Nice-Calvi (NC) and Savona-Bastia (SB). Spatial analysis were execute on a 10x10Km grid cell using ArcGIS 9.1.

Results
Results showed a spatio-temporal heterogeneity on species composition, distribution and sighting rates between the summer (June to September 2011) and the two other periods of the year (March to May 2011, October to April 2011-2012). On the two lines monitored yearly round (TA and LB), the sighting rates on TA were always higher (1.88 to 3.62 sightings of cetacean per 100km) than those on LB (0.77 to 1.23 s.100km^{-1}). Seasonally, the highest sighting rate was recorded during summer on TA and from October to April on LB. Comparing data along 4 lines during summer, the highest sighting rate were recorded in the western part of the Sanctuary along the NC (6.3 s.100km^{-1}) and the TA (3.6 s.100km^{-1}). During the all study period the richest areas both in terms of sighting rates and species richness were located in the south of Toulon, in the middle of the abyssal plain: between Toulon and Ajaccio in spring, north of Corsica (on NC and SB) in summer and offshore Ajaccio during the all study periods. The four frequently sighted species were *S.coeruleoalba, B.physalus, T.truncatus* and *P.macrocephalus*. Species distributions reflect respective habitat preferences: the highest sighting rate of striped dolphin was recorded during summer on NC, an offshore area, while bottlenose dolphin was mainly sighted on LB along the widespread continental shelf. Sighting rate of fin whale showed inverse seasonal line-trends on the two borders of the PELAGOS Sanctuary, according to its migratory pattern. Sperm whale showed a clear preference for the western area (TA) during summer season.*G.griseus, D.delphis, G. melas* and *Z.cavirostris* where mainly sighted on the central routes (NC and SB).

Discussion
Data confirm that the species are highly mobile and that the home range is larger than the Pelagos Sanctuary. Within the Sanctuary, results shows that a high spatio-temporal variability occurs.Some species are present all year round but the area is mostly used by cetacean during summer. Moreover, not all the Sanctuary is used on the same way and different seasons and areas differ in importance in term of species diversity, relative abundance and habitat use. Consequently, to conserve the species, a large scale programme is needed at a Mediterranean scale both, to collect data on species and to manage pressure at an adequate scale. As well at the Pelagos scale, management actions can be maximized by using a multi-scale and multi-temporal approach to take into account seasonality, spatial heterogeneity and species specific characteristics.

Conclusion
The use of ferries as a platform for the collection of data was found to be a valuable, sustainable and cost effective method for monitoring programs on cetacean on a wide temporal and spatial scale, including high sea and international sea areas.

PREDICTING THE RESPONSE OF A SEA-TURTLE NESTING BEACH IN SEA-LEVEL RISE, GERAKAS, ZAKYNTHOS ISL., GREECE

Abstract

This study evaluates the effect of sea level rise on the Gerakas sea turtle nesting beach in the Marine Protected area (MPA) of the National Marine Park of Zakynthos. Spatial, meteorological and grain-size data of the coastal area were collected and introduced to the Leont'yev's morphodynamic model in order to estimate the potential retreat of the beach under 4 scenarios of sea level change. The results have shown that the beach is projected to suffer a considerable retreat/inundation that will directly diminish the available nesting space and consequently pose constrains in the nesting success of the endangered species *caretta caretta*.

Keywords: Ionian Islands, Coastal models, Marine parks, Sea level, Turtles

Introduction

The sea level rise (SLR) is considered as one of the major impacts of climate change that will unavoidably produce significant beach recession [1]. This will affect, among other issues, areas of considerable ecological importance such as sea turtle nesting beaches. This study focuses on the response of Gerakas nesting beach (Gulf of Laganas, Zakyntos, Ionian Sea) on the expected SLR. The Gulf of Laganas is considered as one of the most important nesting areas of the loggerhead sea turtle (*Caretta caretta*) in the Mediterranean since it hosts almost 25% of the total nesting activity [2]. Gerakas is the easternmost beach of the gulf, being 930m in total length, 610m of which formed on fine sand and the remainder (320m) on coarse gravelly material (from East to West). The greater part of the beach is backed by eroding clay cliffs with a small sand dune occurring at the widest section of the beach. The mean nesting density of the beach is about 80 nests per year [2] with an average distance and elevation from the sea ranging from 18.7 to 21.5m and 1m, correspondingly.

Methodology

An RTK GPS together with an echo-sounder was used for the coastal area topographic and the bathymetric surveys, respectively. 10 onshore and offshore bed (sand) samples were collected and analyzed with dry sieving. The wave regime was hindcasted from local wind data (by the National Meteorological Service). Future beach retreat was assessed through the 1-D Leont'yev's morphodynamic model that uses the energetic approach, with the cross-shore changes of the wave energy flux estimated by the wave energy dissipation due to breaking. Sediment transport rates are predicted separately for the refraction, surf and swash zones. Two types of sediment transport are distinguished: (i) the transport due to wave/current interaction and (ii) the run-up induced transport. Beach retreat was estimated for three sea level rises scenarios (0.2m, 0.5m and 1m) [1,3] and also for a storm surge event that produces 2m short-term sea level rise [4] (Fig. 1).

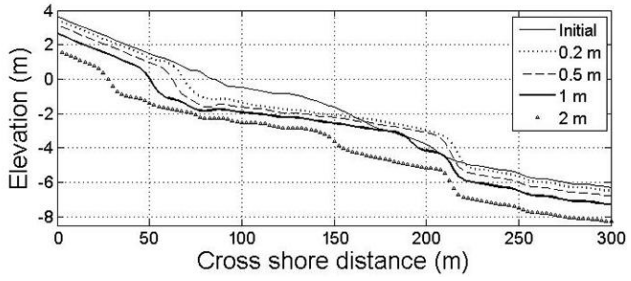

Fig. 1. Profiles of beach retreat under 4 scenarios of SLR.

Results and Discussion

The model outputs were compared with the width/elevations of Gerakas beach (Fig 2). It was found that the sea-level increases will have considerable impacts. In the case of a 0.2m rise the beach retreat was estimated as 13.95m, whereas for the 0.5m and 1.0m rises, 18.8m and 30.1m, respectively. For the worst case scenario (a 2.0m storm surge) beach recession was estimated as 50.75m. These estimates suggest that the beach will potentially lose 44-94% of its width for the first 3 SLR scenarios, whilst in the worst case of a 2.0m storm surge it will be entirely inundated. The beach cannot adapt to the SLR by transgression, as is backed by cliffs. This will promote coastal squeezing, which in return will dramatically reduce the available nesting space and increase conflict issues related to the recreational use of the beach. Ongoing research concerning all the nesting beaches of the MPA (6 in total) will further reveal the possible overall consequences of SLR on the nesting activity in the largest rookery of the endangered species *Caretta caretta* in the Mediterranean, thus allowing for the design and implementation of suitable management measures.

Abstract

L'étude de la nidification au niveau de cinq stations de Kalâat El Andalous, a révélé la présence de sept espèces d'oiseaux d'eau migrateurs nichant au niveau des quatre stations suivantes : la dune littorale, des marais nord, les maris sud et la sebkha littorale. Deux espèces coloniales ont été marquées par un nombre important de nids à savoir la Sterne naine (*Sternula albifrons)* et la Glaréole à collier *(Glareola partincola)*. Ainsi, le complexe de Kalâat El Andalous, semble être un habitat de prédilection pour les oiseaux d'eau migrateurs, propice à la nidification.

Keywords: Birds, Gulf of Tunis, Coastal systems, Lagoons

Introduction

Les oiseaux d'eau sont considérés comme des excellents indicateurs écologiques de l'état des habitats. En raison de leur importante sensibilité aux changements des paramètres environnementaux, ces derniers sont contraints à s'adapter par le phénomène de migration [1]. En Tunisie, plusieurs auteurs se sont intéressés au phénomène de la nidification des oiseaux d'eau au niveau des zones humides ([2], [3]). Les études relatives à ce phénomène au niveau du complexe Kalâat El Andalous sont défaillantes. En effet, la complexité de ce milieu pourrait engendrer une grande diversité spécifique et pourrait être un lieu d'attraction pour les espèces aviaires migratrices et sédentaires. Pour cela, une étude sur la nidification des oiseaux d'eau au niveau des différentes entités du complexe a été appréhendée.

Matériel et Méthode

Le complexe de Kalâat El Andalous, situé au nord est de la Tunisie, abrite divers types d'entités géomorphologiques. Le recensement des espèces d'oiseaux nicheurs a été effectué au niveau de cinq stations de ce complexe, à savoir, les marais sud (KA1), la Sebkha littorale (KA2), la dune littorale (KA3), les marais nord (KA4), la lagune (KA5). Les prospections ont été réalisées au cours du de la saison printanière de l'année 2012 à raison d'une observation tous les quinze jours. De plus, selon le comportement des nicheurs inventoriés, plusieurs critères ont été considérés [4], tels que le nombre de nids occupés, le nombre d'adultes (mâles ou femelles) cantonnés dans des nids, nature du chant de l'oiseau nicheur, parade nuptiale, nombre d'œufs ou de poussins, activités alimentaires.

Résultats et Discussions

Au total 7 espèces nicheuses migratrices (Tab.1) ont été inventoriées au niveau de quatre stations de Kalâat El Andalous (KA1, KA2, KA3 et KA4) à savoir *Himantopus himantopus*, *Burhinus oedicnemus*, *Larus michaellis*, *Fulica atra*, *Charadrius alexandrinus*, *Glareola pratincola* et *Sternula albifrons.* Notons que l'absence des nicheurs au niveau de la station lagunaire (KA5) pourrait être liée à la fréquentation massive de cette zone par les estivants. A l'exception de *Himantopus himantopus*, Sternula albifrons et Glareola praatincola, les autres espèces ont été inféodées à une seule station (Tab.1). Un nid vide de *Himantopus himantopus* a été rencontré au niveau des marais sud (KA1) et des nids avec des œufs cassés et dévorés de *Himantopus himantopus* (KA1) et de *Larus michaellis* (KA4) ont été observés (Tab. 1). Bien qu'ils soient présents au niveau des marais (KA1 et KA4), *Sternula albifrons* et *Glareola pratincola* ne forment des colonies (plus de 10 individus) qu'au niveau de la dune littorale de Kalâat El Andalous.

Tab. 1. Les observations des oiseaux d'eaux nicheurs à Kalâat El Andalous; *: espèce coloniale.

Espèces	zones	observations
Himantopus himantopus (Linné 1758) Echasse blanche	La sebkha littorale (KA2)	-12 nids flottants abritant 12 femelles
	Les marais sud (KA1)	- 1 nid vide - 3 nids aux œufs cassés et dévorés - 1 nid à 3 œufs dont 2 cassés - 1 nid avec deux oeufs - 1 nid abritant 1 femelle
Burhinus oedicnemus Œdicnème criards	Les marais nord (KA4)	-3 couples sans nids
Larus michaellis Naumann, 1840 Goéland leucophée	Les marais nord (KA4)	- 2 nids à un seul œuf chacun - 1 nid avec 3 oeufs - 1 nid avec 2 oeufs détruits lors la 2ème prospection (debut mai).
Fulica atra Linné 1758 (Foulque macroule.)	La Sebkha littorale (KA2)	- Pas de nids, - 11 couples : 1 couple avec 3 jeunes, 6 couples avec 2 jeunes et 4 couples avec un seul jeune.
Charadrius alexandrinus (Linné 1758) (Gravelot à collier interrompu)	La dune littorale (KA3)	- 2 nids à 1 seul oeuf chacun - 4 adultes à comportement de nicheurs
Glareola praticola * (Glaréole à collier)	La dune littorale (KA3)	- 93 nids, ponte moyenne= 2,10 oeufs/ nids
	Les marais sud (KA1)	- 2 nids à 1 seul oeuf chacun
	Les marais nord (KA4)	- 3 nids à deux oeufs chacun
Sternula albifrons Pallas, 1764 * (Sterne naine)	Les marais nord (KA4)	- 2nids à 2 oeufs chacun - 1 seul nid à un oeuf - 30 individus à comportement de nicheur marqué par le transport de petits poissons pour nourrir les oisillons.
	La dune littorale (KA3)	- 54 nids occupés, ponte moyenne = 2,42 oeufs/nids.

Ces résultats semblent traduire que lecomplexe de Kalâat El Andalous, parait un habitat de prédilection pour les oiseaux d'eau migrateurs, propice à la nidification. Ce constat nous amène à suggérer la conservation de cet écosystème côtier, afin de le préserver l'impact des activités anthropiques qui semblent être néfastes pour la nidification.

BIRTH AND POSTNATAL GROWTH OF THE FIN WHALE IN THE CENTRAL MEDITERRANEAN

Lidia Orsi Relini [1]* and Fulvio Garibaldi [1]
[1] DISTAV, C.so Europa, 26 - 16132 Genova - ITALY - largepel@unige.it

Abstract
The stranding data of 72 specimens of fin whale, *Balaenoptera physalus*, in the length range 5,05-16 m, were used to ascertain the calving season, the location of the calving grounds and the postnatal growth in the Central Mediterranean. Fin whales are born in a six month period (September-February), at a length of about 5,5 m, in a restricted latitudinal range: the calving area is situated in the northern part of the Western Mediterranean (Ligurian and Tyrrhenian Sea), close to the main summer feeding area. After one year the whale is about 12 m long and after two years about 14 m.

Keywords: Cetacea, Growth, Ligurian Sea

In non harvested populations of Cetacea, stranding studies and in particular length measures [1] are a very important source of information. Such is the case of the fin whale in Italian waters; in fact a whaling activity never existed in Italy, also if rare killings of whales were observed in the XIX century. In France stranding studies, after ancient work, were organized in regular form in the seventies. In Italy the Società Italiana di Scienze Naturali established a "Centro Studi Cetacei" in the eighties. The first comparative studies of strandings in the Mediterranean, showed larger numbers of whales on the French than on the Spanish coast, and an increasing gradient towards the Ligurian sector. Stranding data used for the present notes were obtained mainly (N= 52) from Italian and French national databases and in part (N=20) from papers appeared before 1970. Data were selected with the aim to deal with really measured specimens: three types were excluded a) measures with a notation of uncertainty (e.g. "about") b) measures assigned by observers on board to animals at sea c) animals whose length was less than 5 m, probably aborted. Retained data are listed below.
The calving season covers 6 months, September to February. The calving area was obtained mapping stranded neonates [2,3]. Data were first assembled per season and growing size and then in a continuous plot covering 3 years (Fig. 1).

Fig. 1. Plot of the length of stranded whales over a time interval of 38 months. In boxes data used to derive average lengths at age.

The plot shows a growth track, which can be considered the initial part of a Von Bertalanffy growth function; three groups of data positioned above the calving season represent birth, age 1 and age 2. The following average sizes at age of the fin whale can be calculated: ***at birth***: 5.6 m, st.d. 0.4 m, N = 16; ***at age 1***: 11.9 m, st.d. 1.1 m, N = 11; ***at age 2***: 14.0 m, st.d. 0.8 m, N = 11.

Present observations may shake old paradigms such as "weaning takes places when the calf is 6 months old and has reached a total length of about 12 m" and "information is lacking to suggest localized calving grounds" which unfortunately recur also in recent literature [4,5]. The former paradigm derives from whalers interest to minimize mother-calf links, but the calf remains with the mother at least one year; the latter from an improper definition of neonate (to 8 m). A whale of 8 m can be several months old. Recent genetic analyses [6] suggest to steer comparative studies of growth to N. Atlantic.

CETACEAN, TURTLE AND PELAGIC SPECIES AND ASSOCIATIONS IN THE CENTRAL-SOUTHERN MEDITERRANEAN SEA: IMPLICATIONS FOR CONSERVATION ACTION

Adriana Vella [1]*
[1] University of Malta - adriana.vella@um.edu.mt

Abstract

A research area of about 120,000km^2 around the Maltese Islands has been the subject of year-round marine research since 1997. Various species have been studied including cetaceans, turtles, elasmobranchs, bluefin tuna and sea birds. Aerial and marine survey techniques allowed for various aspects of species distribution and spatio-temporal associations to be analysed using the data mining (association rule learning) technique. Such results have applications in maritime and conservation management.

Keywords: Cetacea, Turtles, Birds, Conservation, South-Central Mediterranean

Introduction

The research project stationed around the Maltese Islands is a long-term and multi-species field research effort undertaken year-round [1,2]. Mobile species' habitats are typically heterogeneous in their biological and physical properties [3,4]. Understanding the spatio-temporal distributions and multi-species associations can provide insight into the multi-species preferences essential in the development of management and conservation initiatives [3,4].

Methods

A research area of about 120,000km^2 around the Maltese Islands has been the subject of conservation research since 1997. Aerial and marine field research surveys were undertaken to investigate species abundance and distribution using methods adopted by Vella [1,2]. This paper focuses on a pilot consideration of associations among species studied around the Maltese Islands by using a ten-year subset of the data collected. The Data Mining (association rule learning) technique [5] was adopted.

Results and Discussion

The most regular species found in the study area include the Bottlenose (*Tursiops truncatus*), Striped (*Stenella coeruleoalba*), Common (*Delphinus delphis*) and Risso's dolphins (*Grampus griseus*), Sperm (*Physeter macrocephalus*) and Fin (*Balaenoptera physalus*) whales, the Loggerhead turtle (*Caretta caretta*), elasmobranchs, such as, the Giant Devil ray (*Mobula mobular*), and seabirds such as, the Cory's Shearwater (*Calonectris diomedea*) and the Yelkouan Shearwater (*Puffinus yelkouan*). Figure 1 shows the bar graph indicating the extent of association between the turtles, seabirds, common dolphins, bottlenose dophins and fish scatter (different species) at the surface observed in specific areas and seasons, in the research area. With such sound data sets and effective support factor, the associations found are relevant for modelling and decision-making, such as planning spatio-temporal relevant and effective conservation management of mobile and wide-ranging species.

The use of the association rules proves to be effective in highlighting areas of interest for conservation area planning but more so for conservation management in various areas and at different times of the year. With highly mobile species it is becoming increasingly clear that with shifting favourable habitat conditions species will need to be managed for conservation through effectively mobile and adapting management rules. The extent of ecological plasticity of these species will need to be integrated through the considerations of buffer areas around such mobile management zones. To achieve high precision conservation management tools, long-term and year-round data sets are essential.

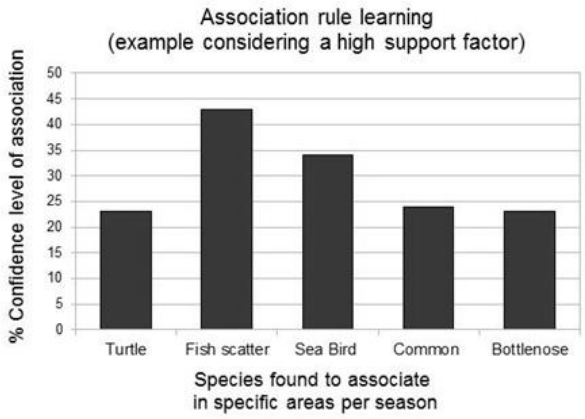

Fig. 1. Bar graph showing an example of a strong association rule learning outcome between multi-species distribution around the Maltese islands.

SYSTEMATIC CONSERVATION PLANNING FOR ISRAEL'S MEDITERRANEAN SEA EXCLUSIVE ECONOMIC ZONE

Eran Brokovich [1]*, Noam Levin [2] and Salit Kark [1]
[1] The Biodiversity Research Group, Dept. of Ecology, Evolution and Behavior, The Hebrew University of Jerusalem, Israel - eran.brokovich@mail.huji.ac.il
[2] The Remote Sensing Lab, Dept. of Geography, The Hebrew University of Jerusalem, Mount Scopus, Israel

Abstract
Marine conservation planning is not as advanced as in terrestrial ecosystems. This is specifically true in the Mediterranean Sea (MS). Recent marine oil and gas discoveries and the process of declaring exclusive economic zones (EEZs) in the MS make systematic conservation planning especially important and timely. Large scale, EEZ, conservation planning, including the understudied deep seas, requires overcoming vast biodiversity data gaps and ongoing efforts for economic development. The eastern MS provides an interesting case study due to recent discoveries and existing efforts for territorial water conservation. Here, we apply the MARXAN decision support tool to prioritize conservation efforts for Israel's MS EEZ (yet to be declared), which will maximize conservation targets while minimizing the threats and the costs of conservation.

Keywords: Levantine Basin, Conservation, Deep waters, Mapping

While systematic conservation planning has substantially advanced in the past decade in terrestrial systems, much less work has been done in marine ecosystems. This is especially true for the Mediterranean Basin, where to date, systematic conservation plans are only beginning to be developed. Such plans are especially urgent in the Mediterranean Sea with the many threats to its nature and biological diversity (1). Located at the crossroads between Europe, Asia and Africa and shared by over twenty countries with over 250 million people, the Mediterranean Sea is an important biodiversity hotspot globally and has many endemic and threatened species. The Mediterranean Sea, unlike the oceans, due to its shape and size, is fully divided into exclusive economic zones and does not have "High Seas" (i.e. areas that do not belong to an EEZ of any country). This may make conservation planning in the region more practical if each Mediterranean country plans its EEZ, ideally coordinating its efforts with other Mediterranean countries.

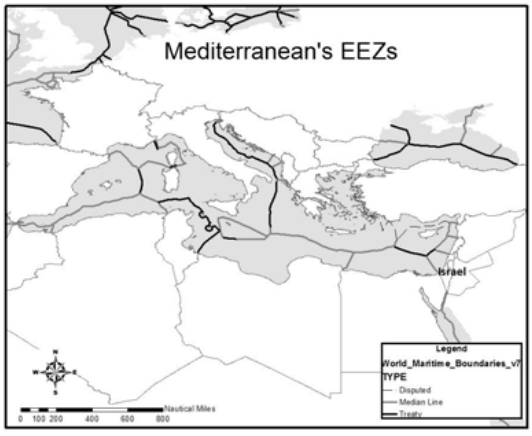

Fig. 1. Exclusive Economic Zones in the Mediterranean Sea. In most countries EEZ borders are yet to be declared (grey). For some there is an agreement in place (bold black) and for others, the exact borders` location is disputed (Thin black).

In Israel, there has been advancement in conservation efforts in the Mediterranean Sea in the past few years, led by Israel`s Nature and Parks Authority, and new efforts to propose a network of marine protected areas in Israel`s Mediterranean Sea territorial waters. These have been developed mainly based on bathymetry and habitat structure and will be discussed and determined in governmental planning committees in upcoming years. While these efforts are very important, they are limited to the territorial waters.

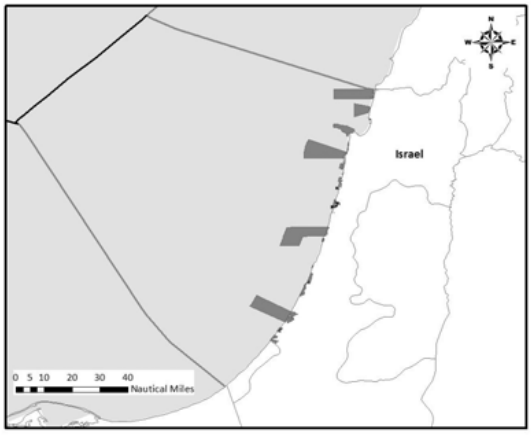

Fig. 2. Israel's EEZ with current and suggested Marine Protected Areas. The only agreed upon EEZ boarder is with Cyprus to the west (in black). MPAs Planned by the authorities are limited to the teritorial water.

While conservation planning has advanced slowly in the region, the threats to biodiversity and to its unique ecosystems are rapidly growing, along with the increase in resource extraction, shipping traffic, fishing efforts, population sizes along the coast, coastal development, invasive species, climate change and many other threats. The new discoveries of natural gas in the Mediterranean Sea within Israel`s EEZ have substantial future implications to both Israel`s energy market and potentially to the Mediterranean ecosystems. With the urgency in developing the ability to extract and transfer this energy resource, the need to develop a systematic conservation plan for Israel`s EEZ has become imperative. While data on biodiversity at the whole EEZ scale is limited, and the task is challenging, we developed the first systematic conservation plan for Israel`s Mediterranean EEZ. We used surrogates for the scarce biodiversity data (i.e. bathymetry, special substrate features, currents etc.) and used available data regarding the threats and the costs of biodiversity conservation. Our data will support the effort for integration of conservation considerations into the current and future planning in the region.

Abstract
According cephalopods short life cycle, population dynamics is mainly determined by between-year variability in reproductive success. Therefore, stock management may be improved after protecting the main spawning areas. The microsites where the European squid, *Loligo vulgaris* spawns within a Marine Protected Area have been identified by deploying an array of 30 artificial structures at diffrent depths. We belive that this species selects the spawning area searching for an optimal temperature range that maximizes egg survival. Our results sugest that adults migrate from off- to in-shore at winter, i.e.,when the water temperature near the cost is appropriate. Sandy bottoms seems to be preferred, which may be related with predator avoidance.

Keywords: Cephalopods, Spawning, Marine parks, North-Western Mediterranean

Introduction
The implementation of Marine Protected Areas (MPA) is one of the keys for the protection of marine species and could be used for fisheries management[1]. However, the high mobility of certain species, such as the European squid (*Loligo vulgaris*) [2], with a home range higher than MPA limits the usefulness of MPAs. Although, this species seems to aggregate at specific areas to spawn [2]. The identification of where and when these spawning aggregations occur may be very important for protecting the future recruits and for maximizing spawning success. The aim of this study is to identify the preferential spawning microsites of *L. vulgaris* within an MPA. The European squid is exploited by the trawling fleet, the small-scale fleet and the recreational fishery[3]. The study was carried out in Cabrera National Park (CNP) a small Archipelago south of Mallorca Island (Fig. 1).

Material and Methods
30 Artificial Spawning Attractors (ASA) were deployed over three main benthic habitats (sand, seagrass and rocky bottoms), and covering different depth ranges (Figure 1). The ASA were monthly sampled from june 2012 until june 2013. Number of egg clutches per ASA was modelled using a Generalised Linear Model (GLM). The model was fitted with the glm function of the R package (http://www.r-project.org/). A Poisson distribution of the response variable (monthly number of eggs clutches per ASA) was considered. The explanatory variables considered were; i) benthic habitat, ii) depth, iii) sea temperature, and iv) the interaction between depth and sea temperature.

Results
We found spawning activity all-year-round but with seasonal changes in the preferred depth for spawning. During colder months, spawning tend to be widespread, including shallow waters. Conversely, during the rest of the year, spawning is limited to deeper sites.

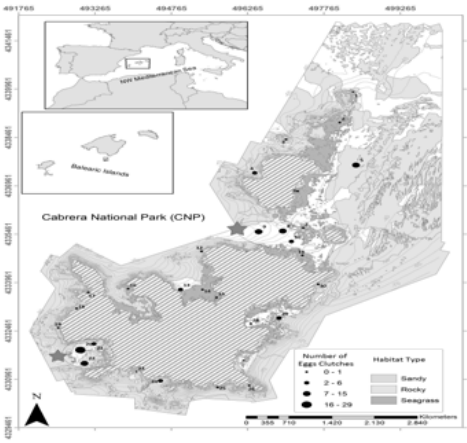

Fig. 1. Sampling area (CNP), distribution of the ASA (black circles). Size of circles indicates the number of the total eggs clutches. Stars indicate principal spawning area.

The GLM showed how the interaction between depth and sea temperature effects on squid spawning ($p<0.05$). In addition, sites with sandy bottoms were preferred as spawning habitat ($p<0.05$). Consequently, two main zones were determined as preferential spawning grounds: Canal and Ses Rates (Fig.1).

Discussion
The spawning at the park extends all-year-round. Our results agree with other studies performed for the same species, both in the Mediterranean and the Atlantic [4,5]. Despite the European squid spawned along all the depth range sampled, results suggests the existence of an optimal depth for spawning in function of the season. They spawned preferentially at shallow waters during cold months and at deeper water at warm months. This spatio-temporal spawning pattern may be linked with the optimal temperature range for maximizing the spawning success[6]. In addition, the spatio-temporal pattern described here is in accordance with the hypothesis of spawning migrations that has been suggested for the same specie and geographic area[7]. Sandy bottoms were preferred for *L. vulgaris* perhaps to avoid predators like *Epinephelus marginatus*[8]. We suggest to implement management measures that take into account the spatio-temporal pattern of spawning would maximize spawning success and would improve stock abundance.

IMPACTS OF OFFSHORE WIND FARMS ON MARINE BIOTA: CHANGES IN BENTHIC AND FISH COMMUNITIES AT NORTHERN EUROPE, ARE THEY COMPARABLE TO MEDITERRANEAN ECOSYSTEMS?

Salud Deudero [1]*, Andrea Gari [1] and Cristina Gonzalez-Andres [1]
[1] Centro Oceanografico de Baleares. Instituto Español de Oceanografía - salud.deudero@ba.ieo.es

Abstract
Deployments of Offshore Wind Farms (OWF) are increasing throughout northern European seas. Few studies are dealing on impacts on marine biota. Revision of OWF monitoring on marine organisms reveals impacts as a result of substrate addition, indicating similar effects to those provided by artificial reefs and fish aggregation devices. Responses from ongoing projects at northern Europe will be discussed for expectation of further developments of OWF at the Mediterranean.

Keywords: Fishes, North-Western Mediterranean, Zoobenthos, Coastal management

Introduction
Marine renewable are increasing throughout northern European [1]. Effects of offshore wind farms on marine biota are diverse including addition of new substrate, creation of electromagnetic fields, noise, vibrations… [2]. Few studies have addressed such impacts. We hypothesized that OWF substrate addition is changing marine community structure; therefore we focus on discerning benthic and fish communities' changes to new substrate addition after OWF deployment. The expectation is that this data can serve as a baseline for establishing trends at Mediterranean ecosystems.

Material and methods
Review and analysis of 9 technical documents and scientific papers including biological data on OWF farms have been performed. OWF from Denmark, Holland, Belgium and England have been considered including temporal variation from 2001 to 2012. Two types of data have been addressed separately: benthic assemblages and fish communities. Permutational analysis of variance on log (x+1) transformed abundance data has been calculated at datasets from OWF, control areas, seasons and years.

Results and discussion

Benthic communities based on 17 taxonomic groups highlighted a dominance of Bivalvia and Nermertina at the OWF areas and a dominance of Amphipoda, Phoronida, Polychaeta at control areas. Benthic invertebrates are significatively differing among OWFs (Permanova, p>0,001). The sampling methodology is also modifying the observed benthic assemblages. Moreover, seasonality is influencing the faunal communities. (Table 1):

Biomass increase in benthic communities can be highly relevant, although little is know about large-scale OWF consequences on marine biota (3). Temporal surveys determined an increase in organic matter, while abundance, species richness and invertebrate biomass was following a similar pattern at both OWF and control areas (4).

Fish species
Several taxonomic groups from 5 OWF studies were quantified. The results highlight differences among offshore wind farms faunal assemblages. Fish species respond more clearly to OWF deployment exhibiting also temporal differences Permanova (Table 2):
Species mobility might explain the observed patterns linked to life cycle of each species. Seasonal variations are tight to environmental variability driving species responses. Time since deployment is also relevant for the observed communities around OWF. Previous studies on demersal assemblages showed a biomass increase of fishes surrounding the wind turbines (5). Future developments at Mediterranean coasts should include those aspects of variability within marine biota responses.

STRIKING DIFFERENCES IN CARRYING CAPACITY VALUES OF FISH BIOMASS AMONG MEDITERRANEAN MPAS

Antoni Garcia Rubies [1]*, Josep Coll Montserrat [2], Mikel Zabala Limousin [3] and Bernat Hereu Fina [1]
[1] Centre d'Estudis Avançats de Blanes (CEAB-CSIC) - tonigr@ceab.csic.es

Abstract
The carrying capacity of commercially interesting fish biomass was calculated in three Balearic MPAs. K values (1) differed among MPAs, and were reached at short times (< 5 yrs.). The differences were explained by environmental factors at small and medium spatial scales: exposure, "rugosity" and nearby abrupt changes in depth. By optimizing the effect of these factors we can get the "ideal MPA" for attaining maximum K values: a rocky outcrop in open sea, beaten by winds and currents, with a complex rocky bottom and pronounced slopes nearby. This case is close to the Medes Islands Marine Reserve, where a much higher value of K was observed, but attained at a far longer period of time (95% K at 25 yrs.). The results demonstrate that K values were regulated "bottom-up" and depend on the environmental factors prevailing in the area.

Keywords: Marine parks, Balearic Islands

Introduction
A population can be considered fully recovered when it reaches the carrying capacity of the system. This is one of the main aims of marine reserves, but has rarely been proven and there is no unanimity in the value of K nor the time necessary to achieve it. In this work we show that variations in K can be explained by the effect of different environmental factors acting at small and medium spatial scales. Knowing the effect of these factors, one can predict how it should be the "ideal MPA" to reach maximum values of K. This ideal environment is very similar to that found in the Medes Islands Marine Reserve, where, indeed, the value of K largely exceeds those observed in the Balearic MPAs, although the time required to achieve it was much longer.

Material and Methods
The study was carried out in three Balearic Islands Marine Reserves (from 2000 to 2011) (1) and the Medes Islands Marine Reserve (from 1991 to 2009). In both cases, visual censuses were conducted using transects (5 x 50m; from 5 to 10m, and 50 x 10m between 10 and 20m depth, respectively). All fish species of fishing interest were evaluated in the Balearic Is., and only 6 species (*Epinephelus marginatus*, *Dentex dentex*, *Dicentrarchus labrax*, *Diplodus cervinus*, *Sciaena umbra* and *Sparus aurata*) in the Medes Is.
The temporal evolution of the total biomass was adjusted to different asymptotic models of limited growth giving the value of K and the time required to achieve it. The K values obtained from Balearic MPAs were related to different environmental variables at small (bottom features, depth, slope and rugosity) and medium spatial scales (surrounding habitats, exposure, fishing effort and nearby abrupt slopes) by means of a generalized linear model analysis in order to ascertain which factors weighed more on conditioning the final value of K (2).

Results
The values of K vary widely, even in no-take zones within the same MPA (Palma MPA, K= 2656g; Freus MPA1, K= 6931g ; Freus MPA2, K= 4226g; Menorca MPA1= 4000g ; Menorca MPA2, K= 2394g 250m^{-2}) and they were reached in a short time period since protection (< 5yrs.). These differences were explained by the combined effect of several environmental factors (Exposure x Rugosity x Offshore slope). Optimizing those factors under this model could allow to reach higher K values, and that was the case of Medes Is. MPA (and other Mediterranean MPAs that can be considered as truly hot spots), where the carrying capacity stands at 12575g 250m^{-2} even though only six fish species of fishing interest have been taken into account. The 95% of that K value was reached after 25yrs of protection (Figure 1).

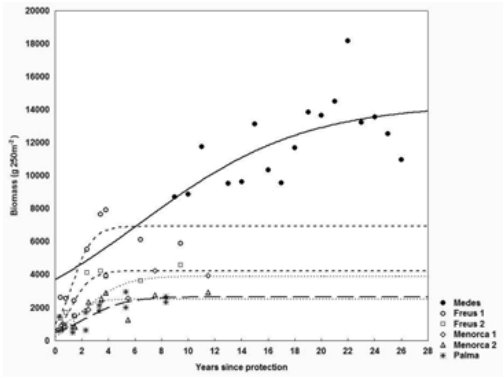

Fig. 1. The differences in carrying capacity and recovery time are evident between the Medes Is. and the Balearic MPAs (only 6 fish species were taken into account in the Medes Is. MPA)

Conclusions
Achieving the maximum biomass is regulated bottom-up by environmental conditions acting at small (Rugosity) and medium (Exposure, Offshore slope) spatial scales. The ideal combination of those factors allow the full development of the largest, long-lived, fish species. That's why the proces to reach the carrying capacity is longer in the "hot-spots", such as Medes Is. than in "normal' sites", although the final value of biomass is much higher (3). Prior knowledge of these factors, will allow us to design what would be ideal MPAs to achieve the highest biomass values of the most targetted, and therefore vulnerable, fish species in the Mediterranean Sea ?

Abstract

Here we assess gaps in the representation of taxonomic, phylognenetic and functional diversity components among coastal fishes in Mediterranean MPAs. We assessed gaps in the representation of coastal fishes and then asked whether MPAs protecteded phylogenetically and functionally more distinct species or whether there was a tendency for conserving more common ones and evaluated the overall conservation effectiveness for these two biodiversity components. We show that the Mediterranean MPA system fails short in achieving an effective conservation of coastal fish taxonomic, phylogenetic and functional diversity and does not provide better biodiversity coverage than random MPA systems. This study reveals multiple ongoing challenges for the extension of the Mediterranean MPA system in the context of the Convention on Biological Diversity.

Keywords: Conservation, Coastal systems, Fishes, Biodiversity, North-Central Mediterranean

The Mediterranean Sea is a remnant of the Tethys Ocean and has shown exceptional levels of marine biodiversity since the late Middle Eocene (42 to 39 Ma; 1). Most of this biodiversity is located on the continental shelf (2), an area that has been historically impacted by numerous anthropogenic threats (3). Amongst those threats, overfishing, often making use of destructive fishing gears is considered as the most prevalently affecting coastal fish populations (4). To counteract those threats about 100 coastal MPAs have been established in the Mediterranean Sea since the sixties (5). Despite their overlap with areas of high taxonomic fish diversity (6), recent investigations revealed that Mediterranean MPAs do not deliver on several important aspects (7).

Here we develop a gap analysis for Mediterranean coastal fishes and measure the MPAs ability to represent three key biodiversity components: taxonomic, phylognenetic and functional diversity. We first assessed gaps in the (taxonomic) representation of coastal fishes in Mediterranean MPAs, with targets being inversely proportional to species' range sizes. We then asked whether MPAs protecteded phylogenetically and functionally more distinct species or whether there was a tendency for conserving more common ones. We evaluated the overall conservation effectiveness of the MPAs using a metric that weights favorably MPA systems that maximize phylogenetic and functional diversity coverage as well as species representation. The effectiveness of the MPA system at protecting biodiversity was assessed by comparison with a null model defined by selecting MPAs at random over the study area. Among the 340 coastal fish species, 16 species were total gaps not covered by any MPA. All the remaining species only partially achieved their representation target. Current Mediterranean MPAs yield less total gap species than expected from locating MPAs at random. However, 30% of the species achieved significantly higher representation targets in random areas than in the current MPAs. Functional and phylogenetic distinctiveness were weakly correlated with target achievement. The observed coverage of functional and phylogenetic diversity was not different than for random systems.

The Mediterranean MPA system fails short in achieving an effective conservation of coastal fish taxonomic, phylogenetic and functional diversity and does not provide better biodiversity coverage than systems where current MPAs are sited randomly. The critical conservation status of the different components of Mediterranean coastal fish biodiversity highlighted here, as well as their spatial mismatches (6), demonstrate that the establishment of transnational conservation strategies would be of great benefit for biodiversity. Whether such pattern was verified for other taxa and habitats, it could have significant implications for the extension of the Mediterranean MPA system in the context of the Convention on Biological Diversity.

Abstract
In the Mediterranean Sea *Cystoseira* forests are locally threatened due to several impacts. The low dispersal capacity of most *Cystoseira* species makes the natural recovery unlikely. The restoration of *Cystoseira* forests can represent a valuable solution and is recommended where the historical presence is recorded and the impacts that led to its loss are no longer acting (a reasoned forestation could be considered also where historical data are not available). MPAs may play a paramount role in the conservation of *Cystoseira* forests, guaranteeing protection from several impacts and representing the source of propagules for the restoration of lost or degraded forests outside their borders. MPAs where *Cystoseira* forests are lacking due to past impacts should be considered as priority experimental sites for artificial forestation.

Keywords: Marine parks, Phytobenthos, Conservation, Restoration, North-Western Mediterranean

Large brown seaweeds play the role of engineer species in shallow waters of temperate and cold waters. In the Mediterranean Sea, marine forests are mainly originated by Fucales of the genus *Cystoseira* that play an important functional role in sustaining complex food webs and maintaining a high biodiversity. As many other large brown seaweeds worldwide, *Cystoseira* forests are regressing due to several impacts, among which a decrease in water quality, coastline overbuilding and the proliferation of herbivores, sometimes an indirect effect of overfishing [1, 2]. Six Mediterranean species of *Cystoseira* are listed in the Annex I of the Bern Convention, and the Mediterranean Action Plan, adopted within the framework of the Barcelona Convention, identifies the conservation of all but one *Cystoseira* species as a priority.

The low dispersal capacity of most Cystoseira species makes the natural recovery unlikely, so that artificial reforestation can represent an extremely valuable solution for lost forests [3, 4]. Large brown seaweeds restoration has been already explored worldwide but only few studies have been carried out in the Mediterranean Sea on *Cystoseira* species (*C. amentacea var. stricta*, *C. barbata*, *C. compressa*). These experiments gave encouraging results, thanks to the highly-efficient reproductive strategy characteristic of the Fucales order. Negative effects of grazing have been observed in several cases, suggesting that, at least in a first phase of artificial reforestation, grazers should be controlled.

The restoration of *Cystoseira* forests is particularly recommended where the historical presence is recorded and the impacts that led to its loss are no longer acting in the area. Nevertheless, forestation could be considered also at sites where the previous distribution cannot be documented, but seems likely based on the local and regional environmental characteristics. Also existing man-made structures may be considered for forestation, whenever the biotic and abiotic environmental factors are compatible, as this would enhance the ecological value of these artificial substrata without compromising their engineering function.

Although pristine *Cystoseira* forests can be found in MPAs, this is not a general rule: several MPAs lack *Cystoseira* forests, while healthy dense forests can still be found in non-protected, but naturally isolated and lowly impacted sites [5]. MPAs can play a paramount role for the conservation of these forests, as they guarantee protection from various human impacts (e.g. overfishing, urbanization) and can reduce others through an integrated management with adjacent areas. Healthy forests in MPAs may represent also an important source of propagules for restoration of lost or degraded forests outside their borders. MPAs lacking *Cystoseira* forests may offer priority experimental sites to identify the factors facilitating the conservation and restoration of damaged forests.

The protection of existing forests should be coupled to regular monitoring programs in order to promptly highlight potential threats and early signs of regression. An ecosystem-based management applied to a network of MPAs with long-term monitoring programs and restoration actions, where necessary, is probably the best perspective for *Cystoseira* forests preservation in the Mediterranean Sea.

Acknowlegdments
The work was realized within the framework of the project MMMPA - Training Network for Monitoring Mediterranean Marine Protected Areas, that has received funding from the European Community's Seventh Framework Programme (FP7/2007-2013) under Grant Agreement n°: 290056 (support of FG and FB) and of the project CoCoNet, under grant agreement N°287844. LA was supported by projects Theseus (EU - FP7 - ENV2009-1, grant 244104), MERMAID (EU FP7 – Ocean – 2011, grant 288710) and by a Fulbright Fellowship while writing the paper.

DYNAMICS, CAUSES OF DEGRADATION AND THE PROGNOSIS OF RESTORATION ZERNOV *PHYLLOPHORA* FIELD (THE BLACK SEA)

Nataliya A. Milchakova [1]*, Nataliyia V. Mironova [1] and Vladimir V. Alexandrov [1]
[1] Institute of Biology of the Southern Seas, Sevastopol, Ukraine - milchakova@gmail.com

Abstract
The current status and causes of degradation of the Zernov *Phyllophora* Field (ZPF) over the last century are analyzed. The *Phyllophora* spp. population state is described, and the necessity of the conservation management plan of and restoration of ZPF as the largest Black Sea MPA are discussed.

Keywords: Phytobenthos, Black Sea, Conservation

Zernov *Phyllophora* Field (ZPF), discovered in 1908 in the north-western shelf of the Black Sea (NWBS), was the largest aggregation of unattached *Phyllophora* in the world with an area of about 11,000 km^2 [1]. Over the last century ZPF has nearly disappeared. *Phyllophora crispa* (= *Ph. nervosa*) dominated here earlier in the depth range from 20 to 50 m and consisted mainly in unattached form. Recently in many ZPF sites, it has been replaced with an attached form of *Coccotylus truncatus* (= *Ph. brodiaei*). *Phyllophora pseudoceranoïdes* which is less common has not been found [2,3]; this species is included in the Red Book of Ukraine (2009) as endangered.

Phyllophora spp. stocks decreased by at the least hundreds times of (Figure 1); sixfold since 1969 till 1978 and further by an order of magnitude since 1978 till 1990. At present, they are estimated to be less than 6–100 thousand tons (wet weight). In 2008 a botanical preserve comprising sufficient part of ZPF was established; now it is the largest MPA of the Black Sea with an area of 4,025 km^2. According to the IBSS R/V expedition data, *Ph. crispa* average biomass decreased by more than an order of magnitude since 1990 to 2011, and the biomass of *C. truncatus* was changed slightly; now their values amount to 2.22 and 12.01 g·m^{-2} respectively [2,3].

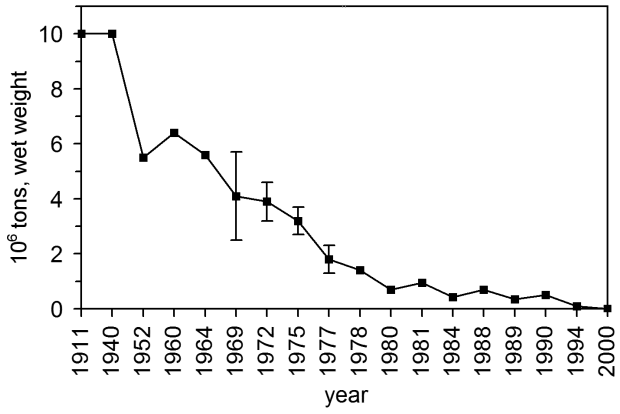

Fig. 1. Long-term dynamics of the *Phyllophora* spp. stock in the ZPF (the Black Sea).

The largest aggregations of both species are concentrated in the south-western part of ZPF; *C. truncatus* occurs throughout the entire area of the field and *Ph. crispa* grows mainly in its southern and central parts. In the population of *Ph. crispa* and *C. truncatus* young and small thalli are dominant. In 2011 in comparison with 1966 an increase in species diversity (32 and 25 species correspondingly) has been found; the Jaccard index of compositional similarity between these years reached to 70%.

Despite the eutrophication level decrease, increased water transparency of the NWBS shelf and putting a ban on commercial *Phyllophora* extraction into action since 1996 (catches ranged from 2,400 to 14,300 tons per year, see Figure 2), the ZPF recovery is not observed. In our opinion, the main causes of catastrophic ZPF degradation were not so much *Phyllophora* catching as sprat bottom trawling, which destroyed *Phyllophora* biocenoses, as well the eutrophication and the general unstable state of the NWBS ecosystem. The most important biological factors limiting the recovery of ZPF are an almost complete disappearance of the *Ph. crispa* unattached form (diploid sporophyte) which produced a significant biomass through vegetative propagation and increased expansion of the attached *C. truncatus* form (haploid gametophyte) characterized by a reduced sporophyte, low reproduction intensity and sensitivity to stress factors.

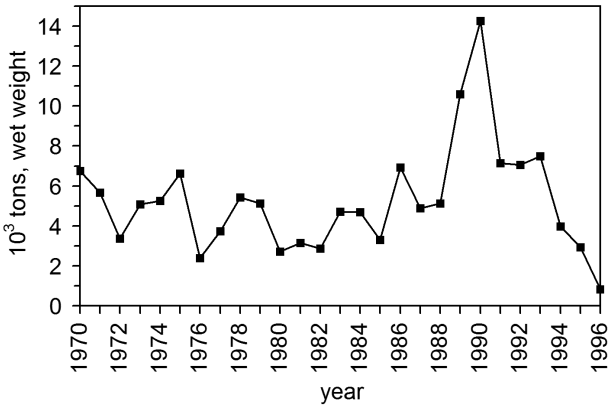

Fig. 2. Dynamics of *Phyllophora* spp. catching in the ZPF (the Black Sea).

Nevertheless, since the MPA was created, recovering of ZPF is unlikely because of the increase of vessel traffic and resource extraction in the NWBS and the entire Black Sea basin. There are several gas condensate fields close to the ZPF borders; their development is planned for the coming years. Taking all of this into account, the most urgent ZPF conservation goals in our opinion are: inclusion of key species and habitats into the European Red List and other documents, development management plan for the ZPF protection with the support of international organizations, and creation of the Black Sea MPA network. It is possible that implementing these goals will permit to change the nature protection paradigm from the protection of species to the protection of a ecosystem, taking into account the compensation principles of the correspondence in use of marine living resources by human to natural ecosystem dynamics.

Acknowledgements. The research has received funding from the EC (FP7/2007-2013) under Grant Agreement No. 287844 for the project CoCoNet ("Towards Coast to Coast NETworks of marine protected areas (from the shore to the high and deep sea), coupled with sea-based wind energy potential").

IS THE PELAGOS SANCTUARY SUFFICIENTLY LARGE FOR THE CETACEAN POPULATIONS IT IS INTENDED TO PROTECT?

Giuseppe Notarbartolo di Sciara [1], Simone Panigada [1]* and Tundi Agardy [2]
[1] Tethys Research Institute - panigada@inwind.it
[2] Sound Seas, Inc.

Abstract
Critical habitats of cetacean populations regularly found in the Pelagos Sanctuary widely extend to the west and south of the Sanctuary's borders, in spite of its large size (87,000 km^2). A reconsideration of the Sanctuary's design to account for this shortcoming is proposed.

Keywords: Cetacea, North-Western Mediterranean, Marine parks

MPAs can provide effective protection to cetaceans [1], although the high mobility of many species presents a challenge to the applicability of MPAs to their conservation. The Pelagos Sanctuary for Mediterranean marine mammals was established in 1999 by a treaty among France, Italy and Monaco [2], to ensure the good conservation status of most of the cetacean species regularly occurring in the Mediterranean, attracted to the area by a particularly favourable feeding environment. However, in spite of its large size (87,000 km^2), the Pelagos Sanctuary includes only in part the critical habitats of the cetacean populations regularly found within its borders.

The fin whale, *Balaenoptera physalus*, a highly mobile, pelagic cetacean found at its highest regional concentrations in the northwestern Mediterranean and particularly within the Sanctuary's boundaries [3], is a case in point. During the last few years, evidence was provided that fin whales occur in important concentrations well beyond the Sanctuary's western boundary, i.e., south of the Gulf of Lion towards the Balearic Islands, where in fact models predicted the presence of fin whale feeding habitat [4, 5]. Tracks of eight fin whales, derived from a satellite tagging experiment we conducted in the area in Sept. 2012 (Fig. 1), while stressing the importance of the Pelagos Sanctuary for the whales, at the same time confirmed the propensity of several whales to spend time to the west of the Sanctuary, in a vast area comprised between the shelf drop in the Gulf of Lion, the west coast of Sardinia and Catalonia. Furthermore, the prediction by the same models of the existence of important fin whale habitat in the Tyrrhenian Sea, just south of the Sanctuary's eastern boundary, were confirmed by observations at sea [6, 7].

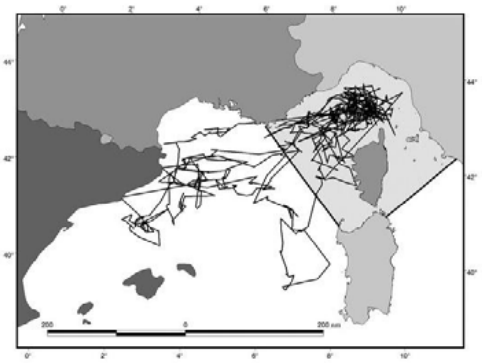

Fig. 1. Tracks of eight fin whales tagged with satellite transmitters in Sept. 2012. The shaded marine area is the Pelagos Sanctuary.

Since threats to cetaceans (e.g., maritime traffic [8], fishing, seismic exploration and effects of climate change) occur throughout the western Mediterranean, extending spatial protection to cover a larger portion of the species' critical habitat would provide a greater potential for addressing these threats. With the significant increase in ecological knowledge acquired in recent years, and with most of the concerned area now having become within national jurisdiction due to the establishment of an EEZ by France and an Ecological Protection Zone by Italy and Monaco, it would now be possible to design and manage a zoned system whereby areas containing cetacean critical habitats outside and within the Sanctuary boundaries are afforded protection. Such system would also contribute to strengthen the bases for the identification of CBD's Ecologically or Biologically Significant Areas (EBSA) in the region, and support the implementation of a Marine Spatial Planning scheme whereby human activities impacting on cetaceans can be made to coexist with environmental protection.

Abstract
The increasing necessity of scientific evidence on the socioeconomic impacts of MPAs, as well as acknowledging them, is of relevance for marine policies. This is especially important at the regional level, such as for the Mediterranean and the Black Sea. However, since a previous work carried out in 2000, no study has analyzed the most recent findings, or performed a comparative review of the socioeconomic impacts of MPAs for the Mediterranean and the Black Sea. The present contribution aims to fill this gap by collecting evidences and analyzing MPAs' socioeconomic impacts, updating and expanding the analysis for the Black Sea. Preliminary results show that MPAs implications on tourism and fishing are important especially in the Mediterranean Sea, whereas in the Black Sea conflicts are likely to arise due to mineral extraction.

Keywords: Marine parks, Economic valuation, Black Sea, North-Central Mediterranean, North-Eastern Mediterranean

Marine Protected Areas (MPAs) have gained popularity worldwide as a management option for marine conservation, fisheries and other human uses of the oceans [1]. As a consequence, MPAs are increasingly common management tools for marine ecosystems and scientific evidence on the socioeconomic impacts of these reserves has gained relevance for marine policies, especially at the regional level, where common policies and regulations can be applied. It was in this line that current international targets, set by the Convention on Biological Diversity, promoted a network expansion of MPAs [2].However, more research is needed in order to understand the socioeconomic impacts of each MPAs, as well as the impacts of scaling marine reserves to regional networks, where many conflicts have been already observed to arise [3]. A work in 2004 estimated the costs and benefits of meeting global MPA network targets [4], however, studies looking at the impacts at a regional level are scarce. Two regions with abundant MPAs are the Mediterranean and the Black Sea, which provide a number of important marine ecosystem services to the wide range of countries that these regions encompass. These countries have the particularities of being geographically constrained by huge regulatory, economic and, even sometimes, geopolitical differences, which conflict with a more sustainable use of the resources. Understanding the socioeconomic impacts of MPAs in these two regions is therefore essential. Already in 2000, a review on the socioeconomic impacts of MPAs in the Mediterranean Sea was conducted [5], and since then, many other studies have tried to understand the various mechanisms in which MPAs can have socioeconomic impacts. However, since the latter review, no other study has analyzed the most recent findings from the literature, or performed a comparative review of the socioeconomic impacts of MPAs for the Mediterranean and the Black Sea. Acknowledging this gap, the present contribution aims to collect and analyze evidences from the Mediterranean, that would allow to update previous reviews [5], as well as performing the same analysis for the Black Sea. The main objectives of the present work are: (i) to conduct an up-to-date review on the state-of-the-art of socio-economic impacts of MPAs in the Mediterranean and Black Sea regions; (ii) to identify the implications of MPAs to the main existing marine activities and uses in the region´s countries; (iii) to derive implications, constrains, suggestions and conclusions for the creation of MPAs networks. In order to fulfill this aims, a review of the literature has been conducted by including studies on MPAs belonging to both EU and non-EU countries. The MPAs dataset was compiled based on the MEDPAN (www.medpan.org) and on the WDPA (World Database Protected Areas; http://www.wdpa.org/) databases and updated with scientific and management report that where found at the country level basis. An extensive bibliographic search was performed by reviewing peer-reviewed papers, gray literature, management plan reports, other scientific reports, books, book chapters, proceedings, policy briefings and personal and web communications that reported any information regarding socioeconomic impacts of MPAs, for each of the countries in the Mediterranean and the Black Sea regions. A set of 190 MPAs are included in the database, where special focus was placed on gathering information and analyzing the impacts per MPA on the different uses and economic activities performed in the area. Impacts of MPAs where identified for the following uses and activities: fisheries (commercial, artisanal, recreational); aquaculture/mariculture; maritime transport; military; extractive (oil and gas, sand, biological resources); renewables (wind, wave); recreational (diving, sailing, tourism, beach, etc); cultural heritage (archaeology) and education and science. The information gathered per use or activity was related to: presence / absence of impact; type of impact; management measures; effectiveness of the management measures; level of social impact; information source and reliability of the information. Based also on an intense bibliographic research, a complete compilation and weighting among the existing marine activities at the Mediterranean and Black Sea was performed followed by the analysis, per country, of the cultural and socioeconomic impacts of MPAs over those activities. With the final updated database, the expected significant differences of the impacts of MPAs, depending on the country and region, were corroborated by preliminary results which show that main relevant socioeconomic impacts of MPAs in the Mediterranean are to be more relevant for fisheries and tourism, whilst impacts on resource extraction are important for the Black Sea region. These regional differences have been further explored by focusing on two case studies, one at the Mediterranean (highlighting impacts of MPAs onto fisheries) and another one at the Black Sea (highlighting impacts of MPAs onto mineral extraction), regional differences as regards to MPAs socioeconomic impacts onto activities are discussed and MPAs networking steps are suggested as a mean to minimize MPAs socioeconomic impacts. A diagram of the steps that have been followed is shown here below:

Fig. 1. Description of the methodological approach for MPA socioeconomic impacts.

EVALUATION ÉCOLOGIQUE DE L'ÎLE RACHGOUN EN VUE D'UN CLASSEMENT EN AIRE MARINE PROTÉGÉE (OUEST ALGÉRIEN)

Djillali Bouras [1] and Mohammed Ramdani [2]*
[1] Université d'Oran Département de Biologie
[2] Université Mohammed V Agdal Rabat, Institut Scientifique - mramdani@israbat.ac.ma

Abstract
L'île Rachgoun est un écosystème abritant d'importantes colonies d'invertébrés benthiques (Cnidaires, polychètes, Mollusques, échinodermes), pélagiques et terrestres. L'herbier est dominé par la posidonie, associée à des algues vertes et brunes. L'étude vise la détermination des potentialités en biodiversité. Il s'agit d'un site de nidification pour le faucon d'Eléonore et du faucon crécerelle. Les pressions anthropiques et climatiques ont contribué à une dégradation avancée du paysage. Ainsi, la nécessité d'engager des actions de sauvegarde de l'ile s'avère impérative. Ce site insulaire concrétise l'ensemble des caractéristiques d'une aire marine protégée pour préserver la biodiversité et le paysage, et intégrer cette région dans un développement durable en associant la population riveraine dans des activités respectant l'environnement.

Keywords: Biodiversity, Algerian Sea

Introduction
Les écosystèmes marins en Algérie subissent de fortes agressions menaçant le paysage et les composantes biologiques. L'ensemble de la façade maritime nationale dépasse 1600 km de long et ne compte aucune aire marine protégée reconnue à l'échelle internationale. Dans cette optique, la proposition de classement de l'Ile Rachgoun ne peut que signaler un des nombreux importants SIBEs de la zone marine dans la partie ouest algérienne. L'île Rachgoun est une brèche de maintien d'un site d'un grand intérêt écologique, représentant un patrimoine naturel soumis à de fortes pressions et reconfigurations (tourisme national accru en été et activités de pêche importantes toute l'année). Le classement de cet écosystème insulaire en aire marine protégée permettra de valoriser à la fois le paysage et les composantes biologiques.

Situation géographique
L'île Rachgoun, appelée aussi Layalla, se localise dans la baie de Beni Saf limitée par le Cap Acra à l'Ouest le Cap Oulhassa à l'Est, et étalée sur 14 km de long. Le site est matérialisé topographiquement par deux plages (plage du Puit ou Madrid et plage Rachgoun) séparées par des falaises rocheuses à l'embouchure de l'oued Tafna. Le secteur côtier et constitué d'une alternance de plages sableux et de rochers au voisinage de la ville de Beni Saf. L'ensemble du littoral est relativement moins peuplé et anthropisée ([1] in Khetib et Rezzoug, 1991).

Richesse paysagère et biodiversité
Les paysages marins algériens sont le théâtre d'une reconfiguration incessante, résultat d'une évolution permanente des compartiments marins et terrestres. Le site insulaire maritime offre un écosystème richement diversifié en flore: *Posidonia oceanica*, *Codium bursa*, *Cystoseira stricta*, *Sargassum* sp. et *Corallina elongata*). A des niveaux de profondeur encore moins importants et sur l'ensemble du pourtour immédiat de l'ile, se développent des ulvales: *Ulva rigida* et *Enteromorpha intestinalis*. La faune ornithologique remarquable est composée du Goéland d'Audouin *Larus audouinii* et du Faucon d'Eléonore *Falco eleonorae*. Nous avons observé également une importante colonie du grand cormoran, du balbuzard pêcheur et du Goéland leucophée *Larus cachinnans*. Nous avons noté une population importante de moules *Mytilus galloprovincialis*, de *Patella gigantea*, d'oursins (*Paracentrotus lividus* et l'oursin noir *Arbacia* sp) et de *Balanus* sp dans les crevasses rocheuses et dans les fissures et les creux du platier environnant. Les annélides polychètes, avec 110 espèces répertoriées, sont représentés principalement par *Stermaspis suctata*, *Nephtys hombergi*, *Lumbrineris latreilli*, *Lumbrineris gracilis*, *Chone filicaudata* et *Chone duneri*. Les arthropodes crustacés sont composés de: *Ampelisca corophium* et de nombreuses espèces de crabes. Les Tanaidacés comptent de nombreuses espèces. Les mollusques (34 espèces) sont largement représentés par les Tellinidés et les Nuculidés. Les Echinidés sont représentés par les oursins, les holothuries et les étoiles de mer. Les ressources halieutiques sont représentées par une vingtaine d'espèces de poisson d'importance économique, ainsi que par les crustacés *Natantia* (crevette rose du large *Parapenaeus longirostris*) et par les Mollusques céphalopodes dominés par le calmar *Loligo vulgaris*.

La zone insulaire est sous l'influence d'une alternance de périodes climatiques stables et instables ayant un impact négatif sur le site et ses composantes, auquel s'ajoutent les actions anthropiques qui aboutissent souvent à une érosion des espèces floristiques et faunistiques. Dans cette optique, trois questions majeures se posent :

Quelle évolution temporelle des sites insulaires en Algérie? Comment gérer cette zone maritime? Quels sont les outils efficaces pour protéger et préserver le paysage et ses composantes biologiques? Quel moyen efficace pour intégrer ce site dans le réseau CoCoNet?

La gouvernance et la protection de la biodiversité de l'Ile Rachgoun exige une évaluation pilotées par des équipes pluridisciplinaires avec la collaboration des décideurs et des gestionnaires. Le site, classé à l'échelle nationale en SIBE, se trouve dans le secteur côtier de Béni-Saf (importante zone portuaire à l'échelle nationale). Son classement en zone marine protégée limiterait amplement tous les types d'agression et de reconfiguration paysagère et préserve la richesse faunistique et floristique marine et terrestre [2-7].

SOCIOECONOMICS OF MARINE PROTECTED AREAS: A REVIEW OF EMPIRICAL EVIDENCES

M. Rossetto [1]*, F. Micheli [2], G. A. De Leo [2], P. Melià [1] and M. Gatto [1]
[1] Politecnico di Milano - marisa.rossetto@nemo.unipr.it

Abstract
Recent trends in the science of marine protected areas (MPAs) highlight the need to strengthen the integration between socioeconomic and ecological aspects in the early stage of the planning process. So far, however, the magnitude and relevance of the socioeconomic consequences of MPA creation are still highly uncertain. Here, we present a synthetic review of the empirical evidences of benefits and costs (B/Cs) of MPAs, in order to inform the planning of future protected areas.

Keywords: Economic valuation, North-Central Mediterranean

Introduction. Marine environments offer extremely valuable resources in terms of extractive and non-extractive uses. The establishment of MPAs, partially or totally limiting human uses, raises important socioeconomic issues that should be included in the planning process at an early stage to increase compliance and general acceptance [1]. However, economic consequences of MPA establishment are often limited to collateral information evaluated *a posteriori* and are generally not integrated in the planning process [2]. Here, we review published empirical evidence of B/Cs of MPA establishment. Results are reported heraafter and summarized in Fig 1.

Fishery-related B/Cs of MPAs. We reviewed 95 ISI papers, focusing on 39 MPAs all over the world, that analyze B/Cs in terms of 1) spillover from MPAs toward fishing grounds; 2) change in market value of exported fishes; 3) effect of protection on catch variability; 4) effect on fishing effort; 5) effect on overall catches. Results show that spillover is a common benefit in well-established marine reserves, as it was detected in about 75% of the case studies. Worldwide, spillover from MPAs has been detected for a suite of different species, including finfish and invertebrates. Spillover of lobster has been observed in 6 Mediterranean MPAs. The increase in mean size of commercially important species in the surroundings of MPAs is another common benefit, detected in 28% of the MPAs under study. On the other hand, only four studies analyzed the effect of MPAs on catch variability. Even though theoretical studies suggest that MPAs could diminish catch variability, in 3 MPAs greater catch variability was detected after protection. Displacement of fishing effort associated with MPA creation was detected in almost 25% of analyzed cases studies that reported biomass export. Only 8 of the 39 empirical studies that analyzed spillover collected enough information to assess the effect of protection on overall catches. In 6 cases, MPAs resulted in a net advantage to local fishermen (fishing yields higher with MPA than without); in 2 cases, instead, a decrease in catches after MPA creation occurred due to excessive reduction of fishing grounds.

Non-consumptive B/Cs of MPAs. We reviewed 20 ISI papers analyzing the B/Cs of recreational use of 28 MPA in coral reef areas and in the Mediterranean. We focused on the effects of protection on 1) increase of touristic activities; 2) improvement of recreational use; 3) damage from increased visits. Attractiveness of protection on tourism and improvement of recreational use have been detected in 14 over the 28 MPAs, especially for divers, snorkelers and sailors. However, information about increased visits is often anecdotal and it is often impossible to distinguish how much of the revenues from touristic activities are due to the MPA presence itself. In 10 MPAs, contingent valuation and travel cost methods were used to estimate recreational users' willingness to pay (WTP) for enjoying the reserve or simply preserving the seascape. Such surveys are extremely useful for determining fees that can be introduced to sustain long-term financing [3]. In 3 MPAs, the estimated annual revenue from tourism could cover MPA's operating and management costs. Despite the importance of tourism as an income voice, 7 studies detected detrimental effects of recreational use on marine habitats [4]. In 2 MPAs, damages from increasing visists have been quantified in terms of decreased WTP for recreational use due to decline in reef quality [5] and crowding [6].

Review on MPAs management costs shows that acquisition, management, enforcement and transaction costs constitute an effective problem for effective management: in a surveys of 83 MPAs worldwide, it emerges that in only 15.7% of the cases current funding was sufficient for effective conservation [7]. The total annual running costs per unit area has been found to decrease with MPA size [7], meaning that MPAs cost more to run, per unit area, where they are small.

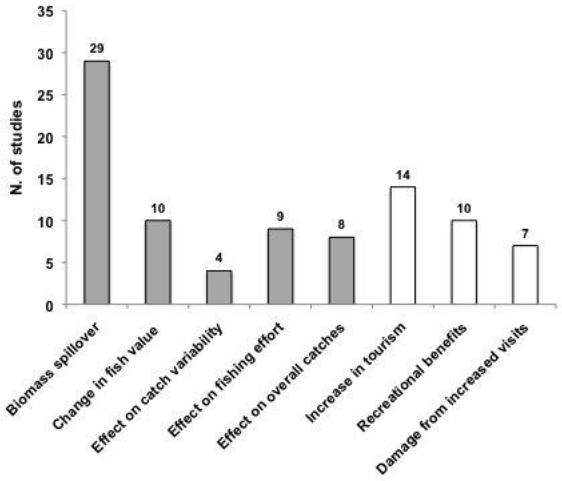

Fig. 1. Number of valuations of socioeconomic effects of MPAs found in the literature. Gray bars refer to consumptive B/Cs, white bars refer to non-consumptive B/Cs.

Conclusion. Our analysis revealed that consumptive users of marine resource can benefit from MPA establishment, as spillover of biomass from reserves is a common benefit in existing MPAs. Non-consumptive benefits are a crucial aspect in determining the degree of financial self-sustainment of MPAs, as long as no habitat damages from increased visits occurr. Information on MPAs management costs shows that economy of scale encourages the expansion of existing networks of MPAs to foster the recovery of marine ecosystems**.**

ANALYSIS OF SHALLOW-WATER MARINE FISH COMMUNITIES OF CROATIA: THE INFLUENCE OF HABITAT AND GEOGRAPHIC VARIABLES ON BETA DIVERSITY

Stewart Schultz [1]* and Claudia Kruschel [1]
[1] University of Zadar - ss@stewartschultz.com

Abstract
We quantified shallow-water fish communities at 135 outer-coast sites throughout Croatia using non-destructive underwater visual-census transects. Species richness and diversity were significantly higher inside MPAs. Both habitat dissimilarity and geographic distance had significant and independent effects on beta-diversity, providing support for both niche- and dispersal models for species assembly. MPA design should target natural habitat mosaics rather than individual benthic habitats.

Keywords: Central Adriatic Sea, Fishes, Biodiversity, Marine parks, Posidonia

Introduction

Fish resources are highly depleted in the Adriatic Sea due to competitive commercial and artisanal fisheries (1). Recovery of these resources and their dependent economies requires both changes in the regulation of extraction activities through ecosystem-based management, and the design of a network of interconnected MPAs embedded within an interdisciplinary plan of integrated coastal-zone management in Croatia (2). The optimal design of an MPA network requires understanding of spatial connectivity patterns and the partitioning of biodiversity across habitat and geographic space (3). Here we report results of the first study to quantify shallow fish community assembly at the scale of the entire Croatian coast.

Methods

We performed a total of 13806 lure-assisted, visual-census field transects of fish communities at 135 outer coast sites in Croatia, for an average of 348 transects per site (minimum 12, maximum 377) (4). Sampling was performed in early and late summer of 2009, 2010, 2011, and 2012 with a mean of 3452 transects per year. These sites spanned the entire coastline from south to north, and included a total of 18 inner and outer islands. Sites were inside and outside 5 MPAs with differing enforcement. Sites differed in shoreline development, the presence and extent of urchin barrens, mean transect depth (1.4 m to 8.1 meters), and benthic habitat. Benthic habitats included rocky reefs, algal beds, bare sand, *Posidonia oceanica* and *Cymodocea nodosa* meadows, and many combinations of these in complex mosaics. The mean fish community was calculated for each site, and community differences among all 9045 pairs of sites were quantified using beta diversity measures. We performed permutational Mantel tests, PERMANOVA, and nonmetric multidimensional scaling to test and visualize relationships between beta diversity and predictor variables.

Results

Our predictor variables were able to explain a maximum of roughly 30% of the beta diversity variation. Variables associated with habitat, including anthropogenic influence and MPA status, generally explained approximately 5-10 times the variation in beta diversity that geographic distance explained. The overall effects of distance and habitat persisted when each was controlled for the other in statistical tests. A small number of key fish species explained a moderate but significant amount of the variation in beta diversity, for reasons currently unknown but perhaps related to stronger habitat preference or to competitive or predatory interactions.

Discussion

If beta diversity is a proxy for negative connectivity, then our results imply that 1) fish communities throughout Croatia are highly connected; 2) the majority of connectivity variation shows no discernable pattern, and 3) the portion that is explained is influenced primarily by habitat characteristics, including the quality of the habitat, e.g. the level of shoreline development and the degree of protection from fish-harvesting activities. The major benthic habitats, including seagrass, unconsolidated sediment, and rocky reefs, each harbor predictably different communities of fish with similar levels of species richness and diversity regardless of geographic location. However, diversity and richness were significantly higher within MPAs. In conclusion, there are no major discontinuities in composition of the fish communities we studied within Croatia; communities on the islands are similar to those on the mainland, and we found moderate differences between northern and southern sites. Most variation was unexplained, and a moderate amount was explained by habitat identity and degree of anthropogenic disturbance. MPA design within Croatia should place a high priority on maintaining a natural habitat mosaic rather than elevating any particular habitat type.

ASSESMENT OF SOFT BOTTOM MUSSEL COMMUNITY STRUCTURE ON THE ROMANIAN BLACK SEA CONTINENTAL SHELF

Adrian Teaca [1]*, Tatiana Begun [1] and Marian-Traian Gomoiu [1]
[1] NIRD for Marine Geology and Geoecology - GeoEcoMar - adrianxteaca@yahoo.com

Abstract
Based on 83 quantitative samples collected between 2009 and 2012 within 20 - 65 m depth, the paper presents the structure of macrobenthic populations inhabiting the soft bottom mussel community from the Romanian Black Sea continental shelf. A total of 140 taxa were recorded, revealing that the community hold various species, annelids being the dominant group (80%) followed by mollusks. This baseline study of the shallow and deeper sedimentary habitats of the mussels bed will be used for the future MPA designation and for the implementation of projects regarding the wind farms settling in offshore area.

Keywords: Biodiversity, Zoobenthos, Black Sea

Introduction. The *Mytilus galloprovincialis* represents a mollusk mass species in shallow (rocky mussels') and in deep waters on the soft bottom. The typical deep mussel bed ranges between 30 - 50 m depth. However, it can occupy an area between 20 - 70 m depth. The total surface of mussels` community in front of the Romanian coast is about 7000 km$^2$, being the second largest community after those of *Modiolula* [1]. During eutrophication period (`70s-`90s) this community suffered major changes in terms of number of species and abundances of dominant species decreasing. This study, based on the results of researches performed in the last 5 years, comes to complete some gaps in the specialty literature concerning spatial distribution of mussel bed on the Romanian Black Sea shelf.

Material and Method. During several national and international cruises carried out in 2009, 2010, 2011 and 2012, 83 quantitative benthos samples were collected between 20 - 65 m depths using a Van Veen-type grab (0.14 m^{-2}), on board R/V „Mare Nigrum". The samples were washed using 1.0 and 0.5 mm sieves. The biomass of bivalves was weighted as wet visceral tissues.

Results and Discussion. A total of 140 taxa belonging to 21 systematic groups were found in the assemblages (Annelida - 36, Mollusca - 38, Crustacea - 26, others - 40). The mean abundance of the macrobenthic populations was 5,076 indv.m^{-2} and 85.4 g.m^{-2} as biomass. Polychaeta had the highest number of species (35) and individuals (Davg-3,200 ind.m^{-2}). The maximum biodiversity (128 species) occurred in the central part of mussels bed (Fig.1).

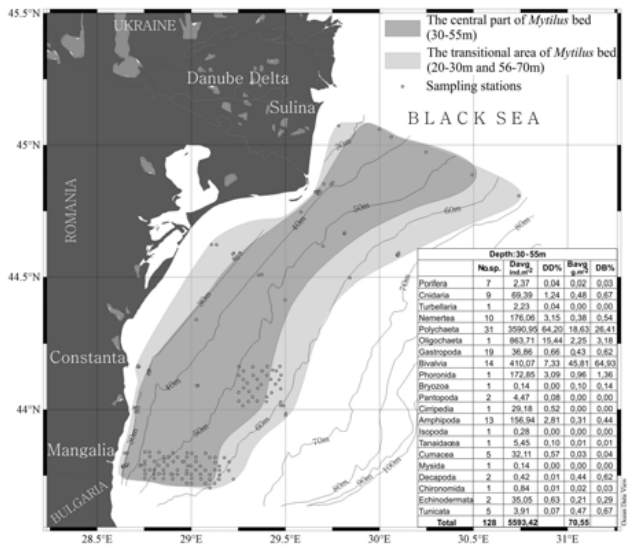

Fig. 1. Distribution of *Mytilus galloprovincialis* community and associated macrofauna along Romanian Black Sea shelf

According to the ecological indices the characteristic species throughout mussel community are: *Heteromastus filiformis* (F%-82), *Nephtys hombergii* (F%-81) and *Prionospio multibranchiata* (F%-52), *Phoronis euxinicola* (F% - 56) and oligochaets (F%-82). In the first 10 ranked species, only 2 crustacean species: *Phtisica marina* (F%-40) and *Iphinoe elisae* (F%-48) were found. The analysis of species distribution on geographic sectors indicated a clear demarcation between the northern sector (under the Danube influence) and the southern one. *Dipolydora quadrilobata* (DD%-21), with maximum densities of 15,000 ind.m^{-2} at 36 m on the Sulina transect, and *Melinna palmata* (DD%-19) with maximum densities of 8,300 ind.m^{-2} at 27 m on the Sf.Gheorghe transect are the species that form a new association in the northern area. The *D. quadrilobata*, recently introduced in the Black Sea (in 2000's), registered greatest development, living on various types of sedimentary substrata [2]. In the southern part, the polichaet *Aricidea claudiae* (max. 2700 ind.m^{-2}) is the characteristic species for the transition interval between littoral coenosis and the typical *Mytilus* one. The constant bivalvia species within the mussel beds are *Abra alba* (F% - 57) and *A. prismatica* (F% - 55). *M. galloprovincialis* as a weight dominant species has a patch distribution with average abundance of 56 ind.m^{-2} and 14 g.m^{-2} w.wt. In the northern part (Sulina - Cape Midia) the mussel is the third species as weight dominance after Mya *arenaria* (31 g.m^{-2} w.wt.) and *M.palmata* (15 g.m^{-2}), the latter forming a distinct association within the mussels` community. Analysis of the *Mytilus* community on bathymetric intervals reveals the importance of this coenotic unity as a biodiversity reservoir. The spatial distribution of the *Mytilus* presents 2 transition zones (20-30 m and 56-70 m), one situated at the limit with the littoral communities and the other with the deep ones, with the true mussels' community (30-55 m) in between (Fig. 1). Thus, within 20-30 m (77 species) the annelids dominate as density (*M.palmata*, oligochaeta, *H.filiformis*), while *M. arenaria*, as biomass, followed by *M.palmata* and *N.hombergii*. The most frequent crustaceans in this area are *I.elisae* (F%-50), *Perioculodes longimanus* (F%-45.5), *Ampelisca sarsi* (F%-40.9) and *Medicorophium runcicorne* (F%-36.4). The stripe between 56-70 m (52 species), marks the transition toward the *Modiolula phaseolina* community, resulting in a qualitative and quantitative impoverishing of macrobenthic populations. Here, the conductor species *M.phaseolina*, dominate numerically and as weight followed by oligochaets and *H.filiformis* (as density), *Mytilus* and *Terebellides stroemi* (as biomass). Only 6 crustacean species dominated in this area: *Eudorella truncatula*, *Stenosoma capito*, *Ph.marina*, *Microdeutopus versiculatus*, *Apherusa bispinosa* and *A.sarsi* (F%-37.5). The most constant at this depth are *Leptosynapta inhaerens* (F%-100) and *Amphiura stepanovi* (F%-87.5). In the central part of the *Mytilus* beds, between 30-55 m depth, numerical dominant are *D.quadrilobata* and *M.palmata*, while the oligochaets' contribution decreased. The mussels and *M. arenaria* reached 54% of total biomass, followed by *N.hombergii* and *M.palmata*. Along with the already mentioned crustacean species, other species like: *Actinothoe clavata*, *Obelia longissima*, *Micrura fasciolata*, *Eumida sanguinea*, *Exogone naidina*, *Oriopsis armandi*, *Phyllodoce mucosa*, *Pusillina lineolata*, *Megamphopus cornutus*, *Synchelidium maculatum and Apseudopsis ostroumovi* are the main cocoenotic species.

MODELLING SPATIAL DISTRIBUTION OF THE ENDANGERED BIVALVE *PINNA NOBILIS* IN A MARINE PROTECTED AREA

Maite Vázquez-Luis [1]*, David March [2], Elvira Alvarez [3] and Salud Deudero [1]
[1] Instituto Español de Oceanografía Centre Oceanogràfic de les Balears - maite.vazquez@ba.ieo.es

Abstract
Pinna nobilis spatial distribution and densities have been analysed through a geostatiscal approach in Cabrera National Park. Model results indicate that benthic habitats play a key role in the spatial distribution of *P. nobilis*, with higher densities in seagrass meadows of *Posidonia oceanica*. The predict map shows some hotspots of density and provide valuable information for the spatial conservation management of this species.

Keywords: Bivalves, Balearic Islands, Coastal models, Density, Mapping

Introduction
Pinna nobilis is a Mediterranean endemic bivalve under strict protection [1]. Population of *P. nobilis* has been greatly reduced during the last decades [2] as a result of anthropogenic activities. MPAs can guarantee protection to this species. Knowledge on essential habitats and spatial distribution for this species is therefore fundamental to promote proper management strategies. Therefore, the aims of the present study are (i) to study density of *P. nobilis* across different habitats in the MPA, and (ii) create a spatial distribution model of *P. nobilis* densities within the MPA Cabrera National Park.

Materials and methods
The study was carried out at the marine protected area (MPA) of Cabrera National Park in the Balearic Islands (W Mediterranean), protected since 1991. A total of 378 visual census were conducted by scuba diving in line transects to survey *P. nobilis* density in all habitats at depths ranging from 4.2 to 50 meters. A total of 1456 *P. nobilis* individuals were censed. The field survey was carried out at the end of July 2011 and July 2012. We used regression kriging (RK) to predict the spatial distribution of *P. nobilis* densities within the MPA. This approach combines the results of a generalized linear model (GLM) with an autocorrelation map of the residuals calculated with ordinary kriging. The GLM was calculated using different environmental variables (ie., depth, slope, habitat, wave exposure and zoning protection) as explanatory variables and using the AIC criterion for model section.

Results and Discussion
P. nobilis maximum densities were found in *P. oceanica* meadows reaching values up to 37.3 ind/100m^2 in a no-take MPA sheltered site (Santa Maria bay at 8 m depth) (Fig. 1). The prediction map showed that the species is present in the whole MPA up to 50 meters depth, and highlights the presence of some hotspots within the MPA (Fig. 2). A map of the spatial distribution of *P. nobilis*, accompanied with knowledge of its population ecology, provides useful information for the management and monitoring of this endangered species in the MPA.

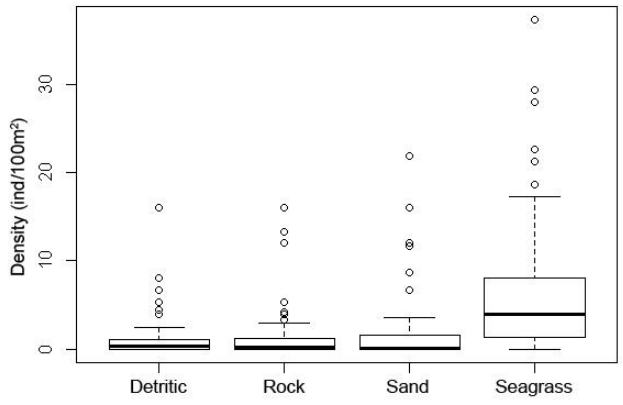

Fig. 1. Box plot of *P. nobilis* density (ind/100m^2) in Cabrera National Park for the different studied habitats. Whiskers: standard error; dots: outliers.

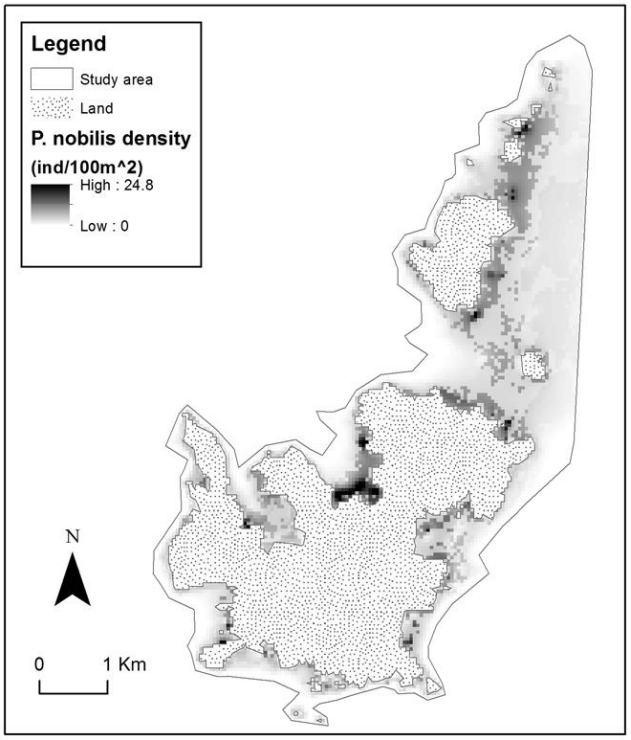

Fig. 2. Prediction map of *P. nobilis* densities within Cabrera National Park MPA.

FEUILLE DE ROUTE POUR AMÉLIORER D'ICI 2020 LE RÉSEAU D'AIRES MARINES PROTÉGÉES EN MÉDITERRANÉE

Marie Romani [1] and Chloë Webster [1]*
[1] Mediterranean Protected Areas Network (MedPAN) - chloe.webster@medpan.org

Abstract
MedPAN, en collaboration avec le CAR/ASP, a développé une base de données des AMP en Méditerranée sur la base d'enquêtes auprès des gestionnaires des sites. Ainsi, une analyse de la distribution géographique des AMP, de leur représentativité, de leur connectivité et de leur niveau de gestion a été menée en 2012 pour identifier les points clés à améliorer au sein du réseau d'AMP dans les années à venir. Ces recommandations ont été détaillées sous forme d'une feuille de route d'ici 2020 élaborée lors du Forum des AMP de Méditerranée qui a rassemblé plus de 300 participants d'une trentaine de pays (scientifiques, gestionnaires, décideurs nationaux et méditerranéens, secteur privé, société civile…).

Keywords: Marine parks, North-Eastern Mediterranean, North-Western Mediterranean, South-Eastern Mediterranean, South-Western Mediterranean

L'inventaire des Aires Marines Protégées (AMP) méditerranéennes, dans la base de données MAPAMED développée par MedPAN et le CAR/ASP, a permis de recenser et de géolocaliser 677 AMP.

Fig. 1. Carte des AMP en Méditerranée

Parmi ces AMP, figurent 161 AMP de statut national, 9 AMP de statut uniquement international et 507 sites Natura 2000 marins. De plus, 55 AMP sont en projet. Ces AMP couvrent une surface totale de près de 114 600 km², soit environ 4,56% de la Méditerranée et 1,08% si l'on exclut le Sanctuaire Pelagos (87 500 km²). 96% des AMP sont localisées dans le Nord du bassin. Les AMP sont essentiellement côtières. Le « bassin algéro-provençal» et la « mer Tyrrhénienne » sont les écorégions les mieux représentées. L'analyse montre que les étages infralittoral et circalittoral sont les mieux représentés dans le système d'AMP qui par ailleurs n'est que très faiblement représentatif des habitats benthiques profonds. *Pinna nobilis, Posidonia oceanica, Tursiops truncatus, Caretta caretta* et *Epinephelus marginatus* sont les espèces les plus fréquemment mentionnées par les gestionnaires d'AMP comme présente dans leur site. La diversité de taille des AMP est grande, la plus petite couvre 0,003 km² et la plus grande (sans compter le sanctuaire Pelagos) couvre environ 4 000 km². 66% des AMP font moins de 50 km². Plus de la moitié des AMP ont plus de 10 ans. L'analyse a ensuite porté sur un panel de 80 AMP. Si plus de 90% des AMP de statut national ont un gestionnaire, 75% des sites Natura 2000 n'en ont pas et 56% d'AMP n'ont toujours pas de plan de gestion. En revanche 70% des AMP ont des états de référence écologique et 80% mènent des suivis réguliers. 84% des AMP indiquent avoir du personnel permanent. Si un quart des AMP a déclaré avoir du personnel assermenté, la plupart d'entre elles s'appuient pour la surveillance sur d'autres partenaires. La part d'autofinancement concerne 36% des AMP.

Lors du Forum organisé à Antalya (Turquie, 25-28 novembre 2012), les acteurs clés des AMP en Méditerranée ont analysé la situation des AMP méditerranéennes et ont identifié les actions nécessaires afin d'établir un réseau écologique d'AMP qui soit efficacement et durablement géré. Ils ont élaboré une feuille de route appelant à une action urgente et visant à atteindre, d'ici 2020, les objectifs établis dans le cadre des engagements internationaux. La vision commune adoptée par l'ensemble des participants est la suivante :
« Mettre en place en Méditerranée, d'ici 2020, un réseau d'aires marines protégées connectées, écologiquement représentatif, géré et suivi de manière efficace, pour assurer la conservation à long terme des éléments clés de la biodiversité marine et soutenir le développement durable de la région de manière significative. » 4 objectifs stratégiques ont été définis ainsi que des actions à mener au niveau local, national et méditerranéen :

1- Mettre en place un réseau écologique d'AMP représentatif et connecté
- les écosystèmes marins sous-représentés identifiés (dans les aires au-delà des juridictions nationales)
- améliorer la qualité et la couverture spatiale des inventaires et des suivis écologiques et des usages
- Une méthodologie devra clarifier à l'échelle régionale la définition de la connectivité, et de la représentativité
- maintenir des bases de données d'AMP nationales et régionales

2- Instaurer une gestion effective, efficace et durable ainsi qu'une bonne gouvernance dans les AMP
- Les systèmes de gestion (y compris les réserves de pêche), devraient être évalués
- une simplification des cadres institutionnels appliqués aux AMP et application des règlementations
- Les AMP de Méditerranée devront mettre en œuvre et actualiser des plans de gestion et d'affaires
- des programmes de sensibilisation, d'échange d'expérience et de renforcement des capacités

3- Développer une gouvernance des AMP Méditerranéenne qui soit intégrée sur le plan territorial et avec les autres secteurs tout en favorisant le partage des bénéfices environnementaux et socio-économiques
- meilleure intégration de l'AMP dans le territoire adjacent
- synergies avec d'autres secteurs (pêche, gestion des bassins versants, surveillance en mer, tourisme, …)
- valoriser les bénéfices pour les communautés locales
- Les approches de l'économie des écosystèmes et de la biodiversité (TEEB) doivent être développées
- tester des politiques « vertes » et des démarches d'« économie bleue »

4- Renforcer les ressources financières pour pérenniser le réseau d'AMP
- l'analyse des besoins financiers des AMP et l'évaluation des systèmes de financement
- renforcer les cadres institutionnels pour améliorer le financement des AMP
- De nouveaux mécanismes de financement durables devront être identifiés et testés

Abstract
Dans le but de valoriser et diversifier les bio ressources exploitables des côtes tunisiennes, 2 espèces d'Holothuries *H. tubulosa* et *H. polii* récoltées dans les franges littorales de Bizerte, Nabeul et au golfe de Tunis ont servi à l'étude de la composition physico-chimique de ces échinodermes. Leur teneur en oligo-éléments a montré respectivement une quantité appréciable en oligo-éléments notamment le calcium. Quant à leur composition en acides gras, et bien que ces espèces ont présenté des teneurs faibles en lipides, elles présentent toutefois un intérêt nutritionnel non négligeable vu leurs teneurs intéressantes en oméga 3.

Keywords: Analytical methods, Calcium, Echinodermata, Tunisian Plateau

Introduction Face aux multiples menaces auxquelles font face les bio-ressources marines comme la surpêche, la pollution, l'érosion de la diversité biologique et le changement global, la valorisation et l'exploitation rationnelle de nouvelles ressources s'imposent. Ainsi, les campagnes de prospections réalisées suggèrent que les rendements horaires de rejets benthiques de la région septentrionale de la Tunisie comprennent jusqu'à 3,3 kg d'échinodermes, principalement des holothuries. Malgré cette richesse, et vu le peu de travaux traitant la qualité nutritionnelle de ces produits de rebus [1] nous nous sommes intéressé dans ce travail à l'analyse des teneurs en oligo-éléments et en acides gras essentiels. **Matériel et méthodes** Les Holothuries étudiées proviennent des régions côtières de Nabeul, Bizerte et du golfe de Tunis. Trois cent individus ont été prélevés vivants par plongée à une profondeur d'environ 7 mètres durant la période allant de septembre 2010 jusqu'à août 2011. Après identification [2] et [3], les Holothuries ont été éviscérées, puis les spécimens conservés à –20°C jusqu'à leur étude. Chaque analyse a été répétée trois fois. Le dosage des protéines a été réalisé selon la norme ISO 937 [4]. Le dosage des cendres a été réalisé selon la norme NFV04-404 [5] par incinération à 550°C. La matière sèche [6] a été déterminée à 103°C ± 2°C. Le dosage des minéraux a été effectué selon la norme NT 76.30. [7] par spectrophotométrie d'absorption atomique. L'extraction des lipides totaux a été réalisée selon la méthode de Bligh et Dyer [8] et l'analyse des acides gras par chromatographie en phase gazeuse (CPG). **Résultats et discussion** L'étude taxonomique a permis de montrer que les 300 individus récoltés appartiennent aux espèces *H. tubulosa (*20%) et *H. polii* (80%). Toutes les analyses statistiques ont montré une différence significative quant à la composition physico-chimique de ces deux espèces d'holothuries ($p<0,005$). En effet, elles sont riches en eau et présentent les teneurs respectives de 89,12±1,07 et 83,87±1,05%. Concernant les teneurs respectives en protéines elles correspondent à 10,56±0,54 et 9,1±0,37 g/100 g. Les teneurs en minéraux ont montré que le calcium est l'élément dominant (91,02±2,25 pour *H. polii* et 85,63±0,9 mg/100 g pour *H. tubulosa)* (tableau 1). En plus, elles présentent des teneurs très intéressantes en cuivre, fer et en zinc.

Tab. 1. Composition en minéraux de *H. polii et H. tubulosa* (mg/100 g).

	P	K	Na	Ca	Mg	Cu	Zn	Fe
Holothuria polii	112,87 ±0,23	224,70 ±0,53	47,44 ±0,62	91,28 ±0,25	32,39 ±0,54	38,98 ±0,2	36,37 ±0,6	6,66 ±0,1
Holothuria tubulosa	101,59 ±0,53	202,08 ±0,48	34,32 ±0,3	85,63 ±0,9	18,39 ±0,42	25,60 ±0,3	19,59 ±0,5	6,20 ±0,1

L'analyse des acides gras montre une richesse en AG saturés avec des pourcentages de 32,34% et 42,11% contre 14,49% et 23,29% pour les AG poly insaturés respectivement chez *H. tubulosa* et chez *H. polii* avec une prédominance de l'oméga 3 (figure1).

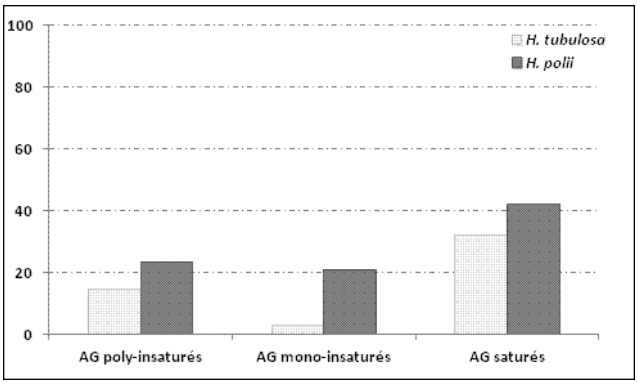

Fig. 1. Composition en acides gras (%) de *H. polii et H. tubulosa*

Conclusion : La caractérisation physico-chimique a révélé qu'*H. polii* et *H. tubulosa* sont riches en éléments minéraux caractéristiques en particulier le calcium et enacides gras intéressants en particulier l'oméga 3 à des teneurs appréciables. Malgré cette richesse nutritionnelle, les holothuries restent toutefois, jusqu'à nos jours, en Tunisie, comme des rejets benthiques non valorisés.

Abstract

Le présent travail a pour but de caractériser, par l'approche biochimique trois espèces de sparidés (*Diplodus annularis, Diplodus vulgaris et Diplodus puntazzo*) provenant du Golfe de Tunis. Les résultats ont montré que la teneur en matière grasse de la chair de ces trois espèces de sparidés varie de 2,25±0,6329 *à* 2,6994±0,4115 g/100g matière fraîche (MF). Les différences entre les taux de lipides de ces 3 espèces restent non significatives ($p<0.001$). Les résultats ont montré aussi que ces poissons sont riches en acides gras polyinsaturés essentiellement pour *Diplodus annularis et Diplodus vulgaris*, avec 44.42 % et 39.37 % d'AGPI de la famille des ω3. Cette étude a permis d'affirmer qu'il ya un rapprochement dans les profils lipidiques *de Diplodus annularis et Diplodus vulgaris* par rapport au profil de *Diplodus puntazzo.*

Keywords: Fishes, Chemical analysis, Fisheries, Tunisian Plateau

Introduction

En Tunisie,la famille des Sparidés est considéréé parmi les ressources halieutiques qui présentent un potentiel économique considérable. Parmi les représentants de cette famille, on cite les espèces du genre *Diplodus* comme *Diplodus annularis*, *Diplodus vulgaris* et *Diplodus puntazzo* dont peu d'études ont ciblé leur composition lipidique.

Matériel et Méthodes

L'extraction des lipides a été réalisée selon la méthode de Folch *et al.,* (1957) modifiée par Bligh et Dyer (1959). La méthylation des acides gras a été effectuée selon la méthode de Cecchi *et al.,* (1985). les esters méthylique sont séparés par chromatographie en phase gazuse.

Résultats et Discussion

Dans la présente étude les trois lots de sparidés ont été échantillonnés à partir de même site (Golfe de Tunis) et à des dates qui sont hors de leurs périodes de reproduction. Les résultats montrent que la teneur en matière grasse des chairs de ces trois espèces de sparidés varie de 2,25±0,6329 chez *Diplodus puntazzo* (DP) à 2,6994±0,4115 exprimés en g/100g matière fraîche (MF) chez *Diplodus vulgaris* (DV) (tableau1).

Tab. 1. Variation de la composition en lipides dans la chair

ESP	LS (cm)	PV (g)	QUT.LIP.100g CH g
DA	10,41± 1,762	32,15±8,28	2,49±0,5718
DV	13,41±0,374	51,055±5,52	2,6994±0,4115
DP	10,35±0,4375	37,28±3,27	2,25±0,6329

Ces teneurs sont caractéristiques des poissons semi-gras (entre 2 et 10%) qui accumulent leurs graisses dans le foie mais aussi dans leurs muscles et dans d'autres tissus tels que le tissu adipeux péri viscéral [1], elles sont relativement basses à cause de la saison de capture (hors de la période de reproduction). D'une manière générale, la composition biochimique des poissons varie essentiellement en fonction de l'espèce, la saison, la période de ponte et l'alimentation [2], [3], [4]. Selon les analyses effectuées par la chromatographie en phase gazeuse, une vingtaine d'acides gras ont été identifiés dans les lipides totaux de la chair des sparidés. Les compositions en acides gras de ces extraits lipidiques sont en accord avec les compositions présentées dans d'autres études sur d'autre espèce de poissons [5], [6]. Le profil lipidique des AG de ces trois espèces de sparidés, révèle que la fraction des AG saturés (A.G.S.) est la plus dominante chez *Diplodus puntazzo* avec des proportions de 47.54 ±0.68%. L'acide gras le plus dominant des AGT est l'acide palmitique (C16:0) avec des proportions élevées chez *Diplodus puntazzo* de 32.97 ±0.42 %, et de façon moins importante chez *Diplodus annularis* et *Diplodus vulgaris* (14.28 ±0.10% et 16.95 ±0.01 %). Cependant, les acides gras polyinsaturés AGPI présentent les taux les plus dominants chez *Diplodus vulgaris* (*DV*) et *Diplodus annularis* (*DA*). Le taux d'AGPI est évalué à environ 47.36 ±0.01 % et 52.11 ±0.10 respectivement pour les deux espèces, tandis que le taux le plus bas est de l'ordre de 23.14 ±0.68 % pour *Diplodus puntazzo* (*DP*). Ce sont essentiellement des AG de la famille des omega 3 et omega 6. Il s'agit de l'acide docosahexaénoïque DHA C22:6 n-3, l'acide éicosapentaénoïque EPA C20:5 n-3 et l'acide linoléique C18:2 n-6. Le taux de l'acide éicosapentaénoique EPA C20:5 n-3 des sparidés *DA* et *DV* sont les plus élevés par rapport aux taux de l'espèce *DP* (respectivement 14. 77 ±0.01 %, 11.22 ±0.02 % et 6.83±0.12). Pour l'acide docosahexaénoique (DHA) C 22:6 n-3, on remarque son abondance chez les deux populations de sparidés. Le taux le plus élevé est pour *DA* et *DV* 26.51 ±0.08 % et 26.23 ±0.14 %. Toutefois, pour *DP* la proportion ne dépasse pas les 7.48± 0.37%. Les teneurs d'EPA et de DHA sont dues essentiellement à leur abondance dans la chaîne alimentaire marine. Toutefois, le rapport EPA/DHA est considéré parmi les meilleurs critères d'évaluation de la qualité des AG. L'étude du rapport A.G.P.I.-ω3/A.G.P.I.-ω6 révèle une teneur supérieure chez les *Diplodus annularis* (7.40) et *Diplodus vulgaris* (6.09).

La forte teneur en A.G.P.I.-ω3 des *DA* et *DV* du large peut être expliquée par l'accumulation des acides gras de la famille des ω3 et /ou une tendance à l'utilisation des acides gras ω6.

Abstract

The effects of the seasonal on the proximate and fatty acid compositions of male and female warty crab from Black Sea were investigated. Important differences were found in proximate and fatty acid compositions for all seasons and gender. There were variations in protein and water content of meat of female and male crabs ($p<0.05$). The results of fatty acid analyses showed that the dominant SFAs were palmitic acid (C16:0) and stearic acid (C18:0). MUFAs in all samples consisted of C16:1, C18:1*n*9, C18:1*n*7, C20:1, C22:1n9. EPA (C20:5*n*3) and DHA (C22:6*n*3) were the main PUFAs in crab meat. The results obtained from the study showed that male and female crab meat is an important fatty acid and protein source.

Keywords: Crustacea, Black Sea

Introduction

Seafood, including crustacean shellfish, is recommended for human diet due to their health-promoting characteristics [1]. In terms of the amount of fat and the proportions of saturated, monounsaturated, and polyunsaturated fat, shellfish provide a healthful diet for humans [2]. Especially, seafood lipids have rich EPA and DHA. These fatty acids have a variety of health benefits, including prevention of sudden cardiac death [3] and chemo preventive effects of cancer [4]. *Eriphia verrucosa*, also called the warty crab, is found in the Black Sea, Mediterranean Sea and eastern Atlantic Ocean from Brittany to Mauritania and the Azores. *E. verrucosa* lives among stones and seaweeds in shallow water along rocky coastlines up to a depth of 15 metres. It is reported to feed on bivalves, gastropods and hermit crabs, or on molluscs and polychaetes. In the Black Sea, *E. verrucosa* is the only native species, capable of breaking into the shells of the invasive snail *Rapana venosa*. The objective of this study was to determine the effects of season and gender on the fatty acid and proximate compositions of warty crab from the Black Sea.

Materials and methods

The crabs were collected as discard products from artisanal fishery (gillnets and trammel nets) and by scuba divers, located in the coast of the Central Black sea of Turkey every season during January and Decembers in 2011 and transported immediately to the laboratory. Claw and body meat were separated manually and analysed in triplicate in terms of fatty acid and proximate composition. Lipid content was measured by the method of Bligh & Dyer [5]. Ash and moisture contents were determined as described by AOAC [6] and protein was determined by the Kjeldahl procedure using a Buchi Digestion System, Model K-424 (BÜCHI Labortechnic AG, Flawil, Switzerland) and a Kjeltec Distillation Unit B-324 (BÜCHI Labortechnic AG). Percent protein was calculated as % Nx6.25. Methyl esters were prepared by transmethylation using 2 M KOH in methanol and *n*-hexane according to the method described by Ichihara et al [7] with minor modification; 10 mg of extracted oil were dissolved in 2 ml hexane, followed by 4 ml of 2 M methanolic KOH. The tube was then vortexed for 2 min at room temperature. After centrifugation at 4000 rpm for 10 min, the hexane layer was taken for GC analyses.

Gas chromatographic conditions

The fatty acid composition was analysed by a GC Clarus 500 with autosampler (Perkin–Elmer, USA) equipped with a flame ionization detector and a fused silica capillary SGE column (30m×0.32mm ID×0.25µm BP20 0.25 UM, USA). The oven temperature was 140ºC, held 5 min, rose to 200ºC at the rate 4ºC/min and held at 220ºC at 1ºC/min, while the injector and the detector temperatures were set at 220 and 280ºC, respectively. The sample size was 1µl and the carrier gas was controlled at 16ps. The split used was 1:50. Fatty acids were identified by comparing the retention times of FAME with the standard 37 component FAME mixture. Two replicate GC analyses were performed and the results were expressed in GC area % as mean values±standard deviation.

Results and discussion

The fat and fatty acid compositions of seafood can vary depending on species, diet, gender, location and season of capture [8,9]. Tsai et al. [10] reported that the total lipid concentrations of blue crab were significantly correlated in gender. Akbar et al. [11] found that the protein content of body meat and claw meat in swim crabs vary, and protein is slightly higher in the edible portion of male crabs than female crabs. In this research, the dominant SFAs were palmitic acid (C16:0) and stearic acid (C18:0). MUFAs in all samples consisted of C16:1, C18:1*n*9, C18:1*n*7, C20:1, C22:1*n*9. EPA (C20:5*n*3) and DHA (C22:6*n*3) were the main PUFAs in crab meat. The results obtained from the study showed that male and female crab meat is an important fatty acid and protein source.

BODY SIZE-WEIGHT RELATIONSHIP, LIPID AND DEFATTED DRY SUBSTANCE CONTENT OF HEPATOPANCREAS IN SQUID *TODARODES SAGITATUS* FROM THE EASTERN MEDITERRANEAN

A. E. Kideys [1], E. Mutlu [1], G. Abolmasova [2], G. Shulman [2], T. Yuneva [2], A. Shchepkina [2] and I. Öztürk [1]*

[2] Institute of Biology for the Southern Seas

Abstract
Some biological characteristics of the European flying squid (*Todarodes sagittatus)* that could be a potential source for the Turkish fishery were studied in the area between off Finike and Rhodes Island, in the northern Levantine Basin of the Mediterranean Sea in October 2000. The study focused mainly on nutritional condition and basic morphological measurements of the squid. Maximum mantle length and wet weight were measured as 40 cm and 2 kg. Stomach content analysis showed that the squid fed on euphausiids, young squids and different species of myctophid fish.

Keywords: North-Eastern Mediterranean, Fisheries, Population Dynamics

Introduction
Despite the fact that the European flying squid (*Todarodes sagittatus*) is the most abundant squid in the Mediterranean, surprisingly, until this study it was never reported from the Turkish waters (1). The region between Rhodes Island and south-western coast of Turkey may become the possible places of squid fishery as this region is known to have good nutritive base due to cyclonic gyre and banks (2) Therefore, the data regarding the biology and morphology of this squid could be of off great importance from the fishery perspective.

Materials and methods
The squid *Todarodes sagittatus* was sampled from a total of eight stations on board the R/V Bilim in October 2000 during the cruise to the eastern Mediterranean. These stations were mainly located around Rhodes cyclonic gyre and also in close distance to the southwestern Anatolia (Off Finike, Turkey). Squids were attracted by light and caught by the "Jiger" mainly during nighttime at these stations. A total of 73 squids caught were weighted to the nearest gram and then their mantle lengths were measured. Determination of sex and stage of gonad development was individually performed for each squid. Additionally, stomachs and hepatopancreases were weighed and stomach-somatic index (SSI) and hepato-somatic index (HSI) were calculated. Subsamples of hepatopancreases were used for determining of dry weight, lipid and defatted dry weight content later at the laboratory (3).

Results
Most squids were caught at stations near to Finike. The maximal length of the squid mantle was about 40 cm weighing 2 kg. These parameters have sex differences: the most of females were bigger than males. Size-weight relations for all examined squids, males and females show a high correlation between length and weight (r^2=0.90-0.98). All individuals were immature males and females (second stage of maturity). There are also close relationships between body (mantle) size of all squids and hepatopancreas weight, their lipid and defatted dry matter content. Positive relationship between hepatopancreas dry weight (% per wet weight) from one side, lipid and defatted dry weight of this organ (%, per wet weight) from another are revealed. Stomach somatic (SSI) and hepato somatic (HIS) indexes were unrelated with size of squids. With two exceptions, the SSI did not exceed 2%; but HIS presented a higher variation with a mean of 2.87±0.88 and CV=35%. All animals fed well and residues of euphausiids, young squids of the same and another species, different species of myctophids etc were founded in stomach content.

Discussion
We did not observed these squids during the cruise all the way from Dardanelles to the Rhodes in the Aegean Sea. However, all stations located in the region between the south of Rhodes and Finike had *T. sagittatus*. According to number of squids caught by "Jigers" the most abundant region for squids in our cruise was the area off Finike, southwestern Turkey. The size and weight of animals in this region were higher than in neighbouring regions. Unfortunately we have no data to allow the estimation of the condition of squids in different regions and their relation with fodder base but further investigations may give positive results for such estimations. Lordan et al (4) found a length-weight relationship of $w = 1.5E\text{-}06L^{3.4721}$ for the same squid where w is wet weight in g and L is dorsal mantle length (mm). They also showed that stomach content of the squid contained 82.1% of fishes including Myctophids, 12.96% of Cephalopoda composed of squids including small specimens of *T. sagittatus*, 4.94% of Crustacea (euphausids). This show that despite the great distance in areas studied by Lordan et al. and us, the food composition are similar in both regions (i.e. northeastern Atlantic and eastern Mediterranean). Results from this preliminary study show that the European flying squid could have a significant potential for fishery and therefore, its stock characteristics need to be evaluated with further studies.

Abstract
The impact of the acclimation to freshwater on the energy metabolism of gills, kidney, liver, and muscle was assessed in *Chelon labrosus*. We found that the exposure to low salinity during 30 days induces significant changes in the fatty acids profiles of all studied organs. However, we noticed that these variations depend on organs and fatty acid types. In the gill and the liver, saturated and monounsaturated fatty acids increased nevertheless polyunsaturated fatty acids remained invariable. Antagonist tendency were recorded in the kidney and the muscle.

Keywords: Aquaculture, South-Western Mediterranean

Introduction
Euryhaline fish shows several metabolic changes and mobilizes large amounts of energy to compensate environmental salinity changes [1]**.** The thick lipped grey mullet *Chelon labrosus* is euryhaline and eurytherme species that can live in environments of different salinities and temperatures: coastal waters, estuaries [2]. In Tunisia, this fish is commonly captured and consumed by the local population. According to [3], the thick lipped grey mullet (*Chelon labrosus*) is useful for semi intensive aquaculture.The purpose of the present study is to assess the impact of acclimation of *C.labrosus* to hypo-osmotic environments on the lipid metabolism of different tissues simultaneously.

Materials and methods
Immature thick lipped grey mullet (*Chelon labrosus*) (30–40g body mass) were provided by an experimental fish culturing centre (INSTM- Centre de Monastir- Tunisia) and transferred to the laboratory at the faculty of sciences of Tunis (El Manar- Tunis). They were acclimated during 30 days in freshwater (5 ppt). Total lipids were extracted with chloroform: methanol (2:1, v/v)) using the method of Folch [4]. Fatty acids were methylated according to the method of Cecchi [5]. Fatty acid methyl esters (FAMEs) were then analyzed by capillary gas chromatography. Data were analysed for significant difference of means, ANOVA, and inspected by Duncan test at level of $p < 0.05$.

Results and discussion
Results showed that low salinity induces the mobilization of lipids in the different studied organs. At fatty acid scale, a total of 29 fatty acids ranged from C14:0 to C22:6ω3 was identified. Results showed that qualitatively, the fatty acid composition were similar in gill, kidney, liver and muscle. However, we observed a differentiated mobilization of fatty acids groups across tissues. In fact, under hyposmotic stress, saturated fatty acids (SFAs) and monounsaturated fatty acid (MUFAs) increased nevertheless polyunsaturated fatty acids (PUFAs) remained invariable in the gill and the liver. In the kidney and the muscle, we noticed that PUFAs increase while the SFAs and MUFAs tend to decrease. *Chelon.labrosus* organs acclimated in freshwater were dominated by the fatty acids C16:0, C16:1, C18:0, C18:1, C18:2n-6, C22:6n-3 and C20: 5n-3. These fatty acids are typically the most quantitatively important fatty acids present in fish although there are slight differences in their order of abundance. The increase in saturated fatty acids (SFAs) and monounsaturated fatty acid (MUFAs) fatty acids in liver and gill could be related with their importance as energy source. Meanwhile the increase of PUFA in kidney and muscle transferred in freshwater particulary DHA and EPA may show that *C .labrosus* tended to mobilize these fatty acids to increase the fluidity of the membrane.

Tab. 1. Organs fatty acid composition (% total lipids) of *C. labrosus* during acclimation to freshwater (5‰) and after a period of 30 days at this salinity.

Abstract
Dans le présent travail, nous avons étudié la variation saisonnière de la composition en acides gras de la seiche commune *Sepia officinalis* appartenant à la famille des Sepiidae et qui fréquente les côtes tunisiennes. Les analyses des acides gras totaux nous ont permis d'identifier pour les deux sexes et durant les quatre saisons, des acides gras saturés, monoinsaturés et polyinsaturés qui varient respectivement entre35,6- 56,68%, 9,03-13,29% et 33,1-54,5%.Les concentrations des acides gras polyinsaturés sont significativement élevées en automne par rapport a l'été, le cas contraire est observé pour les acides saturés.

Keywords: Cephalopods, Gulf of Tunis

Introduction
Les produits de la mer jouent un rôle important dans la nutrition humaine. La baisse enregistrée dans les ressources mondiales halieutiques a favorisé le recours aux céphalopodes ; consommés principalement dans les pays méditerranéens et asiatiques vue leur abondance dans ces régions [1]. En Tunisie, la production des céphalopodes est destinée en grande partie à l'exportation avec 9800 Tonnes en 2011 (65 % de la production est représentée par la seiche commune *Sepia officinalis*) [2]. Comme les autres produits de mer, la qualité nutritionnelle des seiches varie selon les caractéristiques du milieu environnant. Ces dernières présentent des fluctuations saisonnières qui sont à l'origine des changements dans la composition biochimique des organismes marins. Dans ce contexte, nous nous sommes intéressés à l'étude de la qualité lipidique de *Sepia officinalis* en fonction des saisons afin de déterminer la période optimale de consommation et de prélèvement pour une meilleure conservation.

Matériel et méthodes
Les analyses ont été effectuées sur des spécimens récoltés par prise côtière artisanale, avec 12 échantillons (6 mâles et 6 femelles) durant chaque saison. Les lipides totaux ont été extraits par un mélange de solvants chloroforme méthanol (2/1) selon la méthode de Folch et al. [3], après méthylation, les esters méthyliques ont été analysés par chromatographie en phase gazeuse (HP 6890). Pour les analyses statistiques nous avons utilisé un logiciel : Statistica 6.0 (ANOVA- MANOVA).

Résultats et discussion
L'analyse statistique de la teneur en lipides totaux révèle que les variations saisonnières sont non significatives ($p<0,05$). L'analyse des acides gras révèlent que les pourcentages des AGS, des AGMI et des AGPI varient, respectivement, entre 34,7 - 56,7 %, 9,03 - 13,3 % et 33,1 - 54,5 %. Les AGS ont présenté des teneurs faibles en automne et en hiver. Cela est dû probablement au catabolisme de ces derniers afin de compenser l'énergie métabolique perdue. La teneur en AGPI contrairement à celle des AGS a présenté une élévation en automne et une baisse en été. En effet, Les variations saisonnières en AG sont dues à plusieurs facteurs ; la diminution de la température induit une diminution de la teneur en AGS et une augmentation de la teneur en AGPI pour assurer la fluidité de la membrane cellulaire [4] ; le régime alimentaire qui est basé principalement sur des poissons durant la migration vers les profondeurs en automneet le cycle reproducteur[5]. Les principaux acides gras révélèssont : l'acide palmitique (16:0), l'acide stéarique (18:0), l'acide eicosapentaénoïque (EPA 20:5n-3) et l'acide docosahexaénoïque (DHA 22:6n-3) avec des variations selon le sexe et particulièrement des teneurs plus élevées chez la femelle durant toutes les saisons.

Abstract
This study provide the assessment of the nutritional value of the fatty acids components and their health-related lipid indices in the fillet of the wild, the inshore and the offshore farmed sea bream *Sparus aurata* from Tunisian costs. The docosahexaenoic acid (DHA) content and the values of some indicators of the nutritional quality of lipids as the n-3/n-6 ratio, the thrombogenicity (TI) and the Atherogenicity (AI) indices show slightly higher nutritional value of farmed (mainly the inshore reared specimens) vs. wild gilthead.

Keywords: Aquaculture, Tunisian Plateau, Fishes, Physiology

Introduction
Fish constitute an excellent source of highly unsaturated fatty acids considered beneficial for human health [1]. In the Mediterranean countries, marine fish represent an important part of the diet. The gilthead sea bream (*Sparus aurata*) is among the most commonly farmed marine species in the Mediterranean Sea. This species is produced using a large variety of aquaculture facilities and techniques. This study seeks to establish a comparative analysis of the fatty acid profiles and flesh lipid quality in wild, inshore and offshore breeding of the fillet of the sea bream *S. aurata*.

Material and methods
Wild and farmed (N=60) sea bream *S. aurata* of average weight of 61.9 ± 2.5 g and total length of 15.6 ± 1.1 cm were analyzed. Wild specimens were picked up from a local market in Monastir region. The offshore farmed gilthead sea bream came from the intensive culture in floating cages from "The RESPUNA FISH" Company in Monastir and the inshore reared individuals were obtained from "The Station of Tunisian Aquaculture" located in Hergla (Sousse, Tunisia). Total lipids were extracted according to the method of Folch [2]. Lipid extracts were trans-esterified according to [3]. The fatty acid methyl esters were analyzed by capillary gas chromatography. Data was analyzed using the software R Version 2.1.2.1. according to the One Way Analysis of Variance method (ANOVA). Duncan test was applied and differences were considered significant when $p<0.05$.

Results and discussion
The fatty acid composition of the fillet of the wild, the offshore and the inshore farmed *S. aurata* are represented in table 1. Data revels that within the group of main fatty acids identified, the total content of saturated fatty acid (SFA), monounsaturated fatty acid (MUFA) and polyunsaturated fatty acid (PUFA) was alike in the three studied groups ($p>0.05$). However, lipids of the inshore farmed *S. aurata* were characterized by slightly high percentage ($p>0.05$) of PUFAs with 46.28%. Within this fatty acid group, farmed specimens (mainly the inshore reared specimens) are characterized by a higher levels of n-3 series and mainly the DHA ($p<0.05$). Results revealed that farmed specimens exhibit a higher n-3/n-6 ratio as a consequence of their lower content of n-6 fatty acids. As to PUFA/SFA ratio, we noted that all studied *S. aurata* groups show similar values ranging from 1.4 to 1.8. The recorded values were much higher than the minimum recommended value of 0.45, which is considered as appropriate for human diet [4].Concerning the AI and the TI indices, we noted that all studied *S. aurata* groups show similar values ($p>0.05$). The low values of AI and the very low TI reveal a very interesting nutritional quality as well of reared gilthead as compared to the wild ones.

Abstract
Distribution, length composition, CPUE (kg/h), biomass (kg/km^2) indices and growth parameters of *Nephrops norvegicus* from Saros Bay (North Aegean Sea) were determined. Monthly samples were collected (2554 specimens) by bottom trawl from the depth interval 20-500 m, in the period of June 2005-July 2008. Minimum carapace length 21 mm in females, 23 mm in males and maximum carapace length 59 mm in females, 72 mm in males were detected. The mean CPUE, biomass and catch rate were calculated 10.58 kg/h, 186.65 kg/km^2 and 3.8% respectively. Growth parameters estimated using the ELEFAN program as L_∞=81.9 mm (CL), K=0.07 year^{-1}. Length-weight relationship was determined W=0.0004*L$^{3.13}$

Keywords: Biomass, Saros Bay, Crustacea, Growth, Population Dynamics

Introduction
The Norway lobster, *Nephrops norvegicus* is one of the main target species of the commercial fisheries in the Mediterranean continental shelf and have been the subject of important biological and fishery studies [1], [2]. *Nephrops norvegicus* is a sedentary lobster which inhabits burrows constructed in muddy subtrates throughout the continental shelf of the north-eastern Atlantic and Mediterranean [2].

Material and Methods
Samples were collected by a commercial bottom trawl net with a cod end stretched mesh size of 22 mm, at monthly sampling intervals from June 2005 to July 2008 at the range of 20-500 m depths, and there were 184 sampling station (Figure 1). Though, *Nephrops norvegicus* specimens were caught from the depth range of 200-500 m, trawl duration was restricted to 30 min and the vessel speed was kept constant at 2.5 knots during hauling. CPUE was calculated for 1 hour, biomass was estimated using the swept area method [3]. Total and carapace lengths were measured to the nearest 0.01 mm with a caliper. Total weight was measured to the nearest 0.01 g. Length – weight relationship were calculated W=0.0004*L$^{3.13}$.The length data were also used for the direct estimation of growth parameters, applying ELEFAN I [4] implemented by the FISAT package [5].

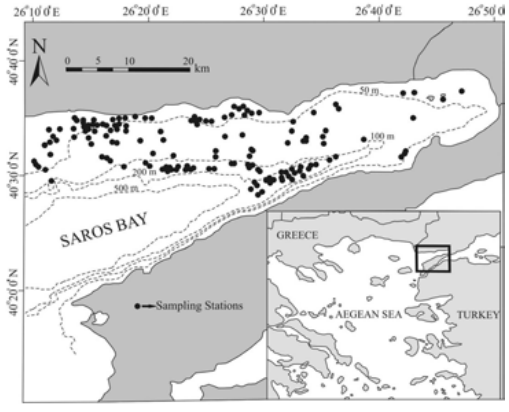

Fig. 1. Sampling stations of Norway lobster in the Saros Bay.

Result and Discussion
In this study, a total of 2554 Norway lobster were sampled. Minimum carapace length 21 mm in females, 23 mm in males and maximum carapace length 59 mm in females, 72 mm in males were determined. The mean CL of females were measured 38 (±0.18) mm and 42 (±0.26) mm for males. Significant differences in the mean carapace length and total length were identified between seasons ($p<0,05$). Von Bertalanffy growth parameters estimated using the ELEFAN program and calculated L_∞=81.9 mm (CL), K=0.07 year^{-1}. That was similar to the other studies [5]. The CPUE, biomass values and frequency of individuals were calculated in all seasons in Saros Bay (Table 1). The specimens were located only in the 200-500 m, and highly CPUE and biomass values between spring and summer period of the years. The reason for this might be the molting period of the Norway lobster which occur autumn and winter seasons of the year [6], and after the molting period the specimens were mostly caught. However, the highest values of abundance, both in number of individuals and in biomass, were located in the 200-500 m depth stratum in the N Aegean Sea [2].

LA SÉLECTIVITÉ CHEZ *HOLOTHURIA POLI*

Nor-Eddine Belbachir [1]* and Karim Mezali [1]
[1] Université Abdel Hamid Ibn Badis de Mostaganem - belbachirnoreddine@hotmail.fr

Abstract
Une analyse granulométrique des sédiments ingérés par *H. poli* et de celui de son biotope, ont été réalisé. La sélectivité de cette espèce a été étudiée à travers l'indice d'électivité. Cette espèce sélectionne préférentiellement les fractions fines et très fines, ce qui démontre qu'elle reconnait les particules riches en matière organique.

Keywords: Echinodermata, Algerian Sea, Behaviour, Sediments

Introduction Les holothuries aspidochirotes joue un rôle important dans le "detritus food web" [1]. La sélectivité chez ces espèces, pourrait être un moyen de partition de la niche écologique et un moyen d'obtenir des aliments avec une grande valeur nutritionnelle.

Matériels et méthodes

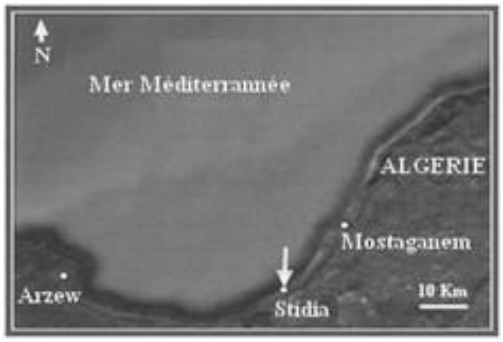

Fig. 1. Situation géographique du site étudié (petite flèche)

Vingt individus d'*H. poli* et le Sédiment du Biotope (SB) ont été prélevés à -3 m de profondeur. Le contenu digestif de chaque individu est isolé et le (%) des différentes fractions granulométriques est déterminé selon le protocole de [2]. La sélectivité dans le choix de la taille des grains, a été étudiée à travers le calcul de l'Indice d'électivité (*E'*) d'Ivlev [3].

Résultats et discussion
H. poli sélectionne préférentiellement la fraction fine (Fig. 2A). Toutefois, c'est la fraction très fine qui est la plus préférée, du moment qu'elle présente le plus haut indice d'électivité (Fig. 2B). Cela s'explique par le faite que les teneurs en matière organique augmentent avec les fractions fines. En effet, les holothuries ont le pouvoir de reconnaître et de sélectionner les particules sédimentaires les plus riches en matière organique [4]. On suppose que nos résultats cohérent avec le model du comportement alimentaire des déposivores marins; ce model cohére avec la théorie de l'"Optimal Foraging" [5].

Abstract
This study describes the length and weight frequency distributions, condition factor and length-weight relationships of round sardinella *Sardinella aurita* Valenciennes, 1847 from Izmir Bay, Turkey. Fish samples were collected monthly (October 2010 - September 2011) during commercial fishing trials using gillnet from Izmir Bay. A total of 707 specimen of *S. aurita* were used for this study. Fish total lengths ranged from 12.1 to 27.1 cm The condition factors were calculated for seasonally with minimum and maximum values as 0.740 (Winter snd Spring) and 0.940 (Summer) for all individuals respectively.

Keywords: Population Dynamics, Aegean Sea, Izmir Bay, Pelagic

Material and Methods
Fish samples were collected monthly (October 2010 - September 2011) during commercial fishing trials using gillnet from Izmir Bay. A total of 707 specimen of *S. aurita* were used for this study [4]. The length–weight relationship was determined for males and females according to the equation $W = a L^b$, where W is total weight (g), L the total length (cm), The parameters a and b were calculated by functional regression, as was the coefficient of determination (r^2). The b value for each species was tested by t-test at the 0.05 significance level to verify that it was significantly different from the isometric growth (b=3). a the intercept and b the coefficient of the functional regression between W and L [3]. condition factor estimated by K=W *100/L3 [1].

Results and Discussion
Fish total lengths ranged from 12.1 to 27.1 cm (Fig. 1).

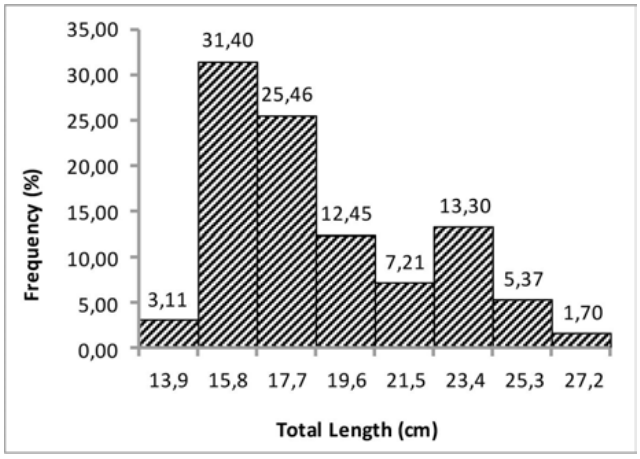

Fig. 1. Length frequency distribution of all individuals (female+male).

The parameters 'a' and 'b' of the length-weight relationships (LWRs) were calculated as $W=aL^b$ and LWRs for males, females and the total sample population determined to be $W=0.0056L^{3.126}$, $W=0.0069L^{3.063}$ and $W=0.0032L^{3.304}$ respectively. The values for allometric coefficient b of the length-weight relationships showed positive allometric growths in the both sexes. All allometric coefficients (b) estimated in this study were within the expected range 2.1-3.7, and according Benegal and Tesch [1978] allometric coefficients may range from 2 to 4. The condition factors were calculated for seasonally with minimum and maximum values as 0.740 (Winter snd Spring) and 0.940 (Summer) for all individuals respectively (Fig. 2).

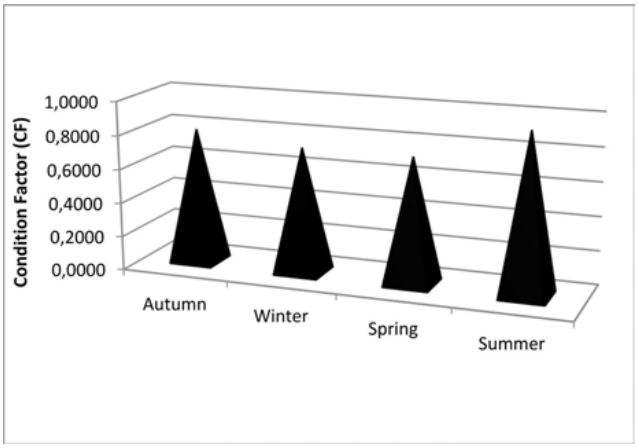

Fig. 2. Seasonal condition factor (CF) for *Sardinella aurita* from Izmir Bay.

Abstract
In this study, import and export amounts in Turkey were examined with the help of the multiple linear regression model by using time series. For that purpose, the general production amount of Turkey's aquaculture was predicted by using the data of the Turkish Statistical Institute (TSI) between 2000-2011, with the help of import and export amounts of Turkey's aquaculture in the study. As a result of this study, a linear model was obtained, and according to the result of the variance analysis (F=2.852; p=0.079), the model was determined to be usable. Besides, it was determined that only 20.6% of the obtained model could be explained with these independent variables.

Keywords: Aquaculture, Fisheries, Fishes, Aegean Sea, Black Sea

Introduction
When we look at the recent import and export datum of fisheries in Turkey, we can see a fluxional course.

Time Series is called series which show the results ranged by time. The purpose of studying with time series is that the future values of the variables in the time series are predictable.

Time Series of Components, Time series are composed of five components; Seasonal fluctuations (M), Long Term Trend (T), Cyclical Fluctuations (K), Rassal Fluctuations (D).

The first three are called the systematic components of time series. Trend can be calculated in three ways: Easy, Moving averages, Regression analysis [1].

The main value is trend and the others are ratios whose averages are 100. Determination of trend The aim is to reveal the absolute value by eradicating the effects of seasonal, cyclical and rassal movements on series. The state of variance being constant in time, Trend is the most commonly used method in time series. Trend can be calculated in three ways: Easy, Moving averages, Regression analysis.

Material and Methods
The price datum and the amount of fisheries production, import and export between the years 1986 and 2011 obtained from TUIK were used [4]. Import and export datum were examined via time series analysis method. Model was found with the help of multiple linear regression models. The collected datum was evaluated by SPSS package.

Results
Import and export datum were used as the factors which affect the amount of production change according to years, in which case; Dependent Variable: Production (1000 tonnes) Independent Variables: Import (1000 tonnes), Export (1000 tonnes) (Fig.1.)[2,3].

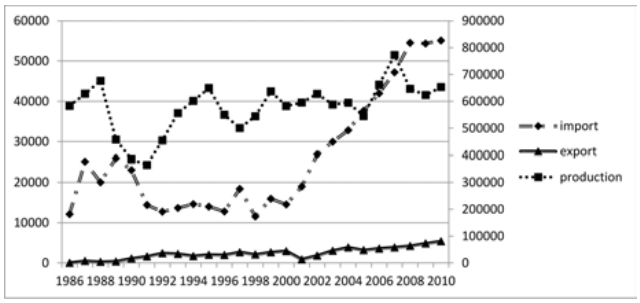

Fig. 1. Production, Import and Export.

The resulting regression equation;

Y = 2.8150 + 0.0011 (Import) + 0.0001 (Export) Independent variables in this model, but this is dealt with in 64.7 % percent explain. remaining 35.3 % other variables need to be disclosed (Tab. 1).

THE STATUS OF THE CATALAN STOCK OF ARISTEUS ANTENNATUS IN RECENT YEARS (2008-2010) COMPARED WITH TWENTY YEARS AGO (1984-1989)

Giulia Gorelli [1]*, Francesc Sardá [1] and Joan B. Company [1]
[1] Instituto de Ciencias de Mar - CSIC - gorelli@icm.csic.es

Abstract
The fishery of the red shrimp *Aristeus antennatus* is one of the main fisheries in the western Mediterranean. In this work we evaluated the status of the *A. antennatus* fishery in the Catalan region (NE Spain) in recent years, 2008-2010, and compared it with the last historical available data, 1984-1989. Fishing mortality and population biomass displayed high inter-annual variability. Population biomass values were higher for the recent period. Yield per recruit analysis showed a general overfishing pattern for both periods. In general inter-annual variability of estimates suggested the existence of non-fishery effects affecting the population dynamics of this species in the area.

Keywords: Fisheries, Decapoda, North-Western Mediterranean

Introduction
The red shrimp *Aristeus antennatus* is one of the main fisheries in the western Mediterranean, where this species is the main target of a deep-sea bottom trawling fleet. Its bathymetric distribution ranges from 100 to 3000 m depth. Ecology and biology of this species have been widely studied, except for the larval phase which is almost completely unknown [1], [2], [3]. In Catalonia it is fished at depths ranging from 400 to 900 m. Here, a great part of the fleets rely on this resource, which in some cases constitutes up to 50% of the income, as for the port of Palamós. Despite the economical importance of this resource in the area, fishery evaluations have not been conducted on regular basis. The last stock evaluation dates back to the period 1984-1989, when size structured data from the fishery were sampled and analyzed in Demestre and Lleonart, 1993 [4]. The aim of this study is to evaluate the status of the *A. antennatus* fishery in the Catalan region (NE Spain) in recent years, 2008-2010, and to compare the status of the stock at that time with the last historical available data, 1984-1989.

Materials and methods
We analyzed by means of a Length Cohort Analysis (LCA) and Yield per Recruit Analysis (Y/R) two series of fishery data (length frequencies in the catches and total catch weight) collected respectively during the two mentioned periods. The stock evaluation for the period 1984-1989 was conducted using length frequencies from Demestre, 1990 [5]. Length frequencies for the period 2008-2010 were obtained from a triennial monitoring data collection conducted by the Catalan regional Government. The statistical package VIT [6] was used to perform the analysis. The Von Bertalanffy growth parameters used in the analysis were taken from Sardá and Demestre, 1987 [7], while natural mortality estimates from Demestre and Martín, 1993 [8]. The parameters of the length weight relationship were obtained from Demestre, 1990 [5]. Annual catch data were supplied by the Catalan regional Government. Given the high sexual dimorphism of this species, the two sexes were analyzed separately.

Results
Mean length frequency distributions in the captures were similar for the two studied periods. Yearly population biomass values estimated by the LCA displayed high inter-annual variability, and were higher for the period 2008-2010 compared to the period 1984-1989 (Table 1). Estimations of the recruitment displayed high inter annual variability. Mean fishing mortality rates (mean F) showed inter annual variability, too, and displayed no trend between the two periods of study. The comparison of yearly mean F values with the corresponding $F_{0.1}$ reference point estimated by the Yield per Recruit analysis highlighted an overfishing pattern for each year of study. Yield per Recruit values showed a trend to slightly decrease among the two periods of study (Table 1).

Discussion
The biomass estimates obtained by LCA almost directly reflect catches, which were considerably higher in the period 2008-2010, as the model interprets high catches as high population biomass. In general, the elevated inter-annual variability of population estimates obtained in this study suggests the existence of non-fishery effects affecting the population dynamics of the red shrimp. Important ecological phenomena described in the area, such as cascading (strong submarine currents which occasionally and heavily affect the resources distribution and their availability in the fishing grounds) could play a crucial role masking the effect of the fishery itself [2]. In this case it would be recommendable the development and use of a stock assessment model able to take into account such effects, in order to produce reliable fishery evaluations on which to base management decisions.

AN INVESTIGATION ON THE RECRUITMENT OF HATCHERY-REARED TURBOT (*PSETTA MAXIMA* PALLAS, 1811) JUVENILES TO NATURAL POPULATION IN THE EASTERN BLACK SEA

Mustafa Zengin [1] and Aysun Gümüs [2]*
[1] Central Fisheries Research Institute, Trabzon, Turkey
[2] Ondokuz Mayis University, Faculty of Science and Arts, Department of Biology, Samsun, Turkey - aysung@omu.edu.tr

Abstract
This study, as being a pioneer work in Turkey was realized by releasing the artificially reared Black Sea turbot juveniles to natural environment. The enhancement of the exploited natural Black Sea turbot (*Psetta maxima* Pallas, 1811) stocks was the main objective in investigation of adaptation, growth and development and restocking capacity of tagged and released individuals.

Keywords: Restoration, Vertical migration, Black Sea

Introduction
Turbot (*Psetta maxima)* is one of the most important commercial species among demersal fishes inhabiting Turkish Black Sea Coasts. Unfortunately, the turbot stocks declined because of the overfishing by a continuously growing fishing fleet and inadvisable management strategies since the last of 1980s [1]. However, turbot has always been a primary target for marine stock enhancement. The first study for the turbot restocking was started in the Turkish Black Sea coast in 1999, with collaboration of CFRI (Trabzon Central Fisheries Research Institute) and JICA (Japan International Cooperation Agency [2].

Material and Method
During 1999-2002, around 30.000 hatched and reared fish of 0-age group and mean length of 13.9 (6.5-20.7) cm were released regularly from 11 different locations between Georgian Board and Sinop Cape. All individuals were tagged externally, numbered with T-bar tags of ten different colors. The material of the tag was composed of polyethylene. The tags were placed intramuscularly nearly between 10^{th} and 15^{th} rays of the dorsal fin. After release, a recapture study was carried out lasting to the end of 2005. For the collection of samples, cooperation was conducted with coastal fishermen offering little rewards such as money, t-shirt, some fishing equipment and posters.

Results and Discussion
In a period of 7 years, 2.2% of the released turbot were recaptured by gill-net and bottom trawl mostly in winter, spring and early summer (Tab. 1). Recaptures were made along the coastal sites within a range of average 60 km from the release locations. Maximum horizontal migrate is 200 km. Vertical migrations reached to a limit of 110 m depth of littoral zone from releasing points. Population migrates and becomes dense in depths of 30-40 m where spawning occurs. There was a linear relationship between vertical/horizontal migrations and age-size groups. The recapture rate appeared to be positively correlated with size of fish and age (Fig. 1).

Individual growth of recaptured fish in length was higher than wild fish caught in same location. Hatchery reared turbot reached to legal minimum catch size in the third year of growth (2+ age group). The latest data on recaptured fish showed that maximum length and weight of tagged turbot are 54.3 cm and 4335 g respectively. In three months following the release, the growth rate of turbot was negative (-0.14 g/day). On the contrary, the following months they have started to put on weight and daily growth rate increased. The daily growth rate is calculated as 0.99 g/day, 2.10 g/day and 2.35 g/day for the age groups of 1, 2 and 3 respectively. A positive correlation has been found between recapturing rate and the size of the fish.

Finally, it is concluded that the tagged turbot population grows a bit faster and matures earlier than the wilds at the same age [3]. Released hatchery turbots seemed to be able to adapt to natural diet within a few months [4]. The findings showed that restocking of turbot has many advantages for the enhancement of commercial fisheries in the Eastern Black Sea coast. Same results were obtained in the case of West European Coasts [5]. Releases of hatchery turbot have been proposed to enhance fisheries recruitment, integrated in a resource management programme of sustainable fisheries and habitat restoration.

RECRUTEMENT DE LA COQUE *CERASTODERMA GLAUCUM* (MOLLUSQUE, BIVALVE) DANS LA LAGUNE MELLAH (ALGÉRIE NORD-EST)

Khalil Melouah [1]*, Brahim Draredja [1] and Hayet Beldi [1]
[1] Université d'Annaba - khalilm11@yahoo.fr

Abstract
La détermination de la phase de recrutement chez la coque *Cerastoderma glaucum* a été étudiée dans la lagune Mellah de mars 2010 à février 2011. Le cycle biologique de cette espèce est caractérisé par un faible recrutement au début du printemps, alors que celui de l'été est plus important et s'étale de juin à septembre.

Keywords: Bivalves, Growth, Lagoons, Recruitment, South-Western Mediterranean

Introduction

Cerastoderma glaucum est un bivalve caractéristique des communautés benthiques phytophiles des milieux lagunaires [1]. Elle a été citée pour la première fois dans la lagune Mellah par Bakalem et Romano [2]. Puis, d'autres études ([3], [4]) traitant en général la répartition de la faune benthique a été réalisée.

Matériel et méthodes

La lagune Mellah est située à l'extrême Est algérien (Fig. 1). Elle totalise une superficie de 865 hectares, avec une profondeur maximale de 5,2 m. Sa communication avec la mer est assurée par un chenal et les apports en eau douce s'effectuent par trois rivières. Le prélèvement mensuel (mars 2010 - février 2011) de la coque est réalisé à partir de trois stations. Afin de récupérer les jeunes stades de ce bivalve, le sédiment est tamisé sur place sur une maille de 1 mm. Les individus sont dénombrés et mesurés (Lt) à l'aide d'un pied à coulisse, puis répartis en classes de tailles de 2 mm d'amplitude.

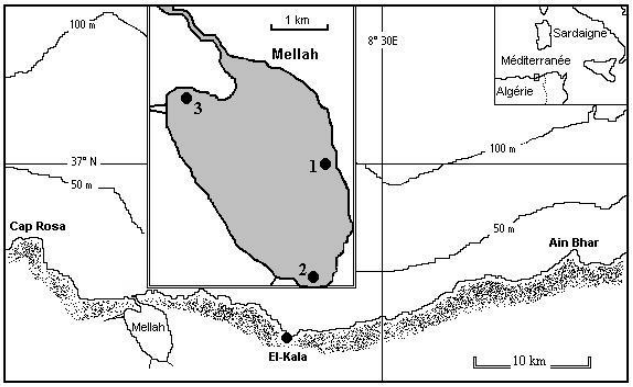

Fig. 1. Position géographique de la lagune Mellah et choix des stations.

Résultats et discussion

L'analyse de la structure des tailles de la coque du Mellah (Fig. 2), fait apparaître en mars un petit lot de juvéniles composé de 4 individus appartenant à la classe de tailles de [2-4[mm. Cette dernière disparaît, pour réapparaître en juin et s'étale sur toute la saison estivale jusqu'à septembre, où l'effectif atteint 20 individus. Le recrutement se poursuit jusqu'à la fin de la saison estivale, d'où l'intérêt du rôle du facteur thermique dans cette phase. Les plus fortes concentrations des jeunes recrues sont rencontrées au Nord-Ouest de la lagune riche en herbier à *Ruppia* sp. En effet, le tapis végétal constitue un abri idéal pour la survie des jeunes stades qui constituent une proie facile pour les prédateurs [5]. Nos constatations concernant l'arrivée de nouvelles recrues concordent avec les résultats rapportés par Labourg et Lasserre [1]. Chez cette même espèce, Guelorget et Mazoyer-Mayère [6] signalent un recrutement plus tardif en automne. Alors que Zaouali [7], indique trois périodes de recrutement ; de mai à juin, d'août à septembre et de décembre à janvier.

POLYMORPHISM IN *HOLOTHURIA (PLATYPERONA) SANCTORI* FROM THE ALGERIAN COASTAL AREA

Karim Mezali [1]*

[1] Universite abdelhamid iben badis F.S.N.V Departement des sciences de la mer et de l'aquaculture - mezalikarim@yahoo.fr

Abstract

The morphological, endoskeleton and genetic criteria were used to compare between individuals of two morphotypes of *H. (Platyperona) sanctori*. In this study, we concluded that both morphotypes (A & B) constitute the same species.

Keywords: Echinodermata, Genetics, Systematics, Algerian Basin

Introduction

The systematic study of holothurians "sea cucumbers" is quite complex. The morphology, size and distribution of ossicles in the body wall tissues are key characters in the determination of these species [1]. *Holothuria (P.) sanctori* is a southern species, which is distributed through the Mediterranean [2, 3] and is widely dominant in many parts of the Algerian Infralittoral [4].

Material and methods

The animals were collected in 3 stations [Sidi Fredj (Algiers), Figuier plage (Boumerdes) and Stidia (Mostaganem)] (Fig. 1B) and then anesthetized with $Mgcl_2.6H_20$ to describe their morphology [1]. The ossicles isolated from a tissue taken in the bleach (12 °) were measured using light microscope (X 20). The fraction of the 16S mtDNA gene and the primers AR (5'-CGCCTGTTTATCAAAAACAT-3') and BR (5'-GCCGGTCTGAACTCAGATCACGT-3') [5] were used. PCR amplification was performed on 49 µL with ddH_2O (30.8 µL), buffer 10 X (5 µL), dNTPs (5 µL), AR (2µL), BR (2 µL), Taq polymerase (0.2 µL), $MgCl_2$ (4 µL) and 1 µL of DNA template. The phylogenetic tree is constructed from the obtained sequences and mtDNA sequence of *Holothuria (Platyperona) forskali* is used as an out group.

Results

1. Morphology and endoskeleton analysis

The morphotype A is dark brown color and the morphotype B has a brownish color and is easily recognized underwater by its white spots clearly visible in dark middle and lightly visible in light middle (Fig. 1A). Ossicle measurements resulting from the comparative study are indicated in table 1.

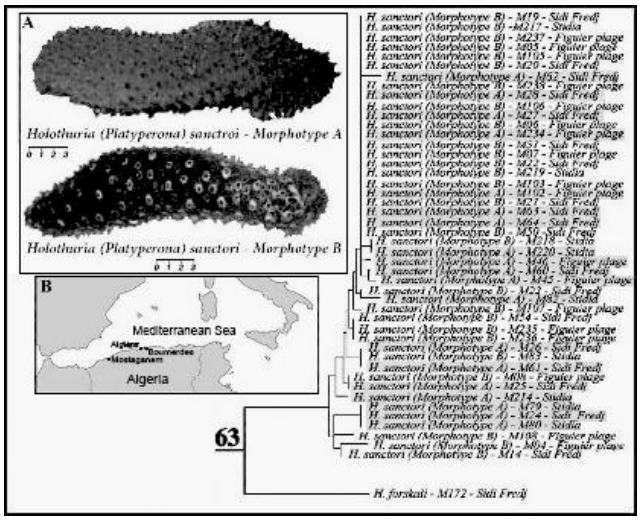

Fig. 1. The studied morphotypes (A); studied sites (B). Left: The 16S neighbour-joining tree using Kimura-2- parameter distance model. The (%) bootstrap1000 replicate is represented.

Tab. 1. The ossicles measurement. N = Number of ossicles.

	Width (µm)	66.64	34.55	60.52	-
	Ratio Length/ Width	**01.23**	**02.87**	**01.19**	-
	Diameter of perforation (µm)	08.45	08.70	11.64	-

2. Molecular analyses

The phylogenetic tree clearly shows that both *H. (P.) sanctori* morphotypes are closely grouped to a single clade with few alternative sites (Fig. 1 left). They are in fact monophyletic.

Discussion

The two morphotypes of *H. (P.) sanctori* are genetically identical and thus represent the same species rather than different species. These two polymorphic and ecotypic forms are characterized by the reduction of their ossicles in size and in number.

GENETIC VARIATIONS AS REVEALED BY INTER- SIMPLE SEQUENCE REPEAT (ISSR) POLYMORPHISM IN *ULVA LACTUCA* (CHLOROPHYCEAE) FROM MARMARA COAST.

Isil Ezgi Eryilmaz [1], Seyma Z. Akarsu [1] and Dilek Unal Ozakca [1]*
[1] Bilecik Seyh Edebali University Faculty of Science and Art Department of Molecular Biology and Genetics - dilek.unal@bilecik.edu.tr

Abstract
Inter simple sequence repeat (ISSR) analysis was used to assess twenty attached *Ulva lactuca* samples collected from different sites distributed from the Marmara Sea. 6 ISSR primers were selected for final analysis. A total of 193 loci were obtained, of which 101 were polymorphic among the thallus studied. Genetic relationships were analyzed with Jaccard's (J) and Dice's (D) distance coefficients. Little genetic variations were found among the selected *U. lactuca* thallus, for instance, the genetic distances ranging from 0.039 to 0.178 with Dice coefficients.

Keywords: Genetics, Marmara Sea, Algae

Introduction: Distribution of genetic variation is not incidental and refers to genetic structure of a population [1]. Methods based on PCR amplifications using arbitrary primers, such as inter simple sequence repeats (ISSR-PCR), provide a new genetic marker by amplifying nuclear non-coding DNA sequences. These sequences, which are called microsatellites, evolve at a much faster rate and are less constrained by selection than protein coding loci. Thus, level of polymorphism is greater in these sequences [2]. ISSR method has been successfully used in studies on the genetic structure of many algae species [3]. *Ulva* sp. (Chlorophyta) is widely distributed from the intertidal to the upper subtidal zones around the world and an environmental problem, green macroalgal blooms, is growing by day by in coastal ecosystem. Major of green tide algae is derived from Ulvophyceae genera [4]. In this study, we investigated the genetic variations of *U. lactuca* collected from ten locations along the Marmara Sea.

Material and Methods: *Ulva lactuca* samples were collected from ten different locations along the Marmara coast, Bursa- Turkey.

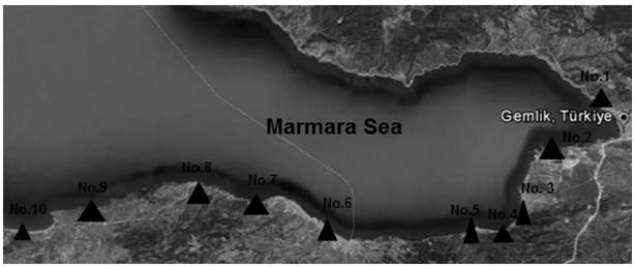

Fig. 1. Collecting points of *Ulva lactuca* in Marmara coast.

Samples coated with silica gels were cleaned with distilled water and preserved at -20°C. DNA extraction was performed according to microprep protocol by Fulton [5]. Extracted DNA amount and purity were checked (OD260/OD280) by nanodrop. After necessary dilutions, ISSR- PCR was performed with 12 ISSR primers; polymorphic bands were detected by 6 of them. Amplified DNA bands of each locus were recorded as binary present (1) or absent (0) in program. Pairwise comparisons were calculated from the 0/1 data matrix, and genetic distances were calculated using Jaccard's and Dice's method [6, 7].

Results and Discussion: In higher plants, ISSR analysis has been used to detect the organization, frequency and levels of polymorphism of different simple sequence repeats [2]. Previously studies demonstrated that the poly (GA) motif is more variable than poly(GT) motif [8, 9]. In the present work, we found that there was significantly difference between variations produced by these two motifs in *Ulva lactuca* thallus.

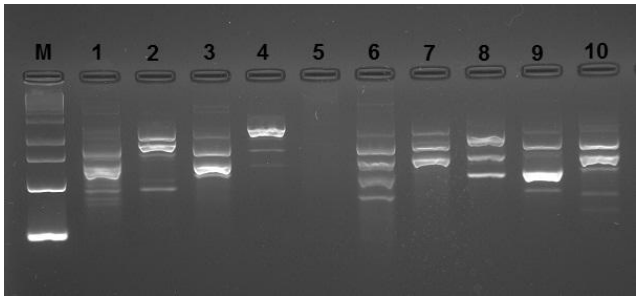

Fig. 2. Amplification of *U. lactuca* DNA samples with ISSR primer 818.

Wang *et al*. (2005) used ISSR technique to detect the genetic diversity of selected Laminaria gametophytes [10]. Wang *et al*. (2006) also reported that ISSR primer produced an average of 5.7 bands with 74% of them polymorphic in Undaria gametophytes [3]. In our analysis we found that there was an average of 6.9 bands, produced by each ISSR primer, with 52.33% of them were polymorphic.

CONTRIBUTION A L'ETUDE DE LA VARIABILITE SPATIO-TEMPORELLE DE DISTRIBUTION ET DE RECRUTEMENT DES PRINCIPAUX STOCKS DEMERSAUX DE LA MEDITERRANEE MAROCAINE

Abdelaziz Zoubai [1]* and Yassine Zahri [1]
[1] Institut National de Recherche Halieutique - a.zoubai@gmail.com

Abstract
Ce travail a pour objet de déterminer l'abondance et le recrutement chez les principaux stocks demersaux en Méditerranée marocaine. Les résultats obtenus ont permis de relever une abondance plus marquée au niveau des strates côtières pour le pageot acarné, la bogue et le rouget de vase et au niveau des grands fonds pour le cas du merlu européen. Le recrutement plus prononcé chez ces espèces est observé en automne et surtout au niveau de la région Est de la méditerranée marocaine où le plateau continental est plus large.

Keywords: Demersal, Alboran Sea, Recruitment

Introduction

En Méditerranée marocaine, peu de travaux ont été consacrés à l'étude de la distribution des sparidés (bogue et pageot acarné), des mullidés (rouget de vase) et des merlucciidés (merlu européen). Ce travail entend contribuer à l'étude de la répartition de ces stocks, leur recrutement ainsi que leur variation spatio-temporelle dans cette région.

Matériel et méthodes

L'étude de la répartition bathymétrique et géographique des espèces est réalisée à partir du traitement des données (rendements et fréquences de tailles) collectées lors des 12 campagnes de chalutage scientifiques effectuées par l'INRH en Méditerranée marocaine, durant la période 2001-2009 durant les saisons d'été, de printemps et d'automne. La couverture de la zone d'étude est réalisée par un réseau d'échantillonnage de 45 stations (traits de chalut) se répartissant de la côte (50 m) jusqu'aux grandes profondeurs (500 m). Les données de taille et de rendement (kg/h) correspondant à chaque espèce ont été groupées en 3 strates bathymétriques (0-100 m, 101-200m, 201-500 m) et deux zones géographiques (zone Ouest et Est d'Al Hoceima). Cette subdivision géographique a été adoptée en raison de la largeur du plateau continental plus étendue dans la région située à l'Est de la Méditerranée marocaine [1]. Les indices d'abondance (kg/h) des espèces étudiées ont été calculés par strate bathymétrique et par zone géographique [1]. La détermination des principaux lieux et saisons de recrutement de ces espèces est faite sur la base de l'analyse des distributions de tailles établies par zone géographique, strate bathymétrique et par saison.

Résultats

1. Indice d'abondance :

L'analyse des indices d'abondance (kg/h) des espèces étudiées calculés par strate de profondeur et par zone géographique montre que pour le pageot acarné l'abondance décroît de l'Ouest à l'Est et de la côte (0-100 m) où les rendements les plus élevés sont réalisés (5,68 à 56,95 kg/h contre 1,3 à 14,4 kg/h respectivement) vers la strate de profondeur moyenne (101-200m) (soit 1,38 à 22,9 kg/h à l'Ouest contre 0,1 à 34,85 kg/h à l'Est); en revanche cette espèce apparaît en très faibles quantités au delà de 200 m (moins de 1 kg/h). Concernant la bogue, on constate que quelle que soit la zone, ce sparidé abonde particulièrement dans les strates de faibles profondeurs (0-100m) ; en effet, les meilleurs rendements enregistrés au niveau de ces strates varient entre 1,39 et 86,06 kg/h dans la région Ouest d'Al Hoceima contre 1,09 et 47,83 kg/h à l'Est. Au delà de 100 m, les rendements sont faibles. Le rouget de vase pour sa part, présente une abondance plus marquée durant toute l'année dans les fonds de moins de 100 m où les rendements observés varient entre 0,29 et 4,11 kg/h à l'Ouest d'Al Hoceima contre 0,68 et 7,88 kg/h à l'Est. Quelle que soit la zone, la distribution bathymétrique de cette espèce est limitée à 200 m. Le merlu européen, espèce à distribution bathymétrique plus large, abonde par contre au niveau des strates de grandes profondeurs (au delà de 200 m) (0,80 à 6,19 kg/h à l'Ouest contre 1,01 à 4,18 kg/h à l'Est).

2. Structure de tailles et recrutement :

Les distributions de tailles obtenues par saison et par strate bathymétrique et géographique permettent de relever chez le pageot acarné, la bogue, le rouget de vase et le merlu européen, une grande abondance de jeunes au niveau des strates côtières (0-100 m), ce qui traduit un recrutement plus marqué en automne surtout au niveau de la zone Est d'Al Hoceima caractérisée par un plateau continental plus large. Au-delà de cette strate de profondeur, s'observent surtout les individus âgés.

Discussion et conclusions

La variation spatio-temporelle observée chez espèces étudiées pourrait être expliquée par différents facteurs, dont notamment le type de fond où vit l'espèce [2], les conditions physico-chimiques (température en particulier) et hydrologique (upwellings etc...) qui exercent une influence directe sur leur cycle biologique [3]. Les résultats obtenus ont permis de relever que la saison d'Automne constitue pour les espèces étudiées, la principale période de recrutement. Cette période concorde bien avec celle observée dans d'autres régions. En effet, des études menées en Méditerranée espagnole situent la période de recrutement marqué au mois d'Août pour le merlu blanc [4]. Tandis que pour le rouget de vase, la période de recrutement plus prononcé coïncide avec la période située entre septembre et octobre [5].

DISTRIBUTION OF THE RARE *CYSTOSEIRA JABUKAE* ALONG THE FRENCH MEDITERRANEAN COAST

Aurélie Blanfune [1]*, Thierry Thibaut [1] and Marc Verlaque [2]
[1] University Nice Sophia Antipolis - EA 4228 ECOMERS Faculté des Sciences, Parc Valrose - blanfune@unice.fr
[2] Aix-Marseille University, Mediterranean Institute of Oceanography

Abstract
Among the Fucales, the rare *Cystoseira jabukae* Ercegovic has been rarely observed along the French Mediterranean coast. We analyzed historical data and mapped the current distribution of this species. Its first record in France dates back the 1990's at Scandola (Corsica). Extensive surveys showed that the species is still present between the sea surface and 35 m in depth, in some localities of Corsica, the Var and the Alpes-Maritimes.

Keywords: Algae, North-Western Mediterranean

Introduction
Some species of Fucales are been recorded in regression in the Mediterranean Sea [1]. We focus our attention on the past and present distribution of the rare *Cystoseira jabukae* Ercegovic along the French Mediterranean coasts. This species is thriving in the sublittoral zone [2].

Méthods
Historical records (before 2000) of *Cystoseira jabukae* have been analyzed in different sources. For the current distribution, we surveyed the entire French Mediterranean coasts (including Corsica) from 2003 to 2010.

Results
Historical data are scarce. In France, they come all from the Marine Reserve of Scandola (Corsica) from 1994 to 1998 (Verlaque herbarium, published paper [3] and unpublished report [4,5]). Currently, populations of *Cystoseira jabukae* are very rare. In Corsica, we only observed the species at Scandola in 2001, at Ajaccio in 2004 and in the Lavezzi Archipelago (Ratino Islet) (Figure 1).

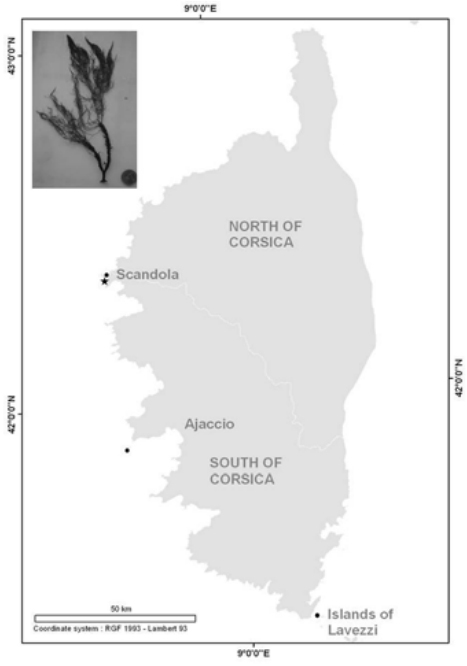

Fig. 1. Observations of *Cystoseira jabukae* in Corsica.

Along the French continental coast, only few more or less isolated individuals were observed in the departments of Var and Alpes-Maritimes (Figure 2).

Fig. 2. Observations of *Cystoseira jabukae* in the Var and th Alpes-Maritimes.

Any dense populations or communities were never found.

Conclusions
The rarity of the *Cystoseira jabukae* populations is alarming and the species could be considered as endangered. *Cystoseira jabukae* has been described by Ercegovic in 1952 but the only historical French data date back to 1994 whereas eminent phycologists as Bornet, Derbès and Solier, Flahaut, Sauvageau, Schousboe, Thuret, are sampling along the French Mediterranean coast since the 19th century. It is highly improbable that historical and recent French observations result from a recent introduction event. We hypothesize that the species was present for a long time but misidentified. The best candidates for such a misidentification could be spineless specimens of *C. sauvageauana* Hamel (= *C. selaginoides* Valiante).

THE RESURRECTION OF *GIBBULA NIVOSA* (GASTROPODA: TROCHIDAE)

Julian Evans [1]* and Patrick J. Schembri [2]
[1] Marine Biology and Ecology Research Centre, University of Plymouth, Plymouth PL4 8AA, UK - julian.evans@um.edu.mt
[2] Department of Biology, University of Malta, Msida MSD2080, Malta

Abstract
The rediscovery of *Gibbula nivosa* from two widely separated cobble beds in 2006, after some 25 years during which no living specimens had been found, suggested that such beds may be an important habitat for this species. Systematic sampling of cobble patches at 15 different locations resulted in the discovery of another three populations, confirming the importance of cobble accumulations as a habitat for this species, but also showing that while certainly not extinct, *G. nivosa* is still quite rare within the Maltese Islands. This, together with its very narrow geographical range, being endemic to Malta, renders *G. nivosa* highly vulnerable to extinction.

Keywords: Biodiversity, Conservation, Endemism, Gastropods, Sicily Channel

Introduction
The Maltese top-shell, *Gibbula nivosa*, is a critically endangered marine trochid gastropod endemic to the Maltese Islands [1,2,3]. This species has always been rare and no live individuals were recorded between 1981 and 2006, despite intensive searches in localities where it used to occur [3]. In 2006, a population of *G. nivosa* was discovered within Sliema Creek, Marsamxett Harbour, while two individuals were also recorded off south-west Comino [1]. Although the main habitat of the Maltese top-shell has been considered to be leaves of the seagrass *Posidonia oceanica*, it has also been reported from under stones in shallow water [4], and the recently discovered populations were all recorded from such a habitat, indicating that cobble beds may be a more important habitat for *G. nivosa* than previously thought [1]. The present study was undertaken to assess the current status of the Maltese top-shell.

Material and Methods
A preliminary survey was carried out along the low-lying coasts of the Maltese Islands to map the presence of shallow-water 'cobble beds', defined as areas ≥ 25 m^2 having a continuous cover of pebbles and cobbles. Fifteen such beds were selected (Fig. 1), and four random samples were collected from each by SCUBA divers, using a 0.1-m^2 circular corer. The length and width of the sampled patched were also measured to estimate coverage. Samples were sorted in the laboratory, all molluscs present were identified, and any live individuals of *G. nivosa* were counted to obtain a measure of population density. Coverage and population density values were used to estimate the total population size within each of the sampled cobble beds with *G. nivosa*.

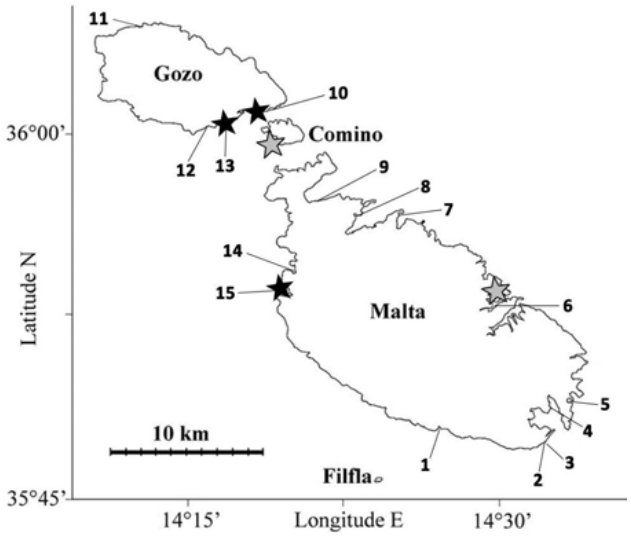

Fig. 1. Map of the Maltese Islands showing the location of the 15 sites with cobble/pebble habitats that where sampled (numbered 1-15); locations where live *Gibbula nivosa* populations were found in the present (black-filled stars) or recent [1,2] (grey-filled stars) studies are also indicated.

Results and Discussion
Live *G. nivosa* were recorded from three of the 15 sampled locations: Hondoq ir-Rummien (Site 10), Xatt l-Ahmar (Site 13) and Fomm ir-Rih (Site 15) (Fig. 1), with mean (±SD) densities of 2.0 ± 2.7, 0.5 ± 0.6 and 11.0 ± 13.4 ind./0.1 m^2, respectively. Given the restricted size of the cobble patches at the three sites, none of which exceeded 50 m^2, estimated population sizes were low, ranging between 250 and 4400 individuals. In the case of Hondoq ir-Rummien and Fomm ir-Rih, the bottom consisted of a sublittoral boulder scree adjacent to the coast, with *P. oceanica* meadows in deeper waters. Small patches of cobbles and pebbles were present as an enclave between these two habitats at depths of 7-12 m. Only the largest cobble patch was sampled at each site, and it is therefore possible that *G. nivosa* also occurred in cobble patches other than the ones sampled.

Following its rediscovery in 2006, *G. nivosa* has now been recorded from five separate locations around the Maltese Islands (Fig. 1), and other small populations may also exist in cobble patches around the Maltese coastline that have not been sampled. While never formally considered to be extinct, its reappearance after a 25-year period during which dedicated searches were unsuccessful [2] makes it a good example of a 'Lazarus species' [5]. All five presently known populations occur within accumulations of cobbles and pebbles, which therefore seem to be the main habitat for this species; past records from seagrass meadows may have resulted from collection of individuals during foraging excursions. This implies that past searches may have been unsuccessful because they were not made in the gastropod's primary habitat. Nevertheless, the present results also indicate that the Maltese top-shell is still a very rare species, being recorded from only three of the 15 sample sites, which, together with its very narrow geographical range (the Maltese Islands), renders it highly vulnerable to extinction.

Acknowledgements: Work on this protected species is in full conformity with the laws of Malta. We thank the Environment Protection Directorate of the Malta Environment and Planning Authority for issuing the necessary permits and for partial financial assistance; additional funding was provided through the European Social Fund under a STEPS scheme grant awarded to JE.

Abstract
From 1999 to 2012 a population of *Paramuricea clavata* has been monitored at 25 m depth inside the Marine Protected Area of Portofino. Data were related to the local temperature trend in summer and autumn season. Results show a pattern strongly affected the recovery due to the 1999 and 2003 massive mortalities and reveal a suffering period also during 2007 and 2011, two years with prolonged summer conditions.

Keywords: Global change, Gulf of Genoa, Cnidaria, Population Dynamics

Background- Introduction
The recorded Mediterranean mass mortalities, during the last decades, have altered the structure of benthic assemblages in the NW Mediterranean Sea ([1], [2], [3], [4]). In the MPA of Portofino a slow recovery of benthic communities has been reported ([5], [6]) on behalf of monitoring efforts increased since the events of 1999 and 2003. Time series, concerning quantitative monitoring and temperature collection, aid in the understanding of recurrence of events and recovery patterns of these communities. Here we present a time series on the structure of a *Paramuricea clavata* population coupled with the temperature profiles of the monitored years (1999-2012).

Materials and methods
Fixed quadrats (five areas of $1m^2$) at 25m were monitored (bimonthly) from 1999 to 2002 (Fig. 1) recording the species and number of colonies, the maximum height (cm), the % damage level per colony, and the epibiosis stage (denuded skeleton=1, new=2, medium=3, old=4). From 2003 to 2012, the monitoring system considered minimum three haphazardously positioned quadrats ($1m^2$). Temperature data (2007-2011) were taken by a stable logger (www.ambienteinliguria.it). Complete depth profile data from previous years is unavailable for this area.

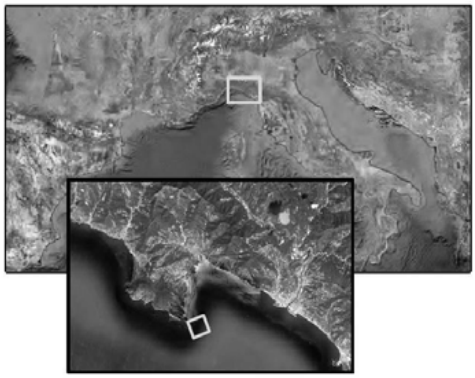

Fig. 1. Study area in the LIgurain sea, Portofino MPA. Detail of the study site, Punta del Faro.

Results and conclusions
Elevated damage percentages coincides with prolonged summer conditions (2007, 2009 and 2011) (Fig. 2). No colonies were detected in 2005 inside the considered quadrats, suggesting, as evidenced also by the high variance of the values of density in the years after, an increase in the fragmentation of the upper boundary of *P. clavata* population.
As shown from our data, no evident mass mortalities have occurred since 2008 in this area and it is possible to perceive at the moment a slow recovering picture as density is yearly increasing, though we also observed a total loss of *Paramuricea clavata* at -20 m. Temperature increase has deepened the upper limit of the gorgonian populations in the Portofino MPA, allowing more extended algal growth and becoming more susceptible to the insertion of allochthonous species.

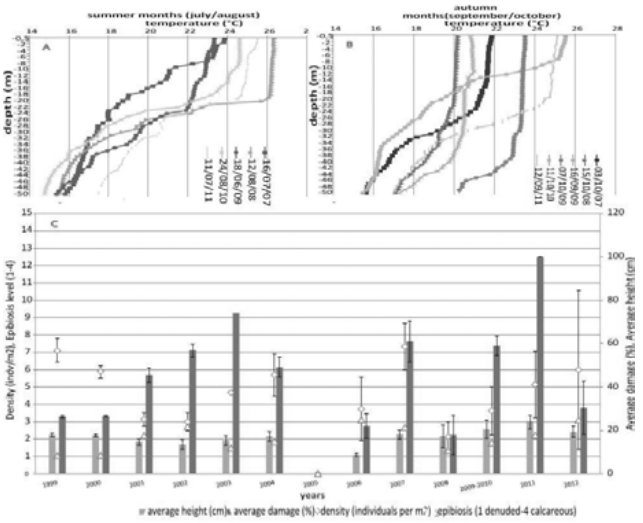

Fig. 2. Temperature and Paramuricea clavata population time series. Top graphs show the temperature profile in depth (A: summer; B: autumn) and bottom graph shows population analysis in time (C) at -25m considering height (cm), damage (%), epibiosis level (1-4) and density (number of colonies per m).

Abstract
Marine ecosystems are experiencing rapid changes due to natural and anthropogenic disturbances. If proper management strategies are to be enforced, these changes on the structure and functioning of the ecosystems need to be documented. In this paper, we describe coral mortality events along the coast of Cyprus and Croatia, including sites with intense land-based human activities (e.g. agriculture). Two recent mass mortality events (2010, 2012) seem to have been induced by prolonged seawater temperature increases during a period of several weeks. Using image-analysis software, *Cladocora caespitosa* colonies were evaluated (% affected area). At nutrient-affected sites, macroalgae and filter feeder organisms compete with corals for space, resulting in higher partial-tissue mortality (>90%) exacerbating thus the effects of the warming event.

Keywords: Cnidaria, Levantine Basin, North Adriatic Sea, Mortality, Temperature

Introduction
The island of Cyprus, located in the high-oligotrophic region of the eastern Mediterranean, provides an appealing ground for the study of coastal ecosystems under limiting and contrasting environmental conditions. Such comparative ecological studies are valuable since responses to disturbances from the same habitat/species can be investigated in relation to the local environment. If proper management strategies are to be enforced, the changes on the structure and functioning of marine ecosystems in response to natural and anthropogenic disturbances need to be considered. In this paper, we describe the 2012 coral mortality event along the coast of Cyprus and compare it to a similar event in Croatia, including selected sites where land-based human activities are likely to have a direct impact on coral habitats.

Material and methods
Using image-analysis software, *Cladocora caespitosa* colonies were evaluated by calculating and comparing the area-percentage of healthy tissue, affected tissue (bleached and freshly necrotic) and bare skeleton (recent, old mortality). The photographic record was acquired during and one to two months after the warming event through systematic diving transects at the eastern coast of Cyprus (two localities, 2-6m depth) and in Croatia (Ciovo Island, depth ranges 5-10m, 10-15m, 15-20m)..

Results
On average, *C. caespitosa* colonies in Cyprus (Fig. 1A) had less than 15% of pigmented tissue, almost 20% of the colony area affected (bleaching and/or incipient necrosis) and around 15% with recent partial mortality associated to the 2012 warming event. One locality (Krio Nero) had a higher percentage of old mortality ($p<0.001$) which can be related to the 2010 warming event. Macroalgae covered significant areas of the coral colonies in Cyprus (30-40%). At the Croatian island of Ciovo (Fig. 1B), corals in general were less affected and had more pigmented areas than in Cyprus. However, the few sampled shallow water colonies in Croatia had the highest percentages (over 40%, $p<0.05$) of affected tissue.

Discussion and conclusions
The 2012 event seems to have been induced by prolonged seawater temperature increases during a period of several weeks in Summer (in August and September), representing the highest warming event of the last 30 years in Cyprus. Seawater temperature in the Levantine basin in general, has increased during the Summer months since at least the '90s [1]. At the nutrient-affected sites, macroalgae and other filter feeder organisms compete with corals for space, resulting in higher partial tissue mortality. Despite this fact, coral colonies are more abundant in those sites, which might be explained by the anthropogenic change of naturally limiting conditions (oligotrophy) of Cypriot waters and the physiology of the particular coral species (auto- vs. heterotrophy). Our results suggest that corals under artificially induced conditions (more commonly found elsewhere in the Mediterranean) respond to environmental disturbances impaired by the macroalgae-dominated community. Monitoring of the coral colonies and the water quality at the studied sites will continue on a seasonal basis, in order to better understand these altered ecosystems and to contribute to the definition of management strategies.

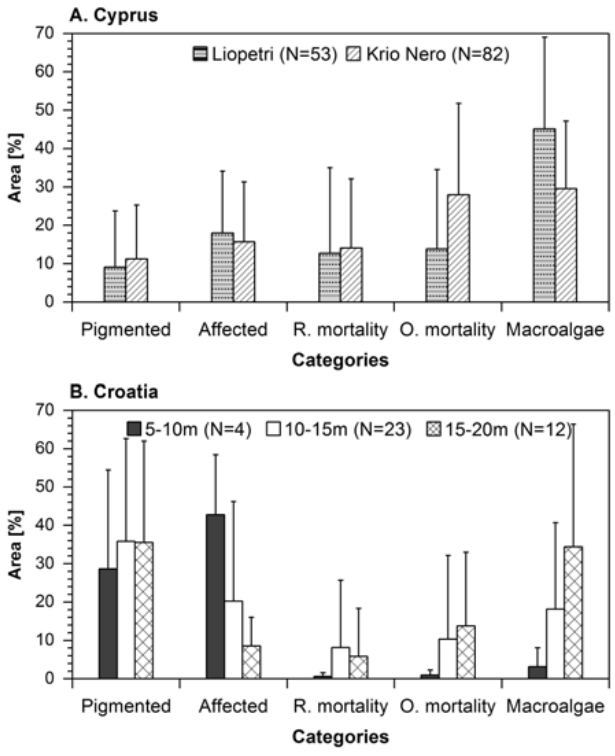

Fig. 1. Mean area-percentage (+1 SD) of tissue condition of *Cladocora caespitosa* colonies and macroalgae at two study sites in eastern Cyprus (A) and at three different depths in Ciovo Island, Croatia (B). Tissue mortality categorized as recent (R) and old (O). N= number of colonies.

MEDITERRANEAN *LITHOPHYLLUM BYSSOIDES* (LAMARCK) FOSLIE RIMS: CHRONICLE OF A DEATH FORETOLD

Thierry Thibaut [1]*, Aurélie Blanfuné [1] and Marc Verlaque [2]
[1] University Nice Sophia Antipolis - EA 4228 ECOMERS Faculté des Sciences, Parc Valrose - thierry.thibaut@unice.fr

Abstract
Most of the *Lithophyllum byssoides* rims have been mapped along the French Mediterranean coasts. These biogenic formations are frequent in Provence and along the west coast of Corsica, and rarer in other regions. Preliminary assessments of their current status showed that most of them are dead or in low vitaly due to the recent sea-level rise. These obversations question about the use of these rims as indicator of Good Ecological State in the european directives.

Keywords: Algae, North-Western Mediterranean

Introduction
In the Mediterranean Sea, under favourable environmental conditions, *Lithophyllum byssoides* (Lamarck) Foslie (Rhodophyta) constitutes at the lower part of the mid-littoral large biogenic constructions referred to as *L. byssoides* rims". Their development is a long process that requires a near-stable or slowly rising sea-level and high sea-water quality over long periods (several centuries). For this reason, they were widely adopted as indicator of Good Ecological State by The Europe (WFD, MSFD, Natura 2000). Unfortunately, today the regression dominates on all studied rims independently of the water quality. This situation has been attributed to the recent acceleration of sea-level rise [1,2]. This hypothesis was tested along the French Mediterranean coasts.

Method
The *L. byssoides* rims were mapped along the littoral cruising slowly on a small boat at few meters from the coast. The vitality of some rims has been evaluated using the method described by one of us [3].

Results
Lithophyllum byssoides rims are frequent along the Pyrénées-Orientales, the Bouches-du-Rhône and the Var departments and the west Corsica, and rarer in the Alpes-Maritimes and the East Corsica (Figure 1).

Fig. 1. Location (black bold lines) of *Lithophyllum byssoides* rims along the French Mediterranean Coast.

Preliminary evaluations confirmed a global regressive trend. Most of rims were dying. Dead parts of rims were most eroded than alive ones. Locally subtidal algae (*Corallina* spp.) grew on the upper surface of rims pointing out a sea-level unfavorable with the life of *L. byssoides* (Figure 2).

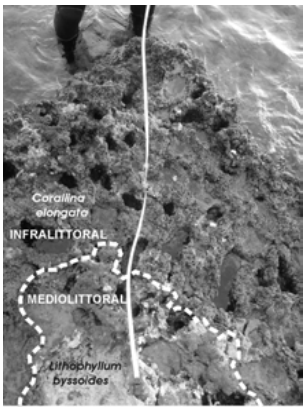

Fig. 2. Upper surface of a *Lithophyllum byssoides* rim colonised by infralittoral algae (Marseille 2013, © Mathieu Imbert).

Conclusions
The present well-developed algal rims were formed during ~300 years of sea-level stabilisation throughout the Little Ice Age (LIA) (1330 till 1640 cal AD). Since the end of LIA, the sea-level is rising at an increasing rate [4]. The average annual rise was estimated at 1.7 ± 0.3 mm.a^{-1} for the 1950-2009 period, and 3.3 ± 0.4 mm.a^{-1} for 1993-2009 [5,6]. The current rate appears too fast for the growth capacities of *L. byssoides* rims and these biogenic formations decline over thousand of kilometres of coast, excluding pollutions as the main cause of regression. Whereas the species *L. byssoides* is not threatened (young individuals are frequently observed higher on the littoral), the thousand years old rims seem to be condemned to disappear. These observations question about the use of *L. byssoides* rims in the European directives.

ROCKY SHORE MOLLUSCAN ASSEMBLAGES FROM NATURAL AND ARTIFICIAL SUBSTRATA IN THE MALTESE ISLANDS

Leanne Bonnici [1]*, Joseph A. Borg [1], Julian Evans [2] and Patrick J. Schembri [1]
[1] Department of Biology, University of Malta, Msida MSD2080, Malta - leanne.bonnici@gmail.com
[2] Marine Biology and Ecology Research Centre, University of Plymouth, Plymouth PL4 8AA, UK

Abstract
The mediolittoral macrofaunal assemblages associated with concrete jetties and natural rocky substrata in two Maltese bays were compared to assess potential differences in the molluscan assemblages between artificial and natural hard substrata. The whole extent of the mediolittoral zone was sampled and the molluscs present were identified and counted. Overall species richness was significantly lower on jetties. Densities of species common on the natural rock, such as *Cerithium* spp. and *Eatonina* spp., were lower on jetties; however, the densities of *Patella* spp. were higher.

Keywords: Artificial reefs, Coastal engineering, Mediolittoral, Mollusca, Sicily Channel

Introduction: Jetties differ from natural shores by being vertical, which results in differences in wave interactions with the structure surface, and by having a different substratum composition and topography. These factors have consequences for the microhabitats required by specialist fauna [1]. Additionally, on jetties, the steep slope results in a considerable reduction in the extent of the mediolittoral zone, such that the area available for colonisation is much smaller [2]. The present study was carried out to test whether jetties support a reduced molluscan diversity, as compared to natural rocky shores within the same locality.

Method: Two localities in northern Malta, with similar exposure and geomorphology, were studied: Ghajn Zejtuna and White Tower Bay. Four stations at each locality, two situated on jetties and two on natural rock, were sampled between August and September 2011. At each station, the biota within three replicate 10 cm-wide belt transects of variable length, extending from the lower to the upper limits of the mediolittoral zone, were scraped off. The length of each transect was measured in order to standardise counts to the same unit area. In the laboratory, all live molluscs were sorted out from each sample, identified to the lowest possible taxon, and counted. Statistical analyses were carried out using PRIMER 6 (Plymouth Routines In Multivariate Ecological Research, PRIMER-E Ltd) and GMAV 5 (Institute of Marine Ecology, University of Sydney, Australia).

Results and Discussion: ANOVA indicated that the total number of species (Fig. 1) was significantly different ($p<0.05$) between the two shore types, with jetties having lower values (range: 2 – 7 species) than natural shores (range: 19 – 25 species).

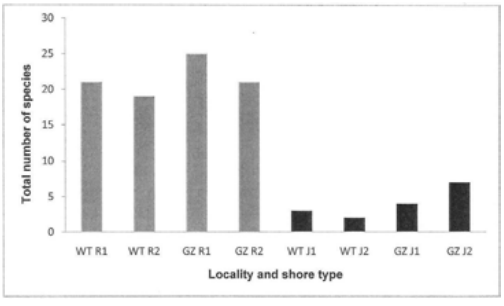

Fig. 1. Total number of mollusc species recorded at each station in the two localities; 'WT' and 'GZ' stand for White Tower Bay and Ghajn Zejtuna respectively; 'R' and 'J' stand for rocky shores and jetties respectively.

Nine species were common to both shore types, 20 species were only recorded on natural shores, while there were no species recorded solely on jetties (Tab.1). Total abundance of molluscs was always lower on jetties; however, this was not statistically significant. *Eatonina* spp. and *Patella* spp. contributed up to 50% to the dissimilarity (obtained from SIMPER analysis) between the two shore types at both localities; *Cerithium* spp. was also an important contributor to the dissimilarity between the two shore types at White Tower Bay.

Tab. 1. List of species recorded on both shore types, together with ones recorded only on natural shores, hence absent from jetties.

Species recorded from both shore types	Species recorded solely from natural shores	
Brachidontes pharaonis	Opisthobranchia sp.	*Lepidochitona corrugata*
Eatonina cossurae	*Acanthochitona* sp.	*Mitra cornicula*
Eatonina fulgida	*Alvania lanciae*	*Ocinebrina edwardsii*
Gibbula sp.	*Omalogyra atomus*	*Phorcus turbinatus*
Mytilaster minimus	*Cardita calyculata*	*Paludinella* sp.
Patella caerulea	*Cerithium* spp.	*Pisania striata*
Patella ulyssiponensis	*Columbella rustica*	*Pisinna glabrata*
Patella rustica	*Conus ventricosus*	*Setia* spp.
Skeneidae sp.	*Irus irus*	*Odostomia* sp.
	Jujubinus gravinae	*Rissoa* spp.

Eatonina spp. were recorded on natural shores at both localities; jetties at Ghajn Zejtuna had a lower abundance of these species, whilst these were absent on jetties at White Tower Bay. All local species of *Patella* (*P. rustica*, *P. ulyssiponensis* and *P. caerulea*) reached higher densities on jetties irrespective of locality. On the other hand, *Cerithium* spp. were absent on jetties in contrast to natural shores at White Tower Bay, whilst the same species were sparse at Ghajn Zejtuna independent of shore type. Most species recorded solely from the natural shores were small molluscs (not exceeding a maximum shell length of 6mm) with few exceptions; moreover, most of the individuals encountered in this study were juveniles. The majority of the species absent from jetties, as well as those recorded in higher abundances on rocky shores (e.g. *Eatonina* spp. and *Cerithium* spp.) are often recorded from the infralittoral or lower mediolittoral amongst algae, in sediment, or under stones[3][4] hence require a more or less moist environment. Such an environment is present within crevices in the mediolittoral zone but these microhabitats were sparse on the concrete jetties. The increased density of *Patella* spp. on jetties could possibly be due to a lower density of other grazers, thus reducing interspecific competition, or due to other biotic and/or physical factors. The present results corroborate those of previous studies that also recorded a lower diversity of mobile species on artificial structures when compared to natural rock, with a number of mollusc species typical of crevices and rock pools on rocky shores being absent from the artificial habitats [2].

DISTRIBUTION AND DEMOGRAPHIC STRUCTURE OF *STRAMONITA HAEMASTOMA* (LINNAEUS, 1767) POPULATIONS ON THE ROCKY SHORES OF THE GULF OF TUNIS

Wafa Boulajfene [1]*, Jihen Boukhicha [1], Oum Kalthoum Ben Hassine [1] and Sabiha Tlig-Zouari [1]
[1] Université Tuis-El-Manar Faculté des sciences de Tunis - wboulajfene@gmail.com

Abstract
The eco-biological study of *Stramonita haemastoma* on the rocky coasts of the Gulf of Tunis revealed the ubiquity of the species, with varying density values depending on the stations. The average size of collected individuals was about 39.13 ±9.95 mm. The sex frequency analysis, showed females dominance. The presence of large sized immatures suggests that there is no relationship between sexual maturity and shell size in this species.

Keywords: Population Dynamics, Gulf of Tunis

Introduction
Stramonita haemastoma (Mollusca: Gastropoda) is a gonochoric gastropod occurring mainly in the lower shore level. In Tunisia, researches related to this species remain limited. For this purpose, an eco-biological study about the distribution, the abundance and the demographic structure of this gastropod was undertaken.

Material and Methods
A total of 12 rocky stations of the Gulf of Tunis were explored during the spring 2012, namely; Pilau Island, Sidi Ali El Mekki, Gammarth, Sidi Bou Saïd, Carthage, Salammbô, La Goulette, Soliman, Sidi Rais, Korbous, Port aux Princes and El Haouaria. In each station, density values were estimated by means of four 10x5m transects equidistant of 10m ([1]). Thus, a total sampling area of 500 m² was explored. In addition, 30 specimens were randomly collected at each station. Shell lengths were measured using an electronic caliper (1/100mm) and sex was determined based on the presence (female) or absence (male) of albumen and sperm ingestion glands.

Results and Discussion
S. haemastoma was found in all surveyed stations except those of Carthage and Salammbô. Estimated density values varied from one station to another?? (Fig. 1). Port aux Princes hosted few scattered individuals (0.4 ind/m²). As for Gammarth, it shelters a dense population of *S. haemastoma* (14 ind/m²). Average size was equal to 39.13 ±9.95mm in the entire Gulf of Tunis. Sizes oscillated between a minimum of 4 mm recorded at Sidi Rais and a maximum of 76.36 mm at La Goulette.

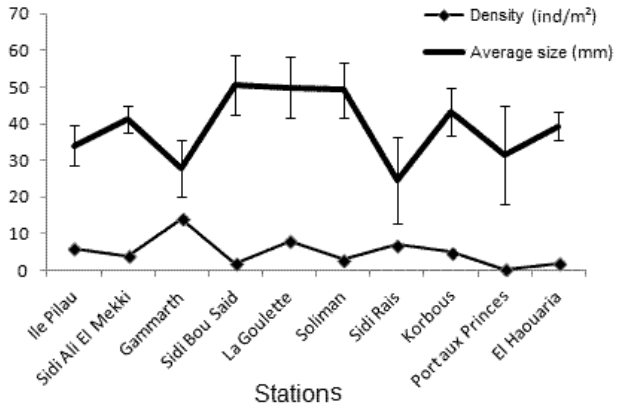

Fig. 1. Spatial variations of the density and the average size of *S. haemastoma*.

Out of a total of 300 collected specimens, males represented only 25.33% with an average size of about 37.28 ±10.38 mm (Fig. 2). Females were more frequent (49%), their average size was equal to 45.91 ±8.81mm. As for immature individuals (25.67%) they were generally small, 87% of them had a size between 15 and 20mm. However, some stations (Sidi Bou Saïd, La Goulette, Korbous and El Haouaria) showed large sized immature specimens (12.98 %) (40 to 55mm).

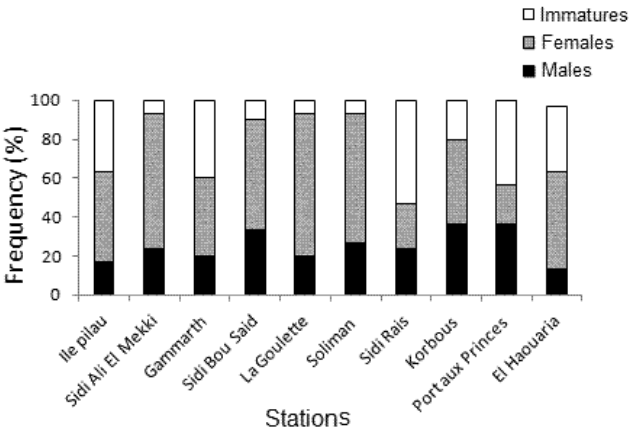

Fig. 2. Sex frequency in *S. haemastoma* in prospected stations.

Although the ubiquityof *S. haemastoma*, the species was not observed in Carthage and Salammbô. Whelk's absence at these stations could be attributed to its refuge in cracks and crevices. The average size estimated in the Gulf of Tunis (39.13 mm) was similar to that recorded in the Mediterranean coast of Morocco (43.06 mm) ([2]) but lower than that reported in the Atlantic Moroccan coast (71.68 mm) ([2]). The observation of large sized immature individuals, confirms that there is no relationship between sexual maturity and size in this species ([3]).

MORPHOMETRIC DIVERSITY OF *STRAMONITA HAEMASTOMA* (LINNAEUS, 1767) ON THE ROCKY SHORES OF THE GULF OF TUNIS

Wafa Boulajfene [1]*, Jihen Boukhicha [1], Oum Kalthoum Ben Hassine [1] and Sabiha Tlig-Zouari [1]
[1] Faculté des sciences de Tunis Campus Universitaire de Tunis, 2092 El Manar, Tunis-Tunisie - wboulajfene@gmail.com

Abstract
A factorial discriminant analysis of morphometric data was performed on 210 specimens of *Stramonita haemastoma* collected from seven prospected stations on the Gulf of Tunis. This analysis showed that although the presence of an inter-populational morphological overlap between studied populations, shape differences were significant.

Keywords: Gastropods, Gulf of Tunis

Introduction
S. haemastoma is a key species contributing to the regulation of intertidal community structure by its predatory behavior. Works on the morphology of this gastropod remain deficient. For this reason, we investigated morphology in this species along the rocky coastline of the Gulf of Tunis.

Materials and methods
210 individuals were collected from 7 stations along the Gulf of Tunis during the spring 2012: Ile Pilau, Sidi Ali El Mekki, Sidi Bou Saïd, La Goulette, Soliman, Korbous, and El Haouaria. On each shell, 10 parameters were measured, using an electronic caliper (1/100 mm): Shell length (L), shell width (W), shell thickness (ST), last whorl length (WL), aperture length (AL), aperture width (AW), siphonal canal length (SL), siphonal canal width (SW), operculum length (OL), operculum width (OW). A logarithmic transformation of morphometric data was performed to increase linearity and normality. The following formula was used to reduce size effect ([1]): $Mtrans = logM - \beta (\log L - \log Lmean)$ where Mtrans is the transformed measurement, M the original measurement, β the within-group slope regressions of the log M vs. log L, L the shell length, and Lmean the overall mean of the length. The transformed variables were used to perform a factorial discriminant analysis (FDA). Afterwards, Wilks test was performed to evaluate the difference between the group means obtained by FDA. Furthermore, the estimation of PCS was used to assess the percentage of correctly classified individuals in their original samples and distinguish the overlap between populations.

Results and Discussion
The results showed that the two first axes explain 69.13% of the total variability. The contribution of the variables in the formation of discriminant axes was represented (Fig. 1).

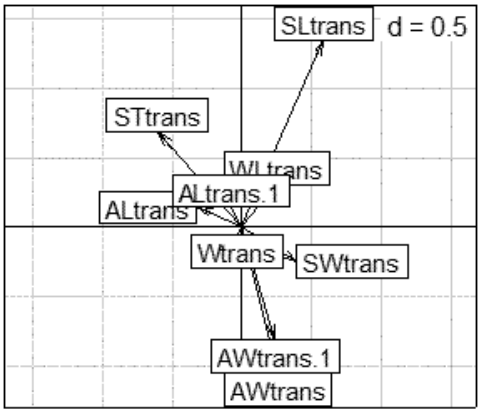

Fig. 1. Contribution of the variables in the formation of the two first discriminant functions.

The plot obtained with the two first discriminant functions (DF1 and DF2) revealed the presence of a large intra-populational heterogeneity leading to an inter-populational overlap (Fig. 2). The populations of La Goulette and Pilau Island have characteristic shapes. Morphological differences in the first sample were mainly associated to shell, operculum and aperture widths. In the second, they were related to shell thickness and aperture length. However, although the overlap between populations, Wilks test showed a significant difference between the groups means obtained by DFA (Wilks' lambda = 0.1671, F = 7.7743, p <0.05). PCS percentages varied between 46.66% in Soliman and 86.66% in Ile Pilau with a mean of 62.85%.

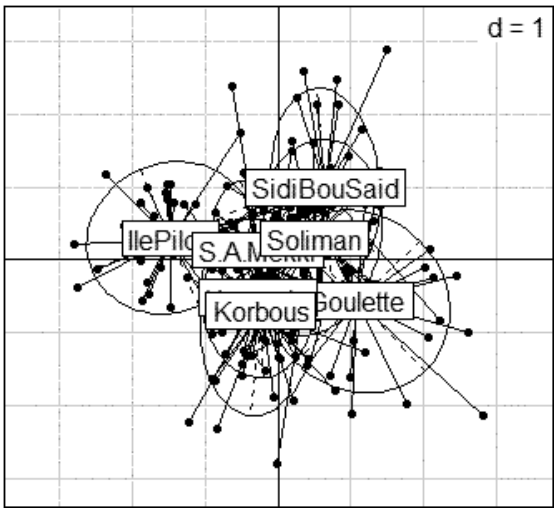

Fig. 2. Factorial Discriminant Analysis (FDA) of studied populations.

The results showed that although the presence of an inter-populational morphological homogeneity between studied populations on the Gulf of Tunis, shape differences are significant. This variability could be related to *S. haemastoma* habitat diversity and associated environmental conditions, particularly wave exposure and desiccation ([2]). These differences seem to confer physical advantages for individuals' survival in their respective niches.

EFFECTS OF AN ARTIFICIAL REEF ON THE SOFT-BOTTOM COMMUNITY (WESTERN ADRIATIC SEA)

Beatrice Brunetti [1]*, Alessandra Spagnolo [1], Elisa Punzo [1] and Gianna Fabi [1]
[1] CNR-ISMAR Ancona (ITALY) - beatrice.brunetti.b@gmail.com

Abstract
The Porto Recanati artificial reef (Adriatic Sea) was investigated starting just after its deployment for a total of five years. Quantitative benthic samples were collected outside (K) and inside the reef (close and far from the concrete modules; C and F, respectively) to evaluate the influence of the artificial structures on the soft-bottom community. No differences were highlighted by MDS and Simper analysis among the three sites in the first year. Starting from the second year the homogeneity between K and F sites was confirmed, whereas C sites always appeared different from the others, due to the presence of hard-bottom species which were more numerous close to the structures.

Keywords: Artificial reefs, North Adriatic Sea, Zoobenthos

Introduction
Artificial reefs (ARs) are generally placed on soft seabed away from natural rocky substrates and may induce either physical and/or biological changes on the adjacent soft-bottom habitats. For example, they can affect currents and waves altering the sediment-size distribution and favouring accumulation of organic material on the seabed. An organic enrichment of sediments may be also induced by the activity of reef-associated organisms. In order to get a deeper knowledge about the benthic communities colonizing the surrounding soft-bottom and to spatially evaluate the reef influence on the seabed, Porto Recanati AR was investigated for five years after its deployment.

Material and Methods
The AR is located 5.5 km offshore at 12.5 m depth on silty-sand bottom. This reef, deployed in spring 2001, covers an area of about 54.5 ha and consists of 222 concrete pyramids (Py) and of 444 concrete poles (P). Each Py is made of five cubic blocks (2x2x2 m; total height: 4 m). The poles (height: 4 m) are placed at regular intervals between the Py and along the perimeter of the AR. Soft-bottom zoobenthic assemblages were sampled in summer from 2001, just after the AR deployment, to 2005. Two sites close to a pyramid (C), two inside the reef area but 15 m away from the structures (F), and two 200 m outside the reef (control sites: K) were randomly selected at each survey. Six samples (40x40 cm) were collected at each site using a suction sampler. Multivariate analyses were performed to identify temporal changes in the composition of macrofauna using PRIMER™ ecological software package ([1], [2]). Prior to analysis, species abundance data were square-root transformed. Similarity among communities having different spatial settlement was evaluated using MDS analysis. Similarity percentage breakdown procedure (Simper; [2]) were used to determine the contribution of individual taxa to the dissimilarity among the three sites (C, F, K), among years and the combination of these two main factors.

Results
In the overall, 202 taxa were identified, mainly polychaetes (75), molluscs (62), crustaceans (48) and echinoderms (10). Most of these taxa (145) were typical of soft bottoms (Sb) and 27 of hard substrates (Hb). The highest density was always obtained at C sites except in 2003 and 2004, reaching the maximum in 2002 (14.9±0.8 ind dm^{-2}). In 2003 and 2004 the greatest abundance was observed at K sites (8.5±2.8 ind dm^{-2} and 12.9±1.6 ind dm^{-2}, respectively) due to the occurrence of *Scapharca inaequivalvis* and/or *Corbula gibba*. Intermediate values were always recorded at F sites. A great homogeneity among sites was observed in 2001 (fig. 1; Tab. 1). The major contributors to this similarity were Sb species, such as *C. gibba*, *Calyptraea chinensis*, and *Kurtiella bidentata*, all censused at the three sites. Starting from 2002, Simper analysis showed low dissimilarity between F and K, intermediate between F and C and high between K and C. It was due to the settlement close the artificial structures of some Hb species (e.g., *Balanus improvisus*) not found at F and K sites or represented by a greater density than at F and/or K (e.g., *Pomatoceros triqueter*, *Hiatella arctica*). At C sites a greater abundance of some Sb organisms with a carnivorous habitus (e.g., *Nassarius nitidus*, *N. pygmaeus*) and/or filter-feeders (e.g., *Paphia aurea*, *K. bidentata*) was also highlighted.

Conclusions
The deployment of AR induced a gradual diversification of the benthic communities living in the surrounding soft bottom from the second year after the immersion. This effect was more consistent close to the structures due to a progressive settlement of Hb species, attracted by the presence of both artificial substrates and specimens of *Mytilus galloprovincialis* fallen down from Py, providing natural hard substrates and new habitat for marine epifaunal organisms rarely occurring in Sb communities. An increase of Sb species mainly represented by filter-feeders and carnivorous was also observed. The first ones were likely attracted by a turn-over of suspended material close to the structures, and the second ones by a greater preys availability.The influence of artificial structures appeared to gradually extend inside the AR up to 15 m from the structures, where a community with characteristics common both to those observed close to pyramids and at the control sites was censused.

TROPHIC RELATIONSHIPS OF FISHES ON MARSEILLES' ARTIFICIAL REEFS ASSESSED BY STABLE ISOTOPE AND STOMACH CONTENT ANALYSES

Pierre Cresson [1]*, Sandrine Ruitton [1], Mélanie Ourgaud [1] and Mireille Harmelin-Vivien [1]
[1] MIO - Aix Marseille Université - pierre.cresson@univ-amu.fr

Abstract
Diets and trophic relationships of fishes of the Marseilles' bay artificial reef system were assessed by the coupled use of stable isotope and stomach content analyses. The results obtained in this artificial environment were comparable with those obtained in natural rocky environments, indicating that artificial reefs do not modify the feeding patterns and trophic structure of the fish community. The predominance of local prey in stomach contents, like some crustacean species, demonstrated that artificial reefs could provide diverse and abundant food resources for most fish species.

Keywords: Artificial reefs, Food webs, Fishes, Stable isotopes, North-Western Mediterranean

Introduction

With the deployment of more than 400 artificial reefs in the bay of Marseilles, RECIFS PRADO is the largest artificial reef program in the Mediterranean Sea. Artificial reefs are considered to be an effective tool to manage fisheries, mainly by their ability to enhance fish biomasses and to sustain small scale coastal fisheries [1]. This deployment represents also a unique scientific opportunity to understand the functioning of a coastal rocky environment under the influence of a large city. This work was aimed to assess the importance of artificial reefs as a food source for fish species, by the coupled use of carbon and nitrogen stable isotope and stomach content analyses. Stomach content analysis is a classical tool, commonly applied to understand the feeding habits of Mediterranean fishes [2]. Stable isotope analysis, a more recent technique in the field of trophic ecology of fishes, is also successfully used in Mediterranean ecosystems [3]. The coupled use of these two complementary techniques allows a better understanding of fish feeding patterns and their trophic relationships [4].

Material and Methods

In summer and winter 2010, 23 fish species were sampled in the Marseilles' bay artificial reefs by spear fishing and trammel nets. C and N stable isotope ratios were determined on white dorsal muscle by mass spectrometry. Prey observed in stomach contents were determined to the lowest taxonomic level and then weighed to assess their quantitative importance.

Results and discussion

The analysis of stomach contents revealed the importance of crustaceans and fishes as fish prey. Crustaceans were the most frequent prey item (80 % of occurrence) and the second of importance by weight. Fish was the first food item by weight. Mollusks, annelids, algae and *Posidonia oceanica* were also consumed, but in lower amounts. The importance of crustaceans in fish diet is consistent with patterns previously observed in other artificial reef systems [5]. The presence of the same crustacean species on the artificial reefs and in stomach contents confirmed the use of artificial reef organisms as a food source for fishes. These results highlighted also the importance of artificial reef complexity to provide shelter for small species and to increase the quantity of food available to predators. Fishes were classified into five groups depending on their diets: "zooplankton feeders", "soft bottom mesocarnivores", "rocky bottom mesocarnivores", "macrocarnivores" and "piscivores".

Fishes displayed a large range of isotopic ratios. For C, the observed range of 2 ‰ between minimal and maximal values reflected the dependence on at least two organic matter sources (planktonic and benthic). The high range observed for N (7 ‰) indicated at least three trophic levels among these species. They were classified in six groups depending on their isotopic ratios. Some discrepancies appeared between the two classifications based on stable isotopes or stomach contents. "Zooplankton feeders" was the only group to be totally common to the two classifications, due to the specificity of their diet on specific and isotopic points of view. Stable isotope ratios differed between benthic and pelagic piscivores, and between labrids and sparids in the "rocky bottom mesocarnivores" group. The coupled use of the two techniques allowed differentiating seven trophic groups among these fish species (Fig.1). The $\delta^{15}N$ value observed for sparids was surprisingly high for omnivorous species.

These results called for a careful interpretation of stable isotope ratios as a direct indicator of diet. They confirmed also that the deployment of artificial reefs does not modify fish feeding patterns and enhances the food resources available for fishes.

Abstract

We studied effects of depth and *Cystoseira balearica* forests canopy height on coastal juvenile fish assemblages of Minorca Island. Results showed a clear differentiation of juvenile fish assemblages due to depth: assemblage in the shallowest range (3-4m) was characterized by higher densities of *Thalassoma pavo*, deeper ones (6-8, 10-12 m) by higher densities of *Coris julis*. Smallest juveniles of both species were more abundant within forests displaying the highest canopy height; meanwhile largest juveniles were more abundant within low *Cystoseira* forests. Also, both species showed predominantly a cryptic behavior on forest of higher canopy height, and a temporal one when canopy was lower. This study supports the importance of preserving healthy *Cystoseira* forests in order to preserve their nursery value for these two Labrid species.

Keywords: Teleostei, Algae, Life cycles, Bathymetry, North-Western Mediterranean

Introduction

Many fish species of the Mediterranean present at least some disjunction between adult and juvenile habitats. Usually adults occupy a broader range of depth and habitats, while juveniles appear in littoral waters in specific habitats [1], called juvenile habitats. For a given species, among juvenile habitats, nursery habitats are characterized by higher nursery value (i.e. contribution per unit area of individuals to adult populations). Nursery value can vary spatially according to factors that create site-specific variation. These factors may be biotic (such as structural complexity) or abiotic (such as water depth) [2]. Along the Mediterranean coasts, *Cystoseira* forests display a high nursery value for some Labridae species [3] but simultaneously are threatened by human pressures, and tend to regress [4]. It is important to understand site-specific factors molding suitability of this nursery habitat in order to design management actions that assure the replenishment of adult fish populations. We aim to study the effect of depth and micro-habitat characteristics (canopy height) on the nursery value of *Cystoseira* forests along Minorca Island coasts.

Material and Methods

In September 2012 we sampled 3 sites of 2 separated localities containing *Cystoseira balearica* forests of similar cover (>70%), at three depth ranges (3-4, 6-8, 10-12 m). In each depth range, a diver haphazardly selected 8 sampling points within the forest. The diver recorded canopy height and cover, as well as abundance, size and behavior of juvenile fishes during 5 minutes within a quadrate area of $1m^2$ [3]. Other habitat parameters (slope, etc.) were kept constant. Analysis of data where made by multivariate and univariate exploratory and inferential approaches, using R and Primer6/Permanova+ softwares [3].

Results and Discussion

Assemblages of juveniles significantly differed according to depth (Fig 1; PERMANOVA, F=10.6, p=0.004). Assemblages at shallow depth were characterized by higher densities of *Thalassoma pavo*, and deeper assemblages by higher densities of *Coris julis*. Additionally, we found for juveniles of *C. julis*, that different juvenile size classes showed contrasted abundance patterns according to depth, which was not the case for *T. pavo*. For both species, smallest juveniles were more abundant within forests displaying the highest canopy height (~13 cm); meanwhile largest juveniles were more abundant within *Cystoseira* forests displaying the lowest canopy height (~5 cm). Furthermore, both species showed more cryptic behavior in forests of higher canopy height, and a rather temporal behavior when canopy was lower. Results are consistent with previous studies investigating the range of depth distribution of juveniles of *C. julis* and *T. pavo* [1]. It has been previously demonstrated for *C. julis* a clear disjunction between adults and juveniles distribution. Not for *T. pavo* [1].

This study may support that when adults are well segregated from juveniles by depth, migration of juveniles to a broader range of depth occurs gradually as they grow and gain maturity. Also this study supports the importance of preserving healthy *Cystoseira* forests (with dense and high canopy) in order to guarantee their nursery value for these two Labrid species.

DISTRIBUTION AND ECOLOGY OF PROSOBRANCHIA GASTROPODS (MOLLUSCA) IN THE NORTH AEGEAN SEA (GULF OF EDREMIT-DARDANELLES)

Muharrem E. Sahin [1] and Mehmet Culha [2*]
[1] COMU, Fisheries Faculty, Dept. of Hydrobiology, Canakkale
[2] IKCU, Fisheries Facul., Depar. of Hydrobiology - msculha@gmail.com

Abstract
The purpose of this study is to determine the structure of community which formed by Prosobranchia (Gastropoda-Mollusca) species in the Anatolian coast of the Dardanelles Strait and the Gulf of Edremit. Samples were taken from a depth of 0.5 - 5 m from eight different stations with the 30x30 quadrate between November 2011 and May 2012. As a result of the study, 36 species belonging to 16 families and 4207 individuals were obtained. The maximum dominant species is Bittium reticulatum (Da Costa, 1778) with a 19% value. Station which has the highest number of species and individuals, including 29 species and 1188 individuals, was Ayvalik. Minimum number of species and individuals is 15 and Altinoluk became the least station that including 190 number of individuals.

Keywords: Biodiversity, Aegean Sea, Dardanelles, Gastropods, Mollusca

Introduction
It is estimated that there are about 5,942 benthic invertebrate species in the mediterranean (622 sponges, 420 cnidarians, about 500 bryozoa, 1,000 annelids, 2,000 molluscs, 154 echinoderms, 6 echiurians, 3 priapulidae, 33 siphuncles, 15 brachiopods, 1 pogonophore, 4 phonorids, 5 hemichordata and about 1,935 arthropods) (Zenetos et al., 2002, 2003). Sampling at the 8 stations was conducted seasonally at various biotopes at depths of 0.5m-5m. The present study was carried out to determine Mollusca fauna biodiversity (Prosobranch Gastropods) in Anatolian coasts of Dardanelles located at the upper-infralittoral zone of the Northern Aegean Sea coasts of Turkey.

Collection and evaluation of the study material
Mollusk specimens were obtained by sampling during November 2011 and June 2012 at 8 stations (Ayvalik, Gömeç, Altinoluk, Assos, Yeniköy, Geyikli, Kumkale and Dardanos). Samplings were performed at depth of 0,5-5m with quadrat (30x30 cm) and spatula for seasonaly. Physicochemical parameters was measured in-situ by YSI 556 MPS probe. Materials collected in the local area were fixed in formalin of 4% to be examined in the laboratory. As a result of the studies in Turkish coasts of the North Aegean Sea carried out 36 species and 4207 specimens have been identified. The seasonal distribution of the physicochemical parameters measured on site as in-situ.

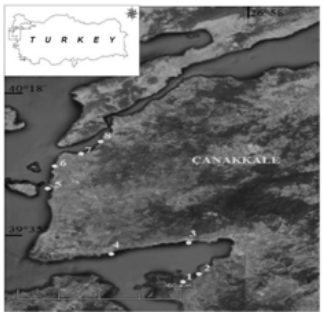

Fig. 1. Research area and sampling stations

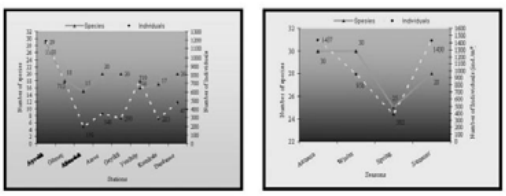

Fig. 2. Distributions of species-specimens and seasonal

Conclusion
As a result of the qualitative investigations on the species identified, Ayvalik station, with the greatest abundance, was found to be represented by 29 species whereas the second most abundant station was established to be assos, geyikli, dardanos stations with 20 species, respectively. As the stations were examined based on the number of specimens, the highest number of specimens (1188) were found at Ayvalik station followed by Yeniköy station (719 specimens) and Gömeç station (712 specimens). Otherwise, the lowest number of species and specimens (15, 190) was found at Altinoluk station (Figure 1). With regard to the seasonal distribution of the species found in study area, autumn and winter was the leading season with 30 species followed by summer; and spring (25 species) with the lowest number of species. In the present seasonal study, the highest number of specimens were observed in autumn, which provided relatively warm waters and optimum environmental parameters (Figure 2), whereas the lowest number of specimens were recorded in spring. The purpose of the present study was to determine the marine Prosobrancia mollusk species at the Anatolian coasts of Dardanelles. A total of 36 species were detected belonged to 16 families.

MARINE UNDERWATER CAVES OF TARKHANKUT PENINSULA (BLACK SEA, UKRAINE), ITS BIOTA WITH EMPHASIS ON SPONGES FAUNA

Alexander Ereskovsky [1]*, Oleg A. Kovtun [2] and Konstantin K. Pronin [2]
[1] CNRS UMR 7263 IMBE - alexander.ereskovsky@imbe.fr
[2] Odessa National I. I. Mechnikov University, Odessa, Ukraine

Abstract
A detailed geomorphological description of five submarine shallow semi-submerged caves from peninsula Tarhankut, Crimea (Black Sea) realized. Investigated their biological characteristics with special attention to sponges species composition and distribution. It was detected seven sponge species (class Demospongiae). These species are tolerant to different hydrological conditions, and some of them have wide geographical distribution.

Keywords: Biodiversity, Black Sea

In recent decades, systematic surveys of littoral submarine caves have received particular attention from the scientific community. The particular environmental conditions of these habitats (absence of light, oligotrophy, and reduced hydrodynamic action) make submarine caves enclave mesocosms of the deep aphotic zone in shallow coastal areas [1]. Due to their relatively small size and ease of accessibility, environmental stability, and presence of communities of endemic and specialized species, dark submarine caves are excellent model habitats to address important ecological and evolutionary questions such as the influence of life cycle and habitat fragmentation on gene flow. In addition, all the information gathered on such habitats can be interpreted in the context of global climate change and can help increase awareness of the related pertinent issues. A special attention in the last decade is given to the submarine caves in the north-western Mediterranean [2]. However, information on the biodiversity of the underwater caves of the Black Sea is extremely fragmentary. The reduced salinity is the most important environmental factor influencing marine biodiversity in the Black Sea. Two to five times fewer species in various taxa of benthic animals live in the Black Sea as compared to the neighboring Mediterranean [3]. A good example of this pattern is the phylum Porifera (sponges): the Black Sea inhabited by 29 species of sponges (about 4.5% of Mediterranean). The main objectives of this study were (1) a detailed geomorphological description of several submarine shallow-water semi-submerged caves from peninsula Tarhankut, Crimea, and (2) their biological characteristics with special attention (3) to study the species composition and distribution of sponges habitat in these caves. It was investigated 5 caves: three semi-submerged and two submerged with length from 9 to 131 m and volume from 61 m^3 to 3060 m^3 (Fig. 1).

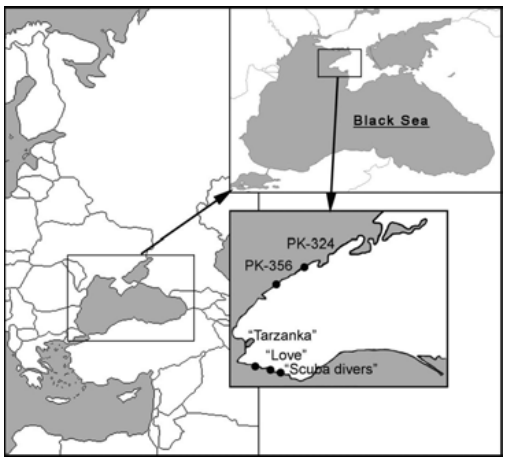

Fig. 1.

Fig. 1. Map of investigated caves.

All of them have karst-abrasive or karst origin. Our research of some caves in SW of Crimea haveshowa numberofnew and very rare troglobiont species, which confirms the existence in the Black Sea marine caves little-known communities. In investigated caves we have detected seven sponge species (all from the class Demospongiae) (Table 1).

Tab. 1. Sponges from underwater caves from Tarchankut (Crimea) and their distribution in relation to the entrance.

Tab. 1.

Sponges	Caves				
	«Scuba divers»	«The love »	PK356	«Tarzanka»	PK-324
Dysidea fragilis (Montagu, 1818)	0 - 3 m	0 - 4 m	0 - 6 m	0 - 4 m	0 - 4 m
Plone vastifica (Hancock, 1849)	0 - 67 m	0 - 40 m	0 - 15 m	0 - 20 m	0 - 9 m
Haliclona flavescens (Topsent, 1893)	0 - 92 m	0 - 40 m	6 - 22 m	2 - 20 m	9 m
Haliclona sp. 2 (branches)	12 - 46 m	6 - 55 m	No	2 - 20 m	No
Geodia stellosa (Czerniavsky, 1880)	24, 36 m	6 - 55 m	No	20 m	4-5 m
Suberites prototypus Czerniavsky, 1880	24 - 36 m	24 - 36 m	10 - 15 m	No	No
Clathria cleistochela (Topsent, 1925)	24 - 30 m	24 - 40 m	No	20 - 25 m	No

All these species have been described by previous authors from the adjacent open sea waters. These species are tolerant to different hydrological conditions, mostly temperature and salinity. Some of them have wide geographical distribution. Our study confirmed the dominance of sponges in the caves of Tarkhankut. However, the community structure of sponges, their abundance and biomass vary from caves. The species composition of sponges from the caves of Crimea is quite different from the sponges composition in Mediterranean caves. This is primarily because the geographical isolation of the Black Sea and the differences in the hydro-chemical parameters of the milieu (water salinity in Tarkhankut is 18-21‰.

AGE, GROWTH AND FEEDING OF THE BLACK GOBY, *GOBIUS NIGER*, IN CANDARLI BAY (AEGEAN SEA)

Halit Filiz [1]*
[1] Mugla Sitki Kocman University Faculty of Fisheries - halit.filiz@mu.edu.tr

Abstract
Age and growth of 681 black gobies (*Gobius niger* L., 1758) (6.2-15.9 cm TL) were studied based on samples collected monthly from the Candarli Bay (Aegean Sea). Age determined from direct reading on otoliths was comprised from zero to five years. The parameters of the fitted Von Bertalanffy growth equation were L_∞= 17.62 cm, k= 0.278 yr^{-1}, t_0= -2.053 for males, and L_∞= 14.10 cm, k= 0.391 yr^{-1}, t_0= -1.198 for females. Stomach contents were mainly Mollusca (%IRI=54.21), Crustacea (%IRI= 36.22), Polychaeta (%IRI= 7.72), Foreminifera (%IRI= 1.40) and Teleostei (%IRI= 0.45).

Keywords: Fishes, Aegean Sea, Teleostei, Population Dynamics

Introduction
The black goby is widely distributed in Eastern Atlantic and Mediterranean Sea (include Black Sea). Despite its abundance along Turkish coasts, only one study [1] concerning the population dynamics parameters of *G. niger* exists. The species is not consumed as food, yet due to its high proportion in the bottom trawl discard, which contributed to its habitat loss and pollution, the black goby population has evaluated as least concern in Turkey [2], thus making any biological data that we could possess of great importance. In this study, information on the age, growth and feeding habits of *G. niger* are presented based on material collected in Candarli Bay, Aegean Sea.

Material and Methods
A total of 681 specimens obtained. Total lengths (TL, cm) were measured to the nearest 0.01 cm and wet weights (W, g) to the nearest 0.01 gram. The mean lengths at age were analyzed separately per sex and were compared statistically using Student's *t* test (p>0.05). Sagittal otoliths were removed, cleaned, dried and stored in labeled plastic tubes. Age was expressed in years, the birthday of the fish being considered to be 1st January. For the estimation of the individual growth rate, the von Bertalanffy growth equation (VBGE) was calculated. The growth performance index (Φ, phi-prime) was employed to compare growth rates. Stomachs were removed from 269 specimens, prey items were identified to group level, measured, counted and weighed on an electronic balance (precision 0.0001 g). Diet composition was evaluated using three measures: the numerical index (%N); the gravimetric index (%W), and frequency of occurrence (%F). The index of relative importance (IRI) was calculated and expressed as a percentage (% IRI).

Results and Discussion
The black goby specimens had total lengths ranging from 6.2 to 15.9 cm, with a mean value of 10.05 cm (S.D.= 1.90). Of the 269 black goby stomachs examined, 257 had food (95.5%) and 12 were empty (4.5%). Mollusca, Crustacea and Polychaeta constituted of 98.15% of the diet. Foraminifera and Teleostei comprised 1.40 and 0.45% of the diet, respectively. Age determination from direct observations on the otoliths resulted in the establishment of six age groups (0, I, II, III, IV and V) for the population sampled (Table 1).

Tab. 1. Comparison of maximum age and age at lengths records.

Area	Study	Locality	Sex	0+	I	II	III	IV	V
Mediterranean	[4]	Adriatic Sea	♂ ♀	7.7 6.2	9.4 7.8	11.9 9.5	13.5 10.4	14.5 11.8	15.5

			♀	-	8.4-9.2	9.2-11.6	11.6-12.4	-	-
	[1]	Izmir Bay	♂	8.18	10.34	11.93	13.29	14.14	14.78
			♀	6.67	8.10	9.90	11.33	12.26	-
	This study	Candarli Bay.	♂	7.81	10.07	11.82	13.41	14.29	15.9
			♀	7.36	8.13	10.05	11.39	12.25	-
Atlantic	[3]	Verse Meer Lake	♂	5.5	8.2	9.5	12.0		
			♀	5.5	8.1	9.6	10.5	11.1	
	[8]	Norwegian coasts	♂+♀	-	4.4	7.1	8.6	9.6	9.3
	[9]	Stanswood Bay	♂+♀	~3	5.6	9.0	10.9	-	-
	[6]	Ria de Aveiro Lagoon	♂	7.6	10.8	11.8	-	-	-
			♀	7.2	10.5	11.5	-	-	-
	[7]	Obidos Lagoon	♂	7.8	10.5	12.2	13.5	-	-
			♀	8.0	10.3	11.9	12.0	-	-

The maximum age reached by specimens of black goby (i.e. 5 years) from the Candarli Bay is within the longevity limits observed over the biogeographical distribution area (Table 1). In terms of mean length per age group (except age V being only males) significant differences were found between the two sexes (p<0.05). Males attain a bigger length than females. These differences between male and female in growth rates and life span have already been noticed by [1, 3-7]. In this study, growth rate of the population has been found relatively low. However, the growth coefficient is highly variable among different studies (k= 0.19-0.91) (Table 2).

Tab. 2. Comparisons of growth parameters.

Area	Study	Sex	L_∞ (cm)	k (year^{-1})	t_0 (year)	t_{max}[A]	Φ' [B]	Locality
Mediterranean	[4]	♂ ♀	18.52 16.58	0.30 0.19	-1.689 -2.571	10.1 15.7	2.01 1.72	Adriatic Sea

	[7]	♂+♀	16.66	0.34	-1.910	8.9	1.97	Obidos Lagoon

[A] t_{max}(life-span)= based on 3/k assumption
[B] $\Phi' = \log k + 2 \log L_\infty$

L_∞ estimated in this study was within the observed total length of males and females. The diet of black goby is based on small benthic invertebrates, generally similar to that of other populations. Therefore, Foraminifera comprised 1.40% of the diet. I believed those foraminiferans are ingested accidentally, together with the animal constituents of the diet.

DIVERSITE DE LA FAUNE PARASITAIRE DE *BALISTES CAPRISCUS* (TELEOSTEI: BALISTIDAE) DU GOLFE DE GABES

Hichem Kacem [1]*, Abderrahmen Bouain [1] and Lassad Neifar [1]
[1] Université de Sfax, Faculté des Sciences, Tunisie - hichemkacem2007@yahoo.fr

Abstract
L'étude parasitologique de 249 spécimens de *Balistes capriscus* (Gmelin, 1788) en provenance du golfe de Gabès (Tunisie) a permis de récolter cinq espèces de parasites dont une nouvelle espèce de Digenea *Hypocreadium caputvadum* (Kacem, Derbel et Neifar, 2011) et deux espèces de parasites signalées pour la première fois en méditerranée.

Keywords: Parasitism, Fishes, Gulf of Gabes

Introduction
Balistes capriscus (Gmelin, 1789) est un poisson amphi-atlantique largement trouvé dans les eaux tropicales et tempérées tout au long des côtes Est et Ouest de l'océan Atlantique [1] et également en Méditerranée [2]. Plusieurs travaux portant sur les parasites du *B. capriscus* de l'océan Atlantique ont été menés [3, 4, 5] mais aucune étude n'a été réalisée en Méditerranée. Le présent travail fournit les premières données sur la faune parasitaire de *B. capriscus* des côtes du golfe de Gabès.

Matériel et méthodes
Durant les quatre saisons, 249 spécimens de *B. capriscus* de taille comprise entre 139 et 427 mm provenant de différentes localités du golfe de Gabès ont été examinés afin de rechercher les ectoparasites et les endoparasites. Les parasites prélevés sont identifiés. Pour chaque espèce parasite, la prévalence et l'abondance moyenne ont été calculées [6].

Résultats et discussion
L'examen des branchies de *B. capriscus* a permis de récolter une espèce de Monogenea *Ancyrocephalus balisticus* et deux espèces de Copépoda *Taeniacanthus balistae* et *Naobranchia variabilis*.
A. balisticus est un des rares représentants du genre *Ancyrocephalus* en Méditerranée. Ce genre se trouve principalement en Atlantique où il est bien diversifié. Ceci pourrait suggérer l'origine Atlantique de *B. capriscus*. *Naobranchia variabilis* présente une large spécificité d'hôtes. En effet, il a été signalé à plusieurs reprises en Atlantique chez plusieurs hôtes appartenant à des familles différentes tels que: Tetraodontidae (*Lagocephalus laevigatus*) Serranidae (*Centropristes striatus*; *Diplectrum formosum*), Pomadasyidae (*Haemulon plumieri*), Monacanthidae (*Ceratacanthus schoepfi*), Diodontidae (*Chilomycterus spinosus, Chilomycterus atinga, Chilomycterus schepfi*), Ogcocephalidae (*Ogcocephalus sp., Ogcocephalus radiatus*), Clupeidae (*Brevoortia paronus*). C'est pour la première fois qu'il est signalé en Méditerranée sur les filaments branchiaux de *B. capriscus.* Ceci est une preuve supplémentaire de l'origine Atlantique de *B. capriscus*. L'examen du tube digestif des poissons récoltés nous a permis de recenser 2 espèces de Digenea appartenant à 2 familles distinctes: Lepocreadiidae(*Hypocreadium caputvadum*) [7]; Apocreadiidae(*Neoapocreadium chabaudi*). Ce dernier a été mentionné chez *Stephanolepis hispidus* sur les côtes du Brésil [8]. Nous le signalons pour la première fois chez *B. capriscus* en Méditerranée et particulièrement dans le golfe de Gabès.

TEMPORAL VARIATION OF LITTORAL FISH & ALGAE, SAMOS, GREECE

Adam King [1]*, Kirsteen MacKenzie [2], Anastasia Miliou [1] and Cristina Acasuso-Rivero [1]
[1] Archipelagos, Institute of Marine Conservation, P.O. 42, Pythagorio, 83103, Samos, Greece - adam@archipelago.gr
[2] University of Southampton, NOCS, European Way, Southampton, England, SO17 1BJ

Abstract
In the region of the eastern Aegean Sea, there is a lack of studies on ecologically important littoral rocky habitats. Using underwater visual census methods, this study focused on the assessment of inter-annual changes in biodiversity of fish and algae in rocky habitats between 2010 and 2012. 60% decline in overall fish population abundance was observed at individual reefs. Two important commercially fished species, *Oblada melanura* and *Mullus surmuletus*, displayed declines in population of 95% and 78% respectively over the three years, indicative of overfishing in the area. Algal biodiversity remained relatively constant, although the presence of the invasive *Caulerpa racemosa* is a cause for concern due to decline in biodiversity of reefs it colonizes.

Keywords: Algae, Aegean Sea, Fishes, Population Dynamics

Introduction
Shallow, algae covered rocky habitats act as feeding, refuge and nursery areas, to adult and juvenile fish of many species [1], [2]. These habitats are of particular ecological significance, and their conservation is of great importance in maintaining coastal fish diversity and abundance [2]. Within the Aegean Sea, the majority of research on shallow coastal fish assemblages has been conducted in the northern Aegean, while studies on benthic algae have been located primarily in the western Aegean Sea [3],[4],[5]. Few studies have been carried out in the eastern Aegean [2], and long-term studies of fish populations are generally lacking throughout the entire Mediterranean [6].

Material and Methods
This study attempts to address this lack of knowledge in the eastern Aegean by studying the inter-annual changes in shallow rocky habitat fish and algae using underwater visual census surveys (UVC) on the littoral zone waters of the Greek island of Samos. UVC surveys were conducted during the months of July to August, 2010 to 2012 inclusive, at three sites located on the south west coast of Samos. Fish transect surveys were conducted over an area of 250m^2, with 36 repeat surveys at per site, per year. 120 algal quadrats of 250cm^2 were conducted along the same transects as the fish.

Results and Discussion
A decline in fish population abundance and biodiversity was observed across all three sites over the three year period, with up to a 60% decline in population abundance at individual sites. Of the 43 fish species observed, 67% displayed a decline in abundance. Two important commercially fished species, *Oblada melanura* [7] and *Mullus surmuletus* [8] showed a 95% and 78% decline respectively, while *Chromis chromis* displayed a 85% decline in abundance (Fig. 1), a cause for concern for coastal diversity in littoral zone waters in the south part of Samos island. Depletion of shallow sublittoral communities in many areas can most likely be attributed to historical overfishing [9].

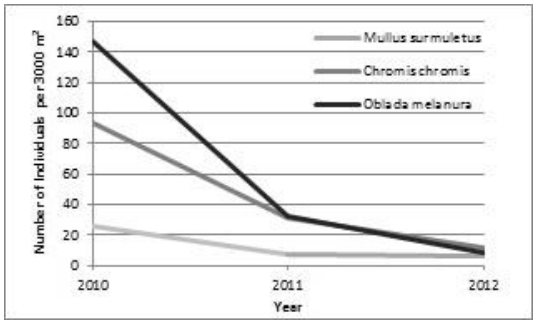

Fig. 1. Change in overall *Mullus surmuletus*, *Chromis chromis* and *Oblada melanura* population between 2010 and 2012 at three sites, Samos, NE Aegean Sea Greece.

Algal assemblages were considerably more stable than fish over inter-annual timescales and little variation in the overall algal biodiversity was observed over the three year period, with only minor changes in both abundance and species composition. However, in 2012 the presence of the invasive species *Caulerpa racemosa* was observed, which is of great concern for sublittoral rocky habitats around Samos, due to the associated decrease in the ecosystem biodiversity of reefs colonised by this invasive algal species [10].

Further longer term studies are essential for continued monitoring and conservation of sublittoral rocky communities and thus coastal biodiversity in the Aegean Sea. The large decline in fish biodiversity and abundance highlighted by this study implies future work should focus on the dynamics and community structure of fish populations over interannual and intra-annual time periods, and monitor the spread of invasive species in these communities.

A STUDY ON MACROBENTHIC BIOTA OF UPPER-INFRALITTORAL ZONE IN SOME ISLANDS OF THE BLACK SEA AND THE SEA OF MARMARA

D. A. Orun [1]* and B Topaloglu [1]
[1] Istanbul University Faculty of Fisheries - orundeniz@hotmail.com

Abstract
The study was carried out to determine benthic biota of hard substrates with environmental variables in the islands, located both at Black Sea and the Marmara Sea,excluding Istanbul Strait. Samples were taken from upper-infralittoral zone of six stations in monthly intervals during a year between May 2011- April 2012. Seven groups organisms were found and Crustacea was the most abundant group.

Keywords: Zoobenthos, Infralittoral, Islands, Marmara Sea, Black Sea

Introduction
Biodiversity represents ecosystem, species and genetic diversity, includes all living groups. The size of diversity in a region is measured by the groups of species. This explained on the basis of conducted regional studies depending on faunistic and floristic studies [1]. Benthic samples were taken from 400 cm^2 size (20cm x 20cm) space (quadrate) by a spatula. It was washed through 500µm mesh sized sieve and fixed by 4% formaldehyde. Morphological characteristics of the samples were examined by stereo binocular microscope and the dominant structure of the communities were analyzed as qualitative and quantitative. For determination of physicochemical properties, water temparature, salinity and dissolved oxygen was measured for each station monthly.

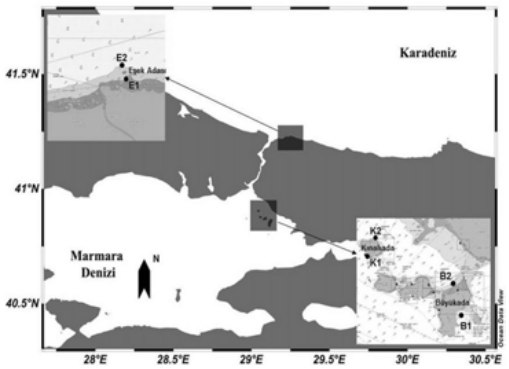

Fig. 1. Sampling stations

The Percentage of Dominance of Systematic Groups
To consider dominance of the systematic groups during the year depending on amounts of species, Crustacea takes the first place with 59 % (Figure 2). The percentage value of systematic groups depends on stations was represent in the figure 3. Polychaeta was the dominant group (33 %) in E2 (in Esek Island). Crustacea (22 %) in K1 (in Kinaliada Island); Mollusca (32 %) in E2 (in Esek Island); Echinodermata (52 %) in B1 (in Büyükada island) Nemertini 44 % in K2 (in Kinaliada); Platyhelminthes 22 % in E1 (in Esek Island); Oligochaeta 40 % in K1 (Kinaliada) was predominately found (Figure 2).
In previous studies, Topaloglu and Kihara (1993) studied on Istanbul Strait benthic communities and found 9 sistematic groups [2]. Balkis and Albayrak (1994) studied on benthic amphipods of Istanbul Strait and they found 9 groups [3]. Albayrak (1996) was studied on Echinoderm fauna of Istanbul Strait and he determined 8 systematic groups [4]. In 2001 Balkis and Albayrak studied on Vermes fauna of Istanbul Strait. In this study Turbellaria was being represented by 2 species, Nemertini by 1, Stematopoda by 4, Polycheta by 23 and Echiuroidea by 1 species [5].

We found an evident correspondence between systematic groups and the environmental situation at each site. According to its fauna, ecological parameters in stations with relatively lower results were poor in terms of diversity. In E1 (Esek Island station 1) and B2 (Büyükada Island station 2) which we found only four taxa, while the other stations were the sites with the greater diversity of benthic macroinvertebrates.

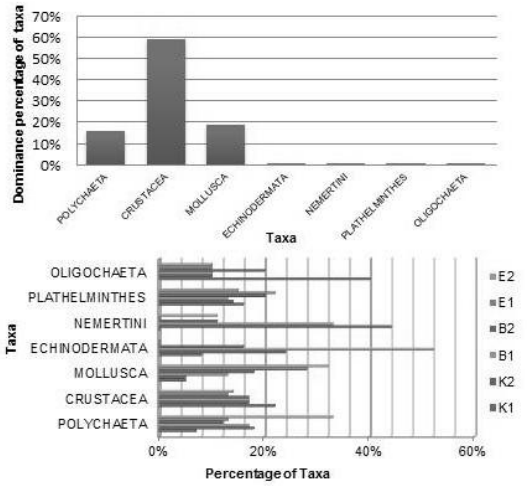

Fig. 2. Dominance percentage of the systematic groups and their distribution in the stations

ÉVALUATION DE LA MACROFAUNE DU SUBSTRAT ROCHEUX DE LA COTE MOSTAGANEM

Aicha Oulhiz [1]* and Dina L. Soualili [1]
[1] Université Abdelhamid Iben Badis, Faculté des Sciences de la Nature et de la Vie - aichahoua@yahoo.fr

Abstract
Durant cette dernière décennie, la macrofaune benthique est utilisée pour évaluer la qualité d'un milieu. Dans cette étude, un inventaire des espèces du macrobenthos de trois sites à substrat rocheux de Mostaganem a été réalisé. Les indices de diversité et les descripteurs statistiques ont été utilisés. Les résultats ont montré un total de 29 espèces, représentées respectivement par 28 sp à Stidia, 16 sp à Kharouba et 21 sp à Hadjadj. Aussi, les stations (Stidia et Hadjadj) semblent être diversifiés et non polluées, par rapport à la station de Kharouba, qui montre les premiers signes de dégradation et de perturbation de son milieu.

Keywords: Biodiversity, Bio-indicators, Supralittoral, Algerian Basin

Introduction
Les écosystèmes côtiers marins du bassin méditerranéen possèdent, en particulier, une richesse spécifique en termes de biodiversité, qui les place immédiatement après les écosystèmes tropicaux. Cependant, ces derniers soufrent depuis fort longtemps de graves problèmes environnementaux (pollution, dégradation des ressources marines, des sols…) [1]. Ce qui n'est pas sans conséquences sur la santé humaine. Parmi les zones les plus affectées par cette pollution, on retrouve celles des cotes algériennes, qui sont considérées comme des zones à hot spot de pollution. C'est dans ce contexte que s'inscrit cette étude, où on se propose de faire une première évaluation de la qualité du milieu de trois sites à substrat dur de la cote de Mostaganem en déterminant les espèces macrobenthiques qui sont actuellement largement utilisées comme bioindicateurs ([2], [3]) pour évaluer la qualité des milieux des zones côtières.

Matériel et méthodes
Trois sites ont été sélectionnés, caractérisés par un substrat rocheux : Stidia, Kharouba et Hadjadj. Les sites ont été choisis d'une part, pour leurs différences d'exposition aux différentes sources de pollution, et d'autres parts pour la richesse biologique qui y règne. L'échantillonnage, a été réalisé en utilisant la méthode des quadras de 1m2, jeté le long d'un transect, définit au hasard sur le substrat rocheux de l'étage médiolittoral des trois sites étudiés, l'inventaire de la population d'invertébrés est réalisé pour quantifier l'abondance et la composition de la population d'invertébrés mobiles ou fixées présentes. La surface totale balisée est de 100 m² dans chaque site. Le calcul des indices biologiques [la richesse spécifique (S) et l'abondance (A)] définies par [4] a été réalisé. Aussi, les indices de diversité [indice de Shannon-Wiener (H') et l'indice d'équitabilité de Piélou] définis par [5] ont été calculés.

Résultats et Discussion
La richesse faunistique globale est très importante au niveau des côtes rocheuses de Mostaganem et principalement au niveau de la cote de Stidia. Elle est représentée par un total de 29 espèces appartenant à quatre groupes zoologiques : les Mollusques; les Arthropodes; les Echinodermes et les Cnidaires (Fig. 1).

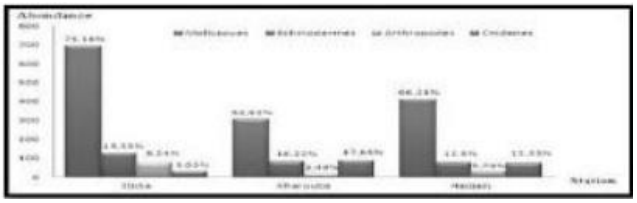

Fig. 1. Répartition des différents groupes zoologique dans les sites étudiés

L'analyse des indices de diversité de Shannon-Weaver et de régularité de Piélou (Fig. 2) met en évidence une présence de peuplements benthiques généralement structurés sur les sites de Stidia et Hadjadj, par apport au site de Kharouba. Sur la base de ses résultats, onpeut classer le degré de pertubation des sites selon le gradient suivant : Site Stidia → Hadjadj → Kharouba (plus perturbé).

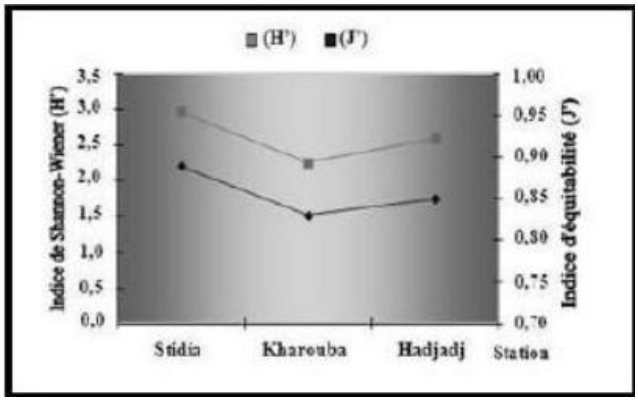

Fig. 2. Synthèse des indices de diversité des trois sites étudiés

Le schéma général d'organisation structurelle des peuplements montre que les sites de Stidia et Hadjadj se manifestent par un peuplement dense et diversifié par rapport au site de Kharouba. Les résultats ont montré, que le site de Stidia est caractérisé par les valeurs, les plus élevés, en abondance, en dominance et en richesse spécifique ainsi qu'en indices de diversité par rapport aux deux autres sites Hadjadj et Kharouba. Donc, l'analyse de la composition des peuplements benthiques a révélé un état général satisfaisant des sites de Stidia et de Hadjadj. Cependant, le site de Kharouba, semble présenter les premiers signes de perturbation et de dégradation du milieu.

MACROFAUNA ASSOCIATED WITH A BANK OF *CLADOCORA CAESPITOSA* (L.) IN THE GULF OF TRIESTE (NORTH ADRIATIC)

Valentina Pitacco [1]*, Martina Orlando-Bonaca [1], Borut Mavric [1] and Lovrenc Lipej [1]
[1] National Institute of Biology, Marine Biology Station, Piran - Valentina.Pitacco@mbss.org

Abstract
The Mediterranean stony coral (*Cladocora caespitosa*, Linneus, 1767) is a native colonial, zooxanthellate, shallow-water coral. It is able to host a diversified faunal assemblage, which is still relatively unknown. A bank of *C. caespitosa* in the Gulf of Trieste was investigated in November 2010. Larger specimens were determined by rapid assessment. Stony coral colonies were measured and eventually broken down for infauna sorting and determination. Taxa composition in colonies differed markedly from surrounding areas. A large number of juveniles were observed in colonies, confirming the importance of this species as a nursery ground.

Keywords: Zoobenthos, North Adriatic Sea, Biodiversity

The Mediterranean stony coral (*Cladocora caespitosa*, Linneus, 1767) is a native colonial, zooxanthellate, shallow-water coral, particularly sensitive to global changes and anthropogenic activities. Due to its shape and size is able to host a diversified faunal assemblage (1). Nevertheless, very little is known about the macrofauna associated with this coral. Solitary colonies of *Cladocora* can be locally abundant (2), while banks are uncommon and have been reported only in the Ligurian (3), Adriatic (4) and Aegean Sea (5). In the Gulf of Trieste a bank of *C. caespitosa* was discovered recently close to Cape Ronek (Slovenia). The aim of the present work was to investigate the invertebrate fauna associated with this biogenic formation, in order to estimate to what extent this coral is important for biodiversity.

The biogenic bank close to Cape Ronek was investigated in November 2010. Largest organisms were determined by rapid assessment immediately after sampling; smallest organisms were stored in alcohol (70%) and analysed in laboratory. Percentage of living polyps was estimated and then colonies were broken down. All animals were sorted and determined to the lowest possible taxonomic level.

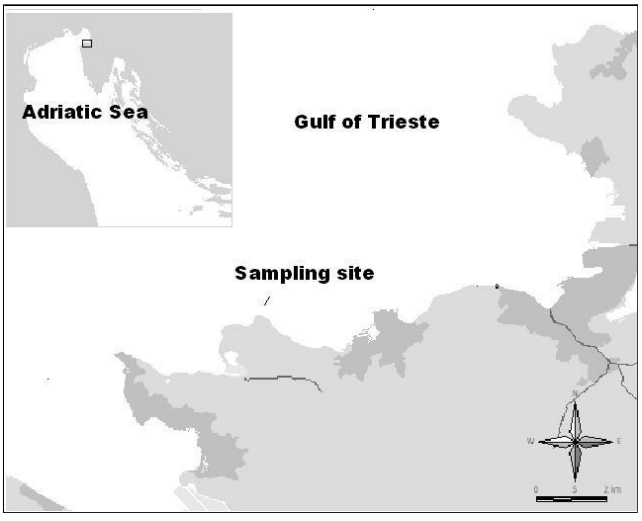

Fig. 1. The map of the sampling site.

Altogether 121 different taxa, belonging to 9 different phyla: Porifera, Cnidaria, Sipunculida, Mollusca, Anellida, Arthropoda, Bryozoa, Echinodermata and Tunicata were found.

Eighty-nine different taxa were identified in *C. caespitosa* colonies. The great majority were polychaetes (50%), followed by mollusks (25%) and crustaceans (16%). 3386 animals were counted; the most abundant were mollusks (50%), followed by polychaetes (20%) and crustaceans (7%). Many of these specimens were juveniles, confirming the importance of *C. caespitosa* colonies as a nursery ground for invertebrates.

In the detritic bottom surrounding colonies 223 individuals were found, belonging to 26 different taxa. Echinoderms were the most abundant (70%), followed by mollusks (22%). The groups with the higher number of taxa were found in mollusks (58%) and echinoderms (27%). Only 5 taxa (4% of the total) were found both within and without *C. caespitosa* colonies and only 3 of them were possible to determine at the species level (*Arca noae*, *Rocellaria dubia* and *Hiatella artica*). These results confirm that *C. caespitosa* is an important bioconstructor, able to create a habitat favourable for different assemblages compared to the surrounding areas. Infaunal assemblages in coral colonies exhibited similar taxa composition, but they differed markedly from assemblages in the surrounding area.

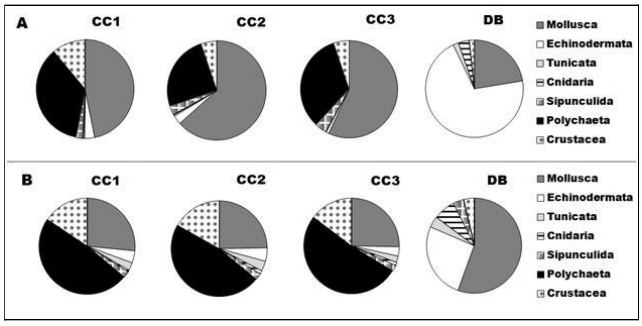

Fig. 2. Percentage of abundance (A) and richness (B) of different phyla (colonial organisms excluded).

RAPID, SHORT AND IMPRESSIVE COLONISATION ON ONE MODULE TYPE OF ARTIFICIAL REEF BY DIDEMNIDAE ASCIDIANS

E. Rouanet [1]*, P. Bonhomme [1], A. Antonioli [1], P. Astruch [1], D. Bonhomme [1] and L. Le Direach [1]
[1] GIS Posidonie - Aix Marseille University - Campus de Luminy Case 901 - 13288 Marseille cedex 09 - France - elodie.rouanet@univ-amu.fr

Abstract
The seasonal study of ecological succession of benthic sessile assemblages associated with the Prado artificial reefs (Marseilles, France) shows rapid and short Didemnidae ascidian colonisation mainly on one module type AR.

Keywords: Artificial reefs, Tunicata, North-Western Mediterranean

Introduction
The colonisation of artificial reefs (AR) by benthic species plays an active role in the determining the structural complexity of the new habitats they provide. Monitoring of benthic colonisation dynamics is essential, especially to understand changes in species diversity, temporal and spatial patterns and benthic assemblages according to module types, which offers a basis for understanding the functioning of this new ecosystem. During the early years of the installation of ARs, assemblages develop very quickly, with the spread and intensive colonisation by pioneer taxa such as Didemnidae ascidians, then by secondary species.

Material and methods
Benthic assemblages associated with the Prado artificial reefs (Marseilles, France) were studied in every season from summer 2009 through autumn 2012 (14 sampling seasons), on 5 types of module (4 in concrete: metal and fakir baskets, cube piles, concrete baffled reefs and 1 in rock: quarry rocks), installed in 2008. Sessile benthic species were studied on the basis of photographic permanent quadrats measuring 25 cm x 25 cm, divided into 100 sub-quadrats. They were analyzed by the indirect visual estimation method [1, 2] to determine species richness and estimate sessile taxa cover (percentage). 200 pictures were taken and analyzed per sampling season.

Results
The morphology of the module types influences colonisation patterns [for more information see 3]. Didemnidae colonisation was significantly different between module types, where mean percent cover is higher in simple, well-lit modules (cube piles) than in complex and shaded modules (metal and fakir baskets, concrete baffled reefs). Values are very low in quarry modules sensitive to sedimentation (quarry rocks) (Fig. 1).

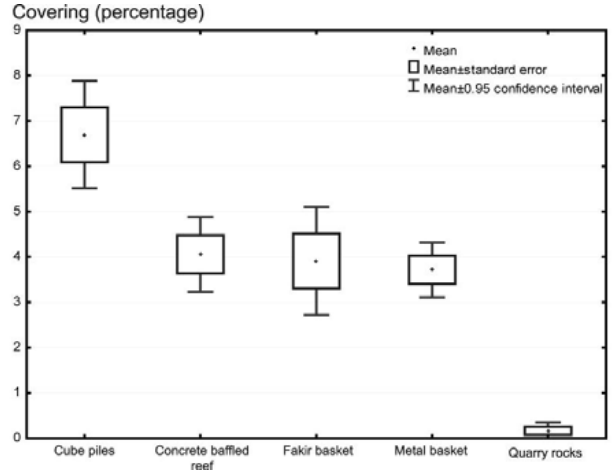

Fig. 1. Mean Didemnidae cover on different types of module (all sampling seasons included).

From the first samplings, on all concrete module types, Didemnidae rapidly reaches a maximum cover 2 years after installation of the ARs, and then these values quickly decrease through subsequent samplings. In spring 2010, on cube piles, Didemnidae occupied a third of its surface and in next sampling (3 months later), this surface was divided by 7.4 (Fig. 2). Mean Didemnidae percent cover was significantly different between years and seasons (Kruskal-Wallis test, $p<0.05$ for both factors). Although in time, peak fluctuations of percent cover were noted every year during the cold water season sampling (winter and/or spring), values were significantly different between these peaks (Kruskal-Wallis test, $p<0.05$) with a decrease over time (Fig. 2).

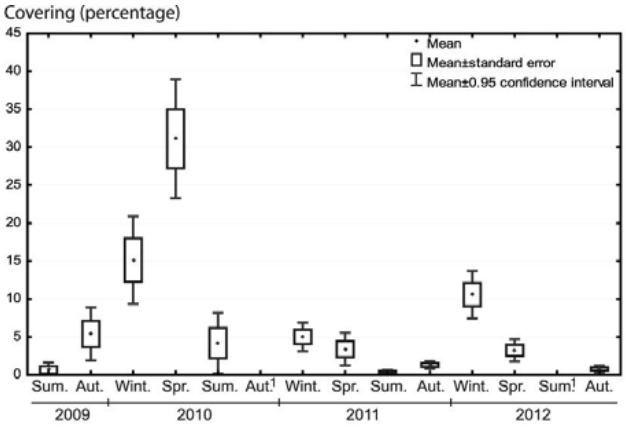

Fig. 2. Mean Didemnidae cover on cube piles module over time. [1]: no data; n = 48 quadrats per season.

Discussion
Settlement, maximum development and decrease of cover of Didemnidae ascidians were rapid after the installation of the Prado ARs and very rapid over time (1 year, from summer 2009 to summer 2010) especially on the well-lit module (cube piles). The decrease of Didemnidae percent cover though sampling seasons is benefits various taxa (macrophyta, corallinales, bryozoa, hydrozoa, porifera) [3]. This impact of this phenomenon on other sessile community development processes remains to be studied.

SOFT BOTTOM SIPUNCULANS IN THE ÇANAKKALE STRAIT (SEA OF MARMARA)

Sermin Acik [1]*
[1] Dokuz Eylul University Institute of Marine Sciences and Technology - serminacik@yahoo.com

Abstract
This study deals with the sipunculan species collected from 17 to 94 m depths at 7 stations in the Çanakkale Strait. A total of 4 species and 169 individuals belonging to four families were encountered. Three species [*Sipunculus* (*Sipunculus*) *nudus*, *Thysanocardia procera* and *Onchnesoma steenstrupii steenstrupii*] are new records for the Sea of Marmara. *Onchnesoma steenstrupii steenstrupii* was the most dominant and frequent species. Brief descriptions of the species and their biometrical and distributional features are given.

Keywords: Zoobenthos, Biometrics, Systematics, Marmara Sea

Introduction
The phylum Sipuncula has almost 150 species belonging to 17 genera worldwide (3), 36 species belonging to 9 genera in the Mediterranean Sea (2 and 4) and 20 species belonging to 9 genera on the coasts of Turkey (1 and 2). The aim of this study is to assess the sipunculan diversity in the Çanakkale Strait, and to give biometrical and distributional features of the species.

Material and Methods
Benthic samples were taken with a van Veen grab (sampling ca. 0.1 m^2 area) at 7 stations (17-94 m) in the Çanakkale Strait in December 2010 (Figure 1). The samples were sieved through a 0.5 mm mesh and fixed with 10% formalin. In the laboratory, sipunculans were identified, counted and preserved in 70% ethanol. Biometrical measurements of the smallest and largest individuals of each species were measured by using an ocular micrometer.

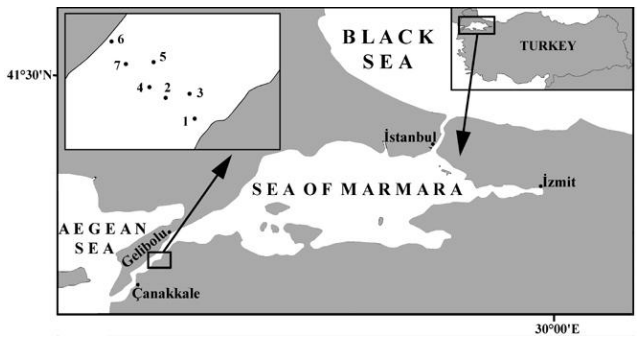

Fig. 1. Map of the investigated area with the location of sampling sites.

Results and discussion
The examination of materials collected on soft substrata in the Çanakkale Strait revealed 4 species and 169 individuals belonging to four families (Sipunculidae, Golfingiidae, Phascolionidae and Aspidosiphonidae). The family Phascolionidae had the majority of specimens (99 individuals, 58% of the total), followed by Aspidosiphonidae (68 individuals, 40%), Sipunculidae (1 individual, 1%) and Golfingiidae (1 individual, 1%), respectively. Among the species, *Onchnesoma steenstrupii steenstrupii* was the most dominant (58% of total number of individuals) and frequent (present in 100% of samples) species. The other common species in the area was *Aspidosiphon* (*A.*) *muelleri* (present in 71.4% of samples). *Sipunculus* (*S.*) *nudus*, *Thysanocardia procera* and *Onchnesoma steenstrupii steenstrupii* were newly reported from the area. With this new records, the known number of sipunculans in the Sea of Marmara was raised from 3 to 6.

Sipunculus (*Sipunculus*) *nudus* Linnaeus, 1766
Body wall thin, light brown. Trunk 120 mm long, 10 mm wide. Introvert bearing triangular scale-like papillae. The number of longitudinal muscle bands on trunk 30. Digitate processes present on brain. Intestinal spiral with 10 coils; attached to body by numerous mesenteries. Two contractile vessels without villi. Two pairs of retractors arise at same level; ventral pair from bands 1-7 and dorsal from bands 7-15. Nephridiopores anterior to anus. Spindle muscle unattached to body wall posteriorly. Two eye spots present.
Distribution Cosmopolitan species (3).

Thysanocardia procera (Moebius, 1875)
Body yellowish-red in colour, with circular base and rounded point. Trunk 4 mm long, 1.5 mm wide. Introvert 6 mm long, 0.7 mm wide. 7 tentacles surrounding bilobed nuchal organ. Distinct brown line present on oral surface of tentacle. Papillae on posterior end of trunk 20-35 µm height, 15-30 µm in diameter; papillae on anterior part of trunk 20-30 µm height, 10-20 µm in diameter. Contractile vessel with distinct villi. Nephridiopores at same level to anus.
Distribution Northeastern Atlantic Ocean and Mediterranean Sea (3).

Onchnesoma steenstrupii steenstrupii Koren & Danielssen, 1875
Pear-shaped or barrel-shaped trunk, 0.8-2 mm long, 0.6-1 mm wide. Introvert partly everted, 0.6-6 mm long, 0.2-0.5 mm wide. 22-23 radiating keels present at posterior part of trunk. Small wart-like papillae on surface of trunk, 15-25 µm long, 15-30 µm in diameter. Spindle and wing muscle absent. Anus located near mouth. Intestine with several coils. Only one retractor attached at posterior part of body. Some specimens with elliptical eggs; longer axis 100-150 µm in diameter, smaller axis 80-125 µm in diameter.
Distribution Atlantic, western Pacific and southwest Indian Oceans, Mediterranean Sea (3) and Red Sea (5).

Aspidosiphon (*Aspidosiphon*) *muelleri* Diesing, 1851
Body wall thin, semi-transparent. Trunk 3-8.2 mm long, 1-1.8 mm wide. Introvert 3.4-9.8 mm long, 0.5-1 mm wide. Introvert with 40-80 rings. Bidentate hooks 13-30 µm tall, 15-30 µm wide; unidentate hooks 15-25 µm long, 15-28 µm wide. Longitudinal musculature continuous. Anal shield with 10-16 longitudinal grooves. Caudal shield with 15-18 radial grooves. Intestinal spiral with 6-14 coils. Retractor muscles attached at near posterior part of trunk. Anus and nephridiopores placed at same level. This species was found within empty shells of gastropods and tubes of the polychaete species *Vermiliopsis* sp.
Distribution Indian Ocean (6), Northeastern Atlantic and Eastern Pacific Oceans, Mediterranean and Red Sea (3).

NOW YOU SEE IT, NOW YOU DON'T: PRESENCE OF *CAULERPA RACEMOSA* VAR. *CYLINDRACEA* (CHLOROPHYTA, CAULERPALES) IN THE MALTESE ISLANDS

Jacqueline Barbara [1]* and Joseph A. Borg [1]
[1] University of Malta, Biology Department - jackie.barbara@gmail.com

Abstract
Caulerpa racemosa var. *cylindracea*, an invasive alga present in the Mediterranean Sea, was first recorded from the Maltese Islands in 1997. Between then and the mid-2000s, the alga spread rapidly and became abundant at most coastal sites around the islands. However, its spatial distribution and abundance decreased rapidly after 2006, such that the alga has become rare to encounter locally. The present work, which formed part of a broader study to assess the influence of *C. racemosa* on hard bottom infralittoral habitats, confirms a large decline in the distribution and abundance of this species in recent years in Maltese coastal waters.

Keywords: Alien species, Algae, Biogeography, Sicily Channel

Introduction
Caulerpa racemosa was first reported from the Maltese Islands in 1997 [1]. Since then, the species spread rapidly, such that it became ubiquitous and abundant around the Maltese Islands [2]. A study by Camilleri undertaken in 2005 [3] concluded that nutrient enrichment promoted an increased abundance of *C. racemosa* in Maltese coastal areas. The main objective of the present study was to gather data on the distribution and abundance of *C. racemosa* around the Maltese Islands, given that preliminary observations indicated a local decline of the species during the past six years.

Methods
Surveys using snorkeling and SCUBA diving were undertaken during summer 2009 at 11 sites located on the northeastern coast of Malta. All study sites had similar exposure and coastal geomorphological characteristics, and were located within the 2 m – 5 m depth range. Estimates of the abundance of *C. racemosa* were carried out at each site by recording the percent cover of the alga in each of three replicate 20 cm x 20 cm quadrats. From three of the sites where *C. racemosa* had a percentage cover greater than 10%, St. Paul's Bay, Salina Bay and Zonqor Point, the algae enclosed within the quadrat were scraped off using a small trowel and transferred to a mesh bag. In the laboratory, the algae from each replicate quadrat were separated according to species and then dried separately at 80°C for 24 hours to obtain estimates of dry weight per quadrat for each alga, including for *C. racemosa*.

Results & Discussion
Of the 11 sites surveyed, 5 did not support any *C. racemosa*, 3 had very sparse growth, and the remaining 3 supported a mean percentage cover of 38.33% - 65% (Tab. 1), although values of percentage biomass obtained from the latter sites were rather low (Tab. 1). Furthermore, the latter 3 sites, where *C. racemosa* had the highest percentage cover and biomass, happen to be characterized by relatively (i.e. compared to the other study sites) poor water quality and elevated nutrient levels. The findings contrast with those of previous studies; for example, in the present study *C. racemosa* was completely absent from St. Thomas Bay and Marsaxlokk, which are known previously to have supported extensive meadows of the alga [2]. Although it is difficult to identify with certainty the factor/s that have led to the observed decline of *C. racemosa* around the Maltese Islands, a possible reason may be decreased nutrient levels in coastal waters, which resulted from nationwide efforts and measures adopted in recent years to improve coastal water quality [4]. *C. racemosa* is a highly opportunistic species and generally invades habitats that are disturbed and degraded, including areas characterized by poor water quality and elevated nutrient levels. Improved water quality seems to have contributed to the decline of the invasive alga and/or increased vitality of native algal species, which have regained their original abundance.

Conclusions
The results of the present work support the hypothesis that the distribution and abundance of *C. racemosa* have declined around the Maltese Islands in recent years, and that this may have resulted from decreased nutrient levels in coastal waters, and the re-establishment of native algae in its stead.

EVIDENCE OF ANCHOR EFFECT IN A *POSIDONIA OCEANICA* SEAGRASS MEADOW UNDER LOW ANCHORING PRESSURE *VIA* A MULTI-CRITERIA GRID

E. Rouanet [1], P. Astruch [1], D. Bonhomme [1], P. Bonhomme [1], E. Rogeau [1], T. de Saint Martin [1] and C. F. Boudouresque [2]*
[1] GIS Posidonie, Aix-Marseille University, Luminy campus, 13288 Marseille cedex 9 France
[2] Aix-Marseille University, Mediterranean Institute of Oceanography (MIO) - charles.boudouresque@univ-amu.fr

Abstract
An index (MCAI: Multi-Criteria Anchoring Index) based upon nine parameters and their weighting is proposed. It evidences the effect of anchoring on the *Posidonia oceanica* seagrass meadow, even under relatively low mooring pressure.

Keywords: Posidonia, Monitoring, North-Western Mediterranean

Introduction

Posidonia oceanica is a Mediterranean seagrass that is sensitive to a variety of anthropogenic disturbances and stress, among them anchoring. The impact of large boats, e.g. cruise ships, is obvious [1,2]. As far as small pleasure boats are concerned, the maximum sustainable mooring pressure on *P. oceanica* meadows has be suggested to be two anchorage events ha^{-1} d^{-1} (annual average), the number of anchoring boats never exceeding 10 ha^{-1} for a given day [3]. Higher anchoring pressure would result in meadow regression. In contrast, under low mooring pressure, the effect of anchors proved to be more or less unclear, whenever the proxies of anchoring pressure were considered separately.

Material and methods

Six sites within the Port-Cros National Park (Provence, France, northwestern Mediterranean Sea), 7 to 9 m depth, were studied in 2011. Mooring has been banned at Site 2 (East Bagaud Island) since 1993 and Site 6 (Pointe Nord) since 2002. Anchoring pressure is very low in summer at Site 1 (East Bagaud Island: 0.08 boat ha^{-1} d^{-1}). It is relatively low at Site 3 (Saint-Pierre Cove: 0.12 boat ha^{-1} d^{-1}), Site 4 (Fausse Monnaie Cove: 0.13 boat ha^{-1} d^{-1}) and Site 5 (Pomme d'Or Point: 0.13 boat ha^{-1} d^{-1}) [4]. Parameters taken into account were: **(i)** *P. oceanica* percent cover, **(ii)** shoot density, **(iii)** bared rhizomes, **(iv)** % of plagiotropic (i.e. creeping) rhizomes, **(v)** number of free uprooted and broken shoots, **(vi)** compactness of the matte, **(vii)** fragmentation of the meadow, **(viii)** density of living individuals of the noble pen shell *Pinna nobilis* and **(ix)** ratio between living and dead or broken *P. nobilis* shells. Parameters (v), (viii) and (ix) are innovative.

Tab. 1. Multi-criteria grid of *P. oceanica* meadow parameters (i through ix), parameter marks (0 through 2) and parameter weighting (1 through 3). Study sites are ranked from absence of mooring (left: 2 and 6) to highest anchoring pressure (right: 4 and 5). In each box: the product of mark and weighting. White = normal status, light grey = intermediate status, dark grey = abnormal status. MCAI = overall mark for a given site.

Para-meter	Wei-ght	Site 2	Site 6	Site 1	Site 3	Site 4	Site 5
i	3	2 x 3 = 6	2 x 3 = 6	1 x 3 = 3	1 x 3 = 3	1 x 3 = 3	0 x 3 = 0

MCAI		30	31	25	18	19	10

Results and discussion

For each parameter (i through ix), at each site (1 through 6), a mark was assigned, based on [3, 5] and field observations: 0 = abnormal, 1 = intermediate and 2 = normal. A few parameters were correlated with the anchoring pressure (i, v and vii), while most of them were not clearly correlated (Table 1). However, the 9 parameters considered are of strongly contrasted importance: percent cover, number of broken shoots and ratio between living ans broken *Pinna nobilis* shells matter more than e.g. bared rhizomes and compactness of the matte. Parameters were therefore weighted (1 through 3). For each parameter at each site, the site mark was the product of parameter mark and parameter weight. The overall mark (MCAI: Multi-Criteria Anchoring Index) for a given site was the sum of the nine site marks (Table 1). For more details, see [6]. While individual parameters give contrasted responses, if any, to low mooring pressure, the multi-criteria response (overall mark, MCAI; Table 1) unequivocally evidences, for the first time, the expected response of the seagrass meadow. However, it is worth noting that the evidence of an effect does not mean that it is beyond the resilience of the meadow: for example, the annual production of new shoots (*via* rhizome branching) can compensate shoot breakage (by anchors).

Abstract
STARE-CAPMED is a research program set up by the Stareso research station (Calvi, Corsica). Its aim is to improve the understanding of processes by which anthropogenic activities have adversed effects on the functioning of Calvi Bay coastal ecosystems. One of its work packages is the monitoring of soft-bottom macrobenthos along 5 gradients of potential anthropogenic pressures. First results suggest that, before summer (summer is the period where man-driven impacts are expected to be stronger due to high tourist frequentation) these sources of potential anthropogenic pressures perturb soft-bottom macrobenthos assemblages.

Keywords: Zoobenthos, Monitoring, Biodiversity, Ligurian Sea

Introduction
The STARE-CAPMED (STAtion of Reference and rEsearch on Change of local and global Anthropogenic Pressures on Mediterranean Ecosystems Drifts) research program aims to 1) improve the understanding of processes by which anthropogenic activities have adverse effects on the functioning of Calvi Bay coastal ecosystems and 2) establish Calvi Bay as a reference area for a long term monitoring to differentiate anthropogenic influences from global influences.
This program has ten work packages, including the monitoring of soft-bottom macrobenthos communities. Surveys are based on 5 potential anthropogenic sources: a wastewater treatment plant emissary, a fish farm, a harbor area, an open boat anchoring area and a river mouth. For each source, 3 areas are sampled: near the source, at a mean distance (±430 m from the source, at a depth of 20 m) and at a long distance (±1400m from the source, at a depth of 40 m).

Material and Methods
Samples were taken before (May) and after (September) the summer (i.e. the period where man-driven impacts are expected to be stronger due to high tourist frequentation). Applied methods followed ISO 16665. Sampling was done by SCUBA diving, using an Ekman grab (0.09 m²). At each station, three samples were taken for macrobenthos analysis, and a fourth one to investigate sedimentologic features. Samples were sieved (1 mm mesh size), sieve residues were fixed with buffered formalin. Specimens were sorted out, counted and identified to the lowest possible taxonomic level, usually the species. The World Register of Marine Species (WoRMS; [1]) was used as reference list. Samples characteristics (Richness Specific (S), Density, Shannon Diversity indices (H' ($\log_2$)), Pielou equitability (J')), Cluster analysis, MDS and Simper analysis were calculated using Primer 6 software. Most used indices were also calculated (AMBI, M-AMBI, IT, ABC Curve and Clarke Indices) to qualify the animal communities present in the sediment. Main sedimentologic characteristics were determined (Median, Skewness indices, Kurtosis indices, COT and MO values) to help for macrobenthic interpretation.

Results and Discussion
In samples from May 2011, a total of 5853 individuals, belonging to 372 species were identified. Polychaeta were the main taxa (64%). AMBI values were comparable across all samples. No macrobenthic assemblage from any area seemed to be majorly perturbed before summer. However, anterior results collected after summer time near the wastewater treatment plant emissary (1992, 2006) and the fish farm (2007, 2008) highlighted perturbations in soft-bottom meadows ecosystems.
The long-term monitoring of the bay system will allow differentiation of perturbations caused by global modifications (e.g. climate change) and perturbations originating from direct, small-scale anthropogenic influences. We can hypothesize that long-term global changes could indirectly induce modifications macrobenthic assemblages through several processes. First, a potential increase of bad weather events frequency and intensity could change the granulometry and organic matter contents near the river mouth and in shallow areas. Moreover, a modification of planktonic assemblages induces perturbations of food webs, and therefore changes organic matter inputs. Finally, the emergence of invasive species such as *Caulerpa racemosa* var. *cylindracea* could cause changes in granulometric conditions [2, 3]. The significant development of this alga in Calvi Bay [4], and its consequences on soft-bottom macrobenthos will be also investigated in the framework of the STARE-CAPMED program.

APPLYING FOURIER ANALYSES TO ASSESS INFLUENCE OF ENVIRONMENTAL FACTORS ON SHELL MORPHOLOGY OF MEDITERRANEAN ENDEMIC BIVALVE *PINNA NOBILIS*

Laura Lozano [1]*, Maite Vázquez-Luis [2] and Salud Deudero [2]
[1] Université de Perpignan (UPVD) & Centro Oceanográfico de Baleares-IEO - laulzn@gmail.com
[2] Centro Oceanográfico de Baleares-IEO

Abstract
Environmental factors such as depth or hydrodynamics can influence the morphology of *Pinna nobilis*. In the present work the variation in shape morphology was studied by Fourier analysis according to different environmental conditions. Important differences were found within juveniles and adults. Discriminant analysis with elliptical Fourier descriptors was able to classify with high accuracy 97.1% of the individuals according to the factors studied.

Keywords: Bivalves, Balearic Islands, Sampling methods, Coastal systems

Introduction The pen shell *P. nobilis* is one of the largest mollusc species, reaching total anteroposterior lengths of up to 1.2 m [1]. Shell morphology is described as triangular, with a pointed anterior end and a more developed posterior part which has a broad and rounded shape. The shell shape is strongly influenced by local environmental factors. This study aims to (1) apply Fourier analysis to determine shell morphology discarding any subjectivity on the size; (2) identify different morphologies among adults and juveniles linked to environmental factors such as depth and degree of exposure to wave action.

Material and methods
For the analyses, digital photographs of *P. nobilis* shells were taken. A total of 136 photos for right valves were chosen because they were more abundant left ones from dead individuals of *P. nobilis* collected in *P. oceanica* seagrass meadows of the Balearic Islands. But when the right valves were absent, then the left one was used. All images of the shells were slightly modified, using Adobe® Photoshop® CS5, to prepare them for digitization. Fourier analysis was calculated with the SHAPE package Iwata and Ukai, 2002 [2]. A principal component analysis (PCA) (PRIMER 6 package) was used to summarize the variance in shape captured by the elliptical Fourier. Followed statistical analysis with SPSS software to verify the correctly classified according to the factors studied by discriminant analyses.

Results and discussion
Results showed two differentiated groups according to their morphology: juveniles and adults (Fig. 1). Moreover, morphologies on juveniles and adults were different within groups according to environmental factors assessed by Fourier analysis. For areas where exposure to hydrodynamics is null, the adults present a more elongated shaped. In contrast, in exposed areas its morphology is fan-shaped. This might be related to wave exposition since at unexposed areas shells can derive energy into growth without having to cope with hydrodinamical forces. However, this pattern does not apply to the juveniles since all have a similar morphology. Regarding discriminant analysis with elliptical Fourier descriptors, four main subgroups were distinguished for juveniles and adults (Table 1) and the 97,1% of individuals were correctly classified through the cross-validation procedure.

n, sample size										

Conclusion
Image analysis technique allows us to clearly identify a wide arrange of *P. nobilis* shell morphologies related to environmental factors. This represents a useful tool to apply *P. nobilis* shell morphology as a bioindicator of the degree of exposure of the location.

Abstract
The fish fauna of a *Posidonia oceanica* seagrass bed influenced by the Marseille sewage outfall was studied in summer and winter between 1980 and 2012, i.e. before and after improvements to the treatment of wastewater. A decrease in species richness, abundance and biomass was observed in summer, but not in winter. A modification of the trophic structure of the fish community also occurred in summer, with a decrease of zooplanktivores and labrids, and an increase in the relative importance of macrocarnivores.

Keywords: Teleostei, Posidonia, Sewage pollution, North-Western Mediterranean

Introduction
Posidonia oceanica seagrass beds provide shelter and food for a diverse fish community [1]. Like other Mediterranean coastal ecosystems [2], these seagrass habitats are subjected to human impacts, such as fisheries and sewage outfalls. The wastewaters of Marseille, the second largest city in France, remained untreated till 1987. They then received physico-chemical treatment that removed 70% of the particulate organic matter (OM). Since 2008, an additional biological treatment has been performed, retaining >90% of the dissolved and particulate OM. This raises the question 'Has the fish fauna associated with *P. oceanica* beds exposed to the sewage discharge been modified following these different treatment phases?'

Material and Methods
Fishes were collected with a small skid trawl in a *P. oceanica* bed located at Plateau des Chèvres (PC) near Marseille, a site frequently exposed to the wastewater of the Cortiou sewage outfall. Standardized trawls were conducted by day and night in summer and winter in 1980 prior to any wastewater treatment [3], in 2000 three years after the primary treatment phase [4], and in 2012 four years after the establishment of the secondary treatment plant.

Results and Discussion
The total number of fish species collected at PC has decreased slightly between 1980 (38 spp) and 2000 (32 spp), and was much lower in 2012 (25 spp). Labridae, Sparidae, Serranidae and Scorpaenidae remained the dominant families, but the diversity of Gobiidae, Syngnathidae, Mullidae and flatfishes was reduced. A significant decrease in fish abundance (70%) was observed in summer between 1980 and 2012 (ANOVA, $p<0.001$), while no difference in abundance was recorded in winter ($p>0.05$) (Fig. 1). The high seasonal variation in fish abundance observed in 1980, diminished over time and was nonexistent by 2012. Similar patterns were observed for fish biomass.

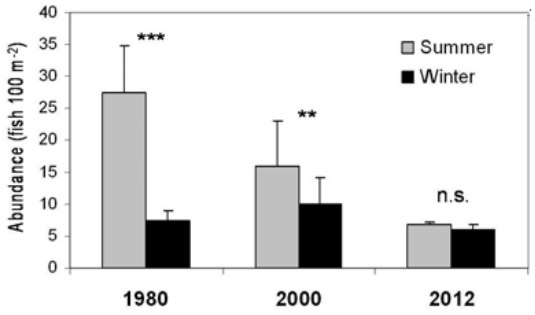

Fig. 1. Mean fish abundance in summer and winter at Plateau des Chèvres during years corresponding to different wastewater treatments.

The trophic structure of the fish community was modified only in summer. Mesocarnivores-1 (labrids) [5], which dominated in 1980 (46%), represented only 26% of the biomass in 2012. The relative importance of zooplanktivores also largely decreased from 1980 (25%) to 2012 (11%), whereas the biomass of macrocarnivores increased significantly (from 19% to 52%). While the decline in mesocarnivores-1 affected all the species, the decline in zooplanktivores was largely linked to the disappearance of the omnivorous *Boops boops*, which prefers waters rich in OM. The increase in macrocarnivore biomass was mainly due to *Scorpaena porcus*, and to *Diplodus sargus* and *D. vulgaris* for mesocarnivores-2. However, no modification of the trophic structure was observed in winter, where mesocarnivores-1 always dominated the community (55-60%), followed by macrocarnivores (22-27%) and zooplanktivores (9-15%).

Although the species richness of the *P. oceanica* fish fauna has declined since 1980, the improvement of wastewater treatments resulted in a decrease in fish abundance and biomass only in summer. The decrease in OM inputs resulted in the decline of species with a low trophic level and an increase in higher trophic level species. Thus, reductions in OM have resulted in a fish community that is now more similar to the typical *P. oceanica* seagrass fish communities of the region.

REGRESSION OF *POSIDONIA OCEANICA* MEADOW: FACT OR FICTION

C. Pergent-Martini [1]*, M. Bonacorsi [1], P. Clabaut [1], V. Pasqualini [1] and G. Pergent [1]
[1] Université de Corse - pmartini@univ-corse.fr

Abstract
The extent of the regression of the *Posidonia oceanica* meadows has been the subject of considerable controversy. Studies of the historical data and previous aerial photographs show that in sectors exposed to moderate pressure, the areas covered by the meadows have remained generally stable. Rates of regression at Mediterranean basin scale should no doubt be relativised, at least concerning the upper limits.

Keywords: Mapping, Phanerogams, North-Western Mediterranean

Introduction
While the regression of the *Posidonia oceanica* (L .) Delile meadows is a fact evidenced in numerous publications [1], the extent of the regression has been the subject of considerable controversy at Mediterranean basin scale. Whereas many authors report massive regression (5 to 8% per year [2]), others propose more moderate values (0 to 10% in the course of the 20th century [1]). The lack of accurate previous references and / or the scarcity of data for many sectors of the Mediterranean make such interpolation difficult. Improvements in the techniques of underwater cartography, the more regular mapping of the sea bed (scientific research, regulatory measures) and the availability of increasing amounts of information regarding new sectors (e.g. the eastern basin) have made it possible to perceive more accurately the distribution of the meadows [3] and to better understand their patterns of change. The aim of the present article is to survey the changes in the areas covered by *P. oceanica* meadows over time along more than 100 km of coastline, presenting moderate pressure, and to determine whether the regressions mainly observed in the vicinity of major urban and industrial centres correspond to a general trend for the whole of the basin or whether they are limited to these sectors.

Materials and methods
The patterns of change over time of the *P. oceanica* meadows were surveyed along the coast of Cap Corse (Mediterranean, France) between 1995 and 2011 on the basis of aerial photographs and side scan sonar. In addition, the availability of aerial photographs dating back to 1960 has provided temporal series for the position of the upper limits of the meadow and of natural superficial monuments (barrier reefs, atolls). The cartographical method used is identical and is based on image processing (Envi 4.4®) and integration in a GIS software (ArcGis 9.3®) with calculation of the scale of reliability [4].

Results
The patterns of change in the areas covered by the *P. oceanica* meadows along the coast of Cap Corse (77% of bottoms between 0 and -40m, in 2011) show, in general, over the past fifteen years a slight decline of 2% (Tableau I), with an improvement in the accuracy of the mapping method used (mean reliability of 79% to 90%). Over the same period, the position of the upper limit has remained relatively stable (decline of 1%; Table I), although the precision increased between 1995 and 2011 (pixel size from 5m to 1m). The natural monuments of the Gulf of Saint-Florent show a natural progression of 2 to 10%, from 1960 to 2011. In contrast, off the port of Macinaggio, the meadow shows a slight regression (7%), between 1995 and 2011, and numerous trawling scars.

Table I: Patterns of change in the *P. oceanica* meadow along the coast of Cap Corse on the basis of aerial photograph and previous maps (a : Molinier [5], reliability = 33% ; b reliability = 79% ; c reliability = 90%).

	1960	1995	2011
P. oceanica meadows (ha)	12 963[a]	10 201[b]	9 970 [c]
Upper limits (0 to-15m) (ha)		2 675	2 645
Port of Macinaggio		169	159
Platform Reef (ha)	2.22		2.26
Barrier Reef (ha)	5.9		6.5
Atolls (m^2)	21		85

Discussion
The reliability of 'historic' maps must often be treated with caution and they can rarely serve as a basis for accurate assessment of the progression or regression of seagrass meadows. On the other hand, the available early 'raw data' (aerial photographs, sonograms) provide crucial information, notably when they are processed using recent and similarmethods. The patterns of change in the *P. oceanica* meadows along the coast of Cap Corse would appear to indicate the stability of the areas covered over the past decades, notably in the position of the upper limits. Other studies in sectors exposed to greater pressure also show that the regression of the upper limits has been relatively limited; for example, in the Provence Alpes Côte d'Azur region, 87% of the surface meadows (from 0 to -15m) have remained stable or progressed since the 1920s [6]. At Mediterranean basin scale, the presence of extensive meadows still preserved from the direct impact of human activities and the limited areas concerned by these impacts, when they do occur, argue in favour of observable rates of regression that are well below certain values recorded in the literature [2]. Nevertheless, the appearance of new forms of pressure (e.g. global change) and the conjunction of different kinds of impact may significantly reduce the resilience of *P. oceanica*, especially along the lower limit.

SUCCESSIONAL PATTERNS OF MACRO-INVERTEBRATE COMMUNITY ON EMPTY PEN SHELLS TRANSPLANTED IN A SOFT-SEDIMENT HABITAT

L. Rabaoui [1], W. Belgacem [1], D. Ben Ismail [1], O. K. Ben Hassine [1] and S. Tlig-Zouari [1]*
[1] University of Tunis El Manar - Faculty of Science of Tunis, Tunisia - s.zouaritlig@gmail.com

Abstract
We describe here an experiment aiming to quantify the contribution of empty pen shells to the richness and structuring the macrofauna in soft-sediment habitat. Empty pinnids were planted and their associated fauna was followed along 120 days and compared to that of the surrounding soft-sediment habitat. The data obtained showed a succession of species richness and abundance, and consequently the diversity descriptors (H' and J') of empty shells fauna. The number of species found was slightly higher in soft-sediment habitat; whereas the highest abundance was noted with pen shells fauna. Multivariate analyses highlighted a discrimination, between the two sample types, due to the presence of some sessile and hard-substrata affinity species in empty pinnids and some motile soft-sediment species in the wider system.

Although the Mediterranean pen shell *Pinna nobilis* was reported to play an important ecological role as an association center of numerous macro-invertebrate species [1; 2], no studies were carried out about quantifying the contribution of this benthic mollusk to the richness and structuring the macro-faunal community of the wider ecosystem. The aim of this study was to compare the structure of associated fauna to empty shells of *P. nobilis* and that of the benthic fauna on soft sediment habitat in the area of Elketef, south-eastern Tunisia. Therefore, the objectives of this study were to follow the occupancy of empty *P. nobilis* shells transplanted and to compare the structure of the macrofauna assemblage associated to the "dead" pinnids and that of soft-sediment habitat. The experimental area was selected between the fishing port of Elketef and the southern edge of Elbibane lagoon (33°11'N, 11°28'E), at about two meter depth. Thirty six empty *Pinna* shells were transplanted along three transects, fixed parallel to the shoreline. In each transect, four empty shells were planted in a line, at three equidistant levels along the transect. The experiment lasted 120 days and samples of empty shells were taken at three times: after 30, 60, and 120 days from the starting date of the experiment. At each sampling time, three samples, of four *Pinna* empty shells each, were taken separately. In parallel, three samples of soft-sediment macro-invertebrates were collected. The species collected from empty shells and sediment samples were identified and counted. Diversity indices (S, N, H' and J') were calculated for each pinnids' sample and each soft sediment sample in each of the three sampling times. The dissimilarity/similarity between the *Pinna* empty shell and soft sediment samples was represented with a non metric multi-dimensional scaling (*nm* MDS). Moreover, the similarity of percentage test (SIMPER) was also carried out to define the species which better contributed to the dissimilarity between *Pinna* shell and soft sediment samples.

A total of 694 specimens belonging to 61 species were collected in empty *Pinna* shell and soft sediment samples. 46 species counting 393 individuals were encountered in *P. nobilis* shells; while in soft-sediment samples, 49 species were found corresponding to a total of 301 individuals. The results obtained herein showed a clear increase in the number of species, and relatively Shannon-Wiener index, along the experiment period. It is worth noting that Pielou's evenness index was found to tend to 1, confirming that the community of empty *Pinna* shells was well structured during the three sampling times (Fig. 1).

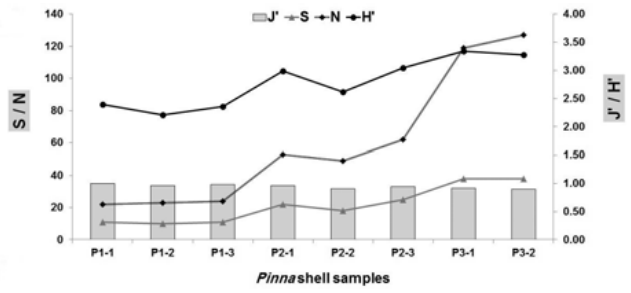

Fig. 1. Variations of species richness (S), total abundance of individuals (N), Shannon-Weiner diversity (H'), and Pielou's evenness index (J') estimated in empty *Pinna* shell samples collected during the three sampling times.

Similar patterns of diversity descriptors were also noted in a similar study with the congeneric species *Atrina rigida* [3]. Multivariate analysis (*nm* MDS) showed a clear separation between two clusters at the level of 20% similarity: the first cluster (A) was represented by empty shell samples, while the second cluster (B) grouped the soft sediment samples (Fig. 2).

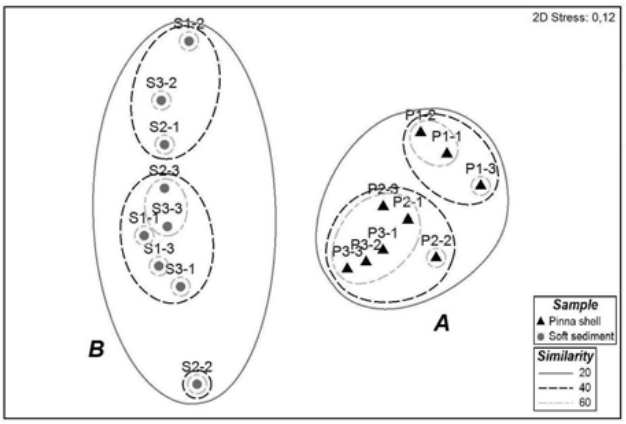

Fig. 2. Non metrical multi-dimensional scaling of *Pinna* shell and soft sediment samples, conducted based on the square rooted data abundances of the species found.

It is evident that the discrimination between empty *Pinna* shell samples is due to the temporal variations of shell colonization by sessile and motile species. With the soft-sediment samples, the discrimination obtained may be explained by the natural temporal variations in the composition and structure of benthic communities due to the seasonal shifts of temperature and salinity. Based on SIMPER analysis, this discrimination between the two types of samples is mainly due to the presence of some sessile and hard-substrata affinity species in empty *Pinna* shells and some motile and soft-sediment affinity species in the soft habitat.

Abstract
This study deals with the structure of zoobenthic assemblages and their relationships with abiotic conditions in Canakkale Strait in 2006 and 2007. A total of 510 species (except Annelida) were identified.

Keywords: Biodiversity, Marmara Sea

Introduction
Fieldwork was carried out along the southern part of the Canakkale Strait, connecting the Sea of Marmara to the Aegean Sea (Turkey). The Strait has a well-defined two-layer stratification associated with a two-layer pattern of water exchange.

Material and Methods
Soft bottom samples (three replicates/station) were obtained seasonally during 2006 by means of 0.1 m2 van Veen grab at 11 stations from depths between 7-26 m. Seven more stations located in the middle of the Strait were sampled by means of van Veen grab, dredge and box-corer from depths between 40-83 m (Fig 1, 2).

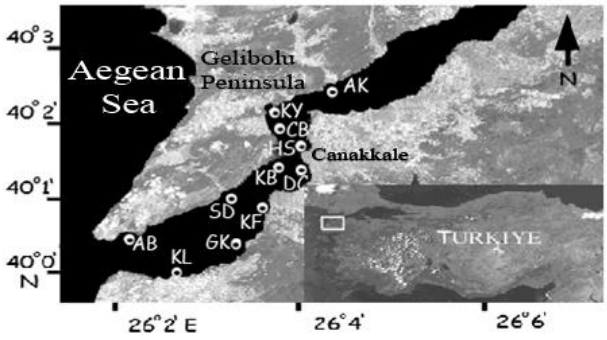

Fig. 1. Map of sites: a)coastal sites (seasonal samplings)

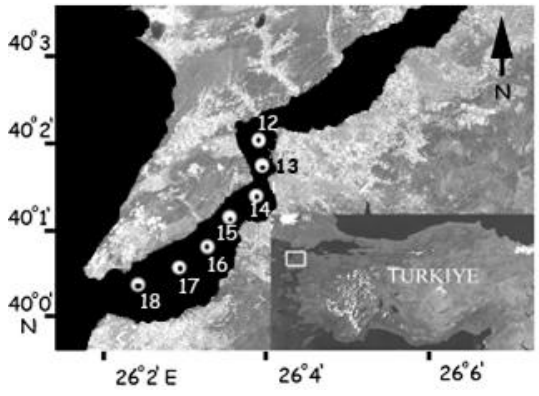

Fig. 2. B)mid-line area (6/ 2007).

Results
A total of 510 species (except Annelida) for a total of 48.969 individuals.m^{-2} were identified, of which 2 Foraminifera (*Cibicides sp.*, *Quinqueloculina seminula* (Linnaeus, 1758)), 9 Cnidaria (*Anemonia sp.*, *Actinia equina* (Linnaeus, 1758), *Caryophyllia (Caryophyllia) smithii* Stokes & Broderip, 1828, *Balanophyllia (Balanophyllia) europaea* (Risso, 1826), *Peachia hastata* Gosse, 1855, *Eunicella* sp., *Clytia* sp, *Nemertesia ramosa* (Lamarck, 1816), *Obelia* sp.), 283 Mollusca [1], 110 Peracarida Crustacea [2], 45 Decapoda Crustacea [3], 1 Leptostraca (*Nebalia bipes* (Fabricius, 1780)), 1 Pantopoda (*Anoplodactylus petiolatus* (Kroyer, 1844)), 3 Cirripedia (*Amphibalanus eburneus* (Gould, 1841), *Verruca spengleri* Darwin, 1854, *Balanus* sp.) 1 Insecta (Ephemeroptera: *Cloeon* sp.), 22 Bryozoa (*Calpensia nobilis* (Esper, 1796), *Monoporella nodulifera* (Hincks, 1881), *Puellina innominata* (Couch, 1844), *Puellina radiata* (Moll, 1803), *Reptadeonella violacea* (Johnston, 1847), *Cryptosula pallasiana* (Moll, 1803), *Porella concinna* (Busk, 1854), *Smittoidea reticulata* (MacGillivray, 1842), *Smittina* sp., *Escharina vulgaris* (Moll, 1803), *Schizomavella auriculata* (Hassall, 1842), *Schizomavella linearis* (Hassall, 1841), *Schizoporella* sp., *Cleidochasmidra* sp., *Microporella ciliata* (Pallas, 1766), *Microporella* sp., *Reteporella couchii* (Hincks, 1878), *Reteporella sudbourniensis* Gautier, 1962, *Reteporella* sp., *Turbicellepora coronopus* (Wood, 1844), *Tubulipora* sp., *Lichenopora radiata* (Audouin, 1826)), 6 Sipuncula (*Aspidosiphon muelleri muelleri* Diesing, 1851, *Sipunculus nudus* Linnaeus, 1766, *Aspidosiphon muelleri kovalevskii* Murina, 1964, *Golfingia vulgaris* (De Blainville, 1827), *Onchnesoma steenstrupii* Koren & Danielssen, 1876, *Nephasoma diaphanes* (Gerould, 1913)), 25 Echinodermata [4] and 3 Chordata (*Ascidiella aspersa* (Muller, 1776), *Ascidiella scabra* (Muller, 1776), *Branchiostoma lanceolatum* (Pallas, 1774)).

Discussion
The large number of rare species recorded led to very low similarity values among stations. No seasonal differences were found among stations. Among abiotic factors, sediment grain size seems to be more effective on zoobenthic distribution [1-4]. Hydrodynamism could be the main stressor factor regulating benthic assemblages and their distribution in Canakkale Strait. Seasonal reproductive periods showed differences according to the various zoobenthic groups. Different feeding types were distinguished for each benthic group. During warm seasons, the presence of the invasive macroalga *Caulerpa racemosa* in the southeastern part of Canakkale Strait seems to encourage settling of some scavenger species.

Abstract
In this study, two fish pathogenic bacteria (*Yersinia ruckeri*, *Lactococcus garvieae*) challenged with *U. crassus* for the pathogenicity characteristics onto mussels were investigated. For this purpose, 10^8 bacteria mL^{-1} were mixed in the water. Mussels were removed turbidity of the water and throw the bacteria as pseudo feces. No mortality and no symptoms of *U. crassus* were noted from any of the groups during observation period. Also, the pathogens were not isolated from the mussels.

Keywords: Bacteria, Aquaculture, Bivalves, Bio-indicators, Gokova Bay

Introduction
Freshwater mussels have ability to filter large volumes of water for respiration and feeding. Therefore these organisms can accumulate large number of bacteria in their body [1]. Since 1994, *Unio crassus* is in the Red List as endangered freshwater mussel species [2]. Aquaculture is one of the options for preventing extinction of this species but they required a host for their glochidia. Host fish are susceptible to some bacterial pathogens and we need to know whether *U. crassus* is also susceptible to these pathogens. In this study, two pathogenic fish bacteria (*Yersinia ruckeri* and *Lactococcus garvieae),*challenged with this mussel for the pathogenicity characteristics onto mussels were investigated.

Materials and Methods
U. crassus samples were collected at 0,5-1 m depth in the Tersakan Stream in Dalaman, Mugla. They transported to the laboratory as dry and put into 10 L of water in the bowls. Mussels were fed daily at a rate of 1% body weight per day with sea bass pellet. The mean weight 55 g and mean length 6 cm of 150 mussels were separated to 6 groups with 2 groups for control, 2 groups for *Y. ruckeri* challenge and 2 groups for *L. garvieae* challenge. Bacterial density was determined by spectrophotometer. 10^8 bacteria mL^{-1} was used both challenge experiment. Septic techniques were used to collect hemolymph samples for recovery of the bacteria. The hemolymph samples were inoculated onto Tryptic Soy Agar (TSA) medium. Suspect colonies were transferred from primary isolation plates and biochemically confirmed using standard bacteriological procedures [3].

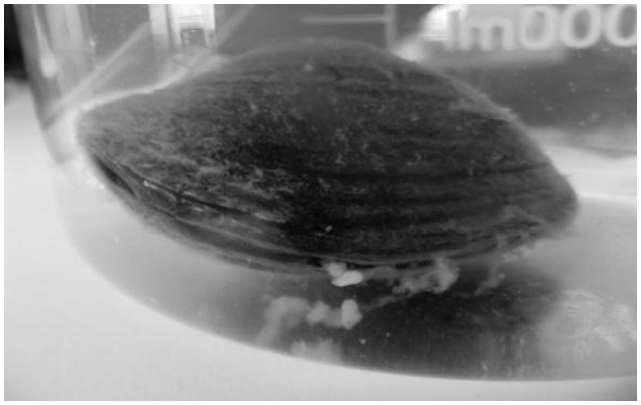

Fig. 1. Mussels cleaned the water and all the bacteria covered with mucus thrown out as pseudo feces.

Results and Discussion
In our study, both fish pathogens could not recovered from mussels. No dead *U. crassus* were noted from any of the groups during the four week observation period. In addition to any symptoms of mussel organs were observed. The previous studies showed that the mussels acquired the *Aeromonas salmonicida, A. sobria, A. hydrophila, Flavobacterium columnare, Pseudomonas fluorescens* cells by siphoning contaminated tank or water of natural habitats [1,4,5]. However, they recovered bacteria from hemolymph tissue of mussels contrary to our findings. Unionids and other freshwater bivalves are important components of freshwater ecosystem. Freshwater mussels also are propagated in captivity for production of pearls. However, infectious diseases of these mollusks have received relatively little attention. Several species of potentially pathogenic bacteria have been isolated from freshwater bivalves, but their role in diseases of bivalves has not been established [6]. Additional research is needed to determine whether other types of pathogens are present in freshwater bivalves. ?It has been shown that the bacterial flora within mussels changes rapidly [7,8]. Starliper et al. [8]; demonstrated that the bacterial flora in mussels changed significantly within 24-hr of a change in water supply. The finding that the bacterial flora rapidly responds to changing water supplies could be used favorably as a means to minimize the risk for introductions of pathogens. Also in this study we observed that, all the groups of mussels cleaned the water and all the bacteria covered with mucus thrown out as pseudo feces (Fig. 1). It was thought that, mussels put into fish tanks may be remove pathogens in the water and prevent outbreaks of fish disease. These findings should be supported by further studies.

MORPHOLOGICAL EVIDENCE FOR ADAPTIVE DIVERSIFICATION OF SYMPATRIC MEDITERRANEAN *PATELLA* LIMPETS

Jihen Boukhicha [1]*, Oum Kalthoum Ben Hassine [1] and Sabiha Tlig-Zouari [1]
[1] Faculté des sciences de Tunis département de Biologie - boukhicha.jihen73@gmail.com

Abstract
The Mediterranean *Patella* limpets (*P. rustica, P. ferruginea, P. caerulea* and *P. ulyssiponensis*), occupy different positions in the shore. This stratification subjects them to a variety of environmental stresses. Shell and radula characters, as well as the (shell surface area/shell volume) ratio were investigated in these four species. We reported inter-specific differences in shell shape, radula relative size and the (SSA/SV) ratio among these limpets. The ecological implications of these strutural adaptations for species survival in their respective niches are discussed.

Keywords: Gastropods, Stratification, Mediolittoral, Mediterranean Ridge

Introduction
The extended distribution of limpets which occur from the upper to the lower shore levels subjects them to a variety of environmental stresses. The Mediterranean *Patella* species encountered in the Tunisian coasts often coexist on the same shore showing different zonation patterns. *Patella rustica* is restricted to the upper midlittoral. *P. ulyssiponensis* dominates the lower midlittoral and the infralittoral and *P. ferruginea* and *P. caerulea* the middle midlittoral. Since the position of the animal in the shore influences the time to air exposure, these species can exhibit varying degrees of structural adaptations.

Material and Methods
In this study, we aimed to investigate shell and radula characters in Mediterranean *Patella* species. In order to do so, 1200 specimens were collected from 22 rocky stations covering the entire Tunisian coastline (from Algero-Tunisian (Tabarka) to Tuniso-Libyan (Zarzis) frontiers). Samples were dissected to remove the radula. Shell was separated from the visceral mass. Shell length (SL), shell width (SW), shell height (SH), shell length from apex to anterior end (SAA) and from apex to posterior end (SAP) and radula length (RL) were measured to the nearest 0.01mm using a digital caliper.
The following shell parameters were estimated for each species: shell conicity (SH/SL), Cone eccentricity (anteroposterior position of the apex: SAA/SAP), Base ellipticity (SW/SL) and radula relative size (RL/SL). The means were then compared using ANOVA. The shell surface area (SSA) and shell volume (SV) were calculated using the formulas of the surface area and volume of a parabolic cone ([1]): SAA=3.6 x R x *SR*(R^2+(4/3) x SH) and SV=(3.14 x R^2 x SH)/2 , with R=(SL+SW)/4. The Log (SSA/SV) ratio was then plotted against shell length, the comparison of the regression slopes was carried out by ANCOVA.

Results and Discussion
The morphological study revealed that shell conicity was highest in *P. rustica* and lowest in *P. ulyssiponensis.* Shell cone eccentricity indicated a very asymmetrical cone in *P. ferruginea* and a more centered apex in *P. rustica*. Shell base ellipticity showed a narrower shell base in *P. ulyssiponensis* and broader in *P. caerulea.* Radula relative size increased from *P. ulyssiponensis* to *P. rustica* (Tab.1).

Tab. 1. Means of the variables describing shell shape and radula relative size.

Shape parameter (Variable)	*P.rustica*	*P.ferruginea*	*P.caerulea*	*P.ulyssiponensis*	ANOVA
Conicity (SH/SL)	0.375	0.326	0.301	0.296	<0.01
Cone eccentricity (SAA/SAP)	0.750	0.563	0.690	0.622	<0.01
Base ellipcity (SW/SL)	0.792	0.807	0.823	0.707	<0.01
Radula relative size (RL/SL)	2.206	-	1.257	1.094	<0.01

Thus, the shells of these species were different in shape, from the flat cone with a narrow base in the low-shore limpet, *P. ulyssiponensis*, to the tall cone with a broad base in the high-shore limpet *P. rustica. P. ferruginea* and *P. caerulea* exhibited intermediate shell shapes between these two extremes. These species-specific combinations of characters are likely to confer specific advantages for limpet survival on the higher shore levels where thermal and desiccation stress are harsh (taller cone: greater water reserve), and on the lower shore levels, where hydrodynamic forces are intense (flatter cone: stronger adhesion to the substratum).

The regressions of the Log (SSA/SV) vs SL plots revealed that all slopes were negative indicating that the ratio progressively decreases as shell length increases (Fig.1). In this context, many studies ([1], [2]) indicated that, in limpets, decreasing the (SSA/SV) ratios by increasing size results in lower body temperature and desiccation. Considering that thermal conditions in rocky shores are harsh, it appeared that shell shape in all Mediterranean *Patella* limpets can be directly related to their resistance to desiccation and high temperature stresses.

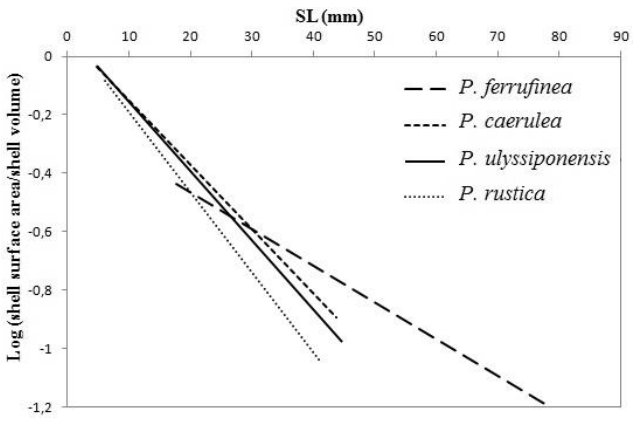

Fig. 1. Plots of the Log (shell surface area/shell volume) against shell length.

The comparison of the Log (SSA/SV) vs SL plots showed that all slopes were significantly different (ANCOVA, p<0.001). Except for small shells, *P. rustica* and *P. ferruginea* displayed respectively the lowest and highest (SSA/SV) ratios. The positions of the curves did not match with species distribution levels in the shore. This is most probably related to differences in external shell architecture as has been demonstrated for other limpets ([3]). In fact, heavily ridged shells (*P. ferruginea*) seem to be able to lose heat more readily than smoother shells (*P.rustica*). Furthermore, radula relative size also increased with increasing level in the shore, suggesting that this might be due to a decreasing abundance of algae with increasing shore level. This result is compatible with the view of [4], according to which, radula length is positively correlated to its increasing usage and abrasion. These data reinforce the evidence of adaptive diversification in Mediterranean limpets and highlights its utility in exploiting their respective niches and its ecological implication for survival.

EPIPHYTIC DIATOM COMMUNITIES ON *ULVA LACTUCA* LINNAEUS IN HOMA LAGOON, AEGEAN SEA

Fatma Colak Sabanci [1]* and Tufan Koray [1]
[1] Ege University, Faculty of Fisheries - sabanci.fatma@gmail.com

Abstract
The taxonomical composition of epiphytic diatoms was investigated at four stations in Homa Lagoon during June 2006 and June 2007. In total, 79 taxa belonging to 23 genera were identified. *Cocconeis scutellum*, *Ctenophora pulchella*, *Grammatophora oceanica*, *Synedra affinis* var. *parva* and *Tryblionella acuminata* were dominat at all stations. The collected seasonal samples at each station constituted three seperate groups in the MDS plot, which were correlated with a combination of environmental variables such as the concentrations of silicate and pH (ρr=0.19).

Keywords: Algae, Diatoms, Lagoons, Izmir Bay, Aegean Sea

Introduction
Diatoms are the major contributors markedly to primary production in estuarine ecosystems and play an important role in food webs in waters. Coastal lagoon ecosystems are a particular type of estuarine systems which varies from freshwater media to excessive salty water media. Homa Lagoon, where the present study is carried out, has both marine, brackish water and fresh water forms in the region due to its wide spectrum of ecologically different biotopes. Studies conducted in this area have been focussed on the physical and chemical properties of the lagoon [1], bivalve culture [2], but microphytobenthic surveys have been conducted recently [3; 4] . The objectives of this work were to describe the species composition of diatom assemblages, to determine which environmental factors explain the composition of epiphytic diatoms and to make a contribution to the largely unknown algal flora of Turkey.

Material and Methods
Homa Lagoon (38° 33' 10"N, 26°49'50"E) is located 25 km to the northwest of the Gulf of Izmir and within the borders of the town of Menemen (Fig. 1). The lagoon has a surface area of 1800 hectares and the depth of the fish trap is maximum 1.5 meters and its depth mostly varies between 0.5 and 1 meter.

Fig. 1. Location of stations in the Homa Lagoon

For the collection of epiphytic diatom samples, the macroalgae *Ulva lactuca* Linnaeus was chosen in the research region. Samples were processed by standard methods, including 10% HCl, 30% H_2SO_4, $KMnO_4$ and oxalic acid [5]. Cleaned diatoms were mounted permanently on slides with Naphrax and identified at 1000× magnification by means of phase−contrast optics with OLYMPUS × 100 Plan-apochromatic oil immersion objectives. Identification at species level was made following descriptions of [6]. In order to determine the temporal distribution patterns, the qualitative data of all stations in each sampling period were analyzed using the cluster and multidimensional scaling (MDS) techniques, based on the Bray-Curtis similarity, using the PRIMER package. Patterns in community structure identified by cluster and MDS analysed were linked to the environmental variables using the BIOENV procedure of Primer.

Results and Discussion
During study periods, total of 79 taxa belonging to 23 genera were identified to the genus or species level. *Cocconeis scutellum*, *Ctenophora pulchella*, *Grammatophora oceanica*, *Synedra affinis* var. *parva* and *Tryblionella acuminata* were dominant among the epiphytic diatom species. When the taxa composition was examined, maximum number of species with18 taxa were found at station 2 and station 3 in September 2006, minimum number of species with 4 taxa was found at station 1 in March 2007. Based on Bray-Curtis similarity values higher than 40%, three groups of stations can be recognized. The stress value for the two-dimensional MDS plot was 0.15, indicating a proper group separation. According to the results of the BIOENV analysis, best matching parameters were the concentration of silicate and pH (ρr=0.19), but effective parameters on species composition in this study area had stated lagoon water temperature, the concentration of nitrogen and silicate [3]. On the other hand as our study was a qualitative study, it was difficult to infer the possible environmental factors which affected the species occurrence and the seasonal fluctuations in the assemblages without quantitative data. Since the distribution of benthic diatoms is not only controlled by the substratum but also by biotic and abiotic factors, the species defined in lagoonal systems are usually quite mixed and often difficult to interpret.

MACROFAUNAL DIVERSITY OF INFRALITTORAL COBBLE BEDS IN THE MALTESE ISLANDS

J. Evans [1]*, M. J. Attrill [1], J. A. Borg [2], P. A. Cotton [1] and P. J. Schembri [2]
[1] Marine Biology and Ecology Research Centre, University of Plymouth, Plymouth PL4 8AA, UK - julian.evans@um.edu.mt
[2] Department of Biology, University of Malta, Msida MSD2080, Malta

Abstract
The Mediterranean "biocoenosis of infralittoral pebbles" has been poorly studied, but is generally considered to be impoverished. Systematic sampling of cobble beds at 17 sites around the Maltese Islands yielded a total of 35,687 individuals belonging to 310 different taxa. Very shallow sites (<2 m depth) had a slightly poorer faunal assemblage than deeper ones (2-12 m depth), but still included 152 taxa. These results suggest that infralittoral cobbles beds may not be as impoverished as previously thought, probably due to the high structural complexity of these habitats.

Keywords: Biodiversity, Infralittoral, Zoobenthos, Sicily Channel

Introduction
In shallow waters of the Mediterranean Sea, accumulations of pebbles and cobbles (particles between 4 mm – 256 mm) occurring in wave-exposed rocky coves support a distinct biotic community known as the "biocoenosis of infralittoral pebbles" [1]. No detailed ecological studies on this biocoenosis appear to have been carried out, but it is generally considered to be impoverished [2]. However, databases of Mediterranean marine fauna list "under stones" as the microhabitat of quite a number of species, and this habitat can be important recruitment ground for decapod Crustacea [3,4], indicating that infralittoral pebbles may be more species diverse than previously thought. In addition, coarse gravel sediments do not only occur in indentations along rocky coasts, but also in slightly deeper waters such as within inter-matte regions of reticulate *Posidonia oceanica* beds where a different suite of species could potentially be present. The present study was carried out to assess the macrofaunal diversity of infralittoral cobble beds in the Maltese Islands, in order to determine whether they are indeed impoverished habitats.

Material and Methods
Seventeen study sites having a continuous cover of pebbles and cobbles of at least 25 m^2 were selected from around the Maltese Islands; these included sites with cobble beds in both very shallow (<2 m) and deeper (2-12 m) waters. In 2011, four random samples were collected from each site by SCUBA divers. The pebbles within a 0.1 m^2 corer were carefully removed by hand and the basal layer of finer granules was scooped out separately. An air-lift suction sampler was simultaneously employed to reduce the risk of missing highly motile organisms, thus ensuring that quantitative samples of the total benthic fauna were collected. Samples were sorted in the laboratory and fauna retained by a 0.5 mm mesh were identified to the lowest possible taxon. Statistical analyses of the resulting species X site matrix were carried out using PRIMER v6 (Plymouth Routines In Multivariate Ecological Research, PRIMER-E Ltd.).

Results and Discussion
A total of 35,687 individuals, belonging to 310 separate taxa were recorded from a total sampling area of 6.8 m^2. The most common groups were Mollusca (118 taxa), Crustacea (89 taxa) and Polychaeta (74 taxa). Spirorbinae spp. accounted for 52.4% of all individuals and 90.3% of the polychaetes; thus Polychaeta was the most abundant faunal group overall, but non-spirorbid polychaetes comprised only 5.6% of the total fauna (Fig. 1). When sessile fauna are excluded, crustaceans were the dominant group; this agrees with studies of cobble sites in Norway, England and Italy [3]. The most ubiquitous species included the tanaid *Leptochelia savignyi*, the decapods *Athanas nitescens* and *Xantho pilipes*, numerous amphipods (of which *Ampithoe ramondi*, *Gammarella fucicola*, *Maera grossimana*, *Melita hergensis* and *Microdeutopus* spp. were the most abundant), the chiton *Ischnochiton rissoi*, the gastropod *Gibbula varia*, the polychaetes *Nereis rava*, Ophelidae spp. and Spirorbinae spp., and the ophiuroid *Amphipholis squamata*.

Cluster analysis indicated that the cobble bed assemblage composition varied with depth, with the very shallow (< 2m) sites generally grouping separately from the deeper ones (Fig. 2). The deeper sites (Cluster B) included 278 different taxa, versus the 152 taxa of 'Cluster A' sites, while 120 taxa were common to sites in both clusters. These results suggest that the biocoenosis of infralittoral cobbles and pebbles may not be as impoverished as previously thought, even if only the very shallow beds described in [1] are considered. This is probably due to the high structural complexity of the cobble habitats, which are characterised by vertical stratification: upper cobble layers can provide numerous interstitial spaces affording shelter to fauna [3,4] while the basal layer of finer sediment supports an infaunal assemblage.

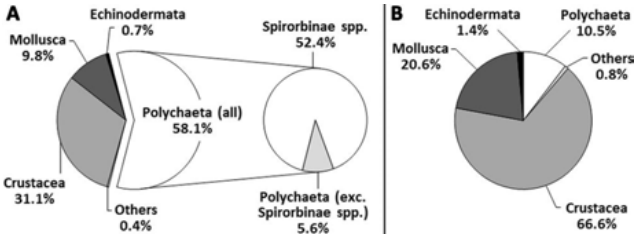

Fig. 1. Percentage abundance of major faunal groups from infralittoral cobble beds at 17 sites when considering (**A**) all macrofauna, and (**B**) non-sessile macrofauna only.

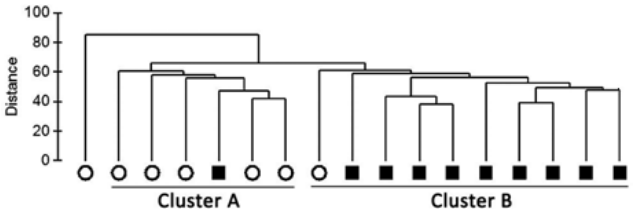

Fig. 2. Dendrogram from group-average hierarchical cluster analysis based on Bray-Curtis resemblances, produced using square root-transformed abundance data for macrofauna from infralittoral cobble beds at 17 sites (Empty circle: Depth <2 m; Filled square: Depth 2-12 m).

ASSESSING ADAPTIVE ABILITIES OF THE MEDITERRANEAN RED CORAL *CORALLIUM RUBRUM* IN AN HIGHLY VARIABLE ENVIRONMENT USING COMMUN GARDEN AND RNA-SEQ APPROACHS.

Anne Haguenauer [1]* and Didier Aurelle [1]
[1] IMBE UMR 7263 Centre d'Océanologie de Marseille - anne.haguenauer@imbe.fr

Abstract
To understand the underlying mechanisms of adaptation to thermal stress in the mediterranean red coral, *Corallium rubrum*, we studied two populations: a shallow one living at the edge of the specie's range (5 m depth), and a deeper one living in more stable thermal environment (40 m). A common garden experiment in aquaria showed different molecular phenotypes depending on the depth of origin of the individuals and of their thermal history. The transcriptome of individuals sampled in situ at 5 m or 40 m depth is currently under analysis, with more than 10^8sequences for both populations. Our study will offer consistent elements to discuss the hot topic "plasticity vs local adaptation" in a context of climate change, and our results emphasize the conservation value of marginal populations.

Keywords: Cnidaria, Global change, Genetics, North-Western Mediterranean

Mediterranean benthic ecosystems, including Mediterranean red coral *Corallium rubrum*, have been deeply impacted by thermal anomalies during the last decades [1]. Adaptive capacities for marine species facing climate change can be understood at two different levels, at the individual level (i.e. phenotypic plasticity) and at the population level (i.e. selection). The Mediterranean red coral, *Corallium rubrum*, is well suited to study adaptative evolution in heterogenous environment. This sessile species is present in contrasted environments with a strong genetic structure [2], and differences of response to thermal stress between populations. To understand the underlying mechanisms of adaptation to thermal stress in this species, we studied three *C. rubrum* populations from different depths (5 m, 20 m and 40 m depth) and therefore different thermal regimes in the same area. We submitted red coral colonies to different heat shocks in aquaria that mimicked in situ stresses in common garden conditions. We measured the expression levels of several candidate genes by real-time PCR. Heat Shock Protein 70 (HSP 70), considered as a real molecular phenotype [4], showed significant differences of expression depending on the depth of origin of the individuals and of their thermal history.

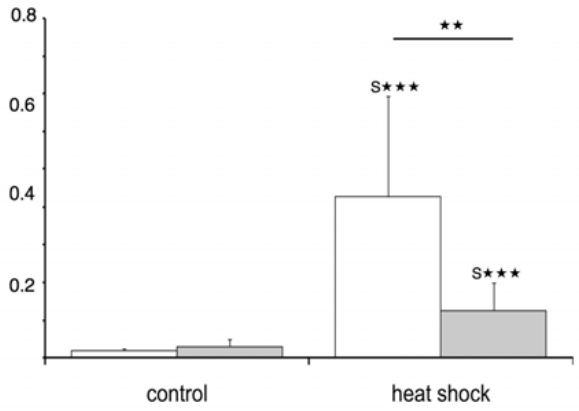

Fig. 1. HSP 70 induction after heat shock for 5 m population (white bars) and 40 m population (grey bars). HSP 70 mRNA expression was calculated using COI as reference gene. Results are represented as mean ± SD. Stars indicates significant differences (3 stars $p<0.008$, 2 stars $p<0.016$), S indicates significant differences between control and stress condition in the same population.

A RNA-seq experiment (Illumina technology) performed on individuals sampled *in situ* at 5 m and 40 m depth is currently under analysis, with more than 10^8 sequences for both populations. This analysis will provide usefull data to look for potential genomic basis for red coral adaptation to climate change. Our study will offer consistent elements to discuss the hot topic "plasticity vs local adaptation" in a context of climate change, and emphasizes the conservation value of marginal populations [5].

ACOUSTIC DETECTION OF BENTHIC ASSEMBLAGES IN A LAND-LOCKED SHALLOW MARINE ENVIRONMENT: GULF OF GERA, LESVOS, GREECE

Evaggelia Manoutsoglou [1], Thomas Hasiotis [1]* and Antonis Velegrakis [1]
[1] Dept. of Marine Sciences, University of the Aegean, Mytilene, Lesvos isl., Greece - hasiotis@marine.aegean.gr

Abstract
In this contribution a geophysical data set and sediment samples and camera images for ground-truthing are used in order to study the morphology of the Gulf of Gera. The observed hummocky relief is due to benthic assemblages and it can be discriminated to five different sub-classes according to their morphological characteristics. The hummocks is probably the result of the regional oceanographic conditions, slow gas seepage and the protected from scallop dredging environment.

Keywords: Aegean Sea, Coastal systems, Mapping, Zoobenthos, Sediments

Introduction
The Gulf of Gera is an enclosed embayment located in the island of Lesvos. It connects with the Aegean Sea through a narrow channel that has a width of 300-800m, a length of 6.5km and depths ranging from 10 to 30m. The area of the gulf is ~42.5Km^2, with a maximum depth of ~18m. The Gulf of Gera receives discharges from seasonal streams/small rivers. Previous studies had focused on the sedimentology and sediment geochemistry [1] as well as on the anthropogenic influences on benthic ecology [2]. The present study examines the embayment seabed morphological features.

Materials and Methods
A single-beam echo-sounder and a side scan sonar survey were conducted for the detection of the seabed morphology. Scuba diving at 2 sites, a drop down camera system and sediment sampling at 43 stations were employed to ground-truth the geophysical results. Grain size analysis was carried out with dry sieving for the coarse fraction and with laser – diffractometry for the fine fraction. For the side scan sonar processing and data analysis/mapping, the SonarWiz Map and ArcGis were used, respectively. Additionally, a 3.5kHz old analog profile aided to the investigation of the subbottom structure of the gulf.

Results and Discussion
The main morphological features identified are numerous small hummocks that populate the seafloor (Fig. 1). They appear in water depths deeper than 12m covering an area of 16.3km^2, have an average height of 1.0m and occur individual or locally coalescing. Based on the hummocks morphological characteristics (shape, dimensions and distribution), 5 sub-areashave been distinguished, each showing a unique pattern (Figs. 1 and 2). An interesting finding is that the sub-area with the higher hummocks (up to 2.0m) appears to develop near the entrance of the bay.

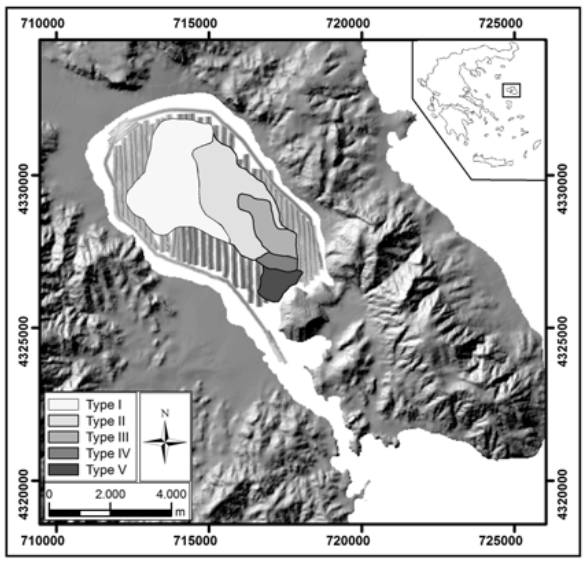

Fig. 1. Hummocky sub-areas extent, over the side scan sonar mosaic.

The 3.5kHz subbottom profile has shown the presence of an almost homogeneous surficial layer 4-9m in thickness that overlies almost concordantly earlier sedimentary units at the central part of the embayment. The bottom-echo becomes more intense at the top of the hummocks. Acoustic anomalies, mainly as small in extent acoustic turbid zones as well as plumes within the surficial layer, imply the potential presence of gas in the sediments. The video images and the seabed sampling revealed that the hummocks consist of assemblages of bivalves (mainly) and gastropods of various sizes, together with fine-grained sediments. Species that are met in considerable abundance are the *Mytilus galloprovincialis, Turritella communis, Vermetus semisurrectus* and *Ostrea edulis*. Very fine muddy sediments are found in the greater part of the embayment and also seem to constitute the hummocks matrix material.
The hummocky seabed morphology may be (i) related to the oceanographic conditions prevailing in the gulf [3], (ii) associated with the slow seepage of gas that has been reported also elsewhere to be connected with high concentration of bivalves and other benthic life [4] and (iii) possibly favored by the prohibition of scallop dredging in the area.

Abstract
The present work assessed the survival and growth rates of *Pinna nobilis* juveniles in a range of eutrophic conditions (fish farm vs MPA) around Mallorca. A high mortality rate of juveniles appears in the locality of high human impact. However, the growth rate of individuals in this area was higher compared to the oligotrophic environment. Differential survival rates are indicating large impact of organic loads and anthropogenic related activities in the first life stages of a vulnerable species.

Keywords: Marine parks, Eutrophication, Growth, Bio-indicators, Balearic Islands

Introduction
The pen shell *Pinna nobilis* is a long-lived organism, presenting a life span of more than 20 years. Its responsiveness to environmental perturbations makes it a good bioindicator of water quality and, therefore habitat conditions [1,2]. Eutrophication and aquaculture-derived effects are affecting benthic species especially at oligotrohic environments. In this study, our mains objectives were (1) to compare the growth plasticity of *P. nobilis* in two trophic environments around Mallorca, (2) to evaluate the success of survival in each environment.

Material and methods
Pinna nobilis juveniles were suspended in the water column at 5 meters depth with seed collectors. 25 individuals were located within the port of Andratx (39 ° 32'38 .36 "N, 2 ° 22'50 .95" E) under a fish farm, i.e. eutrophic environment with high anthropogenic impact. In contrast, 26 individuals were situated in MPA Cabrera National Park (39 ° 8'45 .65 "N, 2 ° 55'54 .48" E), an oligotrophic environment free of any sewage or organic dumping. During the 2 years study (Feb. 2011-Feb. 2013), pen shells were monitored by measuring the length and width of each individual together with mortality rates (6 visits in Andratx and 5 in Cabrera). Growth was calculated by linear regression through the 2 years.

Results and discussion
The study showed that in a eutrophic environment *Pinna nobilis* juvenile survival rates after the first days of exposure to anthropic conditions are a key factor to the population's sustainability. We found a drastic population decline in Andratx samples at the first monitoring visit where the number of individuals is halved, and a smaller percentage decline in the next few days, keeping a survival percentage of <30% at endpoint (Fig. 1). In contrast, Cabrera's survival percentages are larger than 80%. Although survival success in the eutrophic environment is much lower than in the oligotrophic one (difference >50% between the two environments), surviving individuals present higher growth rates (22.65 ± 12.2 mm mean for Andratx and 85.71 ± 4.28 mm mean for Cabrera) (Fig. 2). However, this growth is not natural, since individuals were suspended in the water column, while their natural habitat is benthic and associated mainly to seagrass meadows. However, other studies report higher growth rates in normal conditions [3,4]. The environmental conditions where *P. nobilis* develops will influence their ability to assimilate nutrients. Differential survival rates are indicating large impact of organic loads and anthropic related activities in the first life stages of a vulnerable species.

SPATIAL DIFFERENCES OF STABLE ISOTOPE COMPOSITION AT BIVALVE *PINNA NOBILIS*: ARE THEY RELATED TO NUTRIENTS CONCENTRATIONS OR TO POTENTIAL FOOD SOURCE?

K. Magraner [1]*, S. Deudero [1], M. Vázquez-Luis [1], C. Alomar [1] and J. Alonso-Santos [1]
[1] Centre Oceanogràfic de les Balears - kikamagraner@gmail.com

Abstract
Increased anthropogenic nutrient loading (i.e., eutrophication) due to increasing human population in coastal areas will enhance the degradation of coastal marine ecosystem. The results of our analysis in the mantle of *P. nobilis* suggest an enrichment of $\delta^{15}N$ isotopic values in sites with high concentration of population density. $\delta^{15}N$ signature have been proposed as better tracers of eutrophication than $\delta^{13}C$. The fan mussel *P. nobilis* is a good bioindicator of changes of the Mediterranean littoral environmental quality as proposed by other authors. Spatial differences of stable isotope composition at *P. nobilis* are connected to potential food sources quality/quantity related to nutrients enrichment.

Keywords: Stable isotopes, Nutrients, Balearic Islands, Eutrophication, Bivalves

Introduction Carbon isotopic compositions of animals reflect their diet within about 1 ‰[1] and can be used to identify potential food sources for *P. nobilis* [2]. Several studies have focused on changes in $\delta^{15}N$ as an effect of changes in nutrient loadings from sewage treatment plants [3]. Initial impacts are likely to be missed if measurements are restricted to physicochemical water properties [4]; even though this problem can be solved if indicator organisms are used [4]. The aim of this study was to use *Pinna nobilis* as indicator of anthropogenic effects using stable isotopes analysis ($\delta^{13}C$ and $\delta^{15}N$) in mantle tissue. We hypothesized that: (i) there are spatial differences among localities at different scales (ii) *Pinna nobilis* stable isotopes concentrations are reflecting nutrient concentrations at the studied sites or if they are more influenced by potential food sources.

Material and methods Samples of *P. nobilis* were collected at Balearic Islands (Spain). A total of six sampling stations were selected under an eutrophication gradient and with regard to protection level. A total of 57 *P. nobilis* mantles were sampled. Potential common food sources for *P. nobilis* were collected: phytoplankton, zooplankton, living leaves of *P. oceanica* (P. leaves), epiphytes of *P. oceanica* leaves (P. epiphytes), decaying leaves of *P. oceanica* (P. detritus), the rhizomes of leaving *P. oceanica* (P. rhizomes), and particulate organic matter (POM). Nutrients were determined such as environmental variables. Stable isotope mixing models are used to determine the percentage contribution of the food sources to the fan mussel *P. nobilis*. In this study, we applied the SISUS Bayesian Mixing model.

Results and discussion The results for *P. nobilis* did not show evidence of size-related isotopic variability. The results obtained demonstrated that *P. oceanica* epiphytes made the highest contribution to the $\delta^{15}N$ signature of *P. nobilis* in Andratx, since this sampling site had the highest contribution of sewage compared to the other sampling sites (Figure 1). SISUS results showed that zooplankton made the highest contribution to the $\delta^{13}C$ signature in Illetes, Cargoler and Andratx (Figure 1); these results agree with those found by Davenport et al. [5] which demonstrated that the bivalve *P. nobilis* feeds on zooplankton. *Pinna nobilis* exhibits spatial differences at microscale and mesoscale level in N stable isotope composition as reflected by our results. In this study the mantle of *P. nobilis* was analyzed, providing values of $\delta^{15}N$ of 1.71‰ in Santa Maria Bay and 3.25‰ for Andratx (Figure 2). These variations could be related to nutrients availability of the studied sites [1]. Therefore, *P. nobilis* seems to provide indication of environmental quality linked with anthropogenic nutrient inputs.

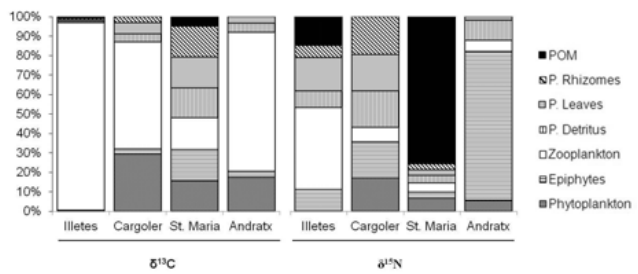

Fig. 1. Mean value from SISUS potential food sources contribution (%) of $\delta^{13}C$ (left) and $\delta^{15}N$ (right) to the diet of *Pinna nobilis* at different studied sites.

COMMUNITY COMPOSITION, DISTRIBUTION AND DIVERSITY OF INVERTEBRATES FROM DEEP-SEA MEDITERRANEAN CANYONS AND ADJACENT SLOPES (FROM 850 TO 3000 M DEPTH).

Ariadna Mecho [1]*, Eva Ramirez-Llodra [1], Jacopo Aguzzi [1] and Joan Batista Company [1]
[1] Institut de Ciències del Mar (ICM-CSIC) - mecho@icm.csic.es

Abstract
Information of bathyal and abyssal non-crustaceans invertebrates is scarce in the Mediterranean Sea, especially in submarine canyons. The present study presents an updated taxonomical classification for these groups and reports new data on their distribution and density in canyon areas and adjacent open sedimentary slopes. Samples were collected from 220 trawls and 36 ROV dives conducted in the Blanes, Palamós and Cap de Creus canyons and their adjacent slopes (north-western Mediterranean), between 850 and 3000 m depth. The most abundant Phylum was the Echinodermata, representing 52.9% of the total invertebrate density (calculated as ind.•km^{-2}), and 48.6 % of the total invertebrate biomass (calculated as kg.•km^{-2}). Five rare species for the Mediterranean were found: a sipunculid, 3 echinoderms and 1 carnivore ascidian.

Keywords: Bathyal, Canyons, Zoobenthos, Systematics, North-Western Mediterranean

Introduction
The western Mediterranean deep basin is composed by a complex collection of markedly different habitats, including sedimentary slopes, submarine canyons and seamounts. The specific geomorphologic characteristics of these habitats and associated abiotic processes result in large scale heterogeneity of the continental margin, allowing for the establishment and maintenance of diverse faunal communities [1]. In the deep Mediterranean Sea, these communities are mainly constituted by fishes and decapod crustaceans, which have been object of intensive taxonomical studies in comparison with other deep-sea fauna such as echinoderms, sipunculids or echiurans [2, 3]. Here, we present a complete taxonomical classification and we redefine the distribution, biomass and abundance of all non-crustacean invertebrates collected in our surveys in the NW Mediterranean since 2008. The results are discussed in relation to the geomorphological and environmental characteristics of the different habitats sampled.

Material and Methods
Samples were collected during 11 oceanographic cruises conducted in the Blanes, Palamós and Cap de Creus canyons and their adjacent slopes between 850 to 3000 m. A total of 220 benthic hauls were conducted and 36 ROV video transects were performed in the three canyons and adjacent area. Of those hauls, 121 samples were obtained by means of an otter-trawl Maireta system, other 43 hauls were conducted with an Agassiz dredge and finally, 56 samples were obtained with an epibenthic sledge.

Results
More than 4686 non-crustacean invertebrates belonging to 60 species were sampled. The most abundant Phylum was the Echinodermata representing 52.9% of the total non-crustacean invertebrate density, followed by the Phyla Brachiopoda (17.4%), Cnidaria (12.9%), Mollusca (10.4%), Echiura (2.7%) and Porifera (2.3%). The Sipuncula, Annelida, Bryozoa, Arthropoda and Chordata together represented 1.1% of the total density. Unidentified specimens represented only 0.3 % (Fig. 1a).
In terms of biomass, the Phylum Echinodermata represented 48.6 % of the total non-crustacean invertebrate biomass, followed by the Phyla Cnidaria (22.5 %), Mollusca (19.9 %), and Brachiopoda (7.2 %). All remaining Phyla represented less than 1% each one (Fig. 1b). The most speciose Phyla were the Mollusca (with 23 species) and Echinodermata (with 11 species). From the 60 species identified, five were considered rare in the Mediterranean Sea. These species were the sipunculid *Phascolosoma (Phascolosoma) turnerae* Rice, 1985, three echinoderms *Hedingia mediterranea* (Bartolini Baldelli, 1914), *Penilpidia ludwigi* (von Marenzeller, 1893) and *Gracilechinus alexandri* (Danielssen & Koren, 1883), and the carnivore ascidian *Dicopia antirrhinum* C. Monniot, 1972. Additionally,10 from the 60 species identified were only reported inside canyon areas.

Discussion
Our study presents new information about taxonomical classification of Mediterranean Sea deep-sea non-crustacean invertebrates and increases the geographic and bathymetric distribution of some of these species. Additionally suggests that canyons could be an important habitat for specific species only present inside the canyons and for rare species.

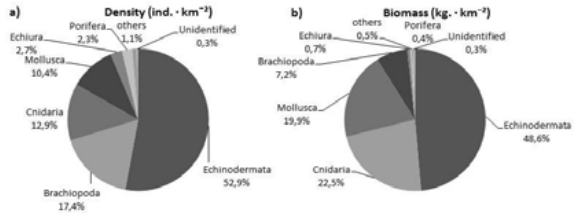

Fig. 1. Non-crustacean community composition. a) Percentage of density (ind.•km^{-2}) by Phylum. b) Percentage of biomass (kg.•km^{-2}) by Phylum.

NEMATODES DISTRIBUTION WITHIN *MYTILUS* COMMUNITY ON THE NORTH-WESTERN BLACK SEA SHELF

Mihaela Muresan [1]*
[1] NIRD for Marine Geology and Geoecology - GeoEcoMar - mmuresan@geoecomar.ro

Abstract
Free-living nematodes from the Romanian shelf have been assessed in relation with the particular niche offered by *Mytilus galloprovincialis* community for feeding, habitat and interspecific relations. An overall of 60 species with densities between 133 and 2,028,580 ind.m^{-2} were found.

Keywords: Biodiversity, Zoobenthos, Black Sea

Introduction
Mytilus community forms one of the most representative community on the NW shelf Black Sea between 30 – 55 m depth, occupying within these limits the muddy sediments biotope. It offers a diverse niche for a rich community of free-living nematodes, being particularly important for their thriving at the limits with the fluctuating environment in terms of salinity gradient from north to south and oxygen concentration deficiency in sediments as moving deeper towards *Modiolula* community.

Material and method
During HYPOX project, in May, July and September 2010 and April 2011, 25 samples were collected within *Mytilus galloprovincialis* community using a Multicorrer, along 4 transects crossing the NW Romanian shelf (Fig.1). The first top 5 cm were retrieved from the tubes and preserved on board with 4-5% formaldehyde buffered.

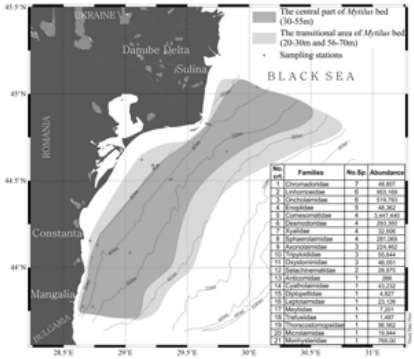

Fig. 1. Nematodes population structure within the *Mytilus* community on the Romanian Black Sea shelf (*Mytilus* distribution map after Teaca, et all., *in press*)

Results and discussions
The assessment of taxonomic diversity revealed a number of 60 species of nematodes belonging to 21 families (Fig.1). In terms of trophic species groups, 37% of species were predators, the rest pertaining to groups of selective deposit feeders, non-selective deposit feeders and epidetritivores. Nematodes densities distribution within stations recorded greater abundances in the northern part of the Romanian shelf, where opportunistic species dominated. Thus, the greatest frequency (F%) and dominance (D%) after abundance had by far the species such as *Sabatieria abyssalis* (F%-84; D%-33) and *S. pulchra* (F%-76; D%-23), *Viscosia minor* (F%-92; D%-7) followed by *Terschellingia longicaudata* (F%-72; D%-10). Generally with low abundances, but found in more than half of the stations were *Eleutherolaimus longus*, *Linhomoeus sp*. Nematodes species richness indices showed a good correlation with distribution of *Mytilus* density within the community, but the muddy substrate had also a favourable influence on species from Linhomoeidae and Comesomatidae. Thus, the greatest diversity of nematodes was recorded, with some exceptions, within the stations situated between 27–50 m depth, comparative with that found at the lower limit of the *Mytilus* community (20-27 m depth), mainly in the northern sector. Actually, between 27 and 50 m depth, the total number of species was 60, while at the inferior fringe (littoral zone) were found only 20 species, but the fewer number of samples taken in this area could bias the results. Anyway, the most frequent associations of nematodes were constituted of *S. abyssalis, V. minor, T. longicaudata, Linhomoeus sp., Halalaimus sp., E. longus, Cobbionema acrocerca.* Slender nematodes have a cryptic life between the *Mytilus* bissus, taking advantage of niche offered and the bacterial mats and organic matter that usually accumulate within the mussels` colonies. Big size omnivores/predators are favoured, here, by prey abundance consisting of other meiobenthic groups, especially ciliates and nematodes. The r-strategists nematodes (non-selective feeders) were the most abundant group. Thus, the easy way of obtaining food and shelter in between mussels and the rich community of tubicole and errant polychaets and oligochaets [1] conducted to an overwhelming community of *Sabatieria*. Excepting *T. longicaudata*, the selective feeders' category had a low contribution (6%) in the nematodes community.
Within the Hypox project some questions have been raised. Can benthic organisms survive after hypoxic events? How their populations have recovered in case those were affected? In the present study, I put the question: Have the nematodes been affected? Has the *Mytilus* community a protective role in their case? I tried to answer to these questions based on the observations on populations' diversity and density found in the summer of 2010 (late July/early August) when a strong hypoxic event occurred, comparing with the same populations parameters found in May 2010 and April 2011. Thus, in July 2010, the sample taken at 42 m depth in Constanta area, the nematodes had very low diversity; an overall of 5 species were found and densities of 105,070 ind.m^{-2}. In the same station, in May 2010, 8 species and 204,288 ind.m^{-2} were found, while in April, 2011, 18 species and 31,790 ind.m^{-2}. Regarding the qualitative composition, in July prevailed *S. abyssalis* (91,936 ind.m^{-2}), in May dominated also *S. abyssalis* with 142,000 ind.m^{-2}, but also predator species and deposit feeders. In April 2011, a rich community of predators, even in very low densities, was present, while *S. abyssalis* recorded much reduced densities comparing with the previous year.

Conclusions
An overall of 60 species of nematodes within *Mytilus* community have been found. It has been evinced a pattern distribution of their densities, a much numerous community being encountered in the northern part, where opportunistic species dominated. In the central part of the *Mytilus* community, the densities were also greater than at its fringe. A variety of morphological and trophic types were also found. It is assumed that *Mytilus* offers a good habitat for nematodes populations in case of dramatic climate events, but this depends of severity and period of exposure. As a preliminary conclusion, it could be said that the nematodes from the *M. galloprovincialis* community has a good resilience capacity, the colonizers (deposit feeders) and predators/omnivores – persisters being the populations' recovery triggers.

Abstract
The scleractinian Oculina patagonica is a species native of Atlantic waters, it's reported for the first time in El-Kala waters, at extreme east of Algeria. Characterization of some colonies observed has revealed an important development of Oculina patagonica; the species presence goes back to more than twenty years. Integrity signs of ecosystems where it has been met are particularly reflected by a high diversity level. Nevertheless, the sizeable extension of colonies out competing those of the endemic Astroides calycularis, corroborates the possible threat constituted by the species on the marine ecosystems of El-Kala

Keywords: Alien species, Monitoring, Competition, Algerian Sea

Introduction
One of the actual priorities in assessing marine ecosystems is the reporting of introduced and/or invasive species. In Mediterranean, some of them (lessepsian or Atlantic) have been given particular attention due to the rapid extension of their distribution areas.The Scleractinian *Oculina patagonica* is one of the most studied introduced species at the level of Mediterranean basin. This species, native of Atlantic waters was introduced *via* maritime traffic and transporting species of economical interest. Within the framework of the biological and ecological study of the marine part of the Parc National d'El-Kala (PNEK) [1], we have listed numerous colonies of *O. patagonica* in three different sites (Fig.1). This first record in the region of El-Kala is the third in Algeria after those of îles Habibas [3] and that of Algiers [6]. In this same framework, we conducted campaigns of biometric measurements of colonies at the Cap Segleb.

Materials and methods
Colonies were observed by scuba diving, they were localized, photographed and depth was recorded. Vertical and horizontal extensions of ten colonies of Cap Segleb were measured. Samples have been taken by scratching for a precise indentifying of the species.

Results
Oculina patagonica has been reported at three distinct sites, respectively at 8m, 12m and 0.5 to 2.5m depth (tab.1).

Tab. 1 Geodesic coordinates of *Oculina patagonica* localizations.

Sites	Depth (m)	Geodesic coordonates (UTM)	Observation
Calle Prisonnière	8m	x=429554 y 4089050	Scuba diving along transect
Cap Gros	12m	x=446613 y=4085738	Scuba diving along transect
Cap Segleb	0.5 to 2.5m	x= 465506 y= 4088242	Ponctual scuba diving

At Cap Segleb, we recorded most important number of colonies on an area surface of 300m^2. Around twenty colonies were listed; they have predominantly regular hemispheric shape (tab.2).

Tab. 2: Biometric measurements of *Oculina patagonica* colonies at Cap Segleb (ST3)

N°colony	(VE-HE) cm	Depth	N° colony	(VE-HE) cm	Depth
1	57-46	80cm	6	16-14	80cm
2	16-21	1,20m	7	15-20	80cm
3	41-33	1.20m	8	21-35	2,50m
4	11-20	60cm	9	6-6	2.50m
5	27-15	60cm	10	77-60	50cm

Discussion
Besides the important number of colonies, their extensions, compared to those of other colonies recorded and measured in Cap Nègre (10 to 40cm) and Galîte (35 to 41cm) in Tunisia, show an important development of *Oculina patagonica* in El-Kala waters, with a maximal extent of colony n°10 (77-60cm). Studies carried out by FINE and collaborators [1] on some colonies, revealed a linear growth rate of 0.6 to 0.75cm/year, experimental colonies transplantations in Marseille showed an annual growth rate a little less than 1m/year [3], implying that a medium colony of an average diameter of 20cm could exist since more than 15 years. According to those authors, it is strongly dependent on colonies shapes. In the present study, some cases of fusing colonies have been observed, reminding how difficult is estimating a colony age whose big dimensions might be due to this fusion. Encrusting colonies of *Oculina patagonica* develop on vertical rocky walls and caves, with coralligenous enclaves species, like the endemic scleractinians *Astroides calycularis* and *Cladocora caespitosa*, reminding the threat of switch by *O. patagonica* that has greater aptitudes for adapting to disturbances and environmental stress.

Conclusion
At present state, the marine ecosystems response to the introduction of *Oculina patagonica* in El-Kala waters is not perceptible, and sites where it has been reported shows integrity signs of marine ecosystems. Nevertheless, changes can occur in structure of these assemblages with apparition of competitive behaviors for space and food, knowing *O. patagonica* has high adaptive abilities thanks to its reproductive mode (sexual and asexual) described by (Karamarsky-Winter et *al.*, 1994) [1], to its Maximal occurrence in disturbed sites (urban pollution, artificial reefs, marinas…), as well as in healthy waters, to the Early maturity of individuals (1-2years old), to the Hermatypic species status showing high adaptive abilities. Developing monitoring programs for assessing the evolution of *O. patagonica* colonies is essential to evaluate their impact on marine ecosystems in El-Kala, essentially by studying growth, reproduction, depth, temperature and salinity intervals for this species survival, as well as functioning of the ecosystems housing it.

Abstract
Species composition, abundance and diversity of macrozoobenthos associated with a *Zostera noltii* bed from the Romanian Black Sea coastal area were assessed in July and October 2010. A total of 1055 individuals belonging to 37 taxa were identified during the study. *Hydrobia acuta* was the dominant species of the assemblage with 20.9% of the total abundance. This species, together with *Mytilaster lineatus*, was also the most frequently encountered. The species richness and abundance were higher in summer than in the autumn.

Keywords: Biodiversity, Phanerogams, Zoobenthos, Black Sea

Introduction. The seagrass community is an important element of coastal benthic environments. Seagrass beds are among the most productive marine communities. As key primary producers, seagrasses represent an important source of food for many organisms, especially in the form of detritus. Eelgrasses are also grazed directly by waterfowl and by some fish species. The dense, matted root system of eelgrasses stabilise soft sediments, improve the nutrient supply of the water column and acts as an important source of organic detritus. Seagrass meadows also increase habitat diversity, providing shelter for a wide variety of marine organisms. For these organisms the seagrass communities serve as important feeding and nursery grounds [1]. In spite of the rich body of literature on the biodiversity of the fauna of seagrass worldwide, there is very few information regarding the qualitative composition, seasonal dynamics and quantitative distribution of zoobenthos from *Zostera* meadows along the Romanian Black Sea coast. Therefore, the aim of this study is to assess species composition and diversity of macrobenthic fauna from *Zostera noltii* beds at the southern Romanian Black Sea coast.

Material and Method. Quantitative samples from a dwarf eelgrass meadow located at Mangalia between 0.6 and 2.3 m depth have been collected by SCUBA and free diving on 28 July 2010 and 2 October 2010 (Fig. 1).

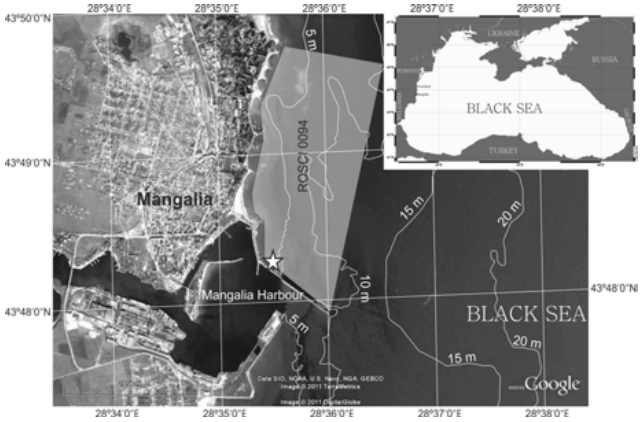

Fig. 1. Map of the southern Romanian Black Sea coast with location of the sampling site

During each sampling campaign seven random replicate samples have been taken in the centre of the meadow with a 10-cm-diameter hand-held corer (to ~10 cm depth). Samples were washed on a 0.5-mm sieve and the retained organisms were preserved in 10% formalin and then transferred to 70% ethanol. All associated macrofauna was sorted under a binocular, identified as possible to the lowest taxonomic rank and counted. The community structure of zoobenthos encountered in *Zostera noltii* meadows was assessed using the following univariate indices: frequency (*F*%), dominance (*D*%), species richness (*S*), Shannon-Wiener diversity index ($\log_2$ base, *H'*), and Pielou's evenness index (*J'*). Cluster analysis and non-metric multi-dimensional scaling (nMDS), based on Bray-Curtis similarity coefficient, has been performed on abundance data.

Results and Discussion. A total of 1055 individuals belonging to 37 taxa (29 species) were identified during the study. Dominant groups in terms of number of taxa were Arthropoda (13 taxa), Annelida (12 taxa), and Mollusca (10 taxa). Mollusks accounted for 59.8% of the total number of individuals, followed by polychaetes (23.4 %) and crustaceans (14.9%). The most abundant species in the *Zostera noltii* meadow were *Hydrobia acuta* (20.9% of the total number of individuals), *Rissoa* sp. (10.9%), *Spio decoratus* (10.6%), *Mytilaster lineatus* (9.3%), and *Ericthonius difformis* (8.4%). According to the frequency index, 16 taxa were designated as constant ($F \geq 50\%$), 3 species were classified as common ($25 \leq F < 50$) and 18 as rare ($F < 25$). The species with highest frequency of occurrence were *Hydrobia acuta* and *Mytilaster lineatus* (100%), *Rissoa* sp., *Abra segmentum* and *Cyclope neritea* (92.86%), *Cerastoderma glaucum* (85.71%) and *Spio decoratus* (64.28%). The mean number of species (16.5±1.6 S.E.) and that of individuals (11,192 ± 2069 ind. m^{-2}) was higher in July than in October (11.3±1.2 S.E. and 8007±1307 ind. m^{-2} respectively). The Mann-Whitney *U*-test showed a statistically significant difference in species number between the two sampled seasons ($U=6$; $P<0.05$), but no statistically significant changes were evidenced for total abundance ($P>0.05$). Also, both diversity and evenness values were usually higher in summer ($H'=3.82$, $J'=0.79$) than in autumn ($H'=3.12$, $J'=0.65$). These seasonal changes were delineated as well by the multivariate techniques (Fig. 2).

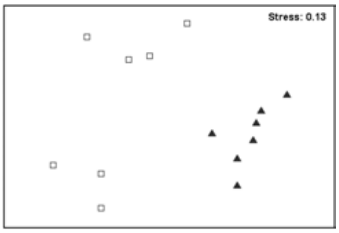

Fig. 2. NMDS ordination plot of samples collected from *Zostera noltii* habitat showing the groups determined by cluster analysis (filled triangles = summer; open squares = autumn).

The faunal assemblages of *Zostera noltii* from the Romanian littoral of the Black Sea proved to be relatively poor as compared to those from the Ukrainian [2], Turkish [3] or Bulgarian coasts [4]. However, the total abundance and species richness of dwarf eelgrass canopy is higher than that of the adjacent bare sediment.

DEPTH DISTRIBUTION OF *CIDARIS CIDARIS* (LINNAEUS, 1758) AND *STYLOCIDARIS AFFINIS* (PHILIPPI, 1845) (ECHINODERMATA, ECHINOIDEA) AROUND THE MALTESE ISLANDS.

Kimberly Terribile [1]* and Patrick J. Schembri [2]
[1] Department of Biology, University of Malta, Msida MSD2080, Malta - kimberly.terribile@um.edu.mt
[2] Department of Biology, University of Malta, Msida MSD2080, Malta

Abstract
The sea urchins *Stylocidaris affinis* and *Cidaris cidaris* (family Cidaridae) are abundant on circalittoral and deeper bottoms off the Maltese Islands. Different authors quote different depth ranges for the two species. The depth distribution in Maltese waters was studied based on material from MEDITS surveys. *S. affinis* was found at depths of 50-550m with the highest relative abundance between 50m and 150m, predominantly on maerl or coarse sedimentary substrata. *C. cidaris* was found from ca. 50m to depths greater than 550m, mostly on sandy-mud.

Keywords: Deep sea ecology, Deep waters, Echinodermata, Sicily Channel

Introduction
Stylocidaris affinis and *Cidaris cidaris* are the most common sea urchins on circalittoral and deeper sedimentary bottoms around the Maltese islands. There is general agreement between authors that these species have different but overlapping bathymetric ranges; *S. affinis* is more commonly found in shallower waters than *C. cidaris*, which has a wider depth range. However, different authors give different depth ranges. For example, Tortonese [1] gives a bathymetrical range of 30-1000m and 50-2000m for *S. affinis* and *C. cidaris* respectively, while correspondingly, Koehler [2] gives 30-150m and 50-400m, and Koukouras *et al.* [3] give 5-180m and 20-250m.

Material and Methods
Samples were collected in 2009, 2010 and 2011 using the MEDITS trawling gear [4] during MEDITS (Mediterranean International Trawl Survey) surveys carried out in the General Fisheries Commission for the Mediterranean's Geographical Sub-Area 15, which includes the Malta 25 nautical mile Fisheries Management Zone. Cidarids were sorted from the by-catch, preserved and transferred to the laboratory where they were identified and counted. Although the two species differ in coloration (normally, *S. affinis* has a reddish coloration and *C. cidaris* is greenish), each individual was identified on the basis of the structure of the large globiferous pedicellariae, which have well defined terminal teeth in *C. cidaris*, but which lack terminal teeth in *S. affinis* [5]. Abundance was standardised to N^o/km^2 of seabed trawled. The grain-size distribution of sediment collected by grab from each station was determined using standard granulometric analysis and sediments were classified following the Udden-Wentworth scale.

Results
The samples from stations in the 51m to 200m depth range had a more or less similar abundance of *C. cidaris* and *S. affinis*, however the relative abundance of *C. cidaris* increased in the deeper stations (Figure 1).

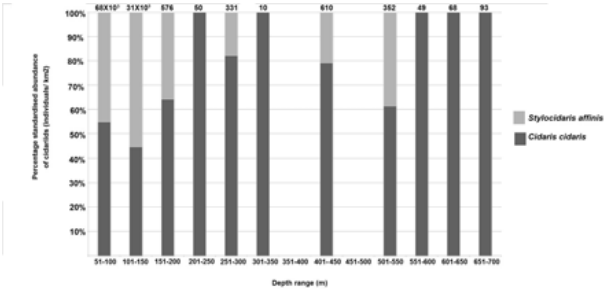

Fig. 1. Stacked bar graph showing the relative abundance of cidarids at different depth ranges around the Maltese Islands, based on MEDITS samples. The figures above each bar are the total number of individuals collected per km^2 from that depth range. No samples were collected from the 351-400m and 451-500m ranges.

Granulometric analysis showed that stations >100m in depth all had sandy-mud bottoms, while stations <100m in depth had bottoms of gravelly sandy-mud, most of which were maerl habitat.

Discussion
In Maltese waters, the two cidarids have a considerable bathymetric distribution, extending from ca. 50m to ca. 700m. At the shallower end (50m - 200m), there is total overlap in distribution with all stations having relative abundances of 45 - 65% and 35 - 55% for *C. cidaris* and *S. affinis*, respectively. The highest relative abundance of *S. affinis* recorded was 55% from the 101-150m range, which suggests an affinity of *S. affinis* for upper circalittoral depths where the bottom is predominantly maerl, or gravelly sandy-mud with rhodoliths. The relative abundance of *S. affinis* with respect to *C. cidaris* decreases with depth such that between 251m and 550m the abundance of *S. affinis* ranges from 17% to 39%. Only *C. cidaris* was present at depths greater than 550m where the bottom is muddy, implying an affinity of *C.cidaris* for fine sediment in the lower circalittoral and upper bathyal.

All the shallower stations where *C. cidaris* was the sole cidarid (200-250m and 300-350m) had fine sediment bottoms. Conversely, where *S. affinis* occurred at large depths (400-450m and 500-550m) the surficial sediment was relatively coarse due to large quantities of empty molluscan shells and shell fragments. This shows that the distribution of the two cidarids is not determined by depth alone, but that the nature of the bottom may be more important. Both species co-occur on rhodolith bottoms at the shallow end of their bathymetric range, however, *S. affinis* can only occur in deep water if there are coarse inclusions, such as shell fragments, in the sediment.

Where both species co-occur, it is crucial to identify each individual on morphological characters, since coloration alone is not diagnostic (some *C. cidaris* individuals in the present study had an orange colour whereas some *S. affinis* had a reticulated coloration rather than the normal overall reddish coloration). Misidentification may be one of the reasons contributing to the variance in depth records of the two species in the literature.

Abstract
Sarcotragus spinosulus is a massive sponge undergoing disease/mortality risks in the Mediterranean Sea. It is among the dominant macrobenthic species of photophilic assemblages in Doganbey area. The aim of this study was to provide a basis for future monitoring attempts of this species in Doganbey, Aegean Sea.

Keywords: Zoobenthos, Aegean Sea, Porifera, Density

Introduction

Sarcotragus spinosulus is a demosponge species inhabiting photophilic assemblages and is generally abundant in shallow waters not exceeding 20 m of depth. Sarcotragus sponges are massive sponges that constitute a habitat for several other species [1]. In the Mediterranean Sea, mass mortality events affected a wide range of species [2] including several sponges and *S. spinosulus* was also reported to be affected by mass mortalities related to anomalously high sea-water temperatures [3]. Another threat for *S. spinosulus* is the canopy development by *Caulerpa racemosa* on sponge surface that can lead to its smothering and even death [4]. In consequence of these risks that might affect *S. spinosulus*, monitoring of its populations is important in order to determine any disease/mortality events. The aim of this study was to provide a basis for future monitoring attempts of this species in Doganbey area.

Material and Methods

The study area (Fig. 1) consisted of boulders spread among sandy bottom/posidonia meadows. *Sarcotragus spinosulus* was among the dominant macrobenthic species of photophilic assemblages covering rocky substratum from 1 to 5 meters deep (Fig. 2). 7 plots of 10 m diameters were randomly laid overall the area in August 2012 and sizes of all *S. spinosulus* specimens within the plot were measured via snorkeling. 3 measurements were considered in order to calculate the sponge size: surface length, width and height. Area and surface calculations were performed by considering the sponge shape as the half of an ellipsoid.

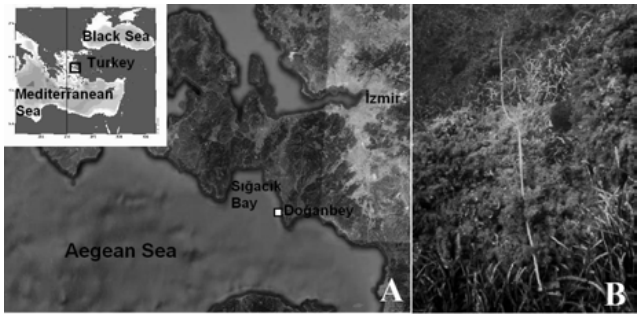

Fig. 1.
Location of the study area (A); The study area consisted of boulders spread among sandy bottom/posidonia meadows (B).

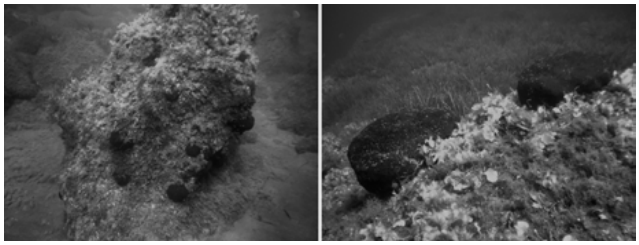

Fig. 2. *Sarcotragus spinosulus* specimens in Doganbey area

Results and Discussion

A total of 165 *S. spinosulus* specimens were observed over an area of 550 m^2. We didn't observe any injuries characteristic of sponge diseases [5] and all sponges within the plots were almost free of epiphytes. *S. spinosulus* density was 0.30±0.18 specimens.m^2 of the area including the soft substratum. The density value seems low compared to other density values [3; 5; 6] because we worked within continuous plots on a mixed substratum and did not use quadrats placed exclusively on rocky surfaces. We estimated *S. spinosulus* density over rocky surface as 1-3 specimens.m^2 via examinations of scaled pictures. The area cover by *S. spinosulus* was 51,32 cm^2/m^2 of the area including the soft substratum. 41% of *S. spinosulus* specimens in Doganbey were 100-1000 cm^3 in volume. 37% were smaller than 100 cm^3 whereas 14% were 1000-3000 cm^3. 5% of the specimens were 3000-5000 cm^3 and only 2% were larger than 5000 cm^3. *S. spinosulus* is the dominant macrobenthic species of Doganbey shallow water benthic community and this study provides a basis for its future monitoring attempts.

ABUNDANCE, SIZE, AND GROWTH RATE OF *GEODIA CYDONIUM* (DEMOSPONGIAE: GEODIIDAE) IN THE NORTHERN ADRIATIC TEMPERATE BIOGENIC REEFS

Eva Turicchia [1]*, Davide Poli [1], Marco Abbiati [2] and Massimo Ponti [2]
[1] Student in Marine Biology (master degree) Università of Bologna - turice01@yahoo.com
[2] Dipartimento di Scienze Biologiche, Geologiche ed Ambientali (BiGeA), Alma Mater Studiorum Università di Bologna

Abstract
Northern Adriatic subtidal biogenic reefs host a large population of *Geodia cydonium* showing heterogeneous distribution with patches of high densities and large mean sizes. Its optimal distance from the coast, in terms of bio-volume, was 4-5 nm. The growth rate in diameter of *G. cydonium* has been estimated in 25.60 ± 11.15 % year^{-1} (± s.e.). Despite the relatively high growth rate, the heterogeneous and fragmented spatial distribution of *G. cydonium* suggests the needs of specific management and conservation strategies of this ecologically and aesthetically valuable species.

Keywords: Porifera, Conservation, Growth, Continental shelf, North Adriatic Sea

Introduction *Geodia cydonium* (Jameson, 1811) is an Atlanto-Mediterranean massive demonspongiae very variable in size, shape and habitus, from sessile and non-sessile morphs ([1], [2]). *G. cydonium* is a habitat forming species, hosting many epibiontic and endobiontic species ([3]). It is listed among the endangered or threatened species (Annex II, Barcelona Convention, 1995), however, its abundance, distribution, and biology are still now not well known. In the northern Adriatic Sea, *G. cydonium* dwells on the subtidal biogenic reefs occurring at 7 to 30 m ([4]). The aims of the present study were to quantify the abundance, distribution, size, and growth rate of *G. cydonium*.

Material and methods Randomly selected specimens of *Geodia cydonium*, leaving on 2 outcrops off Chioggia, were labelled and measured (maximum height, diameter and circumference) since August 2006 and re-measured every time they have been found until 2011. During the summer 2011, population densities and specimens mean size were measured along 10x2 m transects on 5 randomly selected outcrops between Chioggia and Caorle, ranging from 7 to 22 m in depth and from 2 to 8 nm from the coast. A total of 34 transects and 114 specimens were measured. Differences among sites were assessed by one-way ANOVA after check of the homogeneity of variances using the Bartlett test (transform: square root). Volumes of the specimens were obtained by approximating the shape to a sphere. The relationship between distance from the coast and mean size was investigated by non-linear correlation. SCUBA diver volunteers data were obtained from the Reef Check Italia *onlus* database.

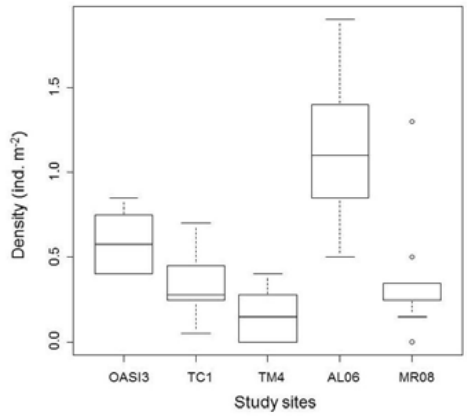

Fig. 1. Box-and-whisker plots of the densities of *Geodia cydonium* in the study sites, ordered by distance from the coast.

Results *Geodia cydonium* showed almost spherical shapes; size range was close to the largest reported in the literature. The estimated growth rates were 25.60 ± 11.15 % year^{-1} (± s.e.) and 14.07 ± 5.15 % year^{-1} (± s.e.) in terms of diameter and circumference, respectively. *G. cydonium* densities among outcrops varied from 0.16 ± 0.05 ind. m^{-2} to 1.15 ± 0.24 ind. m^{-2} (± s.e.; ANOVA P<0.001; Fig. 1). The mean bio-volume of the single specimens reached the higher values at 4-5 nm from the coast (Fig. 2). *G. cydonium* was very abundant in several places along the Adriatic and Ionian coasts (e.g. Porto Cesareo basin, Marsala lagoon, Rovinj) in the '70s, but since the end of the last century most of these populations have become progressively rarefied with smaller individuals (G. Corriero, pers. com.). Reports by volunteers show that the Italian distribution of *G. cydonium* is very fragmented (www.progettomac.it).

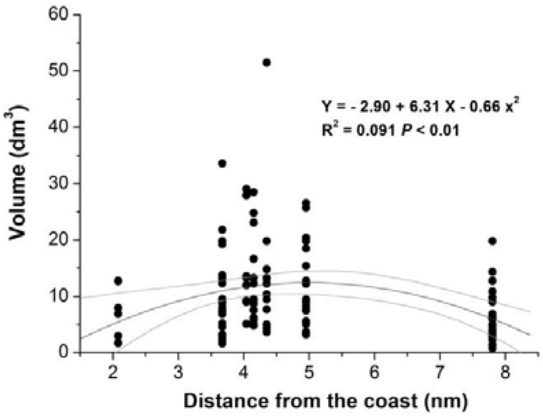

Fig. 2. Non-linear correlation between distance from the coast and specimens sizes in terms of estimated bio-volume.

Discussion *Geodia cydonium*, living on the northern Adriatic subtidal biogenic reefs, showed locally high densities and large mean sizes. Its largest sizes are reached at 4-5 nm from the coast, may be due to the interplay between water turbidity and food availability, largely affected by rivers load, sediments re-suspension, and planktonic blooms. Despite the relatively high growth rate, the heterogeneous and fragmented distribution of *G. cydonium* highlights the need of specific management and conservation strategies for this endangered and ecologically valuable species. **Acknowledgments** The Diving Center Tegnùe Chioggia provided the logistic support and Reef Check Italia *onlus* valuable data.

[5] Institute for Medical Research and occupational Health, Zagreb, Croatia

Abstract
Due to great morphological diversity among species of genus *Trachinus* it is not easy to identify them unequivocally based only on biometric traits. Three different mitochondrial phylogenetic markers (COI, 12SrDNA, 16SrDNA) were examined on total of 87 samples. Results of phylogenetic analyses on all gene markers have managed to distinguish successfully different species among genus *Trachinus*.

Keywords: Fishes, Systematics, Genetics, South Adriatic Sea

Familie Trachinidae (Weeverfish) consists of 2 genera: *Trachinus* and *Echiichthys*. Weeverfish are known for their venomous spines on the gill covers and first few dorsal fins. All species live in sandy or sandy-muddy habitat buried in the ground of benthic, coastal or open ocean area. In the Adriatic Sea four (4) species of Weeverafish are present: *Trachinus draco*, *Trachinus radiatus*, *Trachinus araneus* and *Echiichthys vipera*. Due to great morphological diversity among species of genus *Trachinus* it is not easy to identify them unequivocally based only on biometric traits. (Figure 1.)

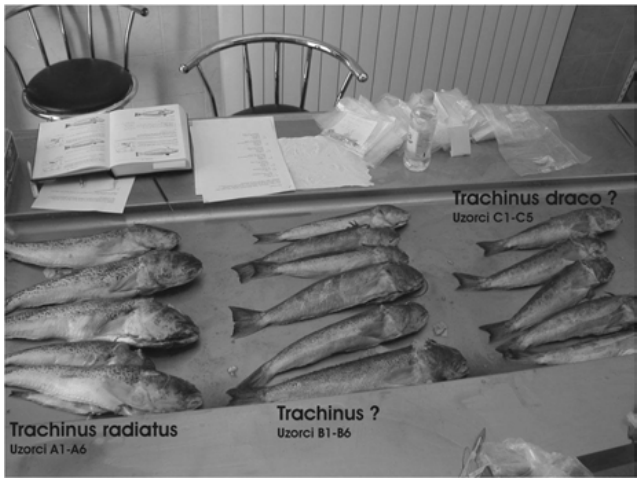

Fig. 1. Caught samples of genus Trachinus.
Question marks represent samples which species discrmination cannot be concluded from morphological and meristc measurements.

The goal of this research was to distinguish species belonging to Trachinidae. Upon DNA extraction (Quigen, DNeasy Tissue kit), and PCR amplification (Quigen, HotStartTaq Plus Master Mix Kit) data for analyses was obtained by standard Sanger sequencing of following markers COI, 12SrDNA and 16SrDNA. Primers used for philogenetic analyses were:
16S [2]
16Sar 5' - CGC CTG TTT ATC AAA AAC AT - 3'
16Sbr 5' - CCG GTC TGA ACT CAG ATC ACG T - 3'
12S tRNA-Val [2]
12SL 13-L5' - TTA GAA GAG GCA AGT CGT AAC ATG GTA - 3'
Titus l-h 5' - GGT GGC TGC TTT TAG GCC - 3'
COI [1]
LCO-1490 5' - GGT CAA CAA ATC ATA AAG ATA TTG G - 3'
HCO-2198 5' - TAA ACT TCA GGG TGA CCA AAA AAT CA - 3'
Phylogenetic analyses were performed via three different methods: Maximum Parsimony (MP), Maximum Likelihood (ML), and Bayesian analysis (BA). Results on all gene markers have shown the same identification pattern of species discrimination (Figure 2.).

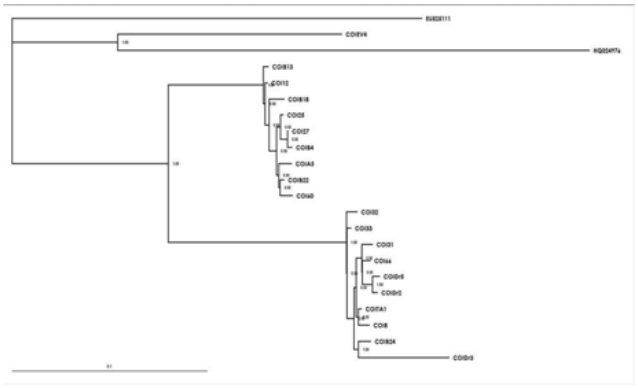

Fig. 2. Rooted consensus phylogram of COI genes from Adriatic Trachinidae inferred via Bayesian analysis after TVM+G model of nucleotide substitution using "Metropolis-coupled Markov Chain Monte Carlo" method. Numbers in nodes represent posterior probabilities. Genetic distance d=0.1

Therefore, our research proved that used genetic markers and applied methods of molecular phylogenetics reconstruction are excellent for species determination quandary inside genus *Trachinus*. It is necessary to conduct further detailed morphological and meristic studies in order to dermine the differences observed by means of molecular phylogenetic analyses.

GENETIC POPULATION STRUCTURE OF THE ENDANGERED DUSKY GROUPER, *EPINEPHELUS MARGINATUS*, IN THE MALTESE ARCHIPELAGO AS REVEALED BY 14 MICROSATELLITE MARKERS.

Molly Sørensen [1]* and Adriana Vella [1]
[1] Conservation Biology Research Group, University of Malta - molly.sorensen@alumni.ubc.ca

Abstract
The objective of this study is to describe the genetic population structure of the endangered marine fish, *Epinephelus marginatus*, in the Maltese archipelago for the purpose of localized conservation management planning. Genetic population structure was determined by examining 89 individuals collected within Malta's Fisheries Management Zone with 14 microsatellite markers. Results of genetic clustering by admixture analysis found one continuous population (K = 1) inhabiting the Maltese archipelago. Further genetic analysis describes a population decreasing in size ($Theta_{(mean)}$ = 2.2), which has gone through a significant size reduction in the past ($M_{(mean)}$ = 0.41) and shows signs of inbreeding (F_{IS} = 0.10, P > 0.001). Results suggest that management should be designed to reflect the archipelago as a single conservation unit.

Keywords: Conservation, Genetics, Teleostei, Islands, South-Central Mediterranean

Introduction
The dusky grouper, *Epinephelus marginatus* (Teleostei: Serranidae), is an endangered marine fish considered to be facing a very high risk of extinction in the wild. Due to concerns of population decline throughout their geographic range, the IUCN has currently listed them as endangered (EN) A2d [1]. Within Malta's Fisheries Management Zone (FMZ), catch landings data (kg) show, over a 62 year period between 1947 and 2009 a decrease in catch landings of over 90% [2]. Their native range includes the Mediterranean Sea, the eastern Atlantic Ocean along the west and south coasts of Africa around the cape to Mozambique as well as Brazil. Characterized by high site fidelity and protracted development to sexual maturity, this reef-associated protogynous hermaphorodite can usually be found in depths up to 50 meters off rocky coastal shores [3]. Localized population structure parameters include pelagic larval dispersal influenced by surface current direction during spawning season along with limited juvenile stage movement. Within Malta, the archipelago is surrounded by a 100 m bathymetry shelf. The predominant surface current direction, during the spawning months of June through August, is from the tip of the archipelago in north-west Gozo toward south-east Malta [4]. The purpose of this research is to describe and define the status of the Maltese population of *E. marginatus* in order to best develop a comprehensive conservation management and monitoring strategy.

Materials and Methods
A total of 89 *E. marginatus* specimens were sampled from the Maltese archipelago FMZ between 2007-2009. Fourteen polymorphic microsatellite markers were used in this study to explicate the population structure. Individuals were genotyped using a Roche 454 Genome Sequencer FLX. Genetic clusters were inferred using multilocus genotype admixture analysis with the software Structure 2.3.4 [5] while molecular and diversity indices and F-statistics were calculated using the software Arlequin 3.5 [6].

Results
A total of 227 alleles were observed within 14 polymorphic loci. Based on multilocus admixture analysis of 89 individuals a single genetic cluster (K = 1) was inferred from the genotypic data. Within group analysis reveals genotypic disequilibrium in 31 loci pair. Mean observed heterozygosity was H_O = 0.68 and the expected heterozygosity was H_E = 0.76. Rare breeding size males (T ≥ 85 cm) were present in all groups with a significantly higher incidence of large size individuals (T ≥ 70 cm) observed, at the tip of the archipelago, in north-west Gozo. Positive Theta (Hom) values were read as an indication of a population decreasing in size ($Theta_{(mean)}$ = 2.2). The Garza-Williams index, for detection of population reduction, interpreted M values less than 0.7 to be indicative of a recent population size reduction and anything less than 0.43 as specific to remnant populations and of a significant size reduction in the past ($M_{(mean)}$ = 0.41). In addition, a global F_{IS} test within the FMZ accepted the null hypothesis of an inbred population ($F_{IS(global)}$ = 0.01, P > 0.001).

Discussion
The Maltese islands are inhabited by single congruent population of *E. marginatus*, likely due to biogeographical isolation due to depth range and larval retention patterns. The 90% decline of catch landing within the FMZ over the last half century is consistent with the results of Theta(Hom), M and F_{IS}, which collectively point to a population which has gone through a significant size reduction in the past, is trending downward and consequently shows indications of moderate inbreeding. In addition, north-west Gozo has been identified as a possible spawning site and area of conservation interest due to the relatively high concentration of large size individuals. Average south-eastern surface currents originating from the northern tip of Gozo during spawning season as a mechanism for pelagic larval dispersal is a probable mode for genetic homogenization within the Malta population. We theorize Gozitan individuals may be an important source population to the rest of the archipelago. Therefore, we recommend management and pilot monitoring efforts initially focus on the northern Gozitan individuals.

MICROSATELLITE LOCI FOR ATLANTIC BONITO *SARDA SARDA*

C. Turan [1]*, M. Gurlek [1], D. Erguden [1], D. Seyhan [1], A. N. Reyhaniye [1] and A. Uyan [1]
[1] Molecular Ecology and Fisheries Genetics Laboratory, Faculty of Marine Sciences and Technology, University of Mustafa Kemal, Iskenderun, Hatay, Turkey - turancemal@yahoo.com

Abstract
Various microsatellite loci were tried for *Sarda sarda* using microsatellite primers which were described or developed for other Scombrid species to understand if they available usage for *S. sarda*. Only five microsatellite loci were successfully amplified with new developed PCR conditions and used for routine analysis of stock identification of *S. sarda*.

Keywords: *Atlantic Bonito, Sarda sarda, microsatellite marker*

Keywords: Genetics, North-Eastern Mediterranean

Introduction

Atlantic Bonito *Sarda sarda* (Bloch, 1793) is a member of family Scombridae and distributed along the tropical and temperate coasts of the Atlantic Ocean, the Mediterranean Sea, and the Black Sea [1] inhabits pelagic neritic waters about 200 m deep [2]. Atlantic Bonito is a migratory species, and little is currently known on the genetic differences between the populations.

Molecular genetics techniques utilize to identify stock structure of marine species. In recent years, microsatellite markers have increasingly been used to identify genetics differences between stocks [3, 4, 5].

There are several genetic studies about microsatellite analysis of some Scombrid species reveal the heterogeneity and characterize stocks. Davies et al. [6] investigated in Albacore Tuna (*Thunnus alalunga*, Bonnaterre, 1788) with twelve polymorphic microsatellite loci and found significant differences between stocks. Similarly, McDowell et al. [7] isolated and characterized seven tetranucleotide markers and these primer sets were also used to amplifying other tuna species. Takagi et al. [8] developed several microsatellite loci for investigating genetic polymorphism in Thunnus species.

To our knowledge, no specialized microsatellite markers currently exist for the Atlantic Bonito *S. sarda*, but there are some for other Scombrid species. In this study, many microsatellite loci were tried for *S.sarda* using other microsatellite primers which were described or developed for other Scombrid species to understand if they available usage for *S. sarda*. Only five microsatellite loci were successfully amplified and used for routine analysis of stock identification of *S. sarda*. The primer sets Tth4 [9], Ttho6, Ttho7 [8], Tth8, Tth34 [7] have been chosen for a successful amplifying process. New PCR conditions were developed for each primer.

Materials and Methods

Genomic DNA was extracted using Standard phenol-chloroform isoamyl alcohol technique [10], and total 459 individuals were extracted and total DNA was visualized by gel electrophoresis (%1.5) and quantified by spectrophotometric assay. To specify and avoid amplifying non specific sequences touchdown PCR method has been used.

Results and Discussion

After screening of the primers developed for other Scombrid species with different PCR conditions, only five microsatellite loci were found to be appropriate for routine analysis. The annealing temperature for each primer set was arranged according to the melting temperature of the primer sets (Table 1). Polymerase chain reaction (PCR) was carried out using a reaction volume of 15µl containing 1U Taq polymerase (Thermo scientific), 2 µM of each primer, 200 mM dNTPs, 25mM MgCl2,10m MTris-HCI pH 8.8, 50 mM KCI and 1 µl template DNA (≈10-25ng). PCR temperature profile consisted of two stages. In first stage; pre denaturation at 95°C for 5 min followed by 20 cycles of denaturation at 94°C for 30 s, annealing at primer-specific temperature for 45s, extension at 72°C for 2 min. Second stage followed by 20 cycles of denaturation at 94°C for 30s, annealing temperature at 56°C for 45s, extension at 72°C for 2 min and final extension at 72°C for 5min. PCR products were separated by electrophoresis on 7.5% polyacrylamide gel and visualized by silver staining. Gel analyzer (1-D Gel Analysis) software version 2010a was used to determine the alleles detected by electrophoresis.

This study preliminary reveal reliable usage of microsatellite loci for Atlantic Bonito *S. sarda*. As a result, the selected microsatellite loci developed and described in other studies for other Scombrid species (Takagi et al. 1999, Clark et al. 2004 and McDowell et al., 2002) can be used for *S. sarda* with the PCR conditions described here.

MOLECULAR SYSTEMATICS OF GENUS TRACHURUS IN TURKISH MARINE WATERS

M. Gurlek [1], D. Erguden [1], D. Yaglioglu [2], F. Turan [1] and C. Turan [1]*
[1] Molecular Ecology and Fisheries Genetics Laboratory, Faculty of Marine Sciences and Technology, University of Mustafa Kemal, Iskenderun, Hatay, Turkey - turancemal@yahoo.com
[2] Faculty of Biological Science, University of Duzce, Duzce, Turkey

Abstract
The systematic relationship of three species of genus Trachurus (Trachurus trachurus, Trachurus mediterraneus, Trachurus picturatus) from Turkish marine waters was investigated using restriction fragment length polymorphism analysis of the mtDNA 16 S, ND 3/4 and ND 5/6 genes.

Keywords: *Phylogeny, Trachurus, mtDNA genes*

Keywords: Genetics, North-Eastern Mediterranean

Introduction
The species of the genus *Trachurus* are widely distributed throughout oceanic waters of temperate, tropical and subtropical seas [1, 2]. Three species of the genus *Trachurus*, *Ttrachurus trachurus*, *Trachurus. mediterraneus* and *Turachurus picturatus*, are found in Turkish waters [3]. The phylogenetic relationships of the three *Trachurus* species using RFLP (restriction fragment length polymorphism) analysis of mtDNA fragments amplified in polymerase chain reaction (PCR). Mitochondrial genes have substantially different rates of evolution and, correspondingly, different levels of resolution for phylogenetic reconstructions [4].

Materials and Methods
Trachurus samples (*T. mediterraneus*: TM; *T. trachurus*: TT; *T. picturatus*: TP) were collected separately by commercial fishing vessels from seven fishing ports in the Black, Aegean, Marmara and north-eastern Mediterranean. Total DNA was extracted from muscle using the Standard phenol: chloroform: isoamyl alcohol procedure [5]. Three mtDNA genes (ND 3/4, ND 5/6, 16 S rDNA) were amplified using universal primers. The primers were;
16 S F: 5'-CG (CT) AAG GGA A (ACT) G CTG AAA-3'
R: 5'-CCG GTC TGA ACT CAG ATC ACG TAG-3'
ND5/6 F: 5'-AAC AGT TCA TCC GTT GGT CTT AGG-3'
R: 5'-TAA CAA CGG TGG TTC TTC AAG TCA-3'
ND3/4 F: 5'-TAA (C/T)TA GTA CAG (C/T)TG ACT TCC AA-3'
R: 5'- TTT TGG TTC CTA AGA CCA A(C/T)G GAT-3'
PCR-products were digested by the set of 6 restriction endonucleases: *Bsur*I, *Alu*I, *Ehe*I, *Hin6*I, *Rsa*I, *Xho*I.
PCR amplification conditions were as follows: 94°C for 4 min followed by 35 PCR cycles. Strand denaturation was made at 94°C for 30 s, annealing at 52°C / 20s 72°C and primer extension at 72°C for 1.5 min. A final extension at 72°C for 5 min was performed. The PCR cocktail were; 1.5 µl 10 x polymerase buffer, 0.5 µl dNTP (10 mM), 0.3 µl Taq DNA polymerase (3 U / µl), 0.10 µl primers, 1 µl template DNA, and water for a total reaction volume of 25 µl. Same amplification conditions were used for all genes.

Results and Discussion
16S rDNA Gene: A total of 34 composite haplotypes was found within 270 individuals. In terms of haplotype diversity were 12, 13, 15 for *T. mediterraneus*, *T. trachurus*, *T. picturatus* respectively.
In UPGMA analysis *T. trachurus* and *T. mediterraneus* revealed close relationship and *T. picturatus* was found to be genetically highly distinct from the two Trachurus species (Figure 1.)

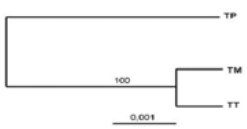

Fig. 1. UPGMA tree of Trachurus species based on 16 S rDNA.

The average nucleotide differences between species have been identified as 0.004924 the highest nucleotide diversity (0.007521) was found between *T. picturatus* and *T. mediterraneus*. The lowest nucleotide differences (0.001262) was detected between T. mediterraneus and T. trachurus.
ND 5/6 Gene: PCR-products were digested by the set of 6 restriction endonucleases: *Bsur*I, *Alu*I, *Ehe*I, *Hin6*I, *Rsa*I and *Xho*I. A total of 2 composite haplotypes was found within 270 individuals. Haplotype diversity was observed as 1, 2 and 1 for *T. mediterraneus*, *T. trachurus*, *T. picturatus* respectively.
In UPGMA analysis, *T. trachurus* and *T. picturatus* were genetically closer to each other and *T. mediterraneus* was found to be highly divergent from *T. trachurus* and *T. picturatus* (Figure 2).
ND3/4 gene: it was monomorphic and RFLP analysis revealed no haplotype diversity and divergence.

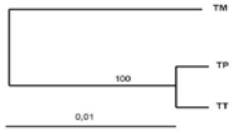

Fig. 2. UPGMA tree of Trachurus species based on ND 5/6.

Separate analysis of three mtDNA gene resulted in different patterns of phylogenetic relationship among the species of Trachurus genus, and only two genes of mitochondrial genes showed polymorphisms.

CLASSIFICATION OF SPECIES WITHIN THE GENUS *HEXANCHUS* AND *HEPTRANCHIAS* THROUGH MTDNA SEQUENCES.

Noel Vella [1]* and Adriana Vella [1]
[1] Conservation Biology Research Group, Department of Biology, University of Malta - noel.vella@um.edu.mt

Abstract
In this study, the mtDNA region from the 12S rRNA gene to the 16S rRNA gene has been sequenced from a number of Hexanchidae specimens (*Hexanchus griseus*, *Hexanchus nakamurai* and *Heptranchias perlo*). A total of 150 polymorphic nucleotide positions have been identified, with the interspecific divergence being 5.46%, while the intraspecific divergence between the identified haplotypes ranged between 0.24% and 0.95%.

Keywords: Elasmobranchii, South-Central Mediterranean

Introduction
The Family Hexanchidae (Order: Hexanchiformes), has only four extant species [1], making this Family one of the smallest shark groups, with its members being described through morphological characters [1,2]. Nonetheless in other shark Families, mtDNA sequences have been readily used as genetic markers to identify or confirm very similar species [3,4].

Methodology
Tissue samples were collected from *Hexanchus griseus* (Central Mediterranean n=6; North-East Atlantic n=4; South-West Pacific n=5; and North-East Pacific n=4); *Hexanchus nakamurai* (North-West Pacific n=4) and *Heptranchias perlo* (Central Mediterranean n=4; North-East Atlantic n=1; and North-West Pacific n=2). DNA was extracted using proteinase K digestion followed by standard phenol-chloroform extraction method. Amplification was carried out using 12SA (AAACTGGGATTAGATACCCCACTAT) and 16SA (ATGTTTTTGATAAACAGGCG) primers [5] (95°C for 4min followed by 30 cycles of 30sec at 95°C, 30sec at 55°C and 1min at 72°C, with a final extension of 10min at 72°C). PCR products were sequenced in both directions using ABI3730xl. Additionally, two homologous sequences [3], one of *Hexanchus vitulus* (a synonym to *Hexanchus nakamurai*) and one of *Heptranchias perlo* were also added to the analyses. Sequences were then aligned together using Geneious R6 and the shortest homologous sequence was used for analyses (1404bp). Intraspecific and interspecific variation were estimated using Arlequin v3 [6], while a Maximum Likelihood phylogram was constructed using the best fit mutation model through MEGA v5 [7].

Results and Discussion
150 polymorphic nucleotide positions were recorded, forming 11 haplotypes. The intraspecific variation ranged between 0.24% and 0.95%, with the highest genetic differences being noted between the most distant sampling locations (Fig 1). Mediterranean specimens of *Hexanchus griseus* and *Heptranchias perlo* shared haplotypes with specimens from the North-East Atlantic Ocean.

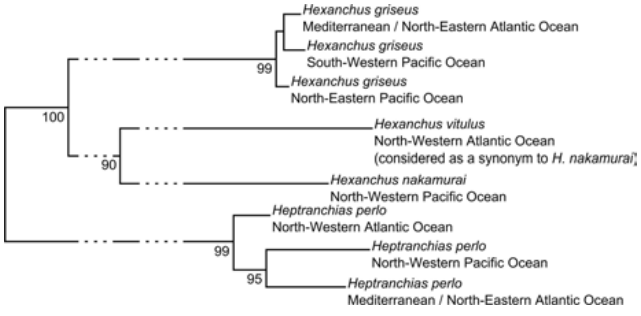

Fig. 1. A schematic phylogram of the three Hexanchidae species analysed in this study. The numbers near nodes represent bootstrap values.

The interspecific genetic divergence was around 5.46%. Clear genetic divergence was noted between the genus *Heptranchias* and the genus *Hexanchus*, with the latter being monophyletic. The genetic divergence within the species *Hexanchus nakamurai*, a senior synonym to *Hexanchus vitulus* [2], was quite high. In fact *Hexanchus nakamurai* specimens collected from the North Western Pacific Ocean exhibited a 4.4% divergence from that originating from the North Western Atlantic Ocean (Fig 1). Similar observations were noted in another study [4], using a different gene, where again high intraspecific divergence was recorded between *Hexanchus nakamurai* of Indo-Pacific origin and that of an Atlantic origin. Thus it can be concluded that there is a possibility of a third species within the genus *Hexanchus*, that is *Hexanchus nakamurai* might be split into a species within the Atlantic Ocean and another one in the Indo-Pacific Ocean. Given that *Hexanchus nakamurai* has been recorded in the Mediterranean Sea, then its identification would be best if supported by phylogenetic analyses to better understand the evolutionary connections of this poorly known species

PHYLOGEOGRAPHY OF THE *HEXANCHUS GRISEUS*, INFERRED FROM THE MTDNA CONTROL REGION.

Noel Vella [1]* and Adriana Vella [1]
[1] Conservation Biology Research Group, Department of Biology, University of Malta - noel.vella@um.edu.mt

Abstract
The mtDNA control region has been sequenced for 129 specimens of Hexanchus griseus. Signficant genetic differences were noted between the Pacific Ocean and the Eastern Atlantic Ocean (including the Mediterranean), giving clear indication of population heterogeneity between Oceans.

Keywords: Elasmobranchii, Malta Trough, Aegean Sea, Valencia Trough

Introduction
Hexanchus griseus is a cosmopolitan shark that is found to occur in various areas around the globe, including the Mediterranean Sea [1, 2]. It is one of the largest Mediterranean sharks, but little is known about its biology and distribution. IUCN has assessed this species as Nearly Threatened on a global scale [3], while in the past year its status on a regional scale, has been downgraded from Nearly Threatened to Vulnerable [4, 5].

Methodology
This study looked into the genetic structure of this shark, using the complete mtDNA control region as a molecular tool to identify subtle differences between 129 individuals originating from different geographical origins, with the main focus being the Mediterranean Sea population. The control region was amplified using newly designed primers, and it was sequenced through the use of five sequencing reactions.

Results and Discussion
The first genetic differences noted were based on the length of the control region. The number of VNTRs varied between locations, but since the mutation processes leading to the formation of VNTRs are different from the other point mutations noted in the control region, then their data was not used in this phylogeographic study. A total of 1258bp were analysed, and exhibited 14 polymorphic sites, with the maximum genetic difference between specimens being that of 1%. The haplotypic diversity noted was 0.743 ±0.023, while the nucleotide diversity was 0.0015 ±0.0010. The mean pairwise difference between individuals was 1.943 ±1.110, and had a Ti/Tv of 1.75, while three indels were also recorded.
Nested clade phylogeographical analysis and the phylogenetic tree (Figure 1) for the control region has shown that there are no sharing of haplotypes between distant locations. In fact, specimens from the Pacific Ocean formed a clade which is distinct from that noted in the Atlantic Ocean (including the Mediterranean Sea), and so the greatest genetic divergence was noted between these two Oceans. Moreover no haplotypes were shared between the North-eastern Atlantic Ocean and the South-eastern Atlantic Ocean. On the other hand Mediterranean specimens do share a haplotype with the North Atlantic Ocean, indicating recent divergence between these two locations.

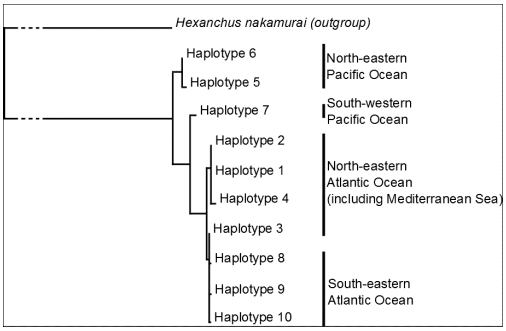

Fig. 1. A phylogram based on Maximum Likelihood analysis of the control region (1258bp) of *Hexanchus griseus* (haplotypes 1 - 10).

It can be concluded that even though this shark is a cosmopolitan species, still its population is subdivided into groups that are genetically different from each other. This stresses the need for conservation measures to tackle each group separately.

Abstract
There's no assessment for the sea urchin diversity in the Mediterranean despite the critical role they have as keystone species. Recent surveys in the Mediterranean show new data about sea urchin diversity and newly introduced species. Data from western Mediterranean countries to Egypt show records of 4 species *Paracentrotus lividus, Arbacia lixula, Sphaerechinus granularis and Psammechinus microtuberculatus.* While the Eastern Mediterranean countries to Egypt show the presence of Diadema setosum which is a recent invader from the Red Sea. Still the southern Levantine, of Egypt coast, lack complementing data for such findings.

Keywords: Biodiversity, Levantine Basin, Echinodermata, Genetics

Introduction
The morphological similarity between the species most common in the Mediterranean Levantine basin along with the lack of studies in Egypt that tackles the biology and ecology of these organisms have resulted in confused nomenclature. Furthermore, the uncertain geographical extent due to continuous introduction of new species has resulted in inconclusive reliability on biogeography [1]. The purpose of this study is to use genetic analysis as a reliable way for classification. Molecular methods depend on isolation and identification of 16S mitochondrial DNA gene was successfully used as a most preferred model for molecular genetics ecology as it support the relationship between morphology and genetics [2]. Therefore, we aimed to isolate and identify 16S mitochondrial DNA gene from selected sea urchins from several locations in Egypt to be used further for sequencing and subsequently in taxonomic and phylogenetic analyses.

Materials and Methods
The samples are collected by SCUBA diving from 2 rocky shore stations of Alexandria coast Abu Qir bay and Miami area Fig (1).

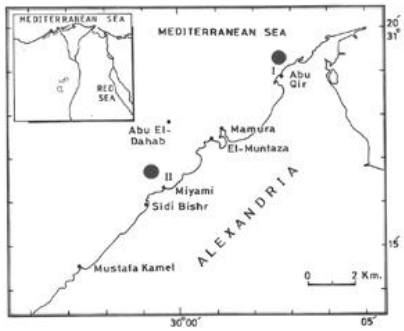

Fig. 1. Map showing locations of collection sites.

Four distinct morphological groups were selected. Gonad and gut specimens were collected from the 4 groups in order to examine their genetic variability. Specimens were quick frozen in liquid N2 and then ground in a clean, sterilized mortar. The genomic DNA was then extracted using Gene JET genomic DNA extraction kit following the manufacturer protocol (Fermentas, #K0721). To amplify partial 16S mitochondrial DNA region (approximately 450-500 bp), two universal primers (F:5'GACGAGAAGACCCTGTGGAGC3' and R:5'ACTTAGATAGAAACTGACCTG3') were designed using Primer 3.0 software based on conserved regions in published sea urchin and sea star sequence data [3]. The PCR was carried out following the manufacturer protocol (Fermentas, #K1071) in Techne TC-plus thermal cycler. PCR products were electrophoresed on 1% agarose gels using 1X TAE buffer containing 200 ng/ml ethidium bromide and then photographed.

Results and Discussion
The morphological examination resulted in 4 inconclusive regular sea urchin groups and they were expected to be *Arbacia lixula, Paracentrotus lividus, Psammechinus microtuberculatus and Sphaerechinus granularis*. However it is known that the juvenile individuals of *A. lixula* and *S. granularis* are sometimes confused with *P. lividus*. The *P. microtuberculatus* is also confused with *P. lividus* when the later has a lighter green color.
The amplified 16S mitochondrial DNA products from all four selected sea urchins showed four bands with different sizes (ranged from 450bp to 500bp) (Fig. 2).

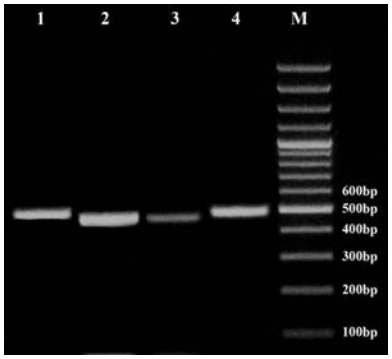

Fig. 2. PCR of 16S mitochondrial DNA fragment of 4 sea urchins (lanes 1-4), M= Marker.

The resulted PCR products are of different size, it is possible that these four sea urchins may be of different species or subspecies. Further confirmation using sequencing will be helpful for taxonomy and phylogenetic classification which will be done shortly after. We conclude that the molecular identification using 16S mitochondrial DNA is proved to be a more reliable way than the morphological approach to solve persisting problems in classification among individuals of sea urchins.

Abstract
This study gives a first molecular insight into the genetic structure of *Pinctada radiata* by analysing a mitochondrial DNA marker in four South-Central Mediterranean populations of this lessepsian bivalve. Specimens were collected from four central Mediterranean locations. Six polymorphic sites were found, defining seven haplotypes. Haplotype and nucleotide diversity values were low to moderate. The low levels of within-population genetic diversity detected in the present study are consistent with a scenario of founder effect, as expected for an invasive species. The shallow genetic structuring among the sampled populations may result from two factors – long larval duration which promotes the homogenization of the genetic pool through an effective gene flow or the current populations may not have had enough time to differentiate.

Keywords: Genetics, Bivalves, Alien species, South-Central Mediterranean

Introduction: The small pearl oyster *Pinctada radiata* was the first lessepsian bivalve reported in the Mediterranean. Successively its introduction for aquaculture purposes has been also documented (Serbetis, 1963; Zenetos *et al.*, 2004). Zibrowius (1992) proposed vessel-mediated dispersal as the most likely modality of introduction, either within fouling communities or as larvae in ballast waters. The three-week larval stage provides a high dispersal potential, as a consequence, species' geographical distribution within the Mediterranean Sea is expected expand progressively. With the present study a first molecular insight is provided into species genetic structure by analysing four Mediterranean populations of *P. radiata* by means of a mitochondrial DNA marker.

Materials & Methods: A fragment of the *COX1* gene was amplified and sequenced in a total of 47 individuals. 10-15 specimens were collected from four south-central Mediterranean locations – Qalet Marku and Bahar ic-Caghaq (Malta), Agios Nikolaos (Crete, Greece) and Gulf of Gabes (Tunisia). Within population genetic diversity was estimated by haplotype (h) and nucleotide (π) diversity indices. A median-joining network was constructed to depict relationships among haplotypes. Analysis of molecular variance (AMOVA Excoffier *et al.*, 1992) was carried out to partition genetic diversity in the within- and among-population genetic diversity.

Results: Overall, six polymorphic sites were found, defining seven haplotypes. Haplotype and nucleotide diversity values were low to moderate, ranging from h = 0.200 to 0.694 and π = 0.0005 to 0.0020, respectively. Highest and lowest values for both estimators were obtained for the Greek and Tunisian populations, respectively. Thirty-five individuals (74%) shared the haplotype H_1, and each of the other six haplotypes differed from H_1 by one mutational step. AMOVA partitioned the largest part of molecular variance (95%) in the within-populations level; the remaining 5% was relative to the among-populations component, that however was significant (Φ_{ST} = 0.054, P = 0.043).

Discussion: The low levels of within-population genetic diversity detected in the present study are consistent with a scenario of founder effect, which is expected for an alien invasive species (Nei *et al.*, 1975). However, the comparison with estimates of samples collected in the species' native range is needed to validate this hypothesis. Nonetheless, the estimates calculated in the present study were lower than those found in the Mediterranean for the alien bivalve *Brachidontes pharaonis*, using the same molecular marker (Sirna Terranova *et al.*, 2007). Moreover, population bottlenecks in Mediterranean *P. radiata* cannot be excluded; at this regard, dramatic demographic collapses has been documented in Tunisia ((Zaouali & Beaten, 1985). The shallow genetic structuring among the sampled populations may result from two main factors. On one hand, the long larval duration may promote the homogenization of the genetic pool through the action of an effective gene flow; on the other hand, current populations may have had not enough time to differentiate since the founder event. The present study represents a first insight into the genetic diversity of the invasive bivalve *P. radiata* in the Mediterranean Sea. In order to disentangle the relative contributions of current and historical factors, the analysis of a larger number of individuals and sampling locations is needed. Moreover, it is fundamental to include populations from the native species' range.

Abstract
This work reports a genetic data of *Octopus vulgaris*, marine species of high commercial value, from nineteen localities of Atlantic, Mediterranean and the Adriatic regions. We used mitochondrial DNA cytochrome c oxidase subunit I (COI) gene to investigate the genetic structure of common octopus. Our results indicated a significant genetic structuring in the study area (Phi_{ST} = 0.136, P <0.001) and highlighted a significant break between Western and Eastern Mediterranean basins. Moreover, our results indicate that O. *vulgaris* in the study area consists of four genetic stocks with an overall significant analogous F_{ST} (Phi_{CT} = 0.167, P< 0.001) value.

Keywords: Genetics, Mollusca, Cephalopods, North-Central Mediterranean

Introduction
The common octopus *Octopus vulgaris* (Cuvier, 1797) is the most important commercial octopus species of the Mediterranean region. It has a wide geographical distribution, including the Mediterranean Sea, the Eastern Atlantic from Southern England to south-western Africa, the Azores, the Canary Islands, Cape Verde, St Helena, the Tristan da Cunha Island, the southeast coast of South Africa in the Indian Ocean, the oceanic islands of the central Southern Indian Ocean, and the waters of Taiwan and Japan. According to FAO statistics, the annual world landings of cephalopods (squids, cuttlefishes and octopuses) was 4313.510 t in 2008 (FAO, 2010). Moreover, the common octopus accounts for about 50% of the total world octopus caught [1].
The objective of the present work was to investigate the phylogeography of this species across a large part of its geographical range, in order to identify the occurrence (if any) of genetic subdivisions over this area. To accomplish this, we employed sequences of the mitochondrial cytochrome oxidase I (COI), a marker largely employed in phylogeographical surveys.

Materials and methods Samples of O. *vulgaris* (513 specimens) were collected from nineteen localities including Mediterranean Sea (western and eastern basins, WM and EM, respectively), Adriatic Sea and Atlantic Ocean. A 641-bp COI fragment was amplified by PCR, using HCO-LCO primer pairs. Both strands were sequenced with the same primers used for PCR. Estimates of population genetic parameters were calculated using Arlequin v.3.5 (Excoffier & Lischer. 2010). Genetic relationships among haplotypes were assessed through the construction of a median-joining network using NETWORK 4.6.0.0 and Network Publisher version 1.2.0.0 (www.fluxusengineering. com). Analyses of molecular variance (AMOVA) were performed in Arlequin to assess the degree of genetic differentiation among individuals, sampling sites and geographical groups with statistical significance assessed by permutation. The main hypothesis tested by AMOVA was the differentiation of WM and EM populations; in particular, we made an attempt to assess the consistency of our results with the four biogeographical discontinuities described by Bianchi (2007) [2].

Results and discussion
The analysis of 513 individuals of O. vulgaris gave 55 haplotypes defined by 49 polymorphic sites. Haplotype diversity (h) was higher in WM samples compared to EM counterparts. It ranged from h=0.416 (Zarzis, Tunisia) to h=0.919 (Porto Santo Stefano, Italy). The haplotype network is presented in Fig.1. The AMOVA testing for overall population genetic structuring among populations was highly significant (Phi_{ST} = 0.136, P <0.001). The largest part of variation was within (86%) rather than among populations (14%). When considering WM versus EM, genetic variation showed the highest significant differentiation when Strait of Sicily and Portopalo samples were grouped in the WM region (Phi_{CT} = 0.102, P< 0.001), consistently with Bianchi's (2007) discontinuity No. 1. The genetic divergence observed between WM and EM samples corroborated results obtained by Fadhlaoui-Zid et al. (2012) [3]. The Siculo-Tunisian Strait is therefore effective in restricting gene flow between the two basins. In addition, significant genetic divergence was detected among the four main biogeographical regions (Atlantic Ocean Eastern Mediterranean, Western Mediterranean and Adriatic Sea) (Phi_{CT} = 0.167, P< 0.001). From a fisheries perspective, the four major genetic stocks identified by our study should be considered for resource management purposes.

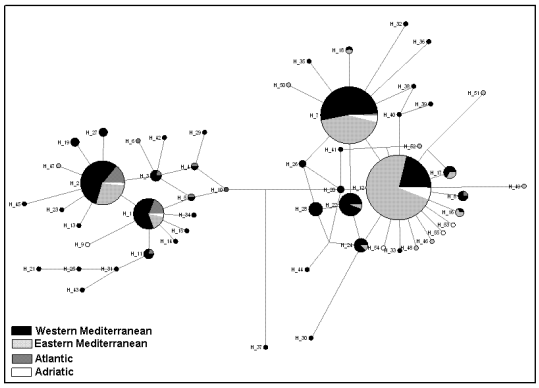

Fig. 1.
Median-joining network among 55 COI haplotypes. Size of circles is proportional to the frequency of each haplotype. The geographical region where each haplotype was found is shown in the legend.

Abstract
The population genetic structure of *Pachygrapsus marmoratus* has been investigated along the Turkish coasts using cytochrome c oxidase subunit I gene (COI) sequences. Our findings revealed high genetic similarity between Black Sea / Turkish Straits System and Mediterranean populations of the species. On the other hand, the composition of mtDNA haplogroups in the haplotype network indicated a weak but discernable differentiation between populations.

Keywords: Crustacea, Genetics, Black Sea, Marmara Sea, North-Eastern Mediterranean

Introduction
The marbled crab, *Pachygrapsus marmoratus* (Fabricius, 1787) (Crustacea: Decapoda: Brachyura: Grapsidae), is a widespread species inhabiting the rocky shores in the Black Sea, the Mediterranean Sea and the eastern Atlantic coasts of Europe and Africa (for details of distribution see d'Udekem d'Acoz, 1999 and Dauvin, 2012). Population genetic structure of the species has been recently investigated throughout the western Mediterranean Sea and the eastern Atlantic Ocean and it has been suggested that there is a recent and weak genetic differentiation between European Atlantic and some Mediterranean populations of *P. marmoratus* (Fratini et al., 2012).

The purpose of the present work is to investigate population genetic structure of *P. marmoratus* on the Turkish coasts from the easternmost part of the Black Sea to the eastern Mediterranean (Aegean and Levantine coasts) using mitochondrial DNA gene cytochrome c oxidase subunit I (COI). That way we aimed to test the hypothesis that the Turkish Straits System (TSS), consisting of the Bosphorus Strait, the Sea of Marmara and the Dardanelles, which is the only connection between the Black Sea and the Mediterranean, may act as a phylogeographic break having a potential to separate the Black Sea and the Mediterranean populations by restricting the gene flow between them.

Materials and Methods
A total of 122 specimens of *P. marmoratus* were collected from 17 sites including 5 from the Black Sea (6 specimens), 3 from the TSS (28 specimens), 7 from the Aegean Sea (67 specimens) and 2 from the Levantine Sea (21 specimens) between 2009 and 2012. We amplified COI mitochondrial DNA gene fragment of these specimens by means of polymerase chain reactions (PCR).

Results and Discussion
Thirty-six COI haplotypes were found in the area of investigation. The haplotype network displayed a star-like shape, with three main haplotypes in the center, surrounded by several rare haplotypes (Fig.1). These main haplotypes differ from each other by only 1-2 mutations in the haplotype network. COI mtDNA sequence data set, the AMOVA test (?=0.51) and shape of the haplotype network showed high level of genetic similarities between Black Sea / TSS and Mediterranean (Aegean and Levantine Seas) populations of *P. marmoratus*. So, the TSS does not seem to act as a distinct phylgeographic break for the populations of the species in this case. All the same, a geographic distribution pattern of haplogroups is discernable, which may indicate a weak restriction of gene flow at least towards one direction, from the Mediterranean to the Black Sea. Extending the sampling sites and increasing the sample size will be useful for better understanding the population structure of *P. marmoratus* and effects of the TSS on the gene flow among its populations.

Abstract
The Mediterranean yellow gorgonian *Eunicella cavolinii* (Cnidaria, Octocorallia) is among sessile species who have suffered mass mortality events following thermal anomalies in the North-Western Mediterranean Sea. We present here the first data on the genetic diversity and structure of this species. The results obtained with four microsatellite markers indicate a strong differentiation between the most distant samples considered here (North Africa, Turkey and France). At a regional scale genetic differences are lower though often significant. No significant differentiation is observed between depths on the same site.

Keywords: Marmara Sea, North-Western Mediterranean, Algerian Basin, Cnidaria, Genetics

Introduction
Many marine invertebrates have suffered in recent years, the combined action of anthropogenic pressures and climate change. Thermal anomalies have already affected various sessile species, particularly populations above the thermocline [1]. The impact of such perturbations depends on the diversity of response between individuals and populations, and on dispersal at the metapopulation level.
Eunicella cavolinii (Koch1887) is a sessile species that was affected by mortality events during the past two decades, with variable levels of tissue necrosis depending on location, depth and individuals [2]. Its distribution is highly patchy in the Mediterranean Sea, which makes the metapopulation dynamics related to the major role of dispersal and gene flow. Genetic analyzes are a starting point for understanding the genetic structure of the yellow gorgonian and to estimate the spatial connectivity at different scales. This will give us some insights into the potential of recolonization in cases of local extinction. Analyzing levels of gene flow will also help understanding how this species might evolve in contrasted ecological conditions.

Materials and methods
We performed an analysis of the genetic diversity of this species using four microsatellite loci and 17 shallow samples separated by an interval of a few tens of meters to hundreds of kilometer issued from contrasted environments of the Mediterranean Sea (Fig. 1).

Fig. 1. Map of the 17 samples of *E.cavolinii* (black and white stars). Samples were collected at different locations and depths for the areas indicated by a white star.

Results
All loci were polymorphic with a total number of alleles ranging from 13, for C20 and C30, to 24, for S14, with a mean value of 17.8 alleles per locus. The observed and unbiased expected heterozygosities varied respectively between 0.30 for SIV (Turkey) and 0.63 for KIA (Algeria) (mean value over populations 0.48 ± 0.23), and between 0.38 for SIV and 0.76 for KIA (mean value over populations 0.55 ± 0.25). The results indicate similar levels of genetic diversity to those observed in the congeneric species *E. singularis* [3]. This diversity is nevertheless lower than that observed with microsatellites for other Mediterranean octocorals (H_{exp} = 0.77 for the red coral, *Corallium rubrum* [4], [5] and H_{exp} = 0.74 for the red gorgonian *Paramuricea clavata* [6], [7]). Pairwise differentiation tests between populations showed high values of Fst (Overall Fst = 0.11), especially between the most distant samples North Africa, Turkey and France. A Principal Coordinates Analysis illustrates the differences between samples and highlights the clear genetic differences between regions (Fig. 2). The non-significant comparisons included mostly samples from sites that were taken at different depths.

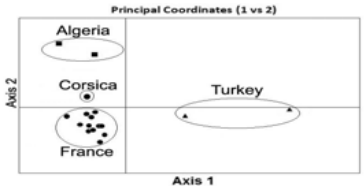

Fig. 2. Principal Coordinates Analysis of the genetic differences between samples.

IMPORTANCE OF SEAMOUNTS-LIKE FEATURES FOR MEDITERRANEAN MARINE HABITATS AND THREATENED SPECIES

R. Aguilar [1]*, X. Pastor [1], S. Garcia [1], P. Marin [1] and J. Ubero [1]
[1] Oceana - raguilar@oceana.org

Abstract
Oceana's exploratory ROV's dives in Western Mediterranean seamounts have collected more than 300 hours of video from deep-sea ecosystem. Findings of threatened species and habitats, like carnivorous sponges, elasmobranches, coral gardens, sponge aggregations, coralligenous beds, etc. or even new species for science like giant foraminifera (Astrorhizidae), or new species for the Mediterranean (i.e. *Anomocora fecunda*), makes this geological features "hotspots" and shelter of species and habitats in regression or considered rare in other Mediterranean areas.

Keywords: Deep sea ecology, North-Western Mediterranean, Deep sea corals, South-Western Mediterranean, Biodiversity

More than 200 underwater elevations have been registered in the Mediterranean (1). They are widely distributed along this sea, but the highest density is in the Western Basin, mainly in Alboran and Tyrrhenian Seas; Sicilian Channel and Balearic Islands are also other important points. Since 2006, Oceana has carried out six expeditions in the Mediterranean performing 129 ROV's dives over 16 seamounts, surveying 208.350 m^2 between -37 and -638 meters deep.

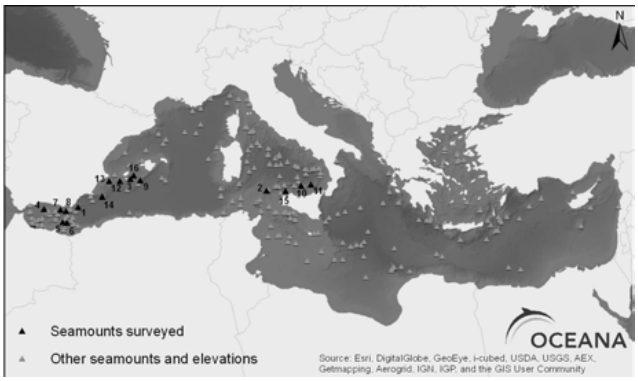

Fig. 1. Abubacer ridge (1), Aceste seamount (2), Ausias March Bank (3), Avempace bank (4), Cabliers bank (5), Catifas bank (6), Chella bank (7), El Sabinar bank (8), Emile Baudot seamount (9), Enareta seamount (10), Filicudi banks (11), Formentera bank (12), Nao mound (13), Palos bank (14), San Vito ridge (15), Ses Olives bank (16).

Cold water corals: *Dendrophyllia cornigera* found in all the seamounts. Reefs of *Lophelia pertusa* and *Madrepora oculata* on Cabliers, Catifas, Chella and Avempace. Other corals found are *Anomocora fecunda, Caryophyllia* spp., *Desmophyllum dianthus, Stenocyathus vermiformis, Pourtalosmilia anthophyllites* and*Javania caileti*. **Gorgonian gardens:** *Paramuricea clavata* and *Eunicella verrucosa* are the commonest on top of seamounts. Other species are *Viminella flagellum*, *Callogorgia verticillata, Acanthogorgia* spp., *Placogorgia coronata, Swiftia pallida, Muriceides lepida, Villogorgia bebrycoides, Bebryce mollis, Nicella granifera* and *Paramuricea macrospina*. **Black corals:** *Leiopathes glaberrima* and *Antipathes dichotoma in* San Vito, Filicudi, Emile Baudot, etc. but also *Antipathella subpinnata & Parantipathes larix* in Chella or Cabliers. **Bamboo corals:** *Isidella elongata* on muddy beds in Ses Olives. **Sea pens:** *Pennatula* spp., *Pteroeides griseum, Virgularia mirabilis* and *Veretillun cynomorium* on soft detritic bottom, *Funiculina quadrangularis* is less abundant, but *Kophobelemnon stelliferum* is the most abundant in some seamounts. **Sponge aggregations:** *Asconema setubalense* found for the first time in the Mediterranean. *Phakellia* spp. on bathyal rocky beds. *Axinella* spp. and tens of different species over rodolith beds. But also in muddy bottoms, like *Thenea muricata*. ***Gryphus vitreus*:** Largest beds on Aceste and Emile Baudot. ***Leptometra phalangium* beds:** Present in all the seamounts; highest abundance in El Sabinar and Avempace. **Coralligenous beds:** Both rodolith beds and coralligenous concretions present in shallower peaks. **Oyster reefs:** *Neopycnodonte zibrowii* in Abubacer, Chella and Emile Baudot. *N. cochlear* also found in Chella. **Mussels' reefs:** Subfossil reefs of *Modiolus modiolus* found in Chella.

Threatened/rare species**: Astrorhizida.** New species of giant foraminifera found in Palos bank. ***Asbestopluma hypogea*.** First recorded in deep areas(2). Registered on Chella, Ausias March, Emile Baudot & Enareta. ***Spongia agaricina*.** Large individuals on Emile Baudot and Ausias March. ***Aplysina* spp. & *Tethya* spp.** in Chella and Emile Baudot. ***Anomocura fecunda*.** Discovered on Chella bank. ***Anthomastus* sp.** Registered in Chella and Cabliers. ***Nidalia* isp.** Identified in Ausias March, Palos bank and El Sabinar. ***Dendrobrachia bonsai*.** Rare gorgonian(3) in Cabliers, Catifas and Chella bank. ***Nicella granifera*.** Found in Chella, Avempace and Cabliers. ***Sideractis glacialis*.** One citation for this species in the Mediterranean(4). Sighted on Ses Olives, Chella and Formentera. ***Savalia savaglia*.** in Chella, Avempace, Cabliers and Emile Baudot. ***Kinetoskias* cf. *smithii*.** First cited in the Mediterranean closed to Gibraltar strait(5). Recorded between Ses Olives and Ausias March; also in Emile Baudot. ***Charonia lampas*.** Gastropod on top of Ausias March and Chella. ***Ranella olearia*.** Common in Emile Baudot, Chella and Palos. ***Neopycnodonte zibrowii*.** Recently discovered mollusk(6) found in Abubacer and Chella. ***Peniagone* sp**. Elasipodid in deep muddy bottoms in Ses Olives and Emile Baudot. ***Epinephelus caninus*.** Aggregations in Chella and Palos Banks. ***Gaidropsarus granti*.** Recorded in Chella bank. Species only found in islands and seamounts(7). ***Cetorhinus maximus*.** Basking over Palos bank. ***Galeus atlanticus*.** It was found in Chella. ***Oxynotus cetrina*.** Several individuals spotted in Chella bank.

Abstract
Presence of over 200 spotted catshark *Scyliorinus canicula* egg capsules associated with long lived black coral *Leiopathes glaberrima* was observed in the South West Coast of Sardinia, describing a thousand years old nursery area for Elasmobranches. The forest, composed by 153 colonies, was discovered during a ROV survey carried out in October 2011 over a rocky elevation of the sea bottom, at depths between 188 and 210 meters. The described zone represents an important component of the ecosystem that deserves special protection.

Keywords: Conservation, North-Western Mediterranean, Deep sea corals, Elasmobranchii

Introduction
Elasmobranches consists of some of the most threatened marine species in the last century, with serious consequences on the entire ecosystem, because of their top position among the food web [3]. Because of this, the importance of identifying shark nursery areas is increasing in order to implement conservation or management measures [1]. Deep gorgonian fields are a sheltered and ventilated spot that increases survivorship of catsharks [1,2]. In this study we report on a *L. glaberima* forest as nursery area of the spotted catshark *S. canicula*, a species that although assessed as Least Concern in the IUCN red list 2012 is object of an increasing scientific interest .

Materials and Methods
The study area, denominated Carloforte shoal (CS) (39°13'42.70"N; 8° 0'9.01"E) is located 11 nautic miles from San Pietro island, SW coast of Sardinia. Before exploring CS, it has been mapped using Multibeam in order to obtain a detailed 3D geomorphological map of the seabed. Video and photo footage of the forest was gathered by a ROV (Remotely Operated Vehicle) "Pollux" during a survey conducted in October 2011 on board of the R/V Astrea, working at depths between 188 and 210 m. A total of 197 minutes of video was recorded during the survey over CS. Every image was elaborated with the software ImageJ in order to calculate the frame area (in m2) and the abundance of black coral colonies (N° m-2 ± ES).The dimensional scale calibration was performed using ROV's laser leds.The occurrence of catshark egg capsules was estimated also on the basis of 215 high resolution photographs.

Results and Discussion
A total of 245 capsules of S. canicula over 153 colonies of L. glaberrima was observed(Fig.2). Size, shape, and texture of the capsules were very similar to those reported for the same species by [4].. Over the total number, in 98 colonies capsules were absent while the maximum was 44 eggs over a 2 meters tall colony. Observed capsules were at different stage of maturation: some of them had a clean surface with a clearly visible yolk, while others were covered with sediments and degraded. This variance in capsule types proves that this area has possibly been a nursery for several generations. Numerous specimens of S. canicula were observed in the area, moving on the muddy bottom surrounding the rocky pinnacle(Fig.1). Other species than the spotted catshark were observed during the survey as a prove that other organisms take advantage of this habitat. By serving as nursery for marine predators, CS is an important component of the ecosystem that deserves special protection[3]. Effectively, considering that the height of the rocky pinnacle is enough to create a physical barrier against trawling, the studied area represents not only a physical protection from harvesting, but also a precious sanctuary for catshark capsules associated with long lived black corals that deserves special protection due its important ecological role.

Abstract
In the Mediterranean, as well as globally, submarine canyons were found to support relatively rich food-webs. It is not known whether this trend applies to ultra-oligotrophic waters bodies. High number of cetaceans sightings above Achziv Submarine Canyon (ASC), motivated the present pioneering study of the local underlying food-web in an attempt to collect more evidence in support of ASC serving as a production "hotspot". All biological data obtained from ASC will be innovative and will throw light on a deep water habitat never before investigated.

Keywords: Canyons, Deep sea ecology, Cetacea, Levantine Basin, Food webs

Introduction
Submarine canyons are potential sinks for particulate materials, including macrophytic debris, organic-rich sediments, and particle-bound pollutants moving along shores and across shallow platforms [1]. By intercepting and trapping littoral sediment drifts, submarine canyons with their heads close to the shoreline, can also act as main drivers of local sediment transport and deposition, thus funneling materials towards the adjacent deep sea [2]As a consequence, canyons often are sites of intense organic enrichment and benthic productivity, producing scavenger-based ecosystem services that may serve as food for higher trophic levels, up to and including top predators such as marine mammals [3]. ASC, one of the prominent submarine valleys of the steep northern Levant margin, is located 3 km off the northernmost reach of the Israeli Mediterranean coastline. Starting 3 km NW of the mouth of Sha'al River, the sinuous canyon runs for about 40 km (to the northwest, reaching a water depth of 1900 m [4] (Fig 1).

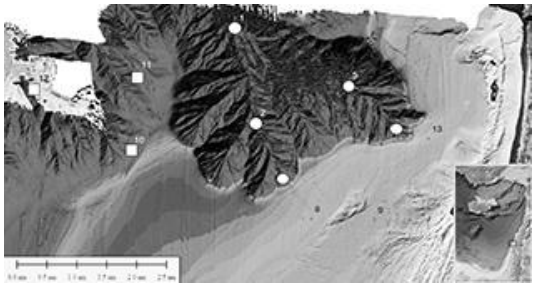

Fig. 1. Sampling stations inside ASC (circles) and adjacent slope (squares).

Material and Methods
Seven research cruises along 3 years were conducted atop ASC, and isobathic control sites. CTD profiles were obtained and samples taken from the water column (nutrients, chlorophyll, bacteria and plankton), seafloor (total organic carbon, benthic invertebrate composition) and fish, mollusks and crustaceans from trap, net and hook systems. The cruises followed and partly coincided with 6 years of marine mammals' surveys in the area.

Results
Preliminary results indicate a high number of common bottlenose dolphin (*Tursiops truncatus*) sightings per unit effort above the ASC relative to the adjoining area to the south with similar survey effort (Fig 2). Benthic invertebrate composition of pooled samples showed higher mean (±SD) abundance (26.9±49.1 vs 5.2±7.2 organisms/500ml; p=0,023) and diversity (6±4.4 vs 2.3±2.1 taxa; p=0.014) inside the canyon and in the adjacent slope, respectively.

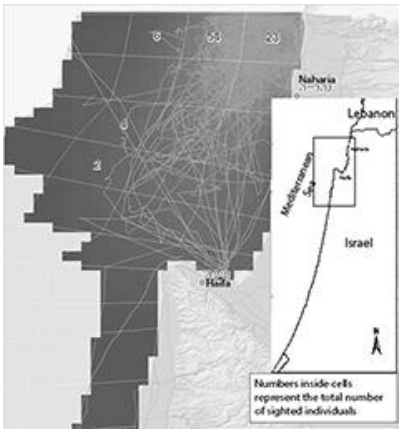

Fig. 2. Grided map of Israel's northern coastline showing survey paths and sightings of common bottlenose dolphin (*Tursiops truncatus*). Upper two cells overlay the ASC.

Discussion
The Mediterranean as a whole and the Levantine basin in particular are ones of the most climatically affected oceanic bodies. Further warming is likely to accentuate oligotrophicity, causing a retreat of local biota into potential productivity hotspots such as the ASC. The collected samples will serve as a belated but essential baseline against which such trends may be evaluated. Along with a declaration process of the ASC and its surrounds as a Marine Protected Area, understanding the regional ecosystem's forming factors is essential.

Abstract
The benthopelagic fauna of the Santa Maria di Leuca cold-water coral province was investigated using the baited lander MEMO during 3 video surveys carried out in 2010 and 2011. The depth examined was between 547 and 790 m. A total of 19 benthopelagic species and 1 at genus level were identified. *Paromola cuvieri, Conger conger* and*Helicolenus dactylopterus* resulted the most abundant species in the coral habitat.

Keywords: Deep sea corals, Biodiversity, Ionian Sea, South-Central Mediterranean

The video inspections are generally less invasive on the fragile deep-sea ecosystem than other experimental or fishing gears and they could also provide information on the habitat selection of the species, their distribution and behaviour. As part of the CoralFISH 7FP EU project and OBAMA-PRIN research, the baited lander MEMO (Marine Environment MOnitoring system) was deployed in the Santa Maria di Leuca cold-water coral province (Central Mediterranean) in June and November 2010, and March-April 2011. MEMO consists of a stainless steel metallic frame, 2 digital cameras, a multiparametric probe, a currentmeter (doppler), an acoustic modem, and an ICT infrastructure capable of managing the entire system. The deployments were carried out in two types of habitat: a coral habitat, that is on a coral mound (C) and a non coral habitat, that is on a muddy bottom (NC). A total of ten deployments between 547 and 790 m were carried out, for a total time of 52 and 38 hours of video records in the coral and non coral habitats respectively. The different species have been identified through morphological characteristics observed in the video frames. The total number of individuals by species has been standardised to the time of video record (N/h) in both coral and non coral habitats. A total of 19 benthopelagic species (1 cephalopod, 5 decapod crustaceans, 5 cartilaginous fishes and 8 teleost fishes) and 1 crustacean at genus level (*Munida spp*.) were identified. In particular, 15 of them in coral habitat and 14 in non-coral habitat. The crustaceans *Bathynectes maravigna, Geryon longipes* and *Munida spp*, the velvet shark *Etmopterus spinax* and the teleosts *Lepidopus caudatus* and *Pagellus bogaraveo* were exclusively recorded in coral habitat. *Paromola cuvieri, Conger conger* and*Helicolenus dactylopterus*, wereobserved in the two habitat typologies;their abundance was greater in the coral habitat than in non-coral habitat; they also resulted the most abundant species in the coral habitat (Fig. 1). Although *P. bogaraveo* has been often observed in the coral habitat, due to the fast swimming of the different individuals its count and abundance estimation could be largely
biased and not included in the figure.

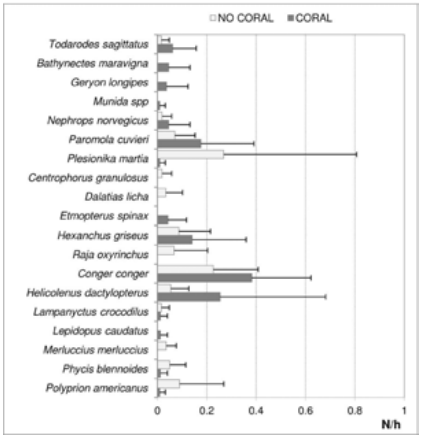

Fig. 1. Average number per hour (N/h) by species recorded in coral and non coral habitats of the SML coral province.

Although a baited lander generally attracts scavenging fish and so it is highly selective [1], the present results confirm the preferential distribution of some benthopelagic species in the SML coral province (Fig. 2) and the exclusive occurrence of *P. bogaraveo* in the coral habitat previously detected by towed cameras and longling surveys [2,3,4]. Although the scavenger behaviour can explain the high frequency of *P. cuvieri* and *C. conger* in both coral and non coral habitats, their greater abundance in the coral habitat, together with *H. dactylopterus*, seems to be indirectly linked to the presence of corals, indicating an habitat selection in some deep-sea species.

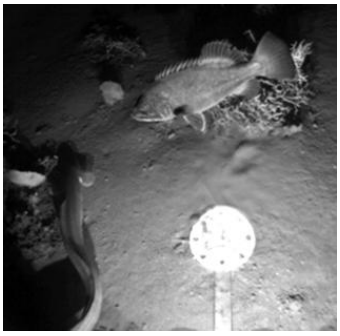

Fig. 2. Digital frame showing *Conger conger* and *Polyprion americanus* in the coral habitat of the SML coral province.

LES EAUX MAROCAINES, ÉSPACE SINGULIER DANS LA ZONE HOT SPOT ATLANTOMÉDITERRANÉENNE?

Mohamed Menioui [1]*
[1] Université Mohamed V-Agdal, Rabat - mohamed.menioui@gmail.com

Abstract
Le littoral marocain, de par sa situation géographique à la croisée des masses d'eaux d'origines et de densités différentes a toujours suscité l'intérêt des scientifiques et des naturalistes, Plusieurs expédions scientifiques internationales y ont été organisées et nombreuses nouvelles espèces y ont été découvertes.

Keywords: Biodiversity, South-Western Mediterranean

Avec ses deux façades atlantique et méditerranéenne, un détroit, des conditions hydrologiques particularités hydrologiques (upwelling), … le Maroc a toujours suscité l'intérêt des scientifiques. Porcupine (1870), Challenger (1873-1876), Travailleur (1882), Talisman (1883), S.S. Valdivia (1893), Princesse Alice et l'Hirondelle (1885, 1915), M. sars (1910), Calypso (1958, 1962), etc. sont certaines des expéditions internationales organisées dans ses eaux qui se continuent jusqu'à nos jours.

Ces investigations ont abouti à la découverte de nombreuses espèces nouvelles (*Natica marrocana*, *Raja marrocana*, *Nereis marrocensis*, *Diopatra marrocensis*, *Fusus marrocanus*, *Plumularia marrocana*, *Stylaster marrocanus*, *Synoicum marrocana*, etc.,…qui portent toujours le nom du Maroc.

Récemment, des prélèvements, très localisés (Fig. 1) y ont permis la découverte de bien d'autres espèces, dont certaines sont validées et publiées:

- *Cerapopsis takamado* Menioui & Myers, 2000 [1], connue de la baie de Dakhla;
- *Bathyporeia ledoyer*i d'Udekem d'Acoz & Menioui 2004 [2], identifiée également dans la baie de Dakhla;
- *Bathyporeia microceras* d'Udekem d'Acoz & Menioui 2004 [2] identifiée également dans la baie de Dakhla;
- *Bathyporeia elkaim*i d'Udekem d'Acoz & Menioui 2004 [2], connue de la région de Rabat, de Dakhla, mais également de la lagune de Khnifiss;
- *Bathyporeia watkini* d'Udekem d'Acoz, Echchaoui & Menioui 2004 [3],
- *Leucothoe Brunnonis* Krapp-Schickel & Menioui 2005 [4], découverte à la Dakhla;
- *Urothoe atlantica* Bellan Santini & Menioui 2005 [5], trouvée dans la baie de Dakhla et découverte dans la Baie de Mdiq;
- *Arcturinoides dakhla*, Menioui et Poor 2007 [6] jusqu'à présent connue de Dakhlala - crevette *Hippolyte lagarderei* d'Udekem d'Acoz, identifiée dans le lagon de Temara, non loin de Rabat.

Certains de ces taxa présentent également d'autres particularités comme:

- l'isopode *Arcturinoides* Kensley, 1977, n'est connu à l'échelle planétaire que par trois espèces : *A. sexpes* en Afrique du Sud , *A. gibbosus* Müller, 1989 dans le Golf d'Aden et l'espèce marocaine *A. dakhla* ;
- le genre *Cerapopsis* Della Valle, n'a été connu que par une seule et unique espèce *C. longipes*, depuis plus d'un siècle (1893-2000) avant la découverte de l'espèce marocaine *C. takamado*,
- l'espèce *Bathyporeia microceras*, endémique du Maroc est morphologiquement très différente es autres espècs du genre ;

Aujourd'hui, trois autres espèces viennent d'être identifiées et sont particulières par leurs répartitions géographiques :

- une espèce du genre *Calozodion* Gardiner, 1973, nouvelle pour la science ;
- le Tanaidacé *Chondropodus* Gutu, 2006 cantonnée qui n'est connu dans le monde que par deux espèces dont une, *C. curvispinus*, qui vient d'être identifiée au Maroc et ;
- le genre *Plectrocopus* Gutu, 2006, monospécifique, connue par l'unique espèce P. spicatus vient également d'être identifié au Maroc.

Conclusion : En plus de la richesse spécifique des eaux marines marocaines, nombreux éléments de cette biodiversité paraissent particuliers. Les recherches taxonomiques, même peu développées sur les crustacés, ont permis de mettre en évidence l'originalité de cette partie de la province lusitanienne qui se singularise en effet, par ses caractéristiques hydrologiques particulières en tant que zone de mélange entre les eaux méditerranéennes et atlantiques et de transition entre les eaux froides du Courant des Canaries et celles chaudes du contre courant équatorial. Ces côtes sont également certaines des quelques rares régions dans le monde baignées en permanence par des upwellings. Il en découle un enrichissement aussi bien quantitatif que qualitatif de la biodiversité marine du Maroc, qu'on commence à peine à connaître et dont l'exploration suggère davantage d'investigations. Il est enfin important de signaler que pour les autres groupes taxinomiques, en particulier les mollusques, nombreuses espèces, non encore identifiées, semblent bien différentes de celles connues, ce qui suggère certainement d'autres originalités taxinomiques et biogéographiques.

OBSERVATIONS OF WATER COLUMN HABITATS BY COMBINING ACOUSTIC BACKSCATTER DATA AND ZOOPLANKTON SAMPLING IN THE NORTHEASTERN BLACK SEA

Elena Arashkevich [1]*, Alexander Ostrovskii [1] and Vladimir Soloveyv [1]
[1] Shirshov Institute of Oceanology RAS - aelena@ocean.ru

Abstract
High-frequency acoustic technology was used to measure the vertical distribution of mesozooplankton. Simultaneously the stratified net sampling was performed to obtain taxonomic and quantitative characteristics of aggregation layers. Collected data revealed the fine structure of mesozooplankton vertical distribution driven by both physical-chemical and behavioral processes.

Keywords: Acoustics, Zooplankton , Black Sea

The Black Sea is a deep basin with the thin active layer. It is characterized by permanent anoxia below the sharp halocline. The depth of the oxic/anoxic boundary varies in time and space within 100-180 m depth interval, depending on the water circulation [1]. After vernal formation of thermocline, four different types of habitats corresponding to physical-chemical properties of the water column are distinguished: i) the upper mixed layer (UML), ii) thermocline, iii) cold intermediate layer (CIL), and iiii) suboxic zone. We studied how the physical-chemical and behavioral properties drive the vertical structure of mesozooplankton distribution in the NE Black Sea. The acoustic scattering technique is a useful tool for observations of distribution and abundance of marine zooplankton [2, 3]. The moored automatic mobile profiler Aqualog [4] equipped with the acoustic Doppler current meter Nortek Aquadopp (2MHz) was deployed at the upper part of the continental slope at the depth of 265-270 m (44°29.44? N, 37°58.38?E) in June 2011 and September 2012. The current meter had a side-looking sensor head transmitting and receiving sound along three narrow acoustic beams. Transducers are mounted on one side to assure that the beams are pointing into the undisturbed flow away from the hydrodynamic boundary layer around the profiler. The profiler also carried the CTD probe Idronaut Ocean Seven 316plus with the dissolved oxygen and oxidation-reduction potential sensors. The profiler made repeated round trips between the near-surface ocean layer and the anoxic zone every 1 h. As a result of the profiling survey we got the time series of the vertical profiles of the ocean parameters including the amplitude of the acoustic backscatter.

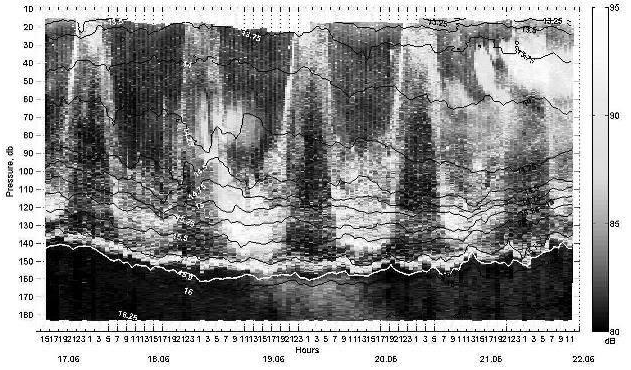

Fig. 1. Time–depth plot of the acoustic backscatter obtained by the profiler Aqualog at the mooring site in the NE Black Sea on June 17–22, 2011. The lines indicate isopycnals of the density anomaly sigma-theta.

Zooplankton was sampled nearby the moored profiler to study the taxonomic and quantitative patterns of zooplankton vertical distribution. Juday net hauls targeted aggregation layers manifested themselves in the in-situ backscattering data. Six layers were sampled: UML, thermocline, two layers in CIL, and two layers in suboxic zone, from the depth of sigma-theta between 15.4 and 15.7 and between 15.7 and 15.9. Time of sampling corresponded with the day and night time aggregations of migrating zooplankters in the deeper and upper layers, respectively, as well as with upward and downward migration. During the surveys, the upper mixed layer had the temperature of 24-25 oC and was inhabited by thermophilic zooplankters (mainly cladocerans and copepod *Acartia clausi*). In both seasons, maximum of fluorescence was located in thermocline and this layer was permanently occupied by heterotrophic dinoflagellate *Noctiluca scintillans* and the younger copepodite stages of *Calanus euxinus* and *Pseudocalanus elongatus*. The older stages of two latter species performed the diel vertical migrations: they aggregated in the lower part of CIL during the daytime and ascended to the thermocline at night. The lower boundary of their daytime aggregation coincided with oxygen concentration of c. 30 micromole/l. The deepest layer of zooplankton aggregation was mainly formed by diapausing *Calanus euxinus* (CVs). Its thickness was 5-7 m and it was limited from below by sigma-theta=15.9. Oxygen concentration in this layer was 3-5 micromole/l. The backscatter amplitude of this aggregation was enhanced persistently throughout day and night (Fig.1). General pattern of fine scale stratification of water column revealed from the backscatter data corresponded to the zooplankton vertical distribution obtained by means of net sampling (Fig.2).

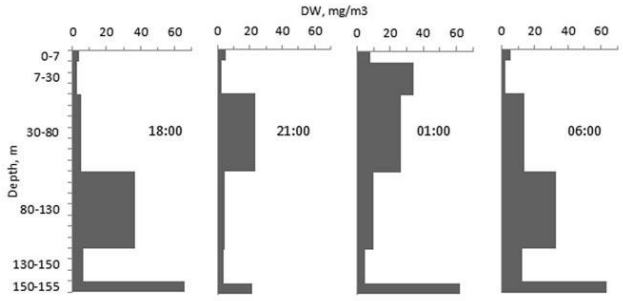

Fig. 2. Vertical distribution of non-gelatinous zooplankton (DW/m3) in the NE Black Sea in 21-22 June 2013

Both migration amplitude and aggregation depth depended on the position of thermocline and the depth of the suboxic layer. It was also modified by zooplankton response to variations in oxygen concentration at the different stages of their life span.

Abstract
Un suivi bimensuel de la qualité de l'eau, de la dynamique et de la structure du peuplement phytoplanctonique, au niveau de la Lagune de Bizerte, a révélé une variation haline assez importante (23.1 – 40.9), une turbidité très irrégulière, un pH alcalin, une forte oxygénation et une température variant entre 12 et 32°C. Sur le plan taxonomique, on a pu identifier 163 taxa (104 diatomées et 53 dinoflagellés) parmi lesquels 23 sont susceptibles d'être nuisibles. L'un des taxa, doté d'un pouvoir toxique assez important à savoir *Alexandrium spp*, a atteint une densité de 63 764 cel.l^{-1}.

Keywords: Lagoons, Phytoplankton, Systematics, Tunisian Plateau

Introduction
Le choix de la lagune de Bizerte pour la présente étude repose sur plusieurs raisons dont les plus importantes sont la richesse du point de vue biodiversité des peuplements phytoplanctoniques dans les écosystèmes lagunaires, les phénomènes sporadiques d'eutrophisation signalés par plusieurs auteurs ainsi que l'effet de la qualité des eaux sur l'activité conchylicole à savoir l'élevage des moules et des huîtres [1], [2], [3], [4]. L'eutrophisation des écosystèmes aquatiques est à l'origine un phénomène ancien et naturel résultant de l'enrichissement des eaux en éléments minéraux nutritifs. Il en résulte un accroissement de la production de biomasse végétale (phytoplancton, macrophytes), une diminution de l'oxygénation et des phénomènes de mortalités [5], [6]. Dans ce travail nous nous sommes intéressé aux fluctuations spatio-temporelles des paramètres physico-chimiques de l'eau ainsi qu'aux concentrations du phytoplancton afin de comprendre la dynamique du peuplement phytoplanctonique dans la lagune de Bizerte.

Matériel et méthodes
La lagune de Bizerte, localisée sur le littoral Nord de la Tunisie septentrionale correspond à une dépression de forme elliptique. Elle est située entre 37° 8' et 37° 14' de latitude Nord et 9° 46' et 9° 56' de longitude Est. La superficie de cette lagune est d'environ 150 km^2 et sa profondeur maximale peut atteindre 12 m. Ce plan d'eau est en communication permanente avec la mer Méditerranée par l'intermédiaire d'un chenal rectiligne et étroit d'une profondeur de 12 m et d'une longueur de 7 km [1]. Les prélèvements ont été réalisés en surface selon la méthode de l'IFREMER. Les échantillons récoltés ont été fixés « *in situ* » au moyen du formol neutralisé au Borax (3%). L'identification et le comptage des taxa phytoplanctoniques ont été effectués par le biais de microscope photonique inversé à contraste de phase de type HUND selon la méthode d'Utermöhl [7]. Les paramètres physico-chimiques de l'eau ont été prélevés « *in situ* » à l'aide d'un multi-paramètre de type WTW.

Résultats et discussion
La température de surface au niveau de la station de Menzel Jemil peut être partagée en 2 périodes : Une période de réchauffement qui caractérise la saison estivale et le début de la saison automnale. Il s'agit d'un réchauffement progressif qui atteint 2 maxima de 31°C l'un le en août et l'autre en septembre. Une seconde période de refroidissement de la masse d'eau qui s'étend de début octobre jusqu'à la fin du mois de décembre. Le début de cette période est caractérisé par une chute thermique puis une température de l'ordre de 23°C. Pendant la saison estivale la station S1, la plus côtière, a connu une influence de la température atmosphérique. L'évolution moyenne bimensuelle de la salinité a été caractérisée par un maximum en juin de l'ordre de 40.87. Les fortes salinités, enregistrées au niveau de la lagune, sont incontestablement liées aux aménagements en amont du lac Ichkeul qui ont engendré la transformation de la lagune en bassin de concentration où les apports en eau douce ne compensent pas la forte évaporation. De ce fait la salinité se trouve nettement plus élevée au niveau des stations S1, S2, S3 qu'au niveau de la station plus au large (S4). La variation de l'oxygène dissous moyen a évolué de manière progressive de 4.85 mg/L en juin à 8.87 mg/L en août avec une valeur ponctuelle assez élevée de l'ordre de 17.31 mg/L enregistrée en mi-septembre. En dépit de la faible variation du pH, les écarts types ont témoigné d'une certaine hétérogénéité spatiale. Les valeurs moyennes du pH ont oscillé entre 8 en juin et 8.27 en novembre. A l'échelle spatiale, c'est la station S2 qui a enregistré la valeur la plus faible du pH (7.9). La valeur moyenne maximale de turbidité (11.57 NTU) a été enregistrée en septembre alors que le minimum (1.40 NTU) a été observé en décembre. Au cours de la saison estivale la turbidité a oscillé entre 2.45 et 5.25 NTU, avec une homogénéité spatiale, ce qui traduit une turbidité relativement faible caractéristique de la saison estivale où l'action du vent est limitée. Concernant les fluctuations spatio–temporelles des densités cellulaires moyennes du phytoplancton total, on remarque l'existence de 2 pics principaux le premier au enregistré au début de septembre (412 257cel.l-1et le second à la fin d'octobre (461 728cel.l-1). Le peuplement phytoplanctonique au niveau de la lagune de Bizerte est composé pricipalement de 5 groupes à savoir les diatomées, les dinoflagellés, les chlorophycées, les euglénophycées et les cyanobactéries. Sur le plan taxonomique, on a pu identifier 163 taxa (104 diatomées et 53 dinoflagellés) parmi lesquels 23 sont susceptibles d'être nuisibles. L'un des taxa, doté d'un pouvoir toxique assez important à savoir *Alexandrium spp*, a atteint une densité de 63 764 cel.l^{-1}.

Abstract

The elemental (C, N, P, Si) composition of the suspended particulate matter is monitored monthly since June 2010 at two contrasted (coastal and offshore) stations of the eastern Gulf of Lion. Surprisingly, nutrient levels are similar at both stations even though detailed seasonal evolutions are different. Both environments have very low levels of phosphate and show recurrent seasonal depletion of this nutriment. Si/N nutrient ratios close to 1 do not reveal potential limitation of diatoms by silicic acid availability although very low levels can be reached in surface waters of the coastal station. The particulate organic matter composition is indicative of marine planktonic origin with C/N ratios close to Redfield and C/Chl a ratios < 50 on average.

Keywords: Phytoplankton, Systematics, Geochemical cycles, North-Western Mediterranean

Introduction

We present data for nutrients, particulate organic matter composition and phytoplankton evolution acquired in the framework of the MISTRALS program, the SPEciMed (Structures of Planktonic Ecosystems in the North-western Mediterranean) project since June 2010.

Methods

Particulate matter composition was analyzed on a CHN analyzer for N and C and by wet oxidation followed by chemical analyses of nitrate and phosphate for N and P (coherence of the two data sets was controlled via organic nitrogen measurements by both methods). Nutrients were analyzed by classical chemical analyses on autoanalyzer for nitrate, nitrite, phosphate and silicic acid. Chlorophyll was measured by a fluorometric method. Phytoplankton species identification, counting and biomass estimations were assessed from microscopical examinations.

Preliminary results

First results show successive periods of phosphate depletions at the two stations, indicative of P limitation during most of the seasonal cycle. Outside from these periods, potential limitation by N or Si (for diatoms) also occur (Fig. 1), as previously shown in this area by Leblanc et al. (2003). Diatoms are the dominant component of microphytplankton. When looking at the C to chlorophyll relationship, a residual concentration of 32 and 38 micrograms C per L respectively at the coastal and the offshore station, together with average C/N elemental ratios close to 6.3, is interpreted as reflecting the presence of a large heterotrophic component.

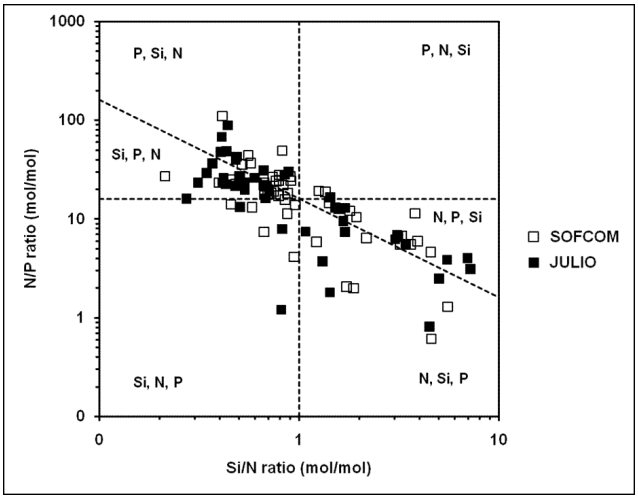

Fig. 1. Si:N:P molar ratio of all data collected at a coastal (SOFCOM) and an offshore (JULIO) stations east of the Gulf of Lion from June 2010 to December 2012. In each area, delimited by the Brzezinski (1985) ratio and by the Redfield et al. (1963) ratio (Si:N:P = 16:16:1), the potential limiting nutrients are reported in order of priority.

Abstract
A method to identify and reconstruct the zooplankton migration patterns based on the spectral analysis of time series of acoustic data is proposed. The method has been validated on long term time series of acoustic backscatter data collected by a 300 kHz ADCP unit in the Ligurian Sea.

Keywords: Zooplankton , Ligurian Sea, Vertical migration, Acoustics, Monitoring

Introduction
Zooplankton presents different migration behaviours according to the species and phase of life, among these, diurnal inverse and twilight migrations have been identified [1]. Acoustic profiling instrumentations provide a long-term and high temporal resolution monitoring, measuring backscatter due to the amount (biomass) of zooplankton, but do not provide detailed information about the species composition [2]. Spectral analysis methods can be used to characterize the vertical migration patterns and their time and space distribution, even in the absence of net sample collection. Here we present a method to identify and reconstruct the zooplankton migration pattern based on the spectral analysis of long term time series of acoustic backscatter from a 300 kHz ADCP unit.

Data and Methods
An upward-looking RDI Sentinel 300 kHz ADCP was operating in the Central Ligurian Sea (43°47.77' N; 9°02.85 E) from 13 September 2003 to 22 February 2006 for a total of 768 days. It monitored the upper thermocline from a depth of 90 m to the surface with 8 m vertical resolution and time step of 1 h during the first deployment, then increased to 30 minutes. After quality check, echo intensity data have been converted into backscattering strength (Sv) according to [3], for each depth cell along each beam and then averaged.

Results and Discussion
The analysis of data clearly shows a 24 h square-wave shape with higher values during night time and minima during day time, due to the main daily zooplankton migration. Minor peaks are also present. Vertical migration lasts one or two hours, then the organisms remain at the reached level for several hours (Fig.1 upper).

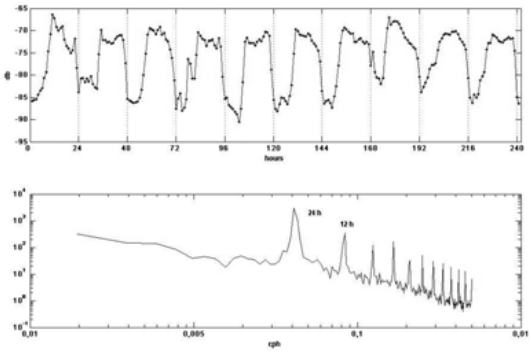

Fig. 1. Ten days sample of hourly backscattering strength data (upper panel) and its corresponding power spectrum (lower panel)

For each bin level, time frequency analysis was performed with a ten days moving window and 24 h time step. The spectra were then time and vertically averaged. The resulting spectrum is dominated by 24 h peak. A secondary peak is on 12 h and a series of peaks appears on the other sub harmonics (8h, 6h,...nh). The spectrum on a simulated 24 h square-wave signal revealed the presence of higher harmonics, but the 12 h secondary peak did not appear. Thus, only 24 h and 12 h periodicity can be assumed representative of vertical migration. To validate this assumption, a second simulation was performed on a signal composed by two square-waves, one having 24 h period and an amplitude of 20 and the other having 12 h period, amplitude 6 and 3 hours phase (Fig.2 upper).

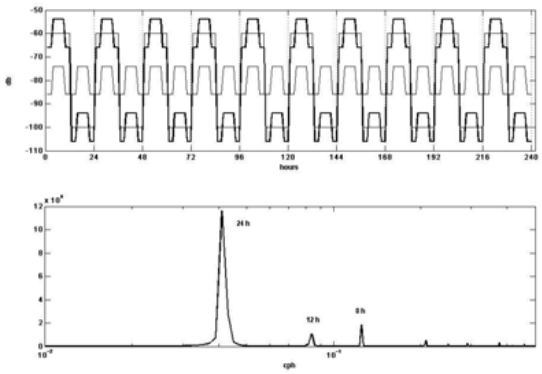

Fig. 2. Ten days of simulated square-wave hourly data (upper panel) and its corresponding power spectrum (lower panel)

The resulting power spectrum in Fig. 2 (lower panel) is consistent with the one obtained from the ten days sample reported in Fig. 1, leading to the identification of two main migration patterns (daily and twilight).
To investigate the occurrence of these patterns, the amplitude of the 24 h and 12 h harmonics were extracted from each spectrum obtained in the previous described time-frequency analysis. Higher amplitude values were observed in late autumn for both 24 h and 12 h signals.

Conclusions
Long term acoustic monitoring devices proved to be a powerful tool to support the study of zooplankton distribution and its variability on many different temporal scales that cannot be satisfactorily resolved by using the discrete net sampling. Two main migration patterns (daily and twilight) have been identified in the study area, characterised by higher amplitude values in late autumn.
The main advantage of the proposed methodology to process such kind of acoustic data is the opportunity to infer the zooplankton composition and its temporal variability through the identification of their migration patterns. At the same time, the presented approach allows to convert biological qualitative observations into a quantitative time series to define a metric for the comparison with ecological numerical models.

Abstract

Fish egg and larval assemblages of two ichthyoplankton surveys carried out in the N.W. Aegean Sea in June 2004 and 2005 were analysed in relation to topographic and oceanographic conditions. The nMDS analysis showed two main geographical groups of stations characterized by different environmental parameters (depth, temperature, salinity and chlorophyll-a) as well as different species composition.

Keywords: Ichthyoplankton, Bathymetry, Chlorophyll-A, Aegean Sea

Introduction Examining spatial and temporal patterns with respect to the distribution and abundance of ichthyoplankton in relation to oceanographic conditions may provide insight into the adaptation of spawning strategies to the prevailing physical and biological processes, as well as the effect of the variability in these processes on year-class strength [1].**Materials and Methods** A grid of 13 stations (Fig. 1) was sampled during two ichthyoplankton surveys in the Thermaikos, Toroneos and Siggitikos gulfs in June 2004 and 2005, using a 60-cm bongo net (0.250 & 0.500 mm nets) with oblique tows. In addition, environmental parameters (temperature, salinity and chlorophyll-a) were measured using a CTD. The eggs and larvae of the 250 mm net were sorted and identified into taxa (family, genus and species if possible) and their abundance expressed as individuals per 10 m^2 filtered water.

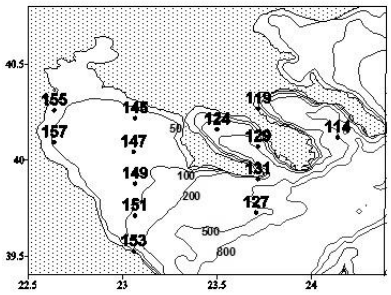

Fig. 1. Map of the study area.

nMDS plots of a Bray-Curtis similarity matrix were produced taking into account the most abundant taxa (taxa with only one occurrence at all 26 stations were excluded). Data were transformed [log(x+1)] to enhance the contribution considering only the most abundant taxa. **Results and Discussion** A total of 53 taxa belonging to 36 families were identified during the two surveys. In the 2004 survey, 47 taxa of fish larvae and 9 taxa of fish eggs were identified. The most abundant larvae were the small pelagic *E. encrasicolus* (28.9% of the total abundance) and *S. aurita* (24.3%),followed by the bathypelagic *C. maderensis* (14.6%). Regarding eggs, the most abundant *species* were *S. aurita* (38.6%)and *E. encrasicolus* (31%). In 2005, 43 taxa of fish larvae and 9 taxa of fish eggs were identified, with bathypelagic larvae *C. maderensis* (25.1%) and *H. benoiti* (15.9%) being the most abundant species, followed by the small pelagic *E. encrasicolus (14%)* and *S. aurita* (12%). Eggs were dominated by small pelagic *E. encrasicolus (37%)* and *S. aurita* (11%). Despite the fact that the main species synthesis is not generally altered between the two years, the total abundance measured in 2005 was almost half for the eggs and almost one third for the larvae compared to 2004. This reduction is caused mainly by small pelagic *E. encrasicolus* and *S. aurita* and less by bathypelagic *C. maderensis* and *H. benoiti*. It is possible that such a decrease is due to the reduction of chlorophyll–a (approximately 40%) in the Thermaikos gulf in 2005 compared to 2004, which is directly affected at the spawning behaviour of small pelagic species in this area. MDS analysis showed two well defined geographical groups of stations, those of Thermaikos and Toroneos + Siggitikos gulfs respectively. Environmental factors and major contributor species are plotted as correlated vectors. The Thermaikos group of stations is characterized by lower depths and higher values of salinity, temperature and chlorophyll-a in comparison with the Toroneos + Siggitikos group (Fig.2a). Regarding the major contributor species, the Toroneos + Siggitikos group is correlated mainly with larvae of bathypelagic species such as *C.maderensis, H.benoiti, M. punctatum, C. braueri* and two neritic species, namely, *C.chromis* and *C. julis* with large dispersal patterns. On the other hand, the Thermaikos group is correlated mainly with eggs and larvae of small and medium pelagic species such as *E.encrasicolus, S.aurita, S. japonicus T. mediterraneus* and larvae of demersal species such as Gobiidae, *S. hepatus, C. macrophalma* and *Callionymus spp* (Fig. 2b)

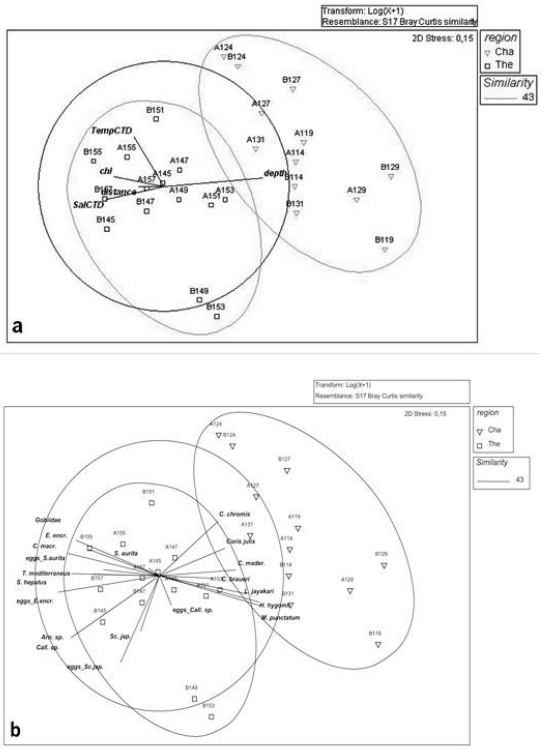

Fig. 2. Plot of the stations distributed using n-MDS analysis. Env. factors (a) and the major contributor species (b) are plotted as correlated vectors.

BIOCHEMICAL COMPOSITION OF VARIOUS TISSUES OF THE CLAM *DONAX TRUNCULUS* FROM THE GULF OF TUNIS DURING GAMETOGENESIS PERIOD

Dhouha Boussoufa [1], Nabila Ghazali [1] and M'Hamed El Cafsi [1]*
[1] Faculté des Sciences de Tunis, Tunisie - mhamed.elcafsi@gmail.com

Abstract
The total lipid, protein and glycogen contents of foot, mantle, visceral mass, gonado-digestive gland, gills and adductor muscles of *Donax trunculus* (Mollusca, bivalvia) from the Gulf of Tunis were analysed during gametogenesis period of the species. Results showed that protein was the major component in the mantle, gills, visceral mass and gonado-digestive gland followed by lipid and glycogen. However, glycogen concentrations in the adductor muscles were greater than those of proteins. The highest levels of lipids, proteins and glycogen were found respectively in gills, foot and adductor muscles which act as reserve organs during gametogenesis.

Keywords: Chemical analysis, Gulf of Tunis, Bivalves

Introduction
Donax trunculus (Linnaeus 1758) Mollusca: Bivalvia, is an Atlantic-Mediterranean warm-temperate species. It has a high commercial value, particularly on the Southern coast of Portugal and Spain [1]. In Tunisia, *D.trunculus* shows a large distribution with sufficient densities to consider its commercial exploitation. Generally, gametogenesis takes place during winter and spring and gamete emission starts in late spring and summer. In this work, a special attention will be given to study the composition in glycogen, proteins and total lipids of six organs (foot, gonado-digestive gland, visceral mass, mantle, gills and adductor muscles) of *Donax trunculus* during the gametogenesis period.

Materials and methods
Samples were taken from the sandy beach of the Gulf of Tunis (the North Eastern coast of Tunisia) in February 2007. Protein levels (mg/g wet weight) and glycogen content (mg/g wet weight) were determined by the methods of Lowry et al. [2] and Du Bois et al. [3] respectively. Total lipids from each sample were extracted with chloroform: methanol (2:1, v/v) [4, 5](mg/g wet weight). The biochemical data have been converted by application of the calorific factors; 5.7 cal/mg for protein, 9,5 cal/mg for lipid, and 4,2 cal/mg for glycogen [6], to give values for the energetic content of the tissues of *Donax trunculus.* Tukey Honest Significant Differences (HSD) multiple comparisons test was conducted to determine differences at a significance level of 5 % ($p<0.05$).

Results and discussion
This study showed that proteins were the major component in the whole individual (61.3 ± 14) and in the foot (81.9±12.5) followed by glycogen and lipids (Tab.1). In the mantle, gills, visceral mass and gonado-digestive gland, lipid levels were higher than those of glycogen. However, proteins still the major biochemical component. In the adductor muscles glycogen concentrations (87.1±10) were greater than those of proteins and lipids ($p<0.05$). The energetic contents of adductor muscles (1,01 Kcal/g wet weight), gonado-digestive gland (0,9 Kcal/g wet weight) and gills (0,84 Kcal/g wet weight) were significantly higher than those of Mantle (0,51 Kcal/g wet weight) and visceral mass (0,48 Kcal/g wet weight). During gametogenesis, the storage of fat, protein and glycogen in the gills, foot and adductor muscle respectively constitutes an energy reserve which will be exhausted during the maturation and release of gametes. In fact, the mobilization and utilization of energy substrates (mainly glycogen and lipids) is essential for the maintenance of metabolism, growth and reproduction of molluscs and other invertebrates [7].

Tab. 1. Biochemical composition of D.*trunculus* during gametogenesis period

	Protein	Glycogen	Total lipid	Calorific content
Whole individual	61.3±14	37.8±11.5	30.8±3	0.8
Gonado-digestive gland	70.3± 9	23.7±14	42.6±6.7	0.9
Foot	81.9±12.5	25.3±3.1	17.7± 4	0.74
Visceral mass	44.1±3	5.6±1.72	22±3	0.48

Abstract

In the present study the biomass and numerical contribution of micronekton organisms responsible of the night Scattering Layers of the upper water column were investigated. Relative abundance in weight and number of individuals of the different groups collected using midwater trawls performed concurrently with the detection of the scattering layers by echosounders are presented.

Keywords: Vertical migration, Open sea, Pelagic, North-Western Mediterranean

Vertical nyctimeral migrations of the different mesopelagic fishes, decapods and cephalopods of the shelf-break and slope zone off the Mallorca Island (western Mediterranean) were already analysed in previous documents (1, 2, 3), showing upper displacement of many species during the night and very low concentrations in the upper layers during day time. Here we investigate the overall relative contribution of the several micronekton groups to the Epipelagic and Deep Scattering layers (DSL) detected with acoustic methods. To this aim the night micronekton samples obtained on the slope region off Mallorca Island in two cruises (December 2009 and July 2010) were analysed. Samples were collected by means of modified Pelagic Trawls (PT, with mouth opening of 200 and 100 m2 for the December and July, respectively) with a cod-end of 10 mm. Complementary information on the presence of the smallest fishes was obtained with an Issaks-Kidd midwater trawl (IKMT of 3 m2) and mesh size of 3 mm to collect smaller specimens.

The nets were placed at the denser scatter layers detected during night time with the Simrad EK60 echosounder at 18, 38, 70, 120 and 200 kHz. Hauls were carried out in the epipelagic layers (hauls from 40 to 80 m) and at the 400 m deep scattering layer (DSL).

Night collections obtained with the PT showed that crustaceans and fish were the most diverse groups contributing to the scattering layers, with crustaceans represented by 14 decapods, 5 amphipods, 3 euphausiids and 1 lophogastrid, and fish represented by 13 species of myctophiforms, 7 stomiiforms and 1 aulopiform.

Most of the biomass in the upper 400 m was due to fishes and crustaceans in winter, and fishes and gelatinous plankton (shiphonophora and jellyfish) in summer (Fig. 1). Molluscs and tunicata accounted for less than 20% of the overall weight obtained in these midwater hauls. In winter all groups showed higher biomasses at the epipelagic levels than at the DSL, but in summer differences were less pronounced. Among fish, those that rendered the highest biomass were species of the family Myctophidae, and particularly Ceratoscopelus maderensis, being higher in summer. Most mesopelagic fishes reach the epipelagic layer during the nyctimeral migration, except for Argyropelecus hemigymnus and the Cyclothone braueri and C. pygmaea, which do not migrate to the near surface layers (these last two species were seldom caught with PT, but their vertical location could be established through the IKMT hauls). Therefore myctophiforms and stomiiforms contributed to the night DSL, and myctophiforms were the main fish responsible for the Epipelagic scattering layers. Crustaceans biomasses were mainly due to the eufausiids and decapod concentrations, with the euphausiid Meganyctiphanes norvegica being the main contributor (both at the epipelagic and DSL), although more abundant in the epipelagic layers. The decapods Sergestes arcticus and Pasiphaea multidentata were the next species of this group in terms of weight. Mollusca were represented by cephalopods, with the main biomass due to Todarodes sagittatus, and the pterpod Cymbulia peroni, whose collections during the winter period accounted for most of the mollusc biomass, particularly at the epipelagic layers. The tunicata Pyrosoma atlanticum showed higher concentrations in winter, and in both periods the highest concentrations were found in epipelagic samples. In summer, however, the contribution of Salpa maxima in the DSL made that higher tunicate biomasses appeared at the DSL. The patterns showed some differences when considering the number of organisms, mostly due to the number of euphausiids, which enhanced the importance of the crustacean group. This was particularly relevant in the winter period, when large concentrations of M. norvegica were collected, at the near surface and DSL, making this group the first in numerical abundance, nevertheless collections of Cyclothone braueri with the IKMT net indicated that these are numerically the most abundant mesopelagic fish in hauls performed with this net at the DSL (1). Although we are aware that the values presented here are strongly dependent on the type of nets and hauls performed and that they can not be taken as the actual biomasses, we think that the results presented offer a clear insight into the main groups responsible for the upper column scattering layers detected with echosounds at night. In summary, myctophid fishes, eufausiids and some invertebrates, particularly Cymbulia peroni and Pyrosoma atlanticum, in winter, and medusae in summer, are the most common and abundant (both in weight and number of individuals) organism encountered in the epipelagic and DSL acoustically detected. Interestingly, other very abundant mesopelagic fishes, such as Cyclothone spp and Argyropelecus hemigymnus, are also important contributors, but just to the DSL.

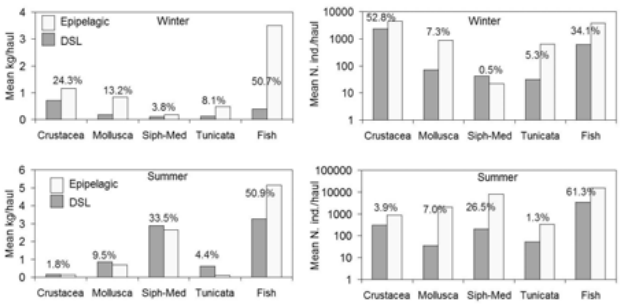

Fig. 1. Contribution of the different micronekton groups to the night Epipelagic and Deep Scattering Layers. Left graphs show mean weight per haul and right graphs indicate mean number of individuals per haul in logarithmic scale.

THE BIOMASS DISTRIBUTION OF ZOOPLANKTON IN CILICIAN BASIN: SPRING AND AUTUMN 2008

Tuba Terbiyik Kurt [1]*, Zahit Uysal [2], Yesim Ak-Örek [2] and Sevim Polat [1]

Abstract
The aim of the current study was to describe the biomass distribution of zooplankton in the Cilician Basin. A total of 20 stations were visited during March and September 2008 as a part of the SESAME (WP3) project. Zooplankton samples were taken from standart depth layers (i.e. 0–50, 50–100, and 100–200 m) using a WP-2 closing net (200 µm). In general, zooplankton biomass was more abundant in coastal areas and was concentrated in the upper layer (to a depth of 100 m) in sampling periods. A similar distribution in biomass was observed in previous studies conducted in other areas of the Eastern Mediterranean.

Keywords: North-Eastern Mediterranean, Zooplankton , Biomass

INTRODUCTION
The Cilician basin is one of the most important regions in the oligotrophic Eastern Mediterranean Sea due to its width and shallow continental shelf, including Mersin and Iskenderun Bays. River inputs, which seem to be the main fresh-water and nutrient sources for the entire Levantine Sea of the oligotrophic Eastern Mediterranean waters, and primary production levels were comparatively higher in the basin [1]. In this study, zooplankton biomass distribution was investigated in order to understand the status of secondary productivity in the Cilician basin.

MATERIAL AND METHODS
Two oceanographic cruises were conducted in the Cilician basin during March and September 2008. Zooplankton samples were taken vertically at 20 stations (Figure 1) from standard depth layers (i.e. 0–50, 50–100, and 100-200 m) using a WP2 closing net (200 µm). Zooplankton biomass was measured as dry weight (mg m^{-3}) according to [2].

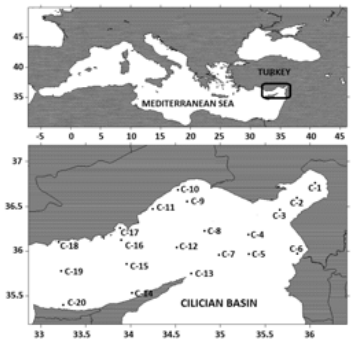

Fig. 1. Sampling stations

RESULTS
Mean zooplankton biomass in the integrated water column (0-200 m) was slightly more abundant in the spring (7.96 ± 6.3 mg m^{-3}) than the autumn (5.7 ± 3.1 mg m^{-3}) and fluctuated from 1.73 to 29.32 mg m^{-3} and from 1.68–to11.5 mg m^{-3}, respectively (Figure 2). The increase in zooplankton biomass was evident in the continental shelf region of the basin, including Mersin and Iskenderun Bays in the autumn. However, zooplankton biomass was higher only in the Iskenderun Bay and the northwestern part of the basin in the spring, excluding Mersin Bay. In the remaining areas of the Cilician Basin, zooplankton biomass showed a nearly homogeneous distribution thorughout the study period. Zooplankton biomass was concentrated in the upper 100 m layer of the study area, and a decrease in biomass values was observed with depth (Figure 2). The observed pattern of distribution in zooplankton has been reported previously in the Mediterranean Sea [3] and closely follows the presence of potential food materials, mainly phyto- and microzooplankton with populations primarily condensed in the upper layer. Furthermore, a previous study conducted in the Cilician Basin [4] illustrated the presence of two contrasting ecosystems: (1) the coastal ecosystem with high concentrations of bacteria, cyanobacteria, phytoplankton, and chlorophyll-*a*; and (2) an extreme oligotrophic offshore ecosystem that is almost denude of such food items. This productive structure in the coastal area could contribute to an increase in zooplankton biomass. We are currently assessing species identification assays and abundance measurements to complement the results already obtained. Furthermore, statistical analyses of ecological variables will be applied to understand the effects of environmental factors on zooplankton in the Cilician basin.

SPATIAL AND TEMPORAL VARIATION IN THE CONDITION FACTOR OF SMALL PELAGIC TELEOSTS IN THE GULF OF LIONS (NW MEDITERRANEAN)

D. Banaru [1]*, T. Ballerini [1], C. Michelot [1], B. Le Bourg [1] and C. Saraux [2]
[1] MIO (Mediteranean Institute of Oceanography), Aix-Marseille University, Campus de Luminy, case 901, 13288 Marseille, France - Daniela.Banaru@univ-amu.fr

Abstract
This paper presents data on the condition factor for sardines, anchovies and sprats in the Gulf of Lions in 2011. The condition factor was estimated through both morphometric measures and C/N ratios. Globally, sprats exhibited a better condition than sardines and anchovies. Sprats showed a better condition in the coastal area, while anchovies presented the best condition on the continental shelf and on the shelf break. The central area was the most favorable for sardines and the most unfavorable for sprats. All species presented a better condition in June than in July. These results suggest an important influence of habitat and feeding resources on small pelagic teleosts condition.

Keywords: Biometrics, Teleostei, Coastal waters, Gulf of Lyon, Trophic relations

Introduction
The study area is situated in the Gulf of Lions (42.4-43.5° N; 3.0-5.4° E) where sardines (European pilchard, *Sardina pilchardus* (Walbaum, 1792)) and anchovies (European anchovy, *Engraulis encrasicolus* (Linnaeus, 1758) were traditionally the most important species in terms of both biomass and fishery landings (about 50%) [1, 2]. However in recent years the biomass of sprats (European sprat, *Sprattus sprattus* (Linnaeus, 1758)), a non-commercial species, has strongly increased while the biomass of sardines and anchovies has decreased causing an important fishery crisis (Bigot J. L., pers. comm.). The three species potentially compete for food and habitat. Individual condition, a strong proxy for fitness and a good indicator of the population health are thought to be strongly related to their feeding environment. Here we tested the hypothesis that the condition factor is species-, space-, and time-dependent.

Materials and methods
A total of 1181 samples of sardines (334), anchovies (365) and sprats (482) varying in size between 3.5 and 16.5 cm, were collected in the Gulf of Lions, covering the western, central and eastern areas, and comprising the coastal area (0-50 m), the continental shelf (50-200 m) and the shelf break (>200 m) (Fig. 1). Sampling was carried out during the IFREMER scientific surveys MEDITS and PELMED in June and July 2011 onboard of the N/O Europe.

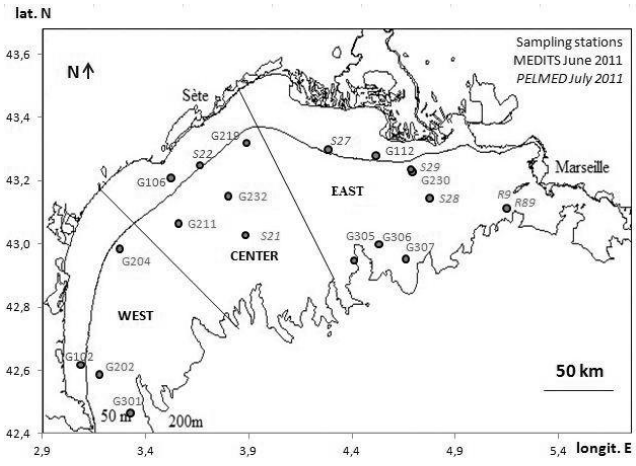

Fig. 1. Sampling stations in the Gulf of Lions

The condition factor was estimated by means of morphometric measures and C/N ratios (related to the lipid content). Individual body-length and wet-weight were used to calculate the relative condition factor Kn (see formula in [3]). Sub-samples of muscle (sardines 10-12 cm, n=31; anchovies 10-11 cm, n=44; sprats 9-10 cm, n=35) were analyzed for C/N ratios using continuous flow mass spectroscopy (CF-IRMS). Data were tested for normality and homogeneity of variance and the effects of different factors (species, area, depth, month) on Kn and C/N values were tested using parametric (Independent T-test (T) or one-way ANOVA (F)) and non-parametric (Mann-Whitney (U) or Kruskal-Wallis (H)) analyses of variance.

Results and discussion
C/N values indicated a better condition for sprats (4.33 ± 0.60) compared to sardines (3.22 ± 0.11) and anchovies (3.17 ± 0.06) (H = 72.2; p= 0.000). Sardines had the best condition in the central area according to C/N values. Contrarily, sprats showed here the lowest condition according to Kn values (Table 1). Anchovies' condition increased with depth, i.e. it was higher on the continental shelf and shelf break than in the coastal area. On the contrary, sprats appeared to be in better condition in the coastal area. All species exhibited a better condition in June than in July (Table 1). The condition factor varied according to the species considered and in space and time. These results might be explained by environmental conditions, potential differences in the composition of plankton assemblages, and individual diet. More data and further analyses are needed in order to better understand the effect of the habitat on these three species of small pelagic teleosts in the NW Mediterranean.

Abstract
Distribution, abundance and size structure of *Lampanyctus crocodilus* and *Lampanyctus pusillus* larvae were analysed. Data were collected during an ichthyoplankton cruise carried out during June 2006. Samples from a total of 39 stations were collected using a Bongo net with 60 cm diameter. Data of abundance were mapped and the results showed that these two lanternfish species were most abundant near Cape Cefalù, in the western part of the study area

Keywords: Ichthyoplankton, Larvae, Mapping, Tyrrhenian Sea

Introduction
Mesopelagic fish are abundant along the continental shelf in the Atlantic, Pacific, and Indian Oceans, but have lower abundance in Arctic and sub-Arctic waters. The dominance of mesopelagic fish larvae in oceanic ichthyoplankton has been described in various parts of the world's oceans ([1], [2], [3]). Most mesopelagic fish spend their larval stages in the productive epipelagic zone of the upper 200 m [3]. They move to the mesopelagic zone when they begin the transformation from the larval to the juvenile stage, when most species start diel vertical migration [4]. Patterns of larval fish distribution originate from complex spatial and temporal interrelationships that are strongly affected by the seasonality and duration of their meroplanktonic existence [5]. The aim of this study was to give some information on the abundance, distribution and size structure of these two lanternfish larvae collected in the southern Tyrrhenian Sea.

Material and methods
Samples were collected during an ichthyoplanktonic survey carried out in June 2006 in the southern Tyrrhenian sea (between Cape Cefalù and Rasocolmo) along the Sicilian coasts. A total of 39 stations were sampled. Oblique tows at constant speed of 2 knots were carried out using a Bongo 60, equipped with a 500 µm mesh size net and a flowmeter. Oblique hauls, from 200 m to the surface were carried out. Samples were fixed in 4% borax-buffered formalin immediately after capture and then analyzed in the laboratory. Larvae of lanternfish were identified according to morphological, morphometric and pigmentation features [6]; the number of larvae collected for each station was expressed as number of larvae/ 10 m^2 of sea surface [7].

Results and discussion
In the ichthyoplanktonic survey, 98 larvae of *L. crocodilus* and 79 larvae of *L. pusillus* were collected. The body is short and plump in *L. pusillus* and more elongate in *L. crocodilus*. In *L. pusillus* melanophores are present on the occipital region, snout, tip of the lower jaw, and posterior margin of the gill cover. There are 32-34 vertebrae in *L. pusillus* and 36-37 in *L. crocodilus* and the transformation stage occur at 12 mm SL in the first and at 19-22 mm SL in the second specimens. The size-frequency distribution of *L. pusillus* ranged from 2.0 to 6.3 mm and from 2.2 to 7.4 mm in *L. crocodilus*. Notochordal flexion is complete in larvae by 5 mm in *L. pusillus*. Distribution maps of the two lanternfish showed that *L. crocodilus* was most abundant in front of Cape Cefalù, in the western part of the study area, in offshore waters, while *L. pusillus* was abundant in front of Cape Cefalù and also in front of S. Agata di Militello (Fig.1,2).

Abstract

This paper presents the correlation of ichthyoplankton assemblages and environmental factors such as depth, temperature, salinity and chlorophyll-a in the North Aegean Sea during the summer of 2008. Depth and chlorophyll-a appeared to have played a significant role on the ichthyoplankton distribution.

Keywords: Ichthyoplankton, Chlorophyll-A, Temperature, Bathymetry, Aegean Sea

Introduction The importance of ichthyoplankton surveys is to detect the spawning areas and protect species in order to enhance their recruitment. North Aegean Sea is an important area for spawning species such as anchovy, round sardinella and Pacific mackerel [1]. The presence and the distribution of ichthyoplankton assemblages are influenced by abiotic environmental factors such as: temperature, salinity, currents, bathymetry and food availability [2, 3].

Materials and methods Ichthyoplankton samples were collected at 212 stations in the time period 12 June – 21 July 2008 in the North Aegean Sea by using WP2 sampler (mouth opening: 0.255 m , mesh-size: 0.200-mm). Environmental parameters (temperature and salinity) were recorded by using CTD sensor. Additionally, monthly satellite data of chlorophyll- a and SST were used for statistical analysis coming from NASA website. In order to define ichthyoplankton assemblages, a hierarchical cluster analysis of a Bray-Curtis similarity matrix calculated between species by ranked larval abundance was performed, considering only those species or groups that represented 1% of the total catch [4]. All data were transformed by log (x+1). Multivariate statistical analysis was performed using the Primer 6 and PERMANOVA+ software packages.

Results and discussion From the ichthyoplankton analysis a total of 35 taxa of eggs and fish larvae were identified which belong to 35 families. The most abundant larvae species were *Engraulis encrasicolus* (60% of the total abundance), *Sardinella aurita* (9%) *Gobiidae* (4%) *Serranus hepatus* (4%),*Trachurus mediterraneus* and *Scober japonicus* respectively (3%), *Chromis chromis* (2%) and *Hygophum hygomii* (2%). The most abundant eggs species were *Engraulis encrasicolus* (51%), *Sardinella aurita (6%*) and *Scomber japonicus (5%*). The Principal Coordinated Ordination (PCO) conducted on stations, which were labeled with their depth, allowed us to distinguish a gradient between the depths. Overlaid four environmental factors; temperature(CTD Sst,Sst, salinity (CTDSal), chlorophyll –a (Chla) and depth(Depth) with vectors it can be observed that the concentration of chlorophyll-a and the CTD SST is increased as the depth is decreased and the salinity is increased as the depth is increased (Fig.1). Plotting the most abundant species as correlated vectors on PCO plots two district groups were defined: the first group includes eggs and larvae of pelagic and neritic species such as *Engraulis encrasicolus (E.enc.,E.enc.eggs), Sardinella aurita (S.aur.), Scomber japonicas(S.jap), Gobiidae(Gob), Serranus hepatus (S.hep), Arnoglossus sp.(Arn), Callionymus sp.(Call),* and *Chromis chromis (C.chr)* and the second one larvae of meso-bathypelagic species like *Ceratoscopelus maderensis(C.mad), Hygophum hygomi(H.hyg), Myctophum punctatum(M.pun)* and *Maurolicus muelleri(M.muel)* (Fig.2). Combining the environmental factors with the species distribution, a significant effect of depth (P=0.001) and chlorophyll-a concentration (P=0.01) was observed by using Permanova test. Species belonging to the first group distributed to stations which are characterized with high concentration of chlorophyll-a and low depth in contrast to species belonging to bathypelagic group distributed to stations with greater depths with relatively low values of chlorophyll-a. Similar correlation of fish larvae assemblages with the environmental factors was observed in the same region [1, 3].

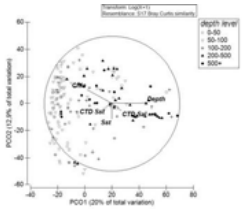

Fig. 1. PCO of stations distribution correlated with environmental factors.

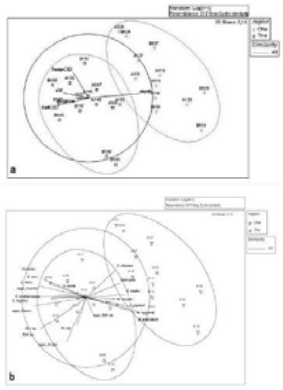

Fig. 2. PCO of stations distribution correlated with most abundant species

DETECTING HABITATS CONSIDERING THE MESOZOOPLANKTON SIZE STRUCTURE AND ENVIRONMENTAL CONDITIONS IN THE GULF OF LION, NW MEDITERRANEAN SEA.

Boris Espinasse [1]*, François Carlotti [1], Meng Zhou [2] and Jean-Luc Devenon [1]
[1] Mediterranean Institute of Oceanography - boris.espinasse@univ-amu.fr
[2] University of Massachussetts

Abstract
Environmental conditions and zooplankton size structure and abundance were investigated in the Gulf of Lion at two periods (May 2010 and January 2011). Several analytic tests were performed in order to define several ecoregions representing different habitats of plankton communities. Three main habitats were found: Coastal area, Rhône plume influence and continental shelf. The size structure of zooplankton community differ following areas and their environmental conditions. The slope of the Normalized Biomass Size Spectrum (NBSS) was weaker in stratified waters and sharper in coastal area meaning presence of more large size zooplankton organisms relatively to small organisms in the zone of Rhône plume influence.

Keywords: Zooplankton , Coastal systems, Biogeography, Analytical methods, Gulf of Lyon

Introduction
The gulf of Lion in northwestern Mediterranean Sea is characterized by a large continental shelf reaching up 40 miles width. Several hydroclimatic processes induce a complex hydrodynamics: several rivers, and especially the Rhône, flow into the gulf of Lion carrying on freshwater, land particles and nutrients; the Northern Current follows the continental slope southward and intrusions of the current inside the shelf occurs draining oligotrophic waters; the winds such Mistral and Tramontane, strong and frequent, create coastal upwellings and control the Rhône plume moving and dilution[1]. Such changing conditions create several habitats for plankton communities in the Gulf of Lion.

Samples strategy
During two cruises (26 April to 7 May 2010, 23 January to 4 February 2011), the whole French continental shelf of the Gulf of Lion was sampled to obtain an overview on the zooplankton community size structure and environmental condotions. 6 transects from the coast to the open ocean were conducted for a total of 135 stations. A laser optical plankton counter (LOPC) was used to estimate abundance, biovolume, and general characteristics of size spectra [2]. The vertical distribution of, the LOPC counts, the chla concentration and the hydrological parameters was investigated in order to highlight their interactions and the main structures.

Main results
Different patterns of particle distributions occur following the water column structure and the bathymetry. A Principal Components Analysis (PCA) was done on physicals and biological parameters to interpret the links between the different parameters. A clustering test allowed us to define 3 spatial areas corresponding potentially to different types of habitat (Fig. 1):
(1) the coastal area, (2) the Rhône plume and (3) the continental shelf area.

The zooplankton size distribution was investigated within the three areas using the normalized biomass size spectrum (NBSS)[3]. The coastal area was characterized by the steepest NBSS and highest chla concentrations, the upwelling and the formation of deep water participated to keep the water mixed. The Rhône plume showed the lowest NBSS slopes associated with strong water stratification. These waters were rich in nutrient promoted high chlorophyll a concentrations in the surface water layer and carried on the continental shelf a lot of organic matter. The continental shelf showed the lowest abundances and was hit by the Liguro-Provençal current depending on the season. The NBSS slopes were higher during winter, meaning the proportions of large organisms were more important during the post bloom period.

MESOZOOPLANKTON IN A STRATIFIED SEMI-ENCLOSED MARINE ENVIRONMENT (VELIKO JEZERO, SOUTH ADRIATIC SEA): ABUNDANCE, BIOMASS AND BIODIVERSITY PATTERNS

Marijana Miloslavic [1]*, Davor Lucic [1], Barbara Gangai [1] and Ivona Onofri [1]
[1] Institute for Marine and Coastal Research University of Dubrovnik - marijana.miloslavic@unidu.hr

Abstract
During a one year study, an analysis was made on the species composition, abundance and biomass distribution of mesozooplankton in the semi-enclosed marine lake Veliko Jezero, in relation to the main physical-chemical properties of the water column. Copepods were found to be the dominant group over the entire sampling period. The highest abundance and biomass were recorded during the summer, while the lowest values were related to the bottom hypoxia during autumn. Increased salinity in the surface during autumn suggests a stronger inflow of open Adriatic waters and coincides with increased biodiversity.

Keywords: Zooplankton , Copepoda, South Adriatic Sea

Introduction
Due to its restricted communication with the open sea, Veliko Jezero (VJ) provides a strong vertical gradient of habitat qualities for zooplankton with strong stratification during the summer, absence of upwelling events [1], relatively stable physical-chemical conditions in deep layers [2] and occasional hypoxia-anoxia in deep layers during stratified conditions [1]. Furthermore, since the whole north-western part of the island of Mljet, including VJ, has been protected as a national park for the past 50 years, limited human activities makes this area very suitable for ecological studies. Thus, isolated zooplankton populations in VJ provide a good opportunity for better understanding the factors that influence their spatial and temporal dynamics. The goal of this study was to examine how a strong vertical gradient in habitat qualities within an enclosed body of water can effect changes in mesozooplankton abundance, biomass and community structure.

Material and Methods
Sampling was carried out monthly from February 2008 to February 2009 at three stations in the VJ (Fig. 1): station A (46 m depth), station B (40 m depth), and station C (33 m depth). A total of 78 samples were collected by vertical hauls from two different depth layers (0-20 m and 20 m to the bottom) using a modified Nansen opening-closing net (125-µm mesh size, 54 cm opening). Hydrographic sampling (temperature, salinity and dissolved oxygen profiles) was performed with a SeaBird OC25 probe. Seawater samples (500 mL) for the measurement of chlorophyll *a* were collected with a Niskin bottle from depths of 0, 2, 20 and 30 m.

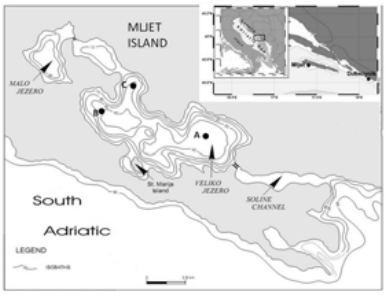

Fig. 1. Location of the sampling stations in the South Adriatic Sea

Results and Discussion
Since VJ is located in a protected national park where human activities are negligible, changes in zooplankton community structure might be related to natural environment variations and ecological interactions. Naturally restricted exchanges with adjacent waters through the Soline Channel (depth 2.5 m, width 10 m) hinder the outflow from deeper layers, which results in significant difference in the density of the surface and bottom layers. Therefore, the layer below 20 m depths was characterized with constantly low temperatures (<13°C), high salinity (>38,3) and Chl *a* concentration. Hypoxia (1 ml/l) was recorded during the autumn at stations A and B below 35 m depths. Increased salinity in the surface during the autumn suggests a stronger inflow of open Adriatic waters. The degree of isolation strongly influences the composition of the community. Therefore, zooplankton populations in the lake were characterized by high abundance and a low number of species compared to the neighbouring open Adriatic. A total of 58 mesozooplankton taxa were identified. Copepods accounted for between 19% and 62% of total mesozooplankton density with the most abundant cyclopoida-oithonids (*Oithona similis* and *O. nana*), and small calanoids *Paracalanus parvus* and *Acartia clausi*. *Paracalanus parvus*, *Centropages typicus*, *C. kröyeri*, *Isias clavipes*, *Oithona nana* and *Euterpina accutifrons* showed their higher preference for the surface layer (0-20 m), while *Calanus helgolandicus*, *Diaixis pygmaea*, *Mesaiokeras hurei* and *Oithona similis* inhabit layers below 20 m depth. Other zooplankton groups that have been recorded in significant numbers throughout the year are *Oikopleura dioica*, *Sagitta setosa*, *Limacina* spp., as well as Bivalvia larvae. A higher Shannon-Wiener biodiversity index was recorded in the upper layer (1.6) than in the bottom (1.3) with a maximum during the late autumn. A positive relationship between total abundance and temperature was recorded with a maximum (24670 ind./m^3) at station C in August in the 0-20 m layer. Average biomass values were higher in the bottom layer (17,4±10,6 mg/m^3) than in the surface (12,0±7,7 mg/m^3). Oxygen decrease at the bottom of stations A and B coincide with the annual minimum of abundance and total dry weight. On the contrary, at station C, where hypoxia was not recorded, a minimum of abundance and biomass was noted in February 2009. Biological forcing could also be an important driver of zooplankton community structure in VJ. Apart from food resources, predation is another biological force that affects zooplankton dynamics. Chaetognaths, with a dominance of *Sagitta setosa*, were present all year round with an average of 73 ind/m^3. Another important component of the VJ zooplankton is the jellyfish *Aurelia* sp. 5 [3], whose food items were copepodites and small adult copepods *Oithona nana* and *Paracalanus parvus*. Nevertheless, our analyses were based on the data available, indicating strong physical forcing as the primary influence on variation in zooplankton dynamics of VJ.

Abstract

The structure of plankton communities is observed on a monthly basis since May 2010 at four stations at the entrance and output of the Gulf of Lion. The first observations document the seasonal and annual variability of particulate matter stoichiometry (particulate organic carbon, nitrogen, and phosphorus, biogenic silica, lithogenic silica and aluminum), nutrients (nitrate, ammonium, phosphate and silicic acid) and taxonomic composition and carbon biomass partition of phytoplankton and zooplankton. Associated to these direct observations by chemical analyses and/or microscopy, vertical profiles of particle size spectra, made by combining LISST (Laser In Situ Transmissiometer Scaterrometer) and LOPC (Laser Optical Plankton Counter), reveal the small-scale vertical structures and the heterogeneity of the plankton vertical distributions.

Keywords: Plankton, Geochemical cycles, Monitoring, Instruments and techniques, North-Western Mediterranean

Introduction

The Gulf of Lion is a shelf ecosystem whose complex dynamic is influenced by the proximity to the Northern Mediterranean Current whose incursions occur in the eastern part, the freshwater inputs from the Rhône and the small coastal rivers of the western part, as well as a particular wind regime dominated by northerly (Mistral) and northwestern (Tramontane) winds. Up to now few studies have investigated the structure of plankton communities and the relationships with the biogeochemical cycles on a seasonal basis (e.g. Leblanc *et al.*, 2003, 2005 ; Gaudy & Champalbert, 1998). As part of the MISTRALS program, the SPEciMed (Structures of Planktonic Ecosystems in the North-western Mediterranean) project is a 4-year observation study of plankton communities including bacteria, phyto-, microzoo- and mesozooplankton and associated biogeochemical cycles of major elements (C, N, P, and Si).

Methods

Samples are collected on a monthly basis since May 2010 at 4 stations located in the eastern (in front of Marseille) and western (in front of Banyuls/mer) regions of the study area. Hydrological and biogeochemical parameters are sampled in the conventional manner since 2010 with a rosette equipped with a CTD, a fluorometer and a transmissometer. Pico- and nanoplankton are assessed by flow cytometry (bacteria, autotrophic picoplankton, nanoflagellates). Microzoo-and microphytoplankton are studied by microscopic analysis. Mesozooplankton is sampled by vertical hauls of WP2 net (200 microns mesh net) and identified by microscopy. The rosette is also equipped with a LISST and a LOPC allowing vertical continuous description of the size structure of particles in the range 2 microns–35 mm.

Preliminary results

The first results serve to document the structure of phytoplankton (dominated by the group of diatoms) and zooplankton (copepods are the main component of mesozooplankton) communities. These are closely related and exhibit a strong interannual variability (Figs. 1 and 2). Thus the success of the development of mesozooplankton appears to be directly related to the intensity of the phytoplankton bloom. Mesozooplankton peaks occur a few weeks after the phytoplankton bloom. However, the interannual variability of particulate organic matter concentrations is less than that of chlorophyll *a*, which suggests allochthonous inputs and redistribution within the ecosystem of the Gulf of Lion. The continuation of data acquisition will now focus on the search for species-specifi relationships between phytoplankton and zooplankton while LISST and LOPC data will be used to highlight the vertical structuring of populations in relation to the seasonal evolution of the surface mixture layer.

FLUCTUATIONS SPATIO-TEMPORELLES DES TINTINNIDES AU NIVEAU D'UN REJET D'UNE CENTRALE ELECTRIQUE A L'EST DE LA TUNISIE

Meher Bellakhal [1]* and Mouna Bellakhal Fartouna [1]
[1] Unité de recherche: Exploitation des Milieux Aquatiques. ISPA de Bizerte. BP15- Errimel- 7080- Tunisie - meher2976@yahoo.fr

Abstract
Le rejet d'une centrale électrique dans la baie de Sousse provoque une élévation de la température de l'eau qui a atteint 36°C durant la période d'étude. Cette élévation est susceptible de perturber la répartition spatio-temporelle du peuplement planctonique entre-autre les Tintinnides. En effet, ces derniers ont présenté les abondances relatives les plus importants (75.7%) et les densités les plus élevées (2248 cellules/L) au niveau des stations les plus proche du rejet.

Keywords: Thermal pollution, Zooplankton , Tunisian Plateau

Introduction
L'un des problèmes écologiques actuels majeurs est le réchauffement global. Du fait de son effet perturbateur sur les différents écosystèmes, plusieurs approches ont été élaborées pour mieux comprendre ses répercussions sur les écosystèmes aquatiques en particulier [1]. L'une de ces approches consiste à étudier l'impact des effluents d'eaux chaudes, éjectées dans les écosystèmes côtiers, par les centrales d'électricités sur les communautés benthiques et pélagiques [2]. Ces études ce sont particulièrement focalisées sur l'influence de ces effluents d'eau chaude sur le peuplement planctonique [3,4]. Les Tintinnides représentent une sous-classe des Ciliés qui sont des Protozoaires généralement de grande taille (50 à 300 µm). De structure complexe dont le corps présente des cils diversement répartis et un noyau complexe formé d'un micronucleus, assumant les fonctions sexuelles et un macronucléus à fonctions de nutrition. Les Tintinnides sont essentiellement marins et exclusivement pélagiques. Leur corps se termine par un pédoncule qui permet à l'organisme de se fixer à la paroi d'une loge qu'ils sécrètent nommée lorica [5]. Quelques espèces sont connues comme des indicateurs des caractéristiques hydrologiques bien définies du milieu [6]. D'autres auteurs ne considèrent pas les Tintinnides comme indicateurs écologiques des écosystèmes marins en raison de leur temps de génération assez rapide de l'ordre d'une journée et de leur adaptation assez importante aux variations des conditions physico-chimiques au sein des masses d'eau [7]. Nous avons pu identifier dans cette étude 14 espèces appartenant à 8 genres dont nous avons étudié les fluctuations spatio-temporelles et établi une classification selon leur abondance relative.

Matériel et méthodes
A proximité d'une centrale électrique, au niveau de la baie de Sousse située sur la côte Est de la Tunisie (35°50' N ; 10°50' W), 20 stations d'échantillonnage, réparties sur 5 radiales séparées l'une de l'autre de 2 Km et dont chacune comprend 3 stations selon les isobathes : 2 m, 5 m et 10 m, ont été prospectées saisonnièrement durant 2 ans. De plus, 2 stations ont été choisies à proximité des canaux d'amené d'eau de mer pour la centrale électrique, 2 autres au niveau du rejet et une station de référence en amont du site selon le sens du courant, ont été également choisies. Les échantillons ont été récoltés à l'aide d'un filet à plancton de 70 µm de mail et fixés au formol neutralisé au Borax (4 à 5%). L'identification et le dénombrement des Tintinnides ont été effectués selon la méthode d'Utermöhl [4].

Résultats et discussion
A l'échelle saisonnière, les Tintinnides ont nettement dominé le peuplement microzooplanctonique au printemps avec une abondance relative moyenne de 95.55% ce qui correspond à la densité moyenne maximale de l'ordre de 1166 cellules/L. En automne, les Tintinnides ont été les moins abondants en représentant uniquement 9.08% des microzooplanctons totaux. Alors qu'en hiver, la densité a été minimale avec une valeur moyenne de 40 cellules/L. A l'échelle spatiale, les Tintinnides ont été les plus abondants au niveau de la station 12 située sur la première radiale et à l'isobathe 2 m avec une abondance relative de 75,70% contre une valeur minimale de 8.06% au niveau de la station 45 située sur la 4ème radiale et à l'isobathe 5 m. En revanche les densités moyennes ont variées entre une valeur maximale de 2248 cellules/L au niveau de la station 22 et une valeur minimale de 91 cellules/L au niveau de la station 210. La classification des 14 taxa de Tintinnides identifiés, selon leurs abondances relatives, montre l'existence de 4 catégories : 4 espèces abondantes, 3 espèces peu abondantes, 4 espèces rares et 3 qui sont accidentelles (voir tableau ci-dessous).

Tab1- Classification des taxa de Tintinnides selon leur abondance relative

Espèces abondantes AR > 10%	**Espèces peu abondantes 1%< AR <10%**	**Espèces rares 0.1% < AR < 1%**	**Espèces accidentelles AR < 0.1%**

HYDROLOGICAL FIELDS AND WEATHER CONDITIONS DURING THE 2 CRUISES COSTEAU 4 AND 6 CONDUCTED IN THE GULF OF LION, NW MEDITERRANEAN SEA.

Boris Espinasse [1]*, Jean-Luc Devenon [1], Meng Zhou [2] and François Carlotti [1]
[1] Mediterranean Institute of Oceanography - boris.espinasse@univ-amu.fr
[2] University of Massachussetts

Abstract
The whole French continental shelf of the Gulf of Lion was sampled at two seasons (April 2010 and January 2011) to detail hydrological fields at the same time of other biological and biogeochemical parameters. Main physical structures were well identified such as the zone of Rhône plume influence, the position of the Northern Current and the areas where cooling processes took place. Impact of river discharges and strong winds on surface layer waters were also investigated.

Keywords: Hydrography, Circulation, River input, Gulf of Lyon

COSTEAU cruises #4 and 6 of the ANR-COSTAS Project have permitted to achieve a dataset of hydrological parameters at the scale of the Gulf of Lions (Western Mediterranean Sea) at the same time of other biological or biogeochemical ones (B. Espinasse, oral com, this issue). These cruises, each of a couple of week duration, took place two times to describe different seasonal contrasted situations, namely between April 25 to May 2nd; January 23 to 27, 2011. During the January cruise, strong northern winds blew regularly during this cruise and play an important role in mixing and cooling the water column.
The Rhône discharge up to 3410 m^3 s^{-1} two weeks before the cruise, largely over the annual average (1721 m^3 s^{-1}) but still under the usual flash flood value (5000 m^3 s^{-1}). In April, winds intensities were weakest and the directions changed frequently. Rhône discharge was slightly under annual average, down to 1343 m^3 s^{-1} during the two weeks preceding the cruise.
Few examples of results obtained by CTD casts during the COSTEAU 4 cruise are showed hereafter for the salinity field for surface values (Fig. 2), the whole domain being covered in less than one week, and for a vertical cross section acquired along an offshore transect linking CTD casts during a day (Fig. 1). On another hand, the weak values of currents (inertial oscillations) measured with a hull-mounted ADCP have permitted to look these spatial distributions as quasi-stationary ones and well representatives to a great extent of their mean value during the time scale under consideration. The Rhone Region of Freshwater Influence (ROFI)[1] , characterized by S < 37, can be seen to spread over a wide surface of the inner part of the Gulf, especially far away from the near mouth river plume zone (S < 33). Typical marine salinity values (S > 38) are more likely encountered in water masses advected by the North Current above the slope at the Eastern entrance of the gulf, and sometimes also deeper on the shelf. Though the formation of coastal dense waters was observed in the center part of the gulf during the COSTEAU 6 cruise (January 2011), no cascading phenomena were recorded along the continental slope, most probably because these waters were not sufficiently dense. All the results of the 2 COSTEAU cruises #4 and 6 are going to be compared with predictions of the hydrodynamical circulation model MARS3D (IFREMER)[2] to get a better and refined insight of spatial and temporal scales of variability.

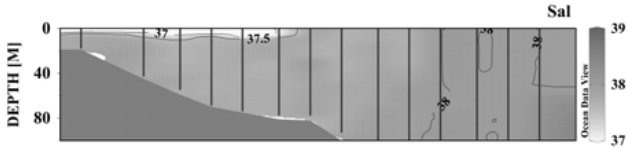

Fig. 1. Vertical distribution of the sea salinity along the transect D during COSTEAU 6 (January 23 to 27, 2011). Black vertical straights represent the CTD casts.

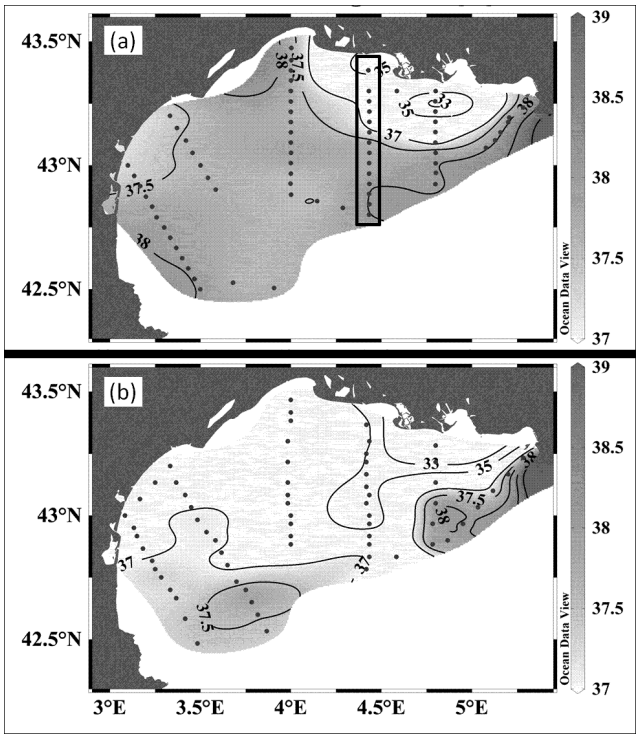

Fig. 2. Spatial distribution of the sea surface temperature during (a) COSTEAU 6 (January 23 to 27, 2011) and (b) COSTEAU 4 (April 27 to May 2nd, 2011). Stations are represented by the black dots and the transect D, detailed in Fig.2, is surrounded in black.

SALINITY AND TEMPERATURE TOLERANCE OF ALIEN COPEPODS *ACARTIA TONSA* AND *OITHONA DAVISAE* IN THE BLACK SEA

Elena Hubareva [1]* And Leonid Svetlichny [2]
[1] Institute Of Biology Of The Southern Seas - ehubareva@mail.ru
[2] Institute Of Biology Of The Southern Seas

Abstract
Effects of salinity and temperature on mortality, egg production and hatching success of *Acartia tonsa* and *Oithona davisae* were studied in the laboratory. The salinity tolerance ranges of these species living in the Black Sea at 18 psu amounted to 2 - 30 psu and 3 - 40 psu for *A. tonsa* and *O. davisae*, respectively. However, after long-term acclimation to 30 and 40 psu the salinity tolerance ranges can be extended up to 40 psu and 50 psu in *A. tonsa* and *O. davisae*, respectively. In the Black Sea *A. tonsa* survive cold period (6 - 8°C) in the stage of resting eggs whilst *O. davisae* overwinter as pre-fertilized females and begin to produce eggs after spring increase in temperature.

Keywords: Copepoda, Alien species, Salinity, Temperature, Black Sea

Introduction
Copepods *Acartia tonsa* and *Oithona davisae* (identified firstly as *O. brevicornis*) were transported to the Black Sea with ship ballast water and established there self-sustaining populations [1, 2, 3]. To colonize new habitat, both species originated from temperate eutrophic coastal areas of the Pacific and Atlantic Oceans had to acclimate to low temperature and salinity of the Black Sea. In order to evaluate the environmental adaptability of *A. tonsa* and *O. davisae*, we conducted laboratory studies of the effects of salinity and temperature on mortality, egg production and hatching success of these species in the Black Sea.

Material and methods
Females of *A. tonsa* and *O. davisae* collected in Sevastopol Bay at 18 psu during autumn-winter period were subjected at 20ºC to a gradual salinity decrease or increase at a rate of 2-3 psu per h during 6 -10 h. In *A. tonsa* and *O. davisae* during 5 d acclimated to 30 and 40 psu, respectively, salinity was gradually increased up to 70 psu. The salinity tolerance ranges in studied species were estimated taking into account the lethal salinity values affecting 50 % of the original numbers in 5 d. Cumulative effect of temperature and salinity on hatching success of subitaneous eggs in *A. tonsa* from autumn population was studied, and the effect of temperature on egg production in O. davisae during winter was investigated.

Results
The salinity tolerance ranges of *A. tonsa* and *O. davisae* living in the Black Sea at 18 psu amounted to 2 – 30 psu and 3 – 40 psu, respectively, after 5 d following gradual salinity changes during 6 - 10 h (Fig. 1 A).

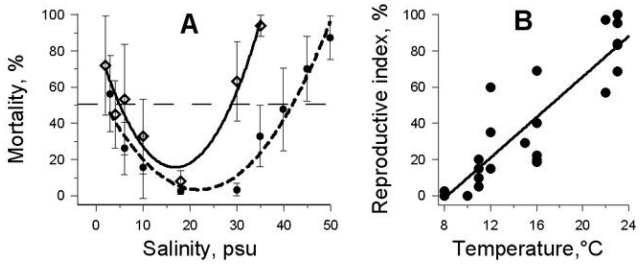

Fig. 1. Salinity tolerance ranges (A) of *Acartia tonsa* (solid line) and *Oithona davisae* (short-dashed line) collected from the Black Sea (18 psu). Salinity tolerance range in females of both species was between the two points denoting 50 % mortality (horizontal long-dashed line) after 5 d of exposure to a given salinity. Relationship between the reproductive index of *Oithona davisae* and experimental temperature (B). Values are means ± SD.

However, after 5 d of acclimation to 30 psu (for *A. tonsa*) and 40 psu(for *O. davisae*) salinity tolerance ranges can be extended up to 40 psu in *A. tonsa* and to 50 psu in *O. davisae*.

A decrease in temperature affected hatching success of *A. tonsa* in the same way as an increase in salinity did. At 18 psu hatching success of subitaneous eggs in *A. tonsa* constituting 78 % at 18 psu and 20°C reduced 2-fold at the same salinity and 8°C and decreased sharply to about 10 % at 40 psu and 8°C. Due to lack of low-temperature tolerance, *A. tonsa* in the Black Sea survive winter in the stage of resting eggs. Life cycle pattern of *O. davisae* in the Black Sea is similar to that in Fukuyarna Harbor (the Inland Sea of Japan) [4]. According to our data, during January to March 2013 the share of females changed from 75 to 100 % of *O. davisae* population. Females transferred from the Black Sea (8°C) to the laboratory after 2-3 d began to lay viable eggs. Reproductive index expressed as the share of egg-carrying females in *O. davisae* population increased in proportion to temperature reaching 100 % at 24°C (Fig. 1 B). This indicates that the maintenance of *O. davisae* population in the Black Sea during cold period depends on the ability of the pre-fertilized females to keep the sperm in a spermatheca until spring increase in temperature.

Abstract

Two seasonal cruises have been conducted in the Gulf of Lion between 2009 and 2011 to document the spatial distribution of plankton communities in spring and autumn. Results obtained for the phytoplankton compartment evidence the major impact of the Rhône River on the horizontal and vertical distributions of phytoplankton biomass. During spring (April-May) 2010, a phytoplankton bloom was observed starting in the plume of the river and then transported westward by the shelf currents. The coastal bloom was dominated by small diatoms: *Chaetoceros* spp. (subg. Hyalochaete) and *Nitzschia longissima*/*Cylindrotheca closterium* cluster. In the course of its westward displacement the bloom progressively sunk and maximum biomass was found close to the bottom in the western part of the study area.

Keywords: Phytoplankton, Diatoms, Blooms, North-Western Mediterranean

Introduction We present data for nutrients, chlorophyll biomass and phytoplankton size spectra and communities acquired in the framework of the COSTAS program in autumn 2009 and spring 2010.

Methods Nutrients were analyzed by classical chemical analyses on autoanalyzer for nitrate, nitrite, phosphate and silicic acid. Chlorophyll was measured by a fluorometric method. Phytoplankton species identification and counting were made by microscopical examinations. A Laser In Situ Scatterometer Transmissiometer (LISST) was also deployed during the autumn 2009 cruise.

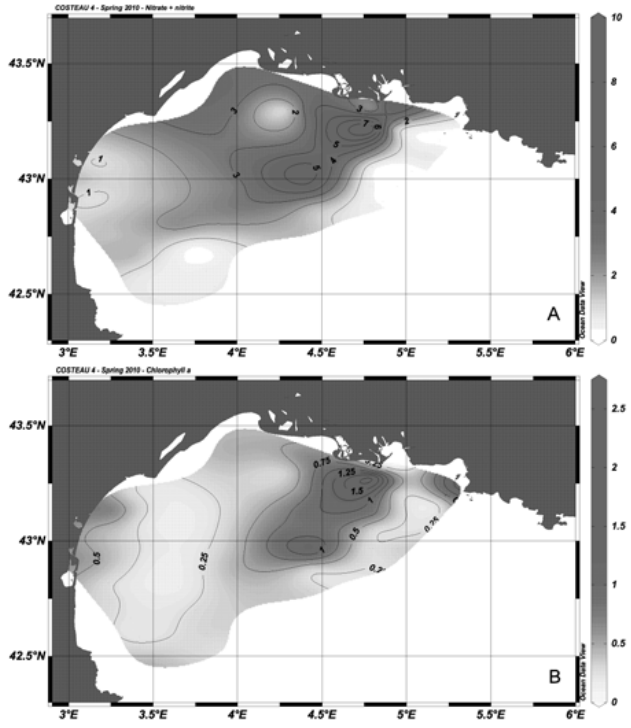

Fig. 1. Surface concentrations of A) nitrate + nitrite (µM) and B) chlorophyll a (µg/L) during the spring (March-April 2010) cruise COSTEAU 4 in the Gulf of Lion.

Preliminary results The distribution of nutrients and phytoplankton is strongly influenced by 1) river inputs (especially Rhone River) and 2) exchange with the North Mediterranean Current (Fig. 1 and 2).

Small delicate diatoms belonging to the genera *Chaetoceros* (subg Hyalochaete), *Nitzschia*, and *Pseudo-nitzschia*, dominated the microphytoplankton of the gulf of Lion. These species developed in spring in the vicinity of the Rhône River plume and were also abundant in autumn together with larger species of the genera *Rhizosolenia* and *Leptocylindrus*. The microphytoplankton community was quite similar to the one observed in 1999-2000 at an eastern offshore station by Leblanc et al. (2003). The eastward displacement of coastal waters was accompanied by the sinking of the spring bloom.

Occasional vertical deployments of a LISST in autumn also allowed observations of small-scale vertical structures inside and below a Deep Chlorophyll maximum (Fig.3).

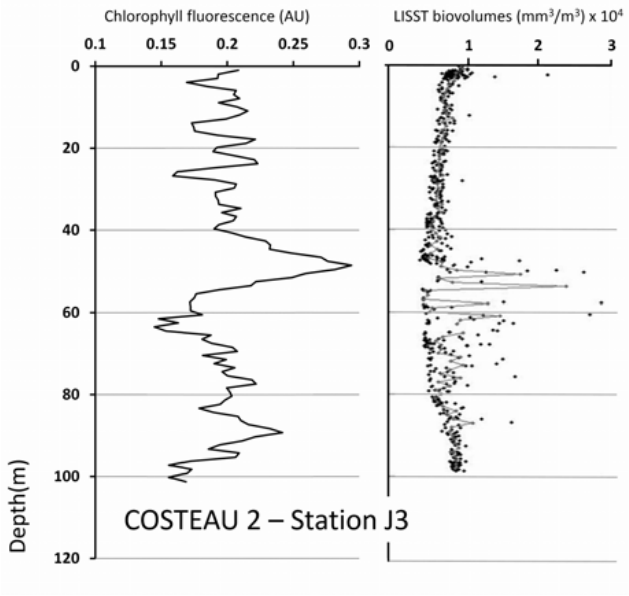

Fig. 2. Comparison of 1 m–averaged fluorescence profile (AU: arbitrary units) and particle biovolumes (1 m–averaged line and individual counts) inferred from LISST measurements at station J3, 43°N/4°36'E (October 2009) during the autumn cruise COSTEAU 2 in the Gulf of Lion.

Abstract
Mesozooplankton was studied during the period between 2008 and 2012 in coastal waters of the Iskenderun Bay in order to characterize temporal distribution of mesozooplankton and their relationship with some environmental factors. Interannual and seasonal fluctuations in abundance and biomass of mesozooplankton were observed in coastal waters of Iskenderun bay. Mesozooplankton peaks were found mainly in spring, summer and autumn, but these peak times were changed among the years. Mesozooplankton was well correlated with all measured environmental variables at 0.01 significant levels. As a result, trophic elements and abiotic factors of study area seems to be effected mesozooplankton standing stock

Keywords: Coastal waters, Zooplankton , Biomass, Iskenderun Bay

Introduction
The coast of marine environment areas are sensitive and variable because of being affected from both variations in terrestrial input and open sea waters. Living organisms, such as zooplankton, are mostly affected these variability. There are several zooplankton studies concerning the distribution of zooplankton groups, abundance and biomass in southern coastal area of the Turkey [1, 2]. However, there aren't any information about interannual variation of mesozooplankton. The aim of this study is to increase our knowledge about seasonal and interannual distribution of zooplankton biomass and abundance as well as impact of some environmental parameters on zooplankton distribution.

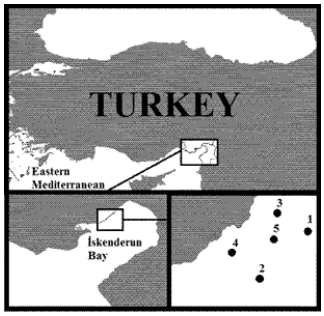

Fig. 1. Study area

Material and Methods
Iskenderun Bay is located in the Eastern Mediterranean. The Bay is approximately 65 km long and 35 km wide, giving surface water body area of a 2275 km (Figure 1). It is a shallow coastal area averaging 100 m maximum depth. Samplings were performed at five stations in the western coastal waters of Iskenderun Bay between 2008 and 2012. Zooplankton was sampled vertically during April, July, October and December of each year. Two samples was towed using WP-2 net (200 μm) at each station for abundance and biomass measurements. Biomass was measured as dry weight and determinated according to [3]. Temperature and salinity were measured using YSI 650 CTD probe at the surface and depths of 5m., 10 m. and 15 m. Chlorophyll-a and phytoplankton abundance were obtained from water samples taken simultaneously at the same depths using a Niskin water sampler. The spearman rank correlation was applied to estimate relationship between environmental factors and mesozooplankton amount by using SPSS V17 software.**Results and Discussion**
Interannual and seasonal fluctuations in mesozooplankton abundance and biomass were observed in the study area (Figure 2). Mesozooplankton abundance varied from 582 ind m^{-3} (spring, 2012) to 10892 ind m^{-3} (spring, 2011), while biomass varied between 2.7 mg m^{-3} (spring, 2012) and 31.38 mg m^{-3} (autumn, 2008). Mesozooplankton peaks were observed mainly in spring, summer and autumn, but these peak times were changed in the years. Spring and autumn mesozooplankton peaks were observed in first two years, whereas spring and summer peaks were observed following two years. In last year, summer and autumn peaks were found. The present study provided results on seasonal variation of zooplankton abundance, biomass and size structure within five-year period in Iskenderun Bay, about which we had limited information. Although five-year study is inadequate to explain interannual variations of zooplankton, it can help to determine the effect of environmental factors varied among years on zooplankton. Mesozooplankton was well correlated with all measured environmental variables at 0.01 significant level. Positive correlation was observed phytoplankton abundance with both biomass and abundance of mesozooplankton. Mesozooplankton abundance was positively correlated with temperature and negatively correlated with salinity, while positive correlation was found between mesozooplankton biomass and chloropyll-a. As a conclusion, it seems that the trophic elements and abiotic conditions was the main factor affecting the mesozooplankton standing stock. Additionally, predation and competitation by planktivorous fishes could be effected structuring the zooplankton community [4]. However, since the effect of fish predation was not studied in this study, it would be inconvenient to comment on the subject.

ZOOPLANKTON COMMUNITY STRUCTURE IN THE GULF OF BANDIRMA (MARMARA SEA): 2006-2008

Benin Toklu Aliçli [1]*, Neslihan Balkis [1] and Muharrem Balci [2]
[1] Istanbul University, Faculty of Science Department of Biology - benin@istanbul.edu.tr
[2] Istanbul University, Institute of Science

Abstract
Zooplankton composition and some environmental variables were investigated seasonally between November 2006- August 2008 in Gulf of Bandirma, Marmara Sea. During the study, 9 Copepoda, 3 Cladocera, 1 species from phylum Cnidaria , 1 species from phylum Ctenophora; 2 holoplankton groups and 8 meroplankton groups were recorded . *Acartia clausi*, which is pollution indicator was dominat species in May 2008.

Keywords: Zooplankton , Marmara Sea

The Marmara Sea has to distinctive water masses that flow in different directions between Mediterranean Sea and Black Sea through Bosphorus and Dardanelles [1, 2, 3]. The Gulf of Bandirma is located in the southern Marmara Sea, Turkey. The Gulf of Bandirma is effected by industrial pollution and anthropogenic activity with high population density. Material was collected seasonally at 3 stations November 2006-August 2008 in Gulf of Bandirma using WP2 plankton net. All zooplankton samples were preserved in 4% buffered formaldehyde. In
additionally some abiotic and biotic parameters was measured at study area.

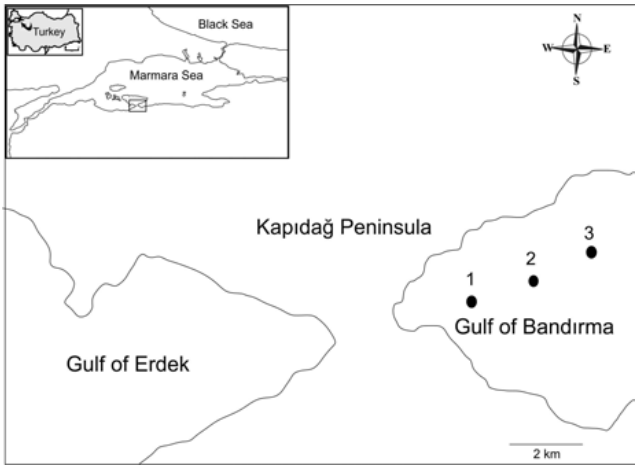

Fig. 1.
Sampling stations in the Gulf of Bandirma

Temperature was chanced between 6.5 °C and 26 °C, salinity 21.4 ppt and 38.5 ppt and also dissolved oxygen value 3.5mg L^{-1}-15.62 mg L^{-1} in the Gulf of Bandirma. Chlorophyll-a ranged between 0.21 µg L^{-1} and 14.79 µg L^{-1} [4]. During the study, 9 Copepoda, 3 Cladocera, 1 species from phylum Cnidaria (*Liriope tetraphylla*), 1 species from phylum Ctenophora (*Pleurobrachia pileus)*; 2 holoplankton groups (Apendicularia, Chaetognatha) and 8 meroplankton groups (Decapoda larvae, Bivalvia larvae, Gastropoda larvae, Polychaeta larvae Echinodermata larvae, Cirripedia larva, Fish eggs and larvae) recorded in Gulf of Bandirma. *Acartia clausi* and *Paracalanus parvus* were the dominant species in the Gulf. *Acartia clausi*, which is pollution indicator was dominat species (1660 ind/m^3) in May 2008. Zooplankton can reflect changes in biotic and abiotic factors of the environment. Indeed, the important environmental problem to be as mucilage formation was observed in 2008 [5]. As a result of excess nutrient loading into coastal areas can cause marine eutrophication and mucilage formation. Cladoceran, *Penilia avirostris* was dominant in August 2008. Indeed, the recent study support the result of the present study [6].

Tab. 1.
Correlation results measured among abiotic and biotic paremeters
(Temp: Temperature; DO: Dissolved oxygen; Chl-a: Chlorophyll-a; TZ: Total zooplankton; ** p<0.01, * p<0.05)

In the the Gulf of Bandirma, salinity has higher negative correlation with temperature (p<0.01) and chlorophyll-a (p<0.05). Also, there are strong positive correlation of total zooplankton with temperature and salinity (p<0.01). The main environmental gradient was generated by water temperature and salinity. On the other hand, total zooplankton abundance was negatively correlated with DO and chlorophyll-a (p<0.01) in the Gulf of Bandirma due to the grazing activity of its on primary producers.

COMITÉ 6

Ecosystèmes côtiers

Président : Enric Sala

Rapports des modérateurs

Advances in ecosystem-based fishery

Nadira Ben Chikh, Algérie

Résumé

La session s?est très bien déroulée. Le débat, au-delà de quelques questions pointues concernant les méthodes utilisées par certains des auteurs, a porté sur une question plus globale: le fait que la plupart des informations concernant la pêche et l?aménagement des écosystèmes sont fragmentées car les études demeurent spécifiques à une région bien précise de la Méditerranée. Une campagne de recherche englobant des informations sur l'ensemble du Bassin méditerranéen est donc recommandée.

Aquaculture impacts on ecosystems

Tanya Tsagaraki, Hellenic Center for Marine Research, Greece

Résumé

During this session a broad range of subjects was covered regarding aquaculture impacts on ecosystems. Topics covered included cultured species health issues, effects of new technologies on cultured species and water bodies, transfer to higher trophic levels and changes in water column chemical and biological characteristics. The attraction of wild fish to farm cages was also discussed along with the ecological effects on an ecosystem level. Although the presentations were not many in number, many interesting topics were brought up and presented during the session.

The discussion that followed the presentations revolved around technical issues regarding sampling approaches and results and, more importantly on the future prospects and issues faced in the field of aquaculture-environment interactions. It was apparent that the development and expansion of aquaculture raises new questions and prospects for future work which the scientific community needs to anticipate and address. The topics covered were diverse and covered issues that have to be considered towards implementing an ecosystem approach to aquaculture.

Biogeographic patterns

Sakina-Dorothée Ayata, LOV, France

Résumé

The session started with a general presentation of the biogeographic patterns of the Mediterranean Sea that could be divided into eight ecoregions following Spalding (2007). The contrasted environmental conditions of the Mediterranean Sea could also allow its division into a dozen of biogeochemical regions, and so we asked how related to these biogeochemical regions were the biogeographic patterns. We then introduced the different presentations by underlining the various methodologies that will be used, the different organisms that will be studied, and the different spatial scales that will be considered.

Following the 3-min communications, a mini-debate started with questions addressed to the different speakers. The important role of the resting stages of planktonic organisms was underlined in the high inter-annual variability of planktonic communities. The mesh size of the plankton nets used during sampling was mentioned. Questions also dealt with the connectivity patterns between the western and eastern basins, the role of the Sicilian strait as an area where ecological niches were overlapping, and as a genetic break identified a little further East than the strait. The last interventions mentioned the few number of specialists of taxonomic identification of copepods in the Med Sea and the different biases that may arise from sampling planktonic organisms.

Biogeographic trends

Sakina-Dorothée Ayata, LOV, France

Résumé

The session started with a brief introduction on the biogeography Mediterranean Sea and the spatial and temporal trends of this biogeography, such as the replacement of certain species by others (extinction, invasion). Three communications followed, presented in a clear and didactic manner. Thereafter the questions mostly addressed specific points, such as the correspondance between the observed abundances' patterns and the hydrodynamical patterns, or the high inter-annual variability of the stocks.

Coastal fisheries

Celia Vassilopoulou, HCMR, Agios Kosmas, Helliniko, Greece

Résumé

Most presentations addressed different issues linked with small scale fisheries, while there were also a number of works on trawl fisheries operating in relatively shallow waters. More specifically, four presentations dealt with trawl fisheries, discussing the effects on habitats and species (Muntadas), trawl discards (Yemisken), as well as the composition of catches in the Black Sea (Yildiz), and in the Levantine Basin, although the latter presentation did not refer to coastal grounds. Five presentations focused on issues related to small scale fisheries; using pingers to reduce by-catch of cetaceans (Ayadi), assessing landings over different habitat types (Seary), studying beach seine catches (Uzer), and addressing the need to collaborate with fishers for more effective management (Meli, Vassilopoulou). One further presentation discussed the capacity of purse seines, while another concerned targeted efforts for restocking caramote prawns.

In general, a high diversity of topics was covered, and an interesting discussion took place following the presentations which highlighted the need to consider the key factors/drivers of each fishery in the specific areas to achieve sustainable management of the resources.

Conservation successes, failures

Sylvaine Giakoumi, Greece

Résumé

During this session a number of conservation issues were presented, mainly exploring the impacts of anthropogenic activities on biodiversity. The examples varied from multiple to single species and threats, assessed stressors? impacts, potentials for recovery and suggested plans for conservation. Further, an intersting example of collaboration between Mediterranean countries exchanging expertise and technology through projects was presented.

Successes and failures of Mediterranean Marine Protected Areas (MPAs) was the main discussion topic during the general debate. Examples of successful MPAs were given, highlighting the successful engagement of stakeholders or ?shareholders?. On the other hand, the lack of enforcement was pointed out as the major failure of current MPAs. In order to achieve the 10% protection target expected by CBD - the Convention on Biological Diversity- there is an urgent need to strengthen enforcement in current MPAs, while expanding present / or creating new MPAs thru systematic approaches that explicitly account for socio-economic factors.

The cost of conservation management was also discussed. The success story of Medes MPA indicates that in the long run, an MPA can be a source of profit and significantly outbalance initial costs. Private sector investments could also play an important role in the creation of new MPAs, but in those cases the engagement of local shareholders should always be secured. Cultural differences throughout the heterogeneous Mediterranean basin prevent the adoption of a single model for the development and management of MPAs. Nevertheless, the fact that conservation can be profitable and that an MPA may be a self-sustainable venture is a message that should be dispatched to shareholders and decision-makers, particularly important in an era of economic recession.

Economic dimension of coastal systems

Pollution and environmental impacts

Vesna Milun, Croatia

Résumé

The presentations included the impact of a power plant on macro-zooplancton abundance as the result of sea temperature elevation (M. Bellakhal). Offshore gas platforms and their biological impacts were further presented (A. Gomeiro) in detail. Another communication focused on the possible influence on seawater quality of recent ship wreck (G. Romanelli). Toxic jellyfish blooms pointed out a problem of great concern in relation to human activities and alien species (B. Galil).

The discussion from the audience was mainly directed to the first theme mentioned.

Pollution hotspots, large cities

Bruno Andral, France

Résumé

Mediterranean cities represent complex systems and hot spots that require special attention. About 120 large cities are located along the Mediterranean coast, about 50% with over 100,000 inhabitants have no wastewater treatment plant. 14 major cities exceeding one million inhabitants including

Due to the fast growing populations of these coastal cities particularly in the southern and eastern areas, large quantities of biological (i.e. viruses, bacteria) and chemical contaminants are released into the sea, through domestic and industrial waste discharges (from, e.g., incinerators, landfills, waste water treatment plants, sewers), the existence of one or more rivers crossing the city, harbour activities, urban runoff (episodic events), coastal structures (e.g., groins and beaches), and desalinisation plants and the release associated to the rainstorms that wash the soil rapidly.

When they host a major harbour, they also provide a main vector for ?biological contamination? like alien species in the waters ballast. Some important sources, as submarine groundwater discharges, atmospheric input are still poorly understood. Other activities related to cities include: fisheries, structures in the open sea (which entail changes in water circulation), off-shore natural resources (e.g., oil, gas, sand, and gravel) extraction, spill accidents (oil and Hazardous and Noxious Substances, HNS), ship-based pollution, etc.

The growth of urban settlements is difficult to stop. Often, Mediterranean cities are trapped between mountains and the sea. Consequently, they tend to expand along the coastline and towards the sea, reclaiming wetlands and the often narrow, shallow marine areas. This inevitably affects the distribution of sediments and coastal ecosystems.

Many of the marine problems related to big cities stem from a lack of adequate knowledge regarding natural fluxes of, and human intervention on waters and sediments, major inputs of material and energy as well as marine ecosystem functioning. A number of recent initiatives, e.g., ICZM protocol, MSFD, and H2020, may help in formulating efficient policies to address these problems. The present document attempts to contribute to the fulfilment of these efforts.

Most of the responses until now are based on regulations and ad-hoc management which are poorly linked to long-term planning and monitoring of the effectiveness of the measures proposed and/or applied. Part of the failure is due to the minimum involvement of various actors, lack of coordination, and low awareness of the general public.

The 13 session presentations were very diverse in their topics (contaminants inputs in the field and modeling their fate in the marine environment and the trophic network, chemical contamination of sediments and biota, modeling discharges of bacteria, effects of water discharges from different processes, methods of détection and analysis) but each emphasized the need to consider the large cities as unique systems which encompass the marine and land domains, together with the human activities carried out therein. Yet, the impact of coastal metropolises on the environment is still not fully assessed and understood, and it is important to increase the knowledge to work in close partnership with relevant, concerned actors of civil society and other key stakeholders to therefore contribute to a new governance model.

Remote sensing

Patrick Bonhomme, AMU, France

Résumé

Remote sensing is the science of gathering information at a distance. The technology provides a descriptive, analytical way to identify geographic features. This includes (i) aerial photographs, (ii) satellite imagery, (iii) acoustic data and (iv) radar imagery. Remote sensing technologies are used to get data sets for a large area in a short amount of time. They are usually the most cost-effective means of getting information for areas that are inaccessible, far away, difficult to traverse but also for areas too large to effectively manage or assess with traditional surveying methods. The use of remotely sensed data is increasing nowadays due to (i) the emergence of commercial remote sensing satellites, (ii) the recent advancements in geographic information systems (GIS) and (iii) the image processing capabilities.

In this session a large variety of applications were presented like the development of a web interface to get real-time sea surface currents in the Malta Channel, the use of side-scan sonar to map habitat or cultural marine heritage, the analysis of the range of the fluctuations of chlorophyll-a concentrations induced by the passage of cyclones, a Posidonia oceanica distribution model based on ecological models, and the assessment of anchoring pressure on Posidonia meadows based upon the development of an automatic high frequency digital photography device. In the end, only three questions were asked to the speakers. The session ended 10 minutes early.

A STANDARDIZED MODEL TO INVESTIGATE THE EFFECTS OF FISHERIES IN THE MEDITERRANEAN SEA: THE CASE OF THE GULF OF LION

Daniela Banaru [1], Tosca Ballerini [1]* and Capucine Mellon-Duval [2]
[1] MIO (Mediteranean Institute of Oceanography), Aix-Marseille University, Campus de Luminy, case 901, 13288 Marseille, France - tosca.ballerini@univ-amu.fr
[2] IFREMER, UMR 212 EME (Ecosystèmes Marins Exploités), Av. Jean Monnet, 34203 Sète, France

Abstract
This paper presents the structure and the particularities of a standardized Mediterranean food web model applied to the Gulf of Lion shelf to investigate the effects of fisheries. This work in developped in the framework of EU-FP7 research program PERSEUS.

Keywords: Gulf of Lyon, Coastal systems, Food webs, Models, Fisheries

Introduction
The Gulf of Lion (GOL) (42°26.3′N, 3°9.9′E; 43°12.6′N, 5°27.5′E) is one of the most productive areas in the NW Mediterranean Sea. Historically, this region has been important for fisheries, with about 90% of the Mediterranean French landings coming from here.
An initial ECOPATH model [1] for the entire GOL region (between 0 and 2500 m, corresponding to 20 400 km^2) was developed in order to describe the food web structure and the fishing impacts on this marine ecosystem [2].
Here, the initial model for the whole GOL region was reduced to comprise the continental shelf only (between 20 and 200 m, 11 000 km^2) where the majority of fishing occurs (between 85% and 100% of total landings according to the fishing gears) and the trophic groups were modified to be consistent with the structure of a standard model for exploited coastal ecosystems in the Mediterranean Sea.

Materials and methods
The ECOPATH "GOL-shelf" model was parameterized for the period 2000-2009. Biomass data come from IFREMER scientific surveys MEDITS and PELMED onboard of the R/V Europe while landings data were taken from the Fisheries Information System, IFREMER. The model comprises 36 trophic groups (2 primary producers, 1 detritus, 1 discards, 11 invertebrate groups, 12 fish, 1 seabird, 1 marine mammal and 7 fishing gears) and it is implemented in both wet-weight and phosphorous.

Results and discussions
Ecosystem groups, fishing gears and main interactions in the "GOL-shelf" model are shown in Figure 1. Trophic levels ranged between 1 for primary producers and 4.8 for marine mammals.
The trophic level of fisheries ranged between 2.6 (various gears on small boats) and 4.1 (purse seine on 24-40 m boats). Sensitivity analyses showed a large negative impact of large trawls (24-40 m) on all food web groups, while the small purse-seine (12-24 m) had the lowest impact.
The main differences between the initial GOL model [1] and the standardized "GOL-shelf" model occurred in terms of biomass and flows.
The "GOL-shelf" model will be used for intercomparisons with similarly structured ECOPATH models for other marine ecosystems in the Mediterranean Sea [3, 4] in the framework of the EU-FP7 research program PERSEUS. Better understanding of the structure and functioning of exploited marine coastal ecosystems is essential for an ecosystem-based approach of fisheries management.

EVALUATION DE LA PRODUCTION HALIEUTIQUE DANS LE SECTEUR DE LA PÊCHE D'ANNABA, EST ALGÉRIEN.

A. Diaf [1]*, N. Benchikh [1], F. Z. Bouhali [1], S. Ladaimia [1] and A. B. Djebar [1]
[1] Laboratoire d'écologie des milieux marins et littoraux, Université Badji Mokhtar Annaba, Algérie - rym_dz23@yahoo.fr

Abstract
La production halieutique de la décennie (2001-2011) dans le secteur d'Annaba est estimée en relevant une période d'accroissement continu de 2001 à 2004 suivie d'une baisse remarquable en 2005 pour aboutir à une amplification du rendement de la pêche entre 2006 et 2011 coïncident avec le développement du secteur. La pêche présente une dominance des petits pélagiques dans les débarquements des 2 ports de pêche d'Annaba et de Chétaibi. La flottille de pêche relevant d'Annaba affiche une progression quantitative et de qualitative, en passant de 257 à 504 navires. La pêche dans le secteur d'Annaba est une activité ancestrale, sa durabilité dépend de la préservation et de la bonne gestion de l'écosystème, de la ressource et de l'organisation de l'activité de pêche.

Keywords: Fisheries, Algerian Sea, Fishes, South-Central Mediterranean

Introduction: L'activité de pêche en Algérie présente une façade maritime de plus de 1200 km renferme une surface de 9,5 millions d'hectares. La pêche et l'aquaculture sont devenues des activités économiques importantes en termes de production alimentaire et de création d'emplois.
Matériels and Méthodes: Annaba est situé à 670km à l'Est d'Alger, étendue sur un littoral long de 80 km depuis Sidi Salem à l'Est (36°53'27" Nord, 08°15'30" Est), jusqu'à Chétaibi (37°05'21" Nord, 07°22'34" Est) à l'Ouest. La méthode d'étude appliquée repose sur une démarche d'investigation auprès des services de la direction de la pêche et des ressources halieutiques (DPRH) [1] et auprès pécheurs du port de pêche d'Annaba et les gardes côte. La récolte de données a conduit à une analyse statistique des rendements de pêche de la dernière décennie de 2001 à 2011.
Résultats: L'analyse de la production halieutique montre 3 périodes bien distinguées : la première allant de 2001 à 2004, marqué par un accroissement continu de la production. Elle est passée de 2116 tonnes à 9046,74 tonnes. De 2004 à 2005, la production connaît une chute considérable avec 8322,92 tonnes. La troisième phase coïncidait avec le développement de secteur de pêche allant de 2006 à 2011 est caractérisée par un accroissement de la production marquant 8361,61 tonnes en 2011. Les captures de pêche, concernant les 2 ports d'Annaba et de Chétaibi, présentent une dominance des petits pélagiques dans les débarquements par rapports aux autres espèces. Cependant la capture des grands pélagiques, crustacés et les mollusques durant cette décennies reste constant par rapport aux poissons démersaux qui semble augmentée entre 2006 et 2009 au niveau d'Annaba et entre 2007 et 2009 au niveau de Chétaibi. Les 6 catégories de pêche son comparées durant la dernière décennie entre les 2 ports. Les valeurs moyennes de chacune sont obtenues à l'aide du test t de Student pour des échantillons indépendants, dont la production de la pêche des poissons démersaux, des grands pélagiques, des requins et raies et des mollusques est statistiquement non significatif, alors que la pêche des petits pélagiques et des crustacés est statistiquement très hautement significative. Ceci concorde avec les résultats précédemment démontrés en exposant l'évolution de la production halieutique par catégorie de pêche durant une décennie (2001-2011). Le nombre de navires connaît un saut effectif essentiellement à partir de 2003 ou le nombre a doublé en 2011. Il est passé de 259 à 504 navires, soit une évolution de 95%. Le nombre des petits métiers reste supérieur aux autres types d'embarcation, alors que les sardiniers sont plus les chalutiers. L'équipage à bord des navires de pêche, se distingue en 3 catégories de professionnels de pêche : les patrons de pêche, les mécaniciens et les marins pécheurs. En regroupant les 2 ports de pêche d'Annaba et de Chétaibi, le collectif marin qui comptait 1606 embarqués en 2001, est passé à environ 3881 inscrits en 2011, soit une évolution de 65% entre les deux années. Cependant, la flottille relevant d'Annaba renferme depuis 2007 un effectif majoritaire de professionnel de la pêche provisoirement inscrit qui contribuent à l'amélioration du rendement de la pêche.
Discussion: La réorganisation de la pêche particulièrement à Annaba doit s'intégrer dans le contexte plus vaste de la politique maritime Algérienne en cours de construction. Selon le bilan des activités du secteur de la pêche, une nette progression de la production qui a atteint les 9046,74 tonnes de poisson de toute nature pour l'année 2004 pour la seul willaya d'Annaba, alors qu'elle était de 2116 tonnes en 2001. Cette avancée s'explique, par l'engouement des jeunes aux métiers de la mer, en 2002 de nombreux jeunes, qui passent par l'école de pêche, ont lancé des projets d'investissement. La production de la pêche durant la dernière décennie (2001-2011),concernant les 2 ports d'Annaba et de Chétaibi, présentent une dominance des petits pélagiques dans les débarquements par rapport aux autres espèces. Ceci représente un facteur principal qui peut expliquer les fluctuations annuelles des débarquements totaux. En effet, l'abondance des petits pélagiques est liée à l'abondance de la nourriture, en particulier le plancton (Zaghdoudi,2006) [2]. Cependant, la pêche en dernière année 2011 n'a pas été bonne. Une baisse sensible de la production de la pêche du golfe d'Annaba a été enregistrée avec seulement 8361,61 tonnes contre 8672,15 tonnes en 2010 et 8720,45 tonnes en 2009, ce qui représente une réduction de la production de plus de 10%. Cette situation s'explique, par les aléas climatiques et par la rareté du poisson et souvent qu'ils soutiennent d'être obligés d'aller au large sans pour autant que la pêche soit fluctueuse. Ceci se répercute sur les prix des différentes espèces de poisson et fruits de mer qui augmentent au grand dam des consommateurs. La flottille de pêche de la willaya d'Annaba a été renforcée atteignant 504 unités en 2011 avec 45 chalutiers, 123 sardiniers, 336 petits métiers. Cependant, malgré l'acquisition de nouvelle embarcation, la flottille de pêche est caractérisé par son état vétuste et, particulièrement, par un taux d'immobilisation très élevé à cause de la difficulté de s'approvisionner de la pièce de rechange du fait de sa rareté sur le marché et les difficultés économique en raison de la difficulté d'accéder aux crédits bancaires. Cet état de fait a laissé une partie importante de la flottille immobilisée dans le port, soumise à de grave détérioration à pour conséquence une faible rentabilité économique par rapport au capital investi.
Conclusion : Le domaine de la pêche de la willaya d'Annaba dispose comme moyens de pêche de chalutiers, de sardiniers, et de petits métiers qui en croissant contribuent à l'augmentation de l'effort de pêche. La flottille relevant d'Annaba affiche cette dernière une progression que quantité et de qualité renfermant toutefois un effectif majoritaire de professionnel de la pêche provisoirement inscrit qui contribue à l'amélioration du rendement de la pêche. L'importance de la pêche et son développement, entraîne une répercussion importante, suite à la surexploitation et l'épuisement amplifiés des ressources halieutiques, ce qui conduit à soutenir de la pêche continentale par le développement de l'aquaculture. Cette nécessité est induite par l'impératif du maintien de l'équilibre entre la satisfaction des besoins en poissons et l'exploitation des ressources halieutiques, de manière à ne pas hypothéquer l'avenir du secteur, et d'éviter le massacre et l'extinction des espèces (MPRH) [3].

A TROPHODYNAMIC APPROACH FOR THE EVALUATION OF FISHERY MANAGEMENT PLANS IN THE GULF OF GABES (SOUTHERN TUNISIA)

G. Halouani [1]*, T. Hattab [1], F. Ben Rais Lasram [1], M. S. Romdhane [1] and F. Le Loc'h [2]
[1] Institut National Agronomique de Tunisie - ghassen.halouani@gmail.com

Abstract

An Ecopath with Ecosim food web model of the Gulf of Gabes (southern Tunisia) was constructed in order to describe its trophic structure and functioning. To assess the impacts of fisheries, an Ecosim routine was applied to predict temporal variation of catches. The model was fitted with time series data of landings for the period 1995-2008. Then, several fishery management plans were simulated by implementing different biological rest-periods. To a better evaluation of each management plan, ecological and socio-economic indicators were calculated. These indicators were used to i) establish a ranking between the fishery management plans, ii) study the effects of conservation measures on the ecosystem.

Keywords: Fisheries, Food webs, Models, Gulf of Gabes

Introduction

The Mediterranean Sea is under natural and anthropic threats and is consequently subject to great changes on its biodiversity and functioning [1]. Fishing activity is one of the factors affecting the Mediterranean ecosystems [2] and especially the gulf of Gabes which is the most important fishing area in Tunisia. Thereby, it would be relevant to quantify fishing activities impacts on the structure and functioning of this ecosystem to further asses fishery management plans (FMPs). The Ecopath with Ecosim (EwE) modelling approach has been used to study the trophic structure of the Gulf of Gabes. Thus, a mass-balance model was developed using Ecopath 6.2 to characterize interactions between resources, to identify keystone species and to evaluate the level of exploitation of the fishery [3]. The trophic model represents an average annual situation of the ecosystem (2000-2005), including 41 functional groups [4]. Among these groups, sharks, zooplankton and benthic molluscs were identified as keystone groups. Furthermore, an important bentho-pelagic coupling has been highlighted. This study revealed that the Gulf of Gabes is unlikely to be sustainably fished and was subject to a high level of exploitation such as other Mediterranean ecosystems [4].

Method

Based on initial parameters inherited from the Ecopath of the Gulf of Gabes an Ecosim model was applied to provide temporal dynamic simulations [3]. This model was fitted to available data of landings for the period 1995-2008. To this end, time series of fishing effort by fishing gear type, catches data and biomasses of main functional groups as well as primary production in the study area (1997-2007) were used to calibrate the Ecosim model. The outputs were compared to the time series of landings to assess the goodness of fit. Then, several fishery management plans were implemented by simulating different rest-periods to analyse the ecosystem feedbacks (Fig. 1). This methodology is part of the integrative approach "Back to the Future" [5], which consists of modelling past ecosystem and simulating management plans as policy goals for the future. For this purpose, ecosystemic indicators (Trophic Level of catches, Kempton Q, Fishing In Balance) and socio-economic indicators (landings and total value of catches by fishing activity) were calculated for each measure throughout the period 1995-2008. Thereafter, an overall ranking between the fishery management plans was established based on the results of these indicators (Fig. 1).

Results and discussion

Results showed that conservation measures involving restriction on the activity of benthic trawls (e.i. Sc5, Sc6, Sc7 and Sc8) were more effective than those requiring a complete closure of the fishery (e.i. Sc1, Sc2, Sc3 and Sc4), (Fig. 1). Indeed, the reduction of bottom-trawling fishing effort has positive impacts on the coastal fishing (20% increase in coastal catches), thus leading to the improvement of the social indicator of these fishing management plans. Furthermore, the contribution of each management measure in terms of catch occurs mainly (up to 80%) during the first two years after the end of the fishing management plan. The exponential decrease of this contribution can be explained by the resiliency of the ecosystem. Besides, according to the Ecosim model, the increase in catches due to the application of conservation measures is not proportional to the duration of the management plan. In fact, comparing two similar scenarios Sc1 and Sc2 corresponding to a closure of the fishery respectively 1 and 2 years has shown that the contribution of the second year in terms of gains in catches is about 50% lower than the first year. Which means that, multiplying the duration of the closure 2 times is equivalent to increasing benefits of the conservation measure by a factor of 1.5. In this perspective, Ecosim could be a relevant modeling tool to evaluate and develop management plans aiming the sustainability of fisheries.

POSSIBLE LINK BETWEEN THE BASIC SCIENCE AND NATIONAL ECONOMIC STRATEGY: A *FISHY* HYPOTHESIS FROM THE NORTHERN ADRIATIC

Romina Kraus [1]* and Nastjenjka Supic [1]
[1] Rudjer Boskovic Institute - kraus@cim.irb.hr

Abstract
Long-term analysis of oceanographic conditions leading to extreme phytoplankton blooms in the northern Adriatic revealed that specific February conditions in the region might play a key role in the entire Adriatic anchovy stock. Even the preconditioning of the February conditions might be feasible. These findings could be a valuable input in the national economic strategy for a sustainable development *via* monetary stimulation grants that Croatia provides for fishery.

Keywords: North Adriatic Sea, Phytoplankton, Blooms, Fishes, Circulation

Introduction
One of the most productive regions of the generally oligotrophic Mediterranean Sea is the northern Adriatic. The Po River freshets induce high production rates in this region, which are especially pronounced in the western part, close to the delta (Fig. 1). Consequently, a west-to-east descending phytoplankton abundance gradient usually forms. However, the area affected by large blooms sometimes enlarges and, in extreme cases, large phytoplankton blooms occur over large areas with a pronounced southward current near the eastern coast between stations SJ107 and RV001 (the Istrian Coastal Countercurrent; ICCC). To broaden our knowledge about factors which induce and/or spread large blooms in the region, we have related the phytoplankton abundance to basic oceanographical and atmospheric parameters and to the Po River discharge rates. In order to investigate possible effects of large blooms on the bio-production in the Adriatic, we compared our data to the Adriatic anchovy catch, *Engraulis encrasicolus* (L.), one of the most important commercial fish species in the Adriatic [1]. We have also investigated surface fluxes and Po River discharge rates for several months preceding a bloom.

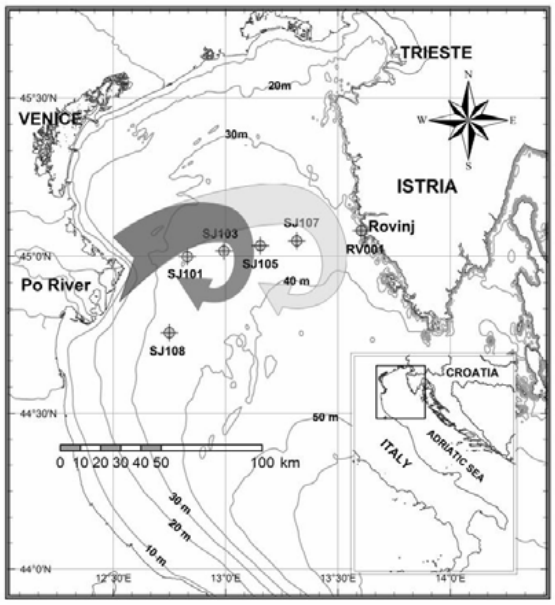

Fig. 1. Northern Adriatic map with sampling stations, along with hypothetic February paths of freshened Po River waters which favour large (dark grey) or extremely large (light grey) anchovy catch in the subsequent year.

Data and methods
We analysed three types of data obtained in the northern Adriatic (Fig. 1) during the period 1990-2004 at 6 stations at the Po River delta-Rovinj section (further on: Po section): monthly/seasonally collected oceanographic data, including components of geostrophic currents relative to 30 dbar surface between stations, monthly averages of surface fluxes and Po River rates, and yearly averages of fish catch data. Correlations were determined with a simple linear regression analysis.

Results with discussion
The highest seasonal phytoplankton blooms are the February ones. The largest February bloom at SJ107, SJ108 and SJ101 occurred in 2004. At the time the ICCC was very pronounced, while cold, low salinity, low density and nutrient rich waters from the vicinity of the Po River delta spread in a thick layer over the northern Adriatic and broadened phytoplankton from the western region over to the eastern one. Large February blooms at these three stations were preceded by an intense Po River influx during the previous June-August, by an intense evaporation in the preceding November and, interestingly, by low Po River rates in November and December. A large phytoplankton abundance at SJ101 and SJ107 in February along with specific distribution of geostrophic currents across the Po section in the same month highly correlated with the anchovy catch of the same year. The obtained correlations were highly dependent on the year 2004, when ICCC, phytoplankton and yearly anchovy catch were of outstanding values. However, a very high bloom at SJ101, which occurred in February 2000, when freshened waters occupied only the western part of the northern Adriatic, preceded another large anchovy catch in 2000. An excess feeding of the anchovy in the pre-spawning period (February) can lead to a higher than usual amount of anchovy eggs, two months later. As the anchovy obtains the commercial length of around 9 cm in about four and a half months, the April generation might significantly contribute to the total amount of the fish catch in the same year (anchovy season lasts throughout the year, with an exceptionally high maximum in September). Based on the obtained results we hypothesize that a February circulation type is basic for the increment of anchovy stock in the same year (Fig. 1). We would like to validate our hypothesis in an international, multidisciplinary study of a larger scope with field data and modelling expertise, as we believe that our insights should be vital in moderating grants for stimulation of anchovy fishing and ultimately could preserve anchovy stock from overfishing in the Adriatic.

A COMBINED METHODOLOGY FOR ASSESSMENT OF THE COMMON DENTEX (*DENTEX DENTEX*) IN THE NORTHERN CORSICA (FRANCE)

M. Marengo [1]*, S. Agostini [1], N. Tomasi [1], V. Valliccioni [1], B. Marchand [1] and E. D. Durieux [1]
[1] University of Corsica Pasquale Paoli UMR 6134 SPE/UMS 3514 Stella Mare –CNRS/UCPP - marengo@univ-corse.fr

Abstract
The common dentex represents a great economic interest for the artisanal fishing in Corsica (France). A combined sampling approach was developed using logbooks and boardings on 11 fishing vessels in the region Bastia-Cap Corse. The purpose of this paper is to evaluate the complementarity and reliability of the methods used (logbook, boarding weighing and size class) for assessing fishing of the common dentex in the Northern Corsica (France). The implications of such methodological approaches for fisheries assessment are discussed.

Keywords: Fisheries, Monitoring, Corsica Trough

Introduction and Methods
In the Mediterranean Sea, artisanal fisheries are characterized as commercial fishers operating in small boat and targeting a high diversity of species [1]. The common dentex *Dentex dentex* (Linnaeus, 1758) is considered as a "noble" species and represents high commercial value for the artisanal fisheries [2], [3]. Under the program Marittimo: Marte +, 11 individual "logbooks" were distributed to fishermen representative of the artisanal fishing activity of the "Bastia-Cap Corse" fishing management area. These logbooks allowed a monitoring of their activity during the fishing season from April to October 2012 based on daily catch declaration. In addition, 38 boardings were conducted by scientists on vessels of these fishermen. The "boarding weight" was calculated using individual weightmeasured onboard using a spring balance (accuracy 0.4 g). A "boarding size class" weight estimation was calculated using the biometric relationships (size-weight): Small (0-40 cm = 0,5971 kg), Middle (40-60 cm = 2,7791 kg), Large (60-80 cm =7,6515 kg) [4], this estimation method being the most used in the Corsican fisheries monitoring.

Results and Discussion
A total of 40 common dentex were sampled over the study period. Results showed a significant difference between these three catch data (Friedman test, p = 0,018), on average in comparison with the "boarding weight" catch, an overestimation of 40% of the "boarding size class" catch and underestimation of 40% of the "logbook" catch. It might be interesting to refine knowledge of the biometric data of common dentex, in order to increase the reliability of the estimated values from these size classes. For "logbook" data, results were heterogeneous during the season and between the fishermen. Generally, fishermen do not enroll the small catches (<2 kg /day) that are not commercialized, this fact could explain this underestimation.The main advantage using fishermen logbook is their usefulness for monitoring the fishing effort according to the seasons. The interest to combine these methods is to obtain a better estimate of the production of common dentex, over the seasons, and to provide tools for fisheries assessment for integrated management and sustainable use of fisheries resources in Corsica.

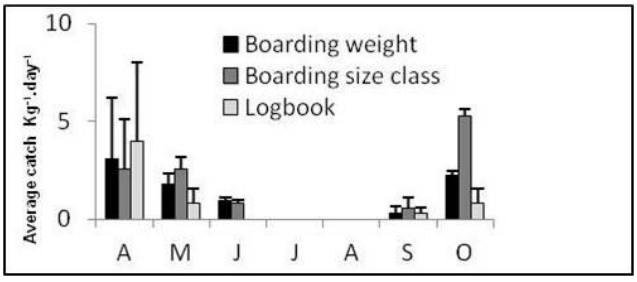

Fig. 1. Comparison of the average catch "boarding weight", compared with the average catch "boarding size class" estimation (all size classes combined) and average catch "logbook" during the fishing season (April-October 2012) for common dentex.

MANAGEMENT PLAN FOR THE BOAT SEINE "SONSERA"

P. Sanchez [1]*, A. Colmenero [1], M. Demestre [1], A. Garcia De Vinuesa [1], J. Lleonart [1], P. Martin [1] and E. Vallejo [1]
[1] Institut de Ciencies del Mar-CSIC - pilar@icm.csic.es

Abstract
A management Plan for the Catalonian "sonsera" (boat seine) is carried out in order to allow the use of this fishing gear. The Co-management Committee of the "sonsera" was formally created with the specific mission to ensure a sustainable activity of the fishery. The fishery is currently being subject of a scientific study to accurately evaluate the state of the stock and its impact on the ecosystem.

Keywords: Fisheries, Monitoring, North-Western Mediterranean

Introduction
The sand eel fishery is carried out traditionally by 25 artisanal boats scattered around 6 fishing ports in the northern coast of Catalonia (NW Mediterranean). Fishing boats operate on a daily basis and landings are entirely devoted to direct human consumption, as the species is highly appreciated in the region.
The "sonsera" is a boat seine use in some parts of Catalonia to catch. Gymnammodytes cicerelus and G. semisquamatus [1] (known as "sonso") as well as some small gobids. "Sonsera" can be referred to both, the gear and the boat [2].
The capture of those species are not possible with any other method due the mesh size necessary to catch the target species, and a depth less than 50 m. Seeing that the EU regulations exclude this kind of fishing, the application of a Management Plan for this fishery it is necessary in order to allow the "sonsera".
A Co-Management Committee (Administration, boat seine's fishermen, scientists and NGOs) was established as the legal figure that is the responsible for the implementation of the Management Plan. The unique authorized sand eel fishery is devoted for provide the necessary information to develop the Management Plan.
The objectives of the management plan are:
Maintenance of historical small-scale fisheries and subsequent adoption of appropriate management measures.
Monitoring the state of exploitation by determining the amount of each catch, fishing effort and the basic biological parameters. Identification the impact of the fishing gear on ecosystem.
Identification of a set of indicators needed to verify both the state of exploitation and the effectiveness of the management measures taken.
Data necessary for the achievement of the objectives:
Fishery data (data series on catches and effort of the boat seine fleet; fleet dynamics during the fishing seasons targeting sand eel (Gymnammodytes cicerelus and G. semisquamatus and gobids). Data on the catches of the boat seine during at least an annual cycle on board professional boat seiners (specific composition of the catches and by-catch).
Biological data on target species (duration of the reproduction period and size-at-first-maturity, and special distribution of the target species). The material will be collected during the on board sampling and examined in the laboratory.
Bio-economic data related to the boat seine fishery.
Analysis of the collected data, diagnosis and definition of the fishing regulations
The analysis of the fishery data is expected to provide a first assessment of the status of exploitation of the target species of the boat seine fishery (sad eel and the dominant gobid species). The methodologies will include at least pseudocohort analysis and depletion model for the cpue data. The spatial distribution of fishing effort during the sand eel and gobids fishing seasons will also be analyzed.
Evaluation of the impact of the fishing gear at ecosystem level. Technical measures will be defined based on the diagnosis, for the sand eel and gobids fisheries.
The economic impact of the measures on these fisheries will be evaluated.
Implementation of the defined fishing regulations: monitoring and surveillance
An essential part of the Management Plan will be the monitoring of the technical measures that will be applied. Surveillance will be the responsibility of the Co-Management Committee. This Management Plan is proposed for duration of 3 years. The result of the application of the technical measures will be revised at least twice during the year by the Co-Management Committee.
Progress of the scientific study up 30 April 2013.

The scientific study started on August 2012 and will be finish on July 2013. Data on landings, effort and landings-per-unit-effort are obtained from the DGPAM (General Direction of Fishing and Maritime Affairs) of the Catalan Government for the period 2000-2012 on a monthly basis.
On the Catalan coast 5 ports report landing of Gimnamodytes spp., with an average of total landings of 403.4 tones for the period 2000-2012 with a maximum of 818,9 tones in 2012 and a minimum of 43.4 in 2007 (Fig 1).

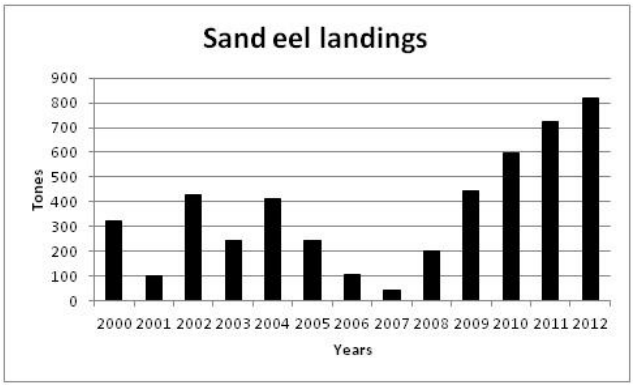

Fig. 1. Sand-eel (Gymnammodytes cicerelus+ G. semisquamatus) annual landings over 2000- 2012 in the five fishing ports in the northern Catalan Coast where the the fishing with "sonsera" is performed.

From 1 August 2012 to 30 April 2013, a total of 91 hauls were carried out on the 5 study ports. A total of 32577 individuals were measured, from them 87.3% were G. cicerelus (Table 1)

Abstract
In the Gulf of Gabès, coastal fishing and bottom trawling are the two predominant fishing activities providing the main part of the fishing production. So far, no study has attempted to model the temporal evolution of the production from these two fisheries. The objective of this study was to propose an explanatory model of the evolution of the production from these two fishing activities during one decade (1995-2006) using time series analysis. The fitted models were both adequate but those explaining bottom trawling's production was more significant than those of coastal fishing. This can be explained by the different practices of coastal fishing on the contrary to bottom trawling. For the latter, the seasonal effect was more pronounced.

Keywords: Tunisian Plateau, Coastal management, Fisheries, Models, Time series

Introduction
The Gulf of Gabès is the most important fishing area in Tunisia (south-western Mediterranean Sea) where bottom trawling and coastal fishery are the most predominant fishing activities. Fisheries management not only requires the knowledge of the biological and the dynamics parameters of the resources but also needs a fine description of the temporal evolution of fishing production. Many authors used time series analysis to explain the production and abundance of species ([4], [5]) and the dynamics of fisheries ([2]). The purpose of this study was to describe data series of the production from coastal fishery and bottom trawling activity in the gulf of Gabès during one decade.

Material and methods
The database for this study obtained from the General Direction of Aquaculture and Fisheries of Tunisia, contains monthly production data from bottom trawling and coastal fishery from 1995 to 2006 in the gulf of Gabès; A classical time series decomposition was used. The bases of this method were described in details in the works of Kendall and Stuart [1] and Makridakis and Wheelwright [3]. Fitted models were implemented in 3 steps: first, the deseasonalized time series data was determined using centered moving average, then this series was adjusted with the adequate model and finally the seasonal components was identified. The established model appears as follows:

$$Yt = St * Tt * Et$$

With: t the period; Y: the production; S: the seasonal component ;T: the trend cycle component and E: the irregular component.

Results and discussion
1. Temporal evolution of coastal fishery and bottom trawling production
For coastal fishing (Fig 1, top), the adjusted trend of the production shows two phases: an important decrease of the production followed-up by a low increase. For the bottom trawling activity (Fig 1, down), it shows also two phases but opposite to coastal fishing: a considerable increase of the production of this activity followed-up by a low decrease of catches.

2. Seasonal components
Regarding the seasonal components, we notice that the both fishing activities had the same evolution: an increase of the production from September to January. Besides, the seasonal effect is more important for bottom trawling activity.

Conclusion
This study allowed us to establish the first model which explains the production from coastal fishery and bottom trawling activity in the gulf of Gabès. The adjustments of the models were significant, besides those for coastal fishery was less significant due to the various techniques and fishing areas. The two activities had similar seasonal effect on the production, but the variance was less marked for the coastal activity which present a great capacity to maintain a stable production by changing fishing gears in response to resources availability.

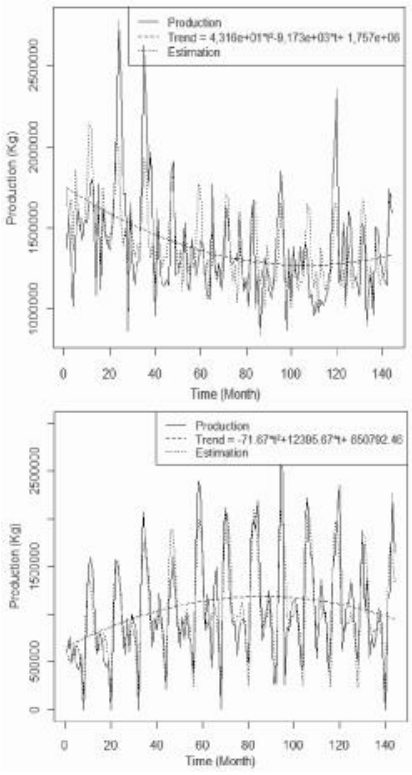

Fig. 1. Trend and fitted model of the temporal evolution of production from coastal fishery (top) and bottom trawling (down) (1995-2006).

WASTE FEED FROM FISH FARMS OF THE EASTERN MEDITERRANEAN AND ATTRACTION OF WILD FISH

Nikos Neofitou [1]*
[1] University of Thessaly - nikneof@uth.gr

Abstract
Fish are attracted to floating structures, including coastal cage fish farms, sometimes in dense aggregations. To understand better the influence of aquaculture on wild fish stocks, we carried out samplings by fishing bait and trammel netting around two Eastern Mediterranean farms. A total number of 54 individuals belonging to 12 species were captured. Striped mullet, salema and white trevally were the species that consumed pellets in great quantity. The results of this preliminary study indicates that feeding behavior of wild fish around fish cages can have important ecological consequences on reducing the environmental effects of aquaculture in Pagasitikos gulf.

Keywords: Aquaculture, Fecal pellets, Fishes, South-Eastern Mediterranean

Introduction
Several previous studies have investigated assemblages of wild fish associated with marine fish farms in the North European and Mediterranean temperate locations [1]. Nevertheless, only few of them have examined the stomach content of wild fish in order to determine the percentage of uneaten pellets that consumed by them [1]. No publication has addressed this topic in the Eastern Mediterranean. Therefore, the specific aims of this preliminary study in a semi-enclosed gulf of the Eastern Mediterranean were to investigate the temporal persistence of wild fish around coastal aquaculture and to study the diet of these fish in order to determine the percentage of uneaten pellets that consumed by them.

Materials and methods
This preliminary study was carried out in Pagasitikos gulf which is located in the Western Aegean Sea. Two marine fish farms were examined: The first is situated at the southeast part and the second at the southwest part of Pagasitikos gulf. These are henceforth referred to as AS and BS farm, respectively. Sea bream *Sparus aurata* and sea bass *Dicentrarchus labrax* are intensively cultured in these farms where they are fed both pelleted and extruded diets. At the time of the study, the average annual standing stocks were 130 and 92 t for AS and BS farms, respectively. The study applied two different sampling methods. One sampling was carried out at the AS farm by fishing bait and two samplings at the BS farm by trammel netting in order to catch wild fish under fish cages. The fishing bait at the AS farm was made in one day (in September) from the walkway of the cages, directly after the early feeding time. The trammel nettings at the BS farm were carried out in two nights (one in September and one in October) and the purpose of the sampling time was to catch as many wild fish around fish cages as possible. The net was 28 to 30 mm square mesh and hauls were made directly adjacent to cages and around the fish farm by lowering the net into the water using a fishing boat. All measurements and analyses of fish stomachs were done according to the procedure described by [2].

Results and discussion
In the present study, we found 12 different species of fish associated with the two farms studied, belonging mainly to the Sparidae and Carangidae (75% of the total captured fish). Combining this total number with similar observations from [2], a total of 33 species belonging mainly to the Clupeidae, Sparidae, Mugilidae and Carangidae were found. The stomach content analysis of wild fish captured around sea cages of the AS and BS farms are shown in Figure 1. Striped mullet, salema and white trevally were the species that consumed pellets in grate quantity (57% of the total captured fish at the AS farm). In previous studies, [2] reported that Mugilids were the taxa that consumed pellets in greatest quantity. This study demonstrates that sampling by fishing bait directly after the feeding time was the most appropriated method (AS farm) in contrast with trammel netting during the night since all the wild fish that captured with this method were fed on natural food or had an empty stomach (BS farm). This finding may imply that in the second case, pellets were digested until the night or that nets stressed fish causing them regurgitation. Furthermore, the preliminary results of the study indicates that feeding behavior of wild fish around fish cages can have important ecological consequences on reducing the organic wastes which are directly released into the receiving environment and may causes eutrophication and/or stress on benthic organisms in Pagasitikos gulf, which is in agreement with the results of previous studies in this region [3, 4].

EFFECTS OF ANTIFOULING PAINTS ON FARMED FISH OF THE EASTERN MEDITERRANEAN

Marina Nikolaou [1]*, Nikos Neofitou [1], Konstantinos Skordas [1] and Labrini Tziantziou [1]
[1] UNIVERSITY OF THESSALY - maze55@live.com

Abstract
In this preliminary study, was examined the accumulation of copper and zink as basic ingredients of antifouling paints in cultured sea bass and sea bream. Samplings were carried out in four Eastern Mediterranean fish farms. Two of them used nets treated with antifouling paints whereas the other two utilized untreated nets. The results showed that almost in all cases the concentrations of heavy metals were higher in fish collected from cages treated with antifouling paints. Furthermore, statistical analysis revealed significant differences in copper and zinc concentrations among the samples from the farms with different use of treatment. These preliminary results indicate that the use of antifouling paints may exert toxic effects in cultured fish.

Keywords: Aquaculture, Fouling, Metals, Fishes, North-Eastern Mediterranean

Introduction
Marine fouling is a growing global phenomenon and it is widely accepted that in the aquaculture industry is an expensive problem. The main protective method against fouling involves the use of toxic antifouling paints. Nevertheless there is little information regarding pollutant levels in cultured fish [1]. The impact of antifouling on the concentration of heavy metals in cultured fish in the Eastern Mediterranean has been addressed only in one experimental study [2]. Therefore, the specific aim of this preliminary study in four aquaculture sites of the Eastern Mediterranean was to detect whether the concentrations of copper and zinc would be related to the use of antifouling treated nets.

Materials and methods
Cultured sea bass *Dicentrarchus labrax* and sea bream *Sparus aurata* were supplied from four fish farms which are located in the Aegean and Ionion Sea (Eastern Mediterranean). Two of them used nets treated with antifouling paints whereas the other two utilized untreated nets. These are henceforth referred to as AF and NAF farms, respectively. A total number of 40 individuals were analyzed (n=10, TW=399.46±109.81g sea bass & n=10, TW=327.70±88.65g sea bream at AF farms; n=10, TW=420.80±73.43g sea bass & n=10, TW=366.98±42.54g sea bream at NAF farms). Metals were analyzed in muscle, liver and gills separately for each tissue and fish (n=120). Samples (about 0.5 g) were dried at 80°C for 48h, weighted and wet digested with concentrated HNO3. Quantitative determinations of copper (Cu) were carried out by graphite furnace atomic absorption spectrometer and zinc (Zn) were carried out by flame atomic absorption spectrometer, using standard addition methods. The one-way analysis of variance (ANOVA) was used to determine statistical significant differences between fish exposed to antifouling treated and un-treated nets.

Results and discussion
Heavy metals concentrations in tissues of the two studied species are summarized in Figure 1. These results showed that almost in all cases the concentrations of heavy metals were lower in samples collected from untreated nets. Maximum concentration of copper and zinc was detected in the liver (28.50 and 435.25 mg kg^{-1} dry wt, respectively) of sea bass at the AF farms. Mean concentration of zinc in liver of sea bass and sea bream was 19 and 14 times higher in AF farms compared to NAF farms. Results generally showed that almost always highest metal concentrations appeared in liver for both studied species, which is in agreement with other studies [2, 3]. In another similar study of the North Europe on farmed salmon, [3] reported lower concentrations of copper in muscle and higher in liver compared to our data. Furthermore, one way ANOVA showed significant differences in heavy metals concentration among the samples of the AF and NAF farms for both studied species ($p<0.001$). All the above mentioned indicates the negative effect of antifouling coatings on cultured fish. In any case, concentration of copper and zinc in muscle of both studied species did not exceed the maximum limits for food (30 and 100 mg kg^{-1} dry wt, respectively) [4].

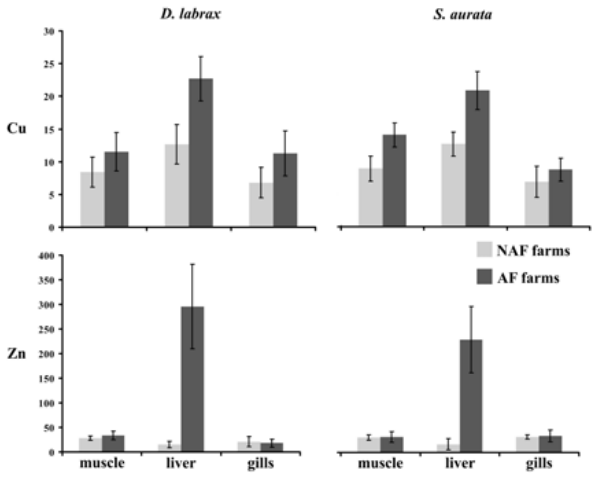

Fig. 1. Mean±SD concentrations of copper and zinc in muscle, liver and gills of cultured sea bass and sea bream (mg kg^{-1}, dry wt)

FIRST REPORT OF SOME PARASITES FROM THE MEDITERRANEAN MUSSEL, *MYTILUS GALLOPROVINCIALIS* LAMARCK, 1819, COLLECTED FROM THE TURKISH BLACK SEA

Ahmet Özer [1]* and Sevilay Güneydag [1]
[1] Sinop University Faculty of Fisheries and Aquatic Sci - aozer@sinop.edu.tr

Abstract
This is the first study on parasites of *Mytilus galloprovincialis* Lamarck, 1819 in Turkish waters. Mussel samples were collected every month between August 2012 and January 2013 at 3 stations in the Sinop coasts of the Black Sea. A total of 840 mussels were examined for parasites using standard parasitological investigation procedures. Five parasite species were identified: *Nematopsis legeri* (de Beauchamp, 1910), *Urastoma cyprinae* (Graff, 1882), *Parvatrema duboisi* (Dollfus, 1923), *Polydora ciliata* (Johnston, 1838) and *Peniculistoma mytili* (Morgan, 1925) Jankowski, 1964. Overall infection prevelance (%), mean intensity and abundance values were 59.88%, 54.73 ± 6.03 and 32.77 ± 2.78, respectively. Infection indices for each parasite species were also determined and presented.

Keywords: Bivalves, Black Sea, Parasitism

Introduction
The Mediterranean mussel (*Mytilus galloprovincialis* Lamarck, 1819) is native to the Mediterranean, Black and Adriatic Seas, but has spread mostly via ballast water and ship hull fouling to many other regions worldwide. It is a major component of the littoral fauna in the Black Sea and is an aquatic product which has economical significance. Total bivalve production value was 45.412 tonnes in 2009 in Turkey ([1]) and all were harvested from nature via mussel collection. A dramatic decrease of 35% was occurred in the years 2007-2011 especially in the Black Sea as a possible impact of predatory marine snail *Rapana venosa* on natural populations. Despite sevaral studies conducted on the parasites of *M. galloporovincialis* where it is distributed ([2], [3], [4], [5]), there is no parasitological report in Turkey. So, this is the first study identifying its parasite fauna and presenting infection indices in Sinop coasts of the Black Sea in Turkey.

Materials and methods
Sampling was carried out between August 2012 and January 2013 at 3 sampling stations representing three ecologically different environments in Sinop coasts of the Black Sea. Mussels were collected by scuba divers and transported in local water to parasitology laboratory at the Faculty of Fisheries and Aquatic Sciences. A total of 840 mussels were examined for parasites using standard methods. Infection prevalence (%), mean intensity and abundance values (with Standard Error) were determined in accordance with [6].

Results
During the investigation period, a total of 5 parasite species were identified; *Nematopsis legeri* (de Beauchamp, 1910) (Porosporidae), *Urastoma cyprinae* (Graff, 1882) (Urastomidae), *Parvatrema duboisi* (Dollfus, 1923) (Gymnophallidae), *Polydora ciliata* (Johnston, 1838) (Spionidae) and *Peniculistoma mytili* (Morgan, 1925) Jankowski, 1964 (Peniculistomatiade). The most prevalent was *N. legeri* (P:47.73%, M.I±S.E: 65.78 ± 7.43), *P. mytili* was less common (P:8.33%, M.I±S.E: 7,62 ± 1.07) and least abundant were *P. duboisi*, *U. cyprinae* and *P. ciliata* (P:4.88%, M.I±S.E: 6.28 ± 0.87; P:3.39%, M.I±S.E: 9.09 ± 1.20 and P:1.30%, M.I±S.E: 1.0 ± 0.00, respectively). Overall infection prevalence (%), mean intensity and abundance values were 59.88%, 54.73 ± 6.03 and 32.77 ± 2.78, respectively.

Discussion
The Mediterranean mussel *Mytilus galloprovincialis* is native to all seas surrounding Turkey. Despite its economical value, there is no study on the parasites and their infection indices in Turkey. Here in the present study, we provided first and detailed data on its parasites and infection indices in nature in Turkish Black Sea coasts.

CHANGES IN WATER COLUMN PLANKTON COMMUNITY COMPOSITION IN RESPONSE TO FISH FARMING IN THE EASTERN MEDITERRANEAN

T. Tsagaraki [1]*, P. Pitta [1], C. Frangoulis [1], G. Petihakis [1] and I. Karakassis [2]

[2] Biology Department, University of Crete

Abstract
Changes in plankton community composition as a response to fish farming were examined in an exposed site in the N. Aegean Sea. Geochemical variables were measured along with abundance and biomass for all plankton groups from bacteria to mesozooplankton. Results showed that farm effects are maximized at stations 100-200 m downstream from the farm. The implications for assessing community responses to perturbations in a dynamic environment are discussed within the context of fish farming.

Keywords: Aquaculture, Food webs, Phytoplankton, Zooplankton , Aegean Sea

Introduction
Although it is widely accepted that the amount of nutrient released by fish farms is substantial ([1], [3]) it has proven quite elusive detecting them in the field ([7]; [8]). It has been shown that the released nutrients are rapidly assimilated into the food web resulting in a quick transfer of nutrients to higher trophic levels [6]. The transfer up the food web has also been shown through increased biomass of wild fish near farming zones [4], the use of farming areas as settlement sites for juveniles [2] and even increase of top level predators in the farm vicinity [5]. However, changes in plankton community structure continue being hard to detect. In this study, the range of organisms studied allow us valuable insights as to how communities fine-tuned for oligotrophic conditions respond to nutrient additions from a farming environment.

Materials and Methods
Station selection was based on current velocity and direction as measured on the day of sampling used CODE type drifters. Water samples were taken within the fish farm area and at 80, 100, 200 and 500 downstream from the fish farm, along with two control stations one upstream and one downstream of the main current direction. Water samples were collected and analysed for particulate and dissolved nutrients, chlorophyll, bacteria, nanoflagejlates and microplankton while mesozooplankton was collected by vertical net tows. Microplankton cells were identified to the genus level and, where possible, to the species level. The dimensions of each cell were measured to obtain the biovolume and calculate the carbon content. Mesozooplanktin was scanned, identified to group level and the abundance, size and biomass of the dominant groups were determined.

Results and Discussion
The community upstream from the farm was typical of oligotrophic conditions in the late summer. At the farm cages and at 80m downstream nanoflagellate abundance started to increase and diatom biomass decreased. Ciliate biomass also started to increase and at the same time cladoceran abundance dropped by an order of magnitude. At the "impacted" stations 100 and 200m downstream the abundance of bacteria, nanoflagellates, cladocerans and copepods peaked and larger dinoflagellates and ciliates also increased. Further downstream these groups slowly returned to background levels. The major changes observed are conceptually summarized in Fig. 1. The results of this study indicate that, as a result of nutrient addition by fish farming operations, the plankton community structure is altered moving from a microbial loop dominated food web upstream from the farm to a more multivorous food web in proximity to the cages.

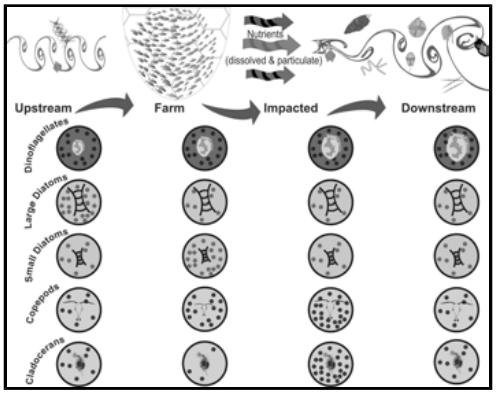

Fig. 1. Conceptual diagram depicting the most important changes in community structure as expressed through abundance (dots within group bubble) and size (organism with group bubble) at different distances from fish farm cages.

Abstract
La détermination des concentrations des métaux lourds dans le sédiment superficiel de la baie de Dakhla, au niveau de 36 prélèvements, a montré des taux relativement élevés malgré l'absence de toute pollution industrielle. La concentration en Cd dépasse le seuil à effet néfaste, ce qui nécessite un suivi des investigations pour identifier la source de contamination et évaluer l'impact sur le milieu et l'aquaculture.

Keywords: Sediments, Aquaculture, Metals, Antalya Bay

Introduction
La baie de Dakhla, située au sud du Maroc, est parmi les écosystèmes les plus productifs du pays et recèle des potentialités écologiques, biologiques et socioéconomiques d'une grande importance avec des gisements naturels de coquillages exploitables tel que :*R. decussata*, *V. verrucosa*, *C. edule*…. Actuellement, elle est le premier pôle conchylicole à l'échelle nationale et l'un des principaux pôles touristiques. Cette étude a pour objet d'identifier la contamination spatiale des sédiments par les éléments métalliques toxiques (Cd, Cr, Cu, Pb, Zn) et indésirables (Al, S, Fe, Ni) et de leur impact sur le développement de la conchyliculture.

Matériels et Méthode
Le réseau d'échantillonnée (fig.1) a concerné les zones conchylicoles et touristiques. D'autres prélèvements, témoins, Taourta et OumLabouire ont été effectués dans la zone franchement marine. Au total, 12 stations ont été échantillonnées, du 1 au 9 juillet 2007, avec 3 réplicas, chacune. Les sédiments récoltés ont été tamisés puis digérés avec du HNO_3, HF et $HClO_4$ selon la méthode No. 3030I [1]. Chaque série de digestion a été validée en parallèle par la digestion d'échantillons certifiés de sédiments (PACS-2, NRCC, Ottawa, Canada). Les mesures des métaux ont été effectuées par spectrophotométrie au plasma à couplage inductif (ICP-AES) (appareil Thermo Jarrell Ash, modèle Atom Scan 25).

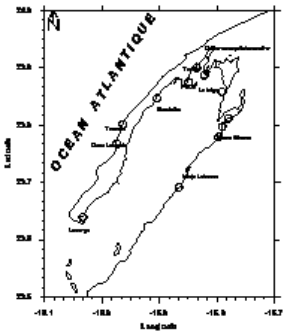

Fig. 1. Situation géographique des stations des prélèvements

Résultats & Discussion
Les teneurs moyennes enregistrées dépassent largement celles observées en 1997 et 2004 [2, 3, 4]. Le Fr, le Ni, l'Al et le S sont présents dans la baie à des concentrations importantes, mais inférieures au seuil à effet mineur. On note une moyenne maximale de 13,4mg/g (Fer), 16,7µg/g (Ni) et 8812µg/g (S) à HojaLalmera. Concernant l'Al, la valeur moyenne maximale enregistrée, à la même station (19mg/g), dépasse le seuil à effet néfaste. Le Cd et le Zn présentent une répartition spatiale similaire à celles du Fr, Ni, Al et S avec, cependant, des concentrations respectives de 4,6µg/g et 58,8µg/g. La classification ascendante hiérarchique (fig. 2) met en évidence la particularité de la station HojaLalmera. Les concentrations moyennes du Cu, Pb et Cr se répartissent d'une manière homogène dans toute la baie avec des valeurs ne dépassant pas le seuil à effet néfaste. Les plus fortes moyennes sont enregistrées à PK25 et Oumlabouir connues pour leur Intense activité touristique.

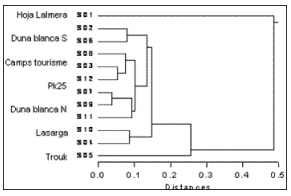

Fig. 2. Classification ascendante et hierarchique des stations

Généralement, le sédiment est utilisé comme indicateur de l'impact des activités anthropiques sur l'environnement aquatique [5, 6], or l'Est de la baie en est dépourvue et par suite cet enrichissement en métaux au niveau de la zone HojaLalmera est à mettre en relation avec les phénomènes d'upwelling permanent et les masses d'eau océanique rentrant par la cote Est [7,2] et les rejets miniers (com. Pers).

Conclusion Ce travail a permis de mettre en évidence la forte contamination de la baie de Dakhla par certains métaux lourds et ce, malgré l'absence de toute pollution anthropique et industrielle. La question des concentrations en Cd, dépassant le seuil à effet néfaste, reste posée et suggère un suivi rigoureux pour identifier la source de contamination et évaluer son impact sur le milieu et sur les activités aquacoles.

Abstract
The discipline of biogeography aims to study the spatial distribution of species in relation with environmental and geographical gradient. Main accepted biogeographies of the ocean only focus on one or two trophic levels of marine ecosystems and thus can hardly be applied for an ecosystem-based management. In this study, we have attempted to identify the main multi trophic associations from phytoplankton to mammals for the Mediterranean Sea. Based on more than 1 millions observations covering 1230 species and on recent statistical approach, the ecoregions of the Mediterranean basin are identified. For each ecoregions the main species association and habitat type are identified and effect of human pressure (both climate change, fisheries and pollution) are discussed.

Keywords: Biodiversity, Biogeography, Coastal systems, Pelagic, North-Central Mediterranean

The discipline of biogeography aims to study the spatial distribution of species in relation with environmental and geographical gradient. Based on the last 20 years of research in this new multidisciplinary field of science, three partition of the global ocean are accepted by the scientific community at a global scale. These global geographical frameworks respectively delineate the main oceanographical, ecological and fisheries basin features. Nonetheless, this division are usually static and focussing on few components of marine ecosystems and thus cannot be applied at a regional scale for an optimal ecosystem resources management. The aim of the work in the MERMEX/PERSEUS projects is first to integrate all biological observations made in the Mediterranean basin and second to infer an ecoregionalisation of the basin based on multi-trophic spatial occurrences of the main species detected. To do so, all Mediterranean databases including open access, national or project cruises and international database have been gathered. Then, based on ecological niche model coupled phytosociological analysis, the spatial distribution and species association of the more dominant species were retrieved. Finally, a multi agglomerative procedure has been applied to detect the ecoregions of the Mediterranean basin and is related to the main biotopes retrieved previously (see other talk proposed during the symposium). The obtained ecoregions delineate the characteristic species assemblage at a multi-trophic level of the Mediterranean Sea and hence, approximate the main trophic web of this basin. These ecoregions are now used as a reference ecological state in the European project PERSEUS.

CHECK LIST OF PLANKTON IN THE GULF OF VLORE (ALBANIA)

Genuario Belmonte [1]*
[1] University of the Salento; CoNISMa OU of Lecce - genuario.belmonte@unisalento.it

Abstract
A check list of plankton species in an Albanian coastal area is presented. Data derive from 384 samples collected with 3 different sampling devices at 20 stations over 2 years (2007-2008) in two oceanographic cruises in the framework of the Interreg CISM project coordinated by CoNISMa. A total of 425 plankton organisms were recognized, 300 of them as species. The plankton of the Gulf of Vlore was dominated by Crustacea, Dinophyta, Diatomeae, and Ciliophora. Only Penilia avirostris was collected with all the sampling devices, this demonstrating that an integrated sampling effort provides a more effective description of the reality. The checklist will be useful for studies in neighbouring areas, suchj as that of the FP7 CoCoNET project. The present inventory is also useful in the framework of EU Marine Strategy Directives

Keywords: Biodiversity, Otranto Strait

Introduction
The check list of plankton species in an Albanian coastal area is presented for the first time. This kind of biodiversity assessment will be of interest for present projects in the South Adriatic Sea and Otranto Channel which will describe the connectivity existing between the two (Italian and Balkan) opposite coasts. Furthermore, any reference list will represent the occasion to judge the representativeness of samples, or surveys, to be carried out in the future.
A list of 151 taxa is already available for benthos of the same area (Gulf of Vlore) (Maiorano et al., 2011). The present contribution wants to add information about the biodiversity of a potentially valuable area for economy (fishery and tourism) and nature protection.

Methods
Over a 2-year PERIOD (2007, 2008), 384 samples were collected using various devices (Niskin bottle, sediment core, plankton net) from 20 sampling stations (18 in the water column, 2 on the sea bottom). The sampling was carried out during two oceanografic cruises conducted in the framework of the CISM Interreg Project coordinated by CoNISMa.

Results and Discussion
A total of 425 different categories of organism were recognized, 300 of them at species level. The plankton assemblage was dominated by Crustacea (133 categories, 85 species), followed by Dinophyta (120 categories, 103 species), Diatomeae (42 categories and species), and Ciliofora (37 categories and species).
Among Crustacea, Copepoda were predominant (110 categories, 79 species).
The data are presented in published, peer-reviewed papers (on phytoplankton, microzooplankton, and resting stages) (Moscatello et al., 2011; Rubino et al, 2013), as well as one paper in preparation (on mesozooplankton) (Belmonte et al., 2012).
Eighy-six categories were found in sediment samples (as resting stages), 219 categories were collected by Niskin bottle and 196 categories by plankton net. Only one category (the Cladoceran *Penilia avirostris*) was collected with all sampling devices, demonstrating that an integrated sampling effort can provide a more effective description of reality. In addition, for 60 cases the record derives from resting stages found in the sediments, with no active stages of the same species found in the water column.
Since this is the first complete inventory of plankton biodiversity in an Albanian bay, nothing can be said about the possible presence of Non Indigenous Species.
The present report is the first assessment of the biodiversity of an area which is scheduled to become part of a Marine Protected Area.
The checklist is also be particularly useful for other studies in neighbouring areas, for example, the study of the water column biodiversity of the South Adriatic Sea and Otranto Channel, which was conducted in the framework of the FP7 CoCoNET Project to assess the connectivity of MPAs on opposite sides of the same basin. The present inventory is also useful in the framework of EU Marine Strategy Directives, which call for reliable data on which to base the assessment of the Environmental Status of marine basins.

Acknowledgments I would like to thank the colleagues which participated with me at the study of the Plankton in the frame of the CISM project: Carmela Caroppo (IAMC CNR Taranto, phytoplankton), Fernando Rubino (IAMC CNR Taranto, dinophyta and related cysts), Salvatore Moscatello (Lab. of Zoogeography and Fauna, Unisalento-CoNISMa Lecce, sample collection and microzooplankton, with related resting stages), Edmond Hajderi (University of Our Lady of Good Council, Tiranë, sample collection and cruise coordination), Margherita Licciano (Lab of Systematic Zoology, Unisalento Lecce, for identification of polychaete larvae), Francesco Denitto (Lab. of Zoogeography and Fauna, Unisalento-CoNISMa Lecce, for the identification of Hydrozoa), Irene Vaglio (Lab. of Zoogeography and Fauna, Unisalento-CoNISMa Lecce, for the identification of Calanoida), Gianmarco Ingrosso (Lab. of Zoogeography and Fauna, Unisalento-CoNISMa Lecce, for the identification of resting stages in the sediments)

DISTRIBUTION AND BIOGEOGRAPHY OF THE COPEPODS IN THE MEDITERRANEAN SEA (MERMEX/PERSEUS)

Abstract
Subtask 1.1.6 of PERSEUS and WP5 of MERMEX aim to propose a more extensive and accurate identification of the pelagic ecosystems within the Mediterranean Sea (bioregionalization). In this context, the aim of this work is to characterize the biodiversity by focusing on the most abundant component of zooplankton: the copepods. We implemented a new dataset of copepod occurrences from the ones already available online, completed with punctual datasets from various published studies. From these numerous punctual observations we gathered, we computed and mapped copepod species richness. Then, we identified areas that could be clustered together on the basis of species' presence. Finally, we modelled the ecological niches (environmental envelopes) of the most recorded species to define ecoregions.

Keywords: Zooplankton , Biodiversity, Copepoda, Mapping, Extra-Mediterranean regions

Introduction
The interest from stakeholders and scientists has been growing towards a better understanding of the biodiversity's spatiotemporal dynamics in the Mediterranean Sea. The subtask 1.1.6 of PERSEUS and the WP5 of MERMEX aim to propose a more extensive and accurate identification of the pelagic ecosystems within the Mediterranean Sea (bioregionalization), i.e. to propose a geographical framework where specific physical and chemical conditions are relatively stable, and where specific communities are likely to be found. The aim of this work is to characterize the biodiversity across the whole Mediterranean basin and to provide a more accurate bioregionalization of the Mediterranean Sea by focusing on the most abundant component of zooplankton: the copepods. Copepods are small (1 to 2 mm) crustaceans of prime interest for the study of pelagic food webs, both from a biological or a biogeochemical point of view. Indeed, they represent the intermediate between the primary production and the higher trophic levels. They are also a key element of the marine biogeochemical cycle of carbon through their production of particulate and dissolved organic matter. Besides, copepods are particularly fit for our purposes since they are ectotherms (meaning their internal temperature is the same as the one encountered in their environment) and unexploited by human activities. As part of the PERSEUS and MERMEX programs, a new dynamic mapping of the biogeochemical provinces has been established (Reygondeau et al., in prep). Some regions of the Mediterranean appear more stable, from a biogeochemical point of view, whereas others appear as much more variable "ecotones". In this context, we wondered how the copepod diversity was distributed over the Mediterranean Sea, and whether the copepod communities significantly differed between the different biogeochemical regions previously described.

Material and Methods
The first part of our work was to review the many studies conducted on the whole Mediterranean Sea (Razouls et al, 2005; Siokou-Frangou et al, 2010) and implement a new database of copepod occurrences from the ones already available online (COPEPOD/ IOBIS, Gbif, SESAME), completed with punctual datasets from various published studies. A total of 94959 punctual observations were gathered within an unprecedented database. From the latter, we have managed to compute and then map copepod diversity in terms of species and genus richness, and relate these to sampling effort, expressed as the number of net tows per geographical cells of 1°. Second, using an adequate distance's measurement for our dataset, we performed a clustering method to identify regions which could be gathered on the basis of their copepod communities. The last part of our study aimed to define the ecological niches (environmental envelops) of the most present species within the new dataset (Reygondeau et al., 2012). These models show the regions of the Mediterranean Sea that are favourable to the development of the species.

Main results and Discussion
We were able to describe the distribution of copepod diversity across the Mediterranean Sea, both at the species and at the genus level. Our data set covered all the Mediterranean Sea, except along the Libyan coast. The highest sampling efforts were recorded in the northwestern part of the Western basin, especially due to CPR (Continuous Plankton Recorder) data, while the lowest effort occurred near the Southern coasts (Levantine Basin, Algeria...) (Fig.1). It appeared that higher sampling effort did not lead to any particular increase in copepod diversity. Indeed, a few tows are enough to characterize the community, if taxonomic identification is done properly. Our results stress the need to realize a few tows in the depleted areas, using comparable sampling strategies. The clustering on raw observations evidenced a large community structure between the Western and Eastern basins, which could be characterized by significantly indicative species. Finally, we were able to estimate the probability of occurrence of 178 species over the whole Mediterranean Sea using niche modelling. These results were then used to describe a biogeography of the copepods in the Mediterranean Sea and to compute an estimate of copepod diversity. Also, clustering on all the niches confirmed and slightly refined the West/East community structure. Comparison with the biogeochemical regions (Reygondeau et al., in prep) hinted towards a "bottom-up" control of the copepod communities.

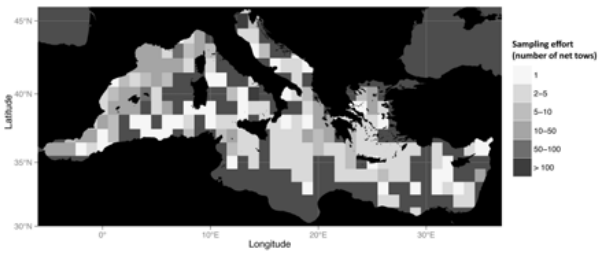

Fig. 1. Copepod data set and sampling effort. The map indicates the spatial coverage of our copepod observation data set. The number of sampling tows projected on a rectangular grid of 1° is also indicated

Abstract
As for many other benthic organisms, sponges are disappearing from several areas. The climate warming seems to be one of the most important causes involved in the phenomenon. Here we gather information on the distribution of the cup-shaped demosponge *Calyx nicaeensis* furnishing a first baseline for future monitoring and first observations regarding its natural history.

Keywords: Porifera, Conservation, North-Western Mediterranean

Introduction
Climate warming is altering the phenology and the distribution of a wide number of species both on land and underwater. To define which species are more vulnerable it is urgent to draw future scenarios for possible mitigation measures. In the Mediterranean Sea,filter feeders such as sponges and octocorals are among the phyla most affected by extended mortality events [1, 2]. Here we gather all the reports we found on the demosponge *Calyx nicaeensis* (Haplosclerida, Phloeodictyidae), a species that seems to be under fast regression in the NW Mediterranean Basin. The lack of a documented baseline does not allow knowing if this species is rare or actually endangered by anthropogenic impacts.

Material and Methods
To supply information about the distribution of *Calyx nicaeensis*, a detailed bibliographic study was performed, adding also unpublished record available on the web and recent records from Apulian coasts and Montenegro. Photo documentations allowed to highlight some peculiar aspects of the natural history of this species related to the collection of rolling coarse sediments and its asexual reproductive strategies (Fig. 1).

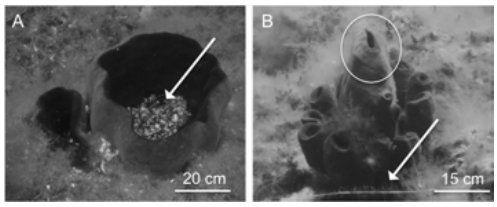

Fig. 1. Fig.1 *Calyx nicaeensis.* A) Sediment accumulation in the exhalant cavity B) Asexual reproduction by basal buds.

Results
Distribution. This sponge has a wide bathymetric range (down to 400 m depth) [4] but is mainly reported from 5 to 55 m depth in many areas of Mediterranean Sea (Tab.1). Its habitat is both *Posidonia oceanica* meadows and coralligenous concretions. When shallow, it is found in pre-cave conditions. *C. nicaeensis*, being with a vertical growth, in several cases was noted damaged by lost fishing lines. Sediment collection. Cup-shaped sponges inevitably entrap coarse sediments. These sponges have different strategies to manage this mound of coarse particles in the exhalant cavity. *C. nicaeensis* likely tend to collapse the osculum when filled by sediments (Fig. 1A). Asexual reproduction. This species shows a peculiar strategy of asexual reproduction, producing buds from the sponge base (Fig. 1B).

Conclusions
The findings of *Calyx nicaeensis* here reported cannot confirm an actual regression phase, anyway this species is certainly disappeared from the Ligurian Sea after its finding in the '60s [3]. A recent documentation from Montenegro, allows mentioning as a threat for this species areas with human impacts (e.g. artisanal fishery, coastal constructions, diving, sewage) and invasive species such as the algae *Caulerpa racemosa* and *Womersleyella setacea.* In conclusion, this species has a distribution highly fragmented, limited in few spots of the Mediterranean, asking for adequate and urgent conservation measures at Mediterranean level [5].

Abstract
Mussels *Mytilus* spp. belong to a group of key species in coastal marine ecosystems. This work demonstrates the dominant presence of Mediterranean mussel *M. galloprovincialis* along eastern Adriatic coast. Morphometric characteristics of sampled mussels were inside normal values for *M. galloprovincials*, with a height/length ratio of 55.89 ± 5.08 % and a width/length ratio of 38.76 ± 3.42 %. Populations of Croatian Adriatic Sea were nearly fixed for the G allele at the Me 15/16 locus as it is usually observed with M. galloprovincialis samples. However, two specimens among the 110 analysed showed a heterozygote genotype: one with an E (*M. edulis)* allele and one with a T (*M. trossulus*) allele. By sequencing PCR products we proved that the 126 bp, 168 bp and 180 bp bands correspond to the G, T and E alleles previously reported.

Keywords: Mollusca, North Adriatic Sea, Genetics

INTRODUCTION
There are four species of mussel of the genus *Mytilus*: *M. californianus* Conrad, 1837; *M. edulis* Linnaeus, 1758; *M. galloprovincialis* Lamarck, 1819 and *M. trossulus* Gould, 1850 [1]. In Europe *M. galloprovincialis* is found in the Black Sea, the Mediterranean Sea and the Iberian Atlantic coasts, *M. edulis* predominates in central and northern Europe, and *M. trossulus* occurs in the Baltic Sea and presumably in some other areas in northern Europe [2]. Identification of *M. edulis, M. galloprovincialis* and *M. trossulus* based on shell shape and morphometric parameters is usually uncertain because of the extreme shape plasticity exhibited by mussels under environmental variation [2]. Molecular markers now allow for positive identification of species although introgression sometimes obscures, if not biases when dismissed, the interpretation [3]. However, no large-scale detailed studies have been carried out to characterise the possible occurrence, even at low frequency, of heterospecific diagnostic alleles in the Mediterranean Sea [4, 5].

RESULTS
Morphometric characterisitcs of mussel shells
Morphometric characterization was done for collected *Mytilus galoprovincialis* (M.g). on the basis of 110 specimens, commercial *M. edulis* and *M. galloprovincialis* 20 specimens each. Morphometric measures were within normal values for *M. galloprovincials*: height/length 55.89 ± 5.08 % and width/length 38.76 ± 3.42 %.

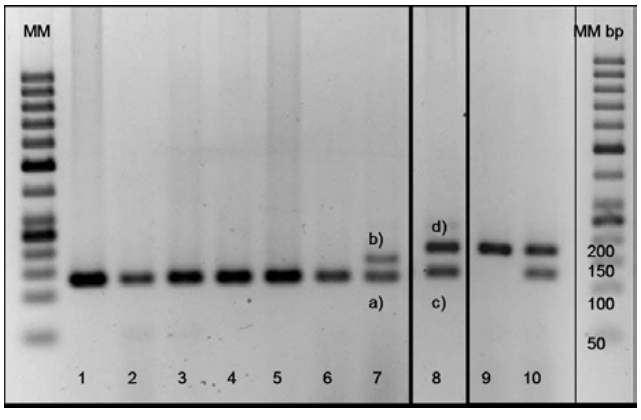

Fig. 1. Agarose gel with Me 15/16 PCR products: 1-6) *Mytilus galloprovincialis*, 7) heterozygous mussel with *M. galloprovincialis* and *M. trossulus*-type alleles, 8) heterozygote mussel M. g. and M. e. 9) control M. edulis and 10) composite sample of M. e. and M. g. with Mw markers (MM).

PCR sample analyses using Me 15/16 primers
Mytilus galloprovincialis (G) alleles were identified in all mussel samples/specimens at all 22 investigated sites. For the first time the presence of mussel heterozygote genotype were detected: M. *galloprovincialis – M. edulis* (GE-type alleles, site 9. Borik) and *M. galloprovincialis – M. trossulus* (GT-type alleles, site 15. Vranjic) using PCR (Mefp-1) amplification and sequencing analyses.
Although there was a tendency for the height/length values of heterozygote individuals to be closer to *M. edulis* (GE: h/l 46.90 %, w/l 38.45 %, GT: h/l 48.91 %, w/l 39.11 %), this was not significant.

Sequence analyses of PCR Me 15/16 products
Purified bands were directly sequenced using the same primers and obtained sequences were afterwards blasted: bands 1-6, 7a, 8c corresponded to *M. galloprovincialis*-type allele (Accession number: D63778.1, 3e-50), band 7b (*M. trossulus*, D50553.1, 5e-54), band 8d (*M. edulis*, AY845258.1, 9e-82), and band 9 (M. edulis, AY845258.1, 2e-83). After comparing the blast results we are confident that different sized PCR products represented the presence of *M. galloprovincialis, M. edulis* and *M. trossulus* adhesive foot protein gene alleles.

CONCLUSIONS
Morphometric measures were within normal values for *M. galloprovincials*: height/length 55.89 ± 5.08 % and width/length 38.76 ± 3.42 %.
Different alleles of the Me 15/16 locus and hybrids are detected in mussel populations of Croatian Adriatic Sea.
Species of the "*M. edulis* complex" or hybrids look very similar but have different growth rates, physiology adaptation, fitness, and therewith different aquacultre potential, pollution and stress tolerance.
Therefore, to prevent possible inaccurate interpretation of biomarker results, beside genetic identification of sampled species, additional parameters are welcome, making sure that the response measured is representative for the species and not for a particular individual of group of specimens.

BATHYMETRIC COMPARISON OF MEGAFAUNA IN THE SOUTH PART OF KYPARISSIA BAY, IONIAN SEA, GREECE

Giorgos Gitarakos [1]*, Pavlos Vidoris [1], Kostas Efthimiadis [1] and Argyris Kallianiotis [1]
[1] H.A.O. - Demeter, Fisheries Research Institute - geogitar@yahoo.gr

Abstract
Three samplings were carried out with bottom trawler in the southern part of Kyparissia Bay to record the fish fauna and to compare the different depth zones. It came out that the depth zones of 40 and 60 meters were more similar between them compared to that of 20 meters. The mean similarities of hauls inside each depth zone as well as the main species responsible for that similarity were calculated with ANOSIM and SIMPER analyses. The level of differentiation between depth zones was calculated with Two-way ANOSIM. The conclusion was that between depth zones species differed significantly, but similarities were also noticed. The most significant mean difference was between the 20 and 60 meter zones.

Keywords: Bathymetry, Ionian Sea, Trawl surveys

Introduction: A series of samplings took place in the southern part of Kyparissia Bay during the maturation study for the creation of an artificial reef. The maturation study aims at the recording of the area's fish fauna in the reef submersion area, the comparison of different depth zones and the assessment of the ecosystem's disorder by calculation of biodiversity indices. **Materials and methods:** Three seasonal samplings were carried out during 2010 (23/5, 2/6 and 30/9) with professional bottom trawler in selected routes so that the hauls to be parallel to the isobaths of 20, 40 and 60 meters. Three hauls per sampling were carried out. The catches were determined in the field in the taxonomic level of species and then they were weighted and measured. Species densities calculated in kilograms per km² were used for the comparison of the depth zones. Only the species that were recorded in at least 2 out of the 9 hauls were used in the statistical analysis. The dendrogram of similarities between the stations (cluster analysis) was calculated with non-parametric, multivariate analysis using the statistical program PRIMER (1) and by the triangular similarity matrix, based on the Bray - Curtis similarity indices between stations, after the transformation of data in [(χ½)½] was carried out. The statistical tests for the differentiation between depth zones and the determination of the main species responsible for the calculated differences were based on the statistical analyses ANOSIM (2) and SIMPER (3). **Results and discussion:** 61 species (47 fish, 6 cephalopods and 8 crustaceans) were recorded during the three sampling periods. 31 of them were used in the analyses since they were recorded in 2 or more hauls. The dendrogram of similarities (Fig.1) indicates that the stations were grouped per depth zone and that the depth zones of 40 and 60 meters are more similar between them than the one of 20 meters which is grouped separately.

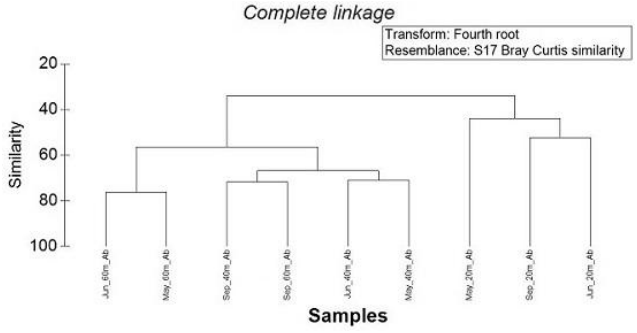

Fig. 1. Dendrogram of similarities for 9 stations sampled during 3 sampling periods. Y axis states % similarity between stations.

Average similarities (%) between hauls in each depth zone and species that contribute to that similarity were calculated with SIMPER analysis (Table I). Two-way ANOSIM was used to calculate *R* values that reveal differentiation between depth zones. *R* values (*R* global 0,667 with significance level 19,5%) show that although there are significant differences between depth zones, there are also similarities concerning species presence and relative abundance. Mean differentiation between the 20 and 40 m. zones was 43,44%, between the 40 and 60 m. zones was 35,71% and between the 20 and 60 m. zones was 52,97%.

Tab. 1. Average similarity for the grouping of stations for 20, 40 and 60 m. zones – Species responsible for the grouping of depth zones (Species) – Average abundance (Av.Abund) per zone - Average similarity of species abundance (Av.sim) - Similarity to standard deviation ratio (Sim/SD) – Contribution % to the similarity (Contrib%) – Cumulative contribution (Cum%).

Group 20m. zone	Average similarity 47,87%				
Species	Av.Abund	Av.Sim	Sim/SD	Contrib%	Cum.%
Mullus barbatus	15699	13,15	16,85	27,46	27,46
Pagellus erythrinus	1943	7,09	4,29	14,81	42,27
Trigla lucerna	130	4,76	6,7	9,94	52,21

Group 40m. Zone	Average similarity 70,17%				
Species	Av.Abund	Av.Sim	Sim/SD	Contrib%	Cum.%
Mullus barbatus	21828	10,46	5,38	14,9	14,9
Pagellus erythrinus	9792	9,93	14,69	14,15	29,06
Spicara flexuosa	4590	8,59	36,3	12,24	41,3
Serranus hepatus	1056	5,57	35,59	7,94	49,24
Trachurus mediterraneus	495	5,07	17,08	7,22	56,46

Group 60m. Zone	Average similarity 70,14%				
Species	Av.Abund	Av.Sim	Sim/SD	Contrib%	Cum.%
Sardina pilchardus	3234	7,21	9,8	10,28	10,28
Spicara flexuosa	7576	6,49	8,35	9,25	19,53
Parapenaeus longirostris	1369	6,03	8,61	8,59	28,12
Mullus barbatus	3586	5,89	8,56	8,4	36,52
Boops boops	1095	5,08	8,75	7,25	43,77
Serranus hepatus	639	4,87	9,86	6,94	50,71

The main species cumulatively responsible for at least 50% of zonal differentiation and their individual contribution was calculated with SIMPER analysis. Those were (with their contribution in parenthesis) *Mullus barbatus* (8,44%), *Spicara flexuosa* (6,58%), *Pagellus erythrinus* (6,31%), *Lepidotrigla cavillone* (5,76%), *Serranus hepatus* (5,51%), *Trachurus mediterraneus* (5,21%), *Boops boops* (4,8%), *Spicara smaris* (4,64%), *Bothus podas* (4,46%) for the differentiation between 20 and 40m., *Parapenaeus longirostris* (9,26%), *Sardina pilchardus* (8,34%), *P. erythrinus* (7,77%), *M. barbatus* (6,37%), *Trigloporus lastoviza* (5,24%), *Engraulis encrasicholus* (4,68%), *Pagellus acarne* (3,67%), *Citharus linguatula* (3,48%), *S. flexuosa* (3,33%) between 40 and 60m. and *S. pilchardus* (9%), *P. longirostris* (7,33%), *Merluccius merluccius* (5,86%), *B. boops* (5,42%), *S. flexuosa* (4,72%), *T. mediterraneus* (4,7%), *M. barbatus* (4,19%), *S. smaris* (3,88%), *S. hepatus* (3,78%) and *Sepia elegans* (3,38%) for the differentiaton between 20 and 60m. zones.

BATHYMETRIC DISTRIBUTION OF NON-DECAPOD CRUSTACEAN INVERTEBRATA SPECIES IN THE DEEP NORTHERN AEGEAN SEA

Onur Gönülal [1]*
[1] Istanbul University - ogonulal@istanbul.edu.tr

Abstract
The objective of the present study is to describe non-crustacean invertebrata species community in the deep northern Aegean Sea. We sampled non-crustacean invertebrata inhabiting the depth zone between 500 and 1500 m off the Gökçeada island (northern Aegean Sea). A total of 15 species of non-crustacean invertebrata has been identified at 33 stations.

Keywords: Deep sea ecology, North Aegean Trough, Zoobenthos

Introduction
The deep-sea environment is characterised by distinct vertical gradients of pressure, light, temperature and food availability [1]. The Mediterranean differs from other deep-sea ecosystems in terms of its species composition [5]. Typical deep-water groups, such as foraminifera and glass sponges are absent in the deep Mediterranean, while other faunistic groups (fishes, decapod crustaceans, mysids and gastropods) are poorly represented compared to the NE Atlantic [3] . Reviews on the biology and ecology of the Mediterranean deep sea have been published in recent years [4-5]. Depth-related changes in benthic fauna have frequently been studied in North-West and Central Mediterranean sea. Methods The deep-slope non-crustacean invertebrata fauna of the North Aegean sea was sampled with baited traps. A total of 33 stations were sampled between May 2010 and November 2011 in north eastern Aegean Sea trench (Fig 1). A total of 15 species belonging to various order were determined in five bathymetric intervals, 500-600 m, 600-800 m, 800-1000 m, 1000-1500 m. The results were analysed in terms of composition and distribution of benthic and benthopelagic bait-attracted species depth strata.

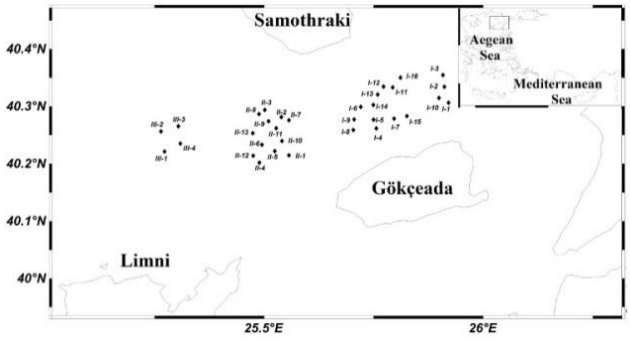

Fig. 1. Sampling station

Results and Discussion
The paucity of number of species in reported from deep sea ecosystems is mainly caused by sampling difficulties that result in low replicate numbers. Occurrence and percentage occurrence in all samples and bathymetric ranges were calculated for each species (Table 1). The most common species was *Euspira fusca*. It is followed by *Eurydice spinigera*. *Epimeria cornigera* and Polychaeta III sp. were present only at the deepest stratum (1000-1500 m). Changes in the species composition of the non-decapod crustacean fauna in the Northern Aegean sea consist basically in a decrease of the number of species with depth although the lowest numbers were not found at the deepest stations In adddition two pelagic gastropod *Diacria trispinosa* and *Cavolinia gibbosa* together with the gastropoda *Scaphander punctostriatus* are new record for the Turkish seas.

Tab. 1. Depth range, occurrence in numbers of each species in the total of samples (O), and percentage occurrence of each species in the total samples (% F) within each depth interval *new record for the Turkish seas

Abstract
The population genetic structure of *Palaemon elegans* has been investigated along the Turkish coasts using 16S rRNA and COI mitochondrial genes. Our findings revealed two distinct haplogroups in the region which were defined in a previous study. Dispersal of these two haplogroups which potentially correspond to separate cryptic species seems to be affected by the two layered current regime of the Turkish Straits System.

Keywords: Crustacea, Genetics, Black Sea, Marmara Sea, North-Eastern Mediterranean

Introduction
The detection of population differentiation in the marine realm is not straightforward due to the high dispersal capabilities of eggs, larvae and adults (Palumbi 1994; Ward et al. 1994). In addition, geographic barriers, considered to comprise one of the main mechanisms of speciation are far less obvious in the marine environment (Cunningham & Collins 1998; Palumbi 1994; Ward et al. 1994). However, all these generalizations may not be valid in every situation. Many studies have shown that high dispersal capabilities of marine organisms do not necessarily translate into high levels of realized gene flow (see Patarnello et al. 2007). In addition, straits can act as potential geographic barriers to gene flow in the marine environment (e.g. Briggs & Bowen 2012; Goldstien et al. 2006). In this study, we investigated the role of a unique marine ecosystem, the two-layered current regime of the Turkish Straits System (TSS), on the genetic structure of *Palaemon elegans* Rathke, 1837 populations. The system, consisting of the Bosphorus Strait, the Sea of Marmara and the Dardanelles, is the only connection between the Black Sea and the Mediterranean.

Materials and methods
210 samples of *P. elegans* were collected from 21 sites comprising the Black Sea (six), TSS (four) and the Mediterranean (eleven), and partial fragments of the mitochondrial large subunit rRNA (16S) and cytochrome oxidase subunit I (COI) genes were amplified and sequenced.

Results and discussion
The results showed 33 haplotypes and 52 variable sites (30 parsimony informative sites) for 16S ($h = 0.78 \pm 0.018$ and $\pi = 0.0151 \pm 0.0026$), and 78 haplotypes and 59 variable sites (34 parsimony informative) for COI ($h = 0.91 \pm 0.015$ and $\pi = 0.0395 \pm 0.0007$). Two different haplogroups (referred to as Group I and Group II) were retrieved for both of the genes in the haplotype networks. The analysis of molecular variance (AMOVA) indicated high levels of genetic structure among the populations ($\Phi = 0.78$ for 16S and $\Phi = 0.91$ for COI) when populations were grouped as Group I and II. Phylogenetic trees constructed using neighbor-joining and maximum likelihood methods also supported the differentiation of the groups I and II as two distinct clades. Reuschel et al. (2010) revealed a complex population structure in *P. elegans* and clearly distinct genetic lineages using 16S rRNA and COI mitochondrial genes with samples from Northeastern Atlantic, Baltic Sea, entire Mediterranean, Black Sea and Caspian Sea. Their defined haplogroups of Type II and Type III match our groups II and I, respectively. In our study, Group I with samples distributed relatively evenly includes specimens from all sampling sites. On the other hand, Group II consists mostly of samples from the Mediterranean, with only a few from the Black Sea and the TSS. It is likely that due to the two-layered currents of the TSS flowing in opposite directions (from the Black Sea to the Aegean at the top layer, and vice versa in the bottom), Group I was able to disperse from the Black Sea to the Mediterranean relatively easily after the last ice age. On the other hand, group II, originating in the Mediterranean was not able establish itself as effectively in the Black Sea (which has brackish water characteristics). Type III in Reuschel et al. (2010) which correspond to our Group I also seems to prefer brackish water habitats. Reuschel et al. (2010) suggested that these different genetic types may correspond to separate cryptic species and our findings also support the existence of two taxa of *P. elegans* around Turkey as well.

FISH COMMUNITIES AND THEIR DEPTH DISTRIBUTION AT VERTICAL CORRALIGEN REEFS IN THE ADRIATIC

Alen Soldo [1]* and Igor Glavicic [1]
[1] DEPARTMENT OF MARINE STUDIES, UNIVERSITY OF SPLIT - soldo@unist.hr

Abstract
Transect visual census method was used to investigated fish communities at vertical corraligenous reef from the surface to 50 m of depth. Total of 32 different fish species were observed, while the analysis indicated that temperature is the dominant factor influencing the depth distribution of the fish species during the summer period.

Keywords: Biodiversity, Central Adriatic Sea, Fishes

Introduction
Nowadays, in many marine habitats capture methods for obtaining various data are not allowed, thus replaced by non-destructive observational techniques, such as underwater visual census methods (UVC). Within various UVC methods, transect method is often used, but it is usually based on research of horizontal transects at depths mainly to 15 m, rarely exceeding 20 m, and nearly never 40 m. Consequently, underwater reefs with vertical walls deeper of 40 m were not investigated, so far.

Material and Methods
The study was carried out during July-August 2012 in area of the island of Hvar channel, central eastern Adriatic. Exact point of study was underwater reef, more than 200 m distant from a coastline, shaped as elliptical truncated and oblique cone. Highest point of the reef is at 9,1 m of depth, while deepest at 60,7 m. One side of the reef has a nearly uniform slope of an 90 degrees angle and exactly that part of the reef was chosen for this study. Base of the chosen part is at 50 m of depth, thus, that was also a deepest depth of the investigated area. Each transect length was 50 m, while width, or height as transects are vertical, was 5 m, making total of 10 transects. Two same divers were used each time, both experienced and skilled in diving and in fish and other marine species identification, for a recording of transects [1]. Compressed air was used for deeper depths while Nitrox as a decompression gas. Total of 15 dives were carried out using HD video camera while additional two dives were performed using photo camera for obtaining high resolution photos of smaller species used for their accurate identification. Temperature changes were measured at the end of each transect and additionally stored by Mares Icon HD diving computer.

Results and Discussion
Cover of the investigated reef area is coralligenous, with dominant species, depending on depth, green algae *Codium bursa* and *Flabellia petiolata*, bryozoan *Pentapora fascialis*, ascidian *Halocynthia papillosa*, and corals *Eunicella cavolini* and *Parazoanthus axinellae*. Total of 32 different fish species were observed, belonging to 13 families, with Sparidae, represented by 9 species, as dominant. Composition of fish species observed during this research showed high similarities with results of census study on the rocky coasts in western Adriatic area [2]. *Diplodus vulgaris* was dominant by number and total weight. Within all species only *Chromis chromis* was observed in all transects, from surface to 50 m. Second most distributed fish was *Coris julis*, absent only from surface to 8 m depth. Third most distributed species was *Gobius auratus*, present in all transects, except in water column, as this species lives exclusively in close contact with bottom. Correspondence analysis of species depth distribution (Fig.1) showed high similarities of transects 5-15 m, 25-35 m and 35-45 m. Transects 5-15 m and 45-50 m were most different compared to others probably due to reason that 5-15 m transects were above thermocline, while 45-50 m transect is the only one in contact with sandy bottom. The analysis indicated that temperature is the dominant factor influencing the depth distribution of the species during the summer period. Lowest number of species was observed exactly above and below the thermocline which usually occurred from 12 to 16 m of depth (Fig. 2). Species observed exclusively above the thermocline were *Symphodus tinca, Triperygion delaisi, Serranus scriba, Oblada melanura, Sparus aurata* and *Sarpa salpa*, while species observed only below the thermocline were *Labrus bimaculatus, Phycis phycis, Conger conger, Gobius geniporus, Gobius cruentatus, Gobius kolombatovici, Thorogobius ephipiatus, Serranus cabrilla, Scorpaena notata, Scorpaena scrofa, Spondyliosoma cantharus, Lithognathus mormyrus* and *Trigla lyra*.

Abstract
Cartographie du stock d'*Ostreopsis* macroalgal sur les côtes méditerranéennes françaises. En région PACA les Alpes-Maritimes sont des sites favorables, ainsi que la région de Marseille. En Corse, l'*Ostreopsis* est ubiquiste, mais la côte Ouest est la plus concernée. En Languedoc-Roussillon, l'*Ostreopsis* est très faiblement présent. Une analyse temporelle avec imagerie satellitaire et modélisation montre la complexité de l'évolution des stocks, mais pointe le rôle possible des dessalures issues des bassins versants.

Keywords: North-Western Mediterranean, Coastal waters, Blooms, Algae, River input

Le projet OSCREEN, soutenu par l'Agence de l'Eau RM&C, a permis à l'été 2011 de cartographier la présence du microflagellé épibenthique potentiellement toxique *Ostreopsis* spp sur le littoral méditerranéen français.

Les évaluations ont été faites à partir de trois prélèvements de macro-algues en juin, juillet et août, sur 80 stations du littoral méditerranéen français. Après séparation des macro-algues, les cellules d'*Ostreopsis* ont été dénombrées soit par la méthode Utermhöl, soit avec des lames de Sedgewick-Rafter, après avoir établi l'équivalence des méthodes.

On a pu ainsi établir la variabilité de sa présence sur les trois régions Provence-Alpes-Côte d'Azur, Corse et Languedoc-Roussillon. L'*Ostreopsis* se révèle présent à des niveaux très variables, sans doute en raison de la configuration de la côte (faciès rocheux et couverture macroalgale), et de la variabilité de facteurs environnementaux tels que la température et la salinité.
1. en région PACA, le secteur Est (globalement les Alpes Maritimes) réunit les sites où les dénombrements sont les plus significatifs. Le Var et les Bouches-du-Rhône semblent moins touchés, à l'exception de la région de Marseille (exemple des îles du Frioul).
2. en région Languedoc-Roussillon, l'*Ostreopsis* est présent, mais à des niveaux faibles qui semblent indiquer l'absence d'enjeu d'ordre sanitaire ou environnemental.
3. en Corse, l'*Ostreopsis* est ubiquiste, et la côte occidentale atteste de niveaux de présence significatifs, surtout entre Propriano et l'Île Rousse.

Sur huit stations d'observation, une analyse temporelle des stocks macroalgaux d'*Ostreopsis spp.*, couplée avec l'utilisation d'outils d'imagerie spatiale et de modélisation hydrodynamique, a montré la complexité des interprétations des tendances, mais a mis en évidence le rôle probable des dessalures et de leurs apports induits sur l'ampleur des efflorescences de l'*Ostreopsis spp.* La figure 1 illustre la relation entre la variabilité de la salinité établie pour chacun des huit sites, *t*émoin des conditions pluviométriques qui ont caractérisé l'été 2011 ainsi que des apports des bassins versant , et l'importance des stocks d'*Ostreopsis* macro-algal rencontrés sur ces sites.

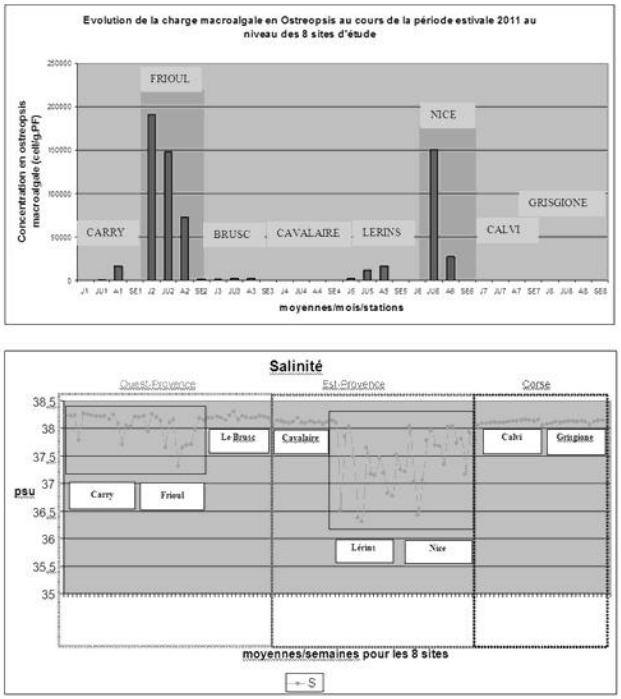

Fig. 1. Relation entre les stocks marcoalgaux d'*Ostreopsis* et la variabilité de la salinité sur les huit sites

ON THE RECENT INCREASE OF *PENAEUS (MELICERTUS) KERATHURUS* STOCK IN NORTHERN AND CENTRAL ADRIATIC SEA: POSSIBLE EXPLANATIONS

Carlo Froglia [1]*, Giuseppe Scarcella [1] and Alessandro Lucchetti [1]
[1] C.N.R. - ISMAR, u.o.s. Ancona, Largo Fiera della Pesca, 60125 ANCONA - ITALY - c.froglia@alice.it

Abstract
The penaeid shrimp *Penaeus (Melicertus) kerathurus*, never recorded in the Northern Adriatic before the 20th century, has become a valuable fishery resource in the last 20 years. The stock increase in the Adriatic may be related to the warming of the basin and the build-up of suitable nursery grounds all along the West coast, after the construction of detached breakwaters to reduce erosion of sandy beaches.

Keywords: Central Adriatic Sea, Fisheries, Tropicalization, Decapoda, North Adriatic Sea

The caramote shrimp is a large Mediterranean autochthonous shrimp that lives on soft bottoms of the continental shelf, usually at less than 60 meters depth; juveniles enter lagoons and are common on coastal grounds in late summer and autumn. It is caught mainly with bottom trawls and fixed set nets. Therefore it could not escape attention of fishermen and early naturalists. It was reported, already in the early 19th century, from all over the Mediterranean Sea as: *Cancer kerathurus* Forskål, 1775 (Smirne and Alessandria), *Alpheus caramote* Risso, 1816 (Nice), *Melicertus tigrinus* Rafinesque-Schmaltz, 1814 (Sicily).
But in the Adriatic Sea, one of the best studied areas of the Mediterranean Sea, it was unknown until the second half of the 19th century. The first record, from the South-eastern Adriatic, dates to 1863 [1] and Pesta in 1918 [2] still considered its presence in the North Adriatic Sea as doubtful.
Nowadays it is a highly valuable fishery resource in the northern and central Adriatic Sea (GSA-17), with annual landings estimated around 500 tons, peaking in the last quarter of the year, when the new generation of shrimps, born in summer, moves offshore and is fully recruited to the fishery.
Penaeus kerathurus has always been a high priced shrimp, due to its large size and the quality of meat, but statistics of its landings are not available for the Adriatic Sea prior to 1980's, because the few specimens caught were sold in mixed boxes of first category sea-food. Landings significantly increased at the end of 1980's and separate statistics for the product auctioned in the main gross fish-markets were recorded. Data available for the main fishing harbour of the Central Adriatic (Ancona) and of the North Adriatic (Chioggia) [3] are presented in Fig. 1.

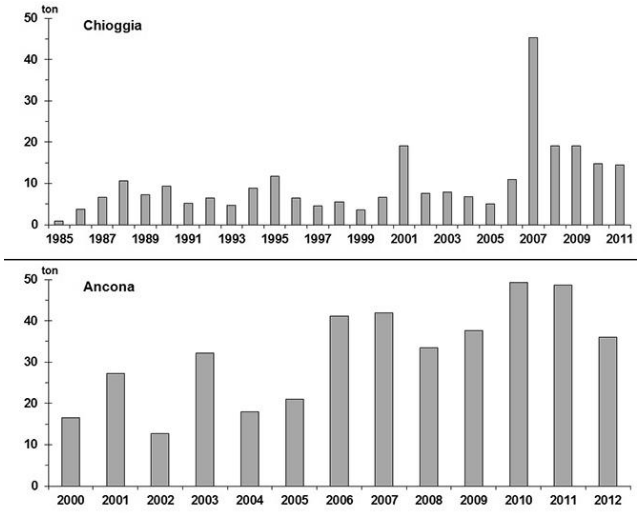

Fig. 1. *Penaeus kerathurus* auctioned yearly in the fish-markets of Ancona and Chioggia.

A marked reduction of the landings of *Nephrops norvegicus* was recorded in the same years. *Nephrops norvegicus* is a cold-temperate species, distributed from southern Iceland to Morocco, whereas *P. kerathurus* is a warm-temperate species, distributed from Angola to southern England.

Thus the increase, and northward expansion, of the Adriatic stock of *P. kerathurus* could be regarded as another example of "meridionalization" of northern sectors of the Mediterranean sea, as consequence of its warming [4]. But at least two other factors have acted synergically.
1) The Italian annual ban of trawling for 30-45 days at the end of summer, in force since 1987, and the other measures taken more recently to reduce the fishing effort exerted by towed gears in coastal waters have been highly beneficial to *P. kerathurus*, characterized by short life-span (max. <3 years), fast growth and reproduction at the end of first year of life (in the early summer). Limited effects could be expected from this reduction of fishing effort, for *N. norvegicus*, that has a different life history (long living, slow growing and first spawning only in the third year of life).
2) In the last 50 years, detached breakwaters have been built parallel to the shore, at 100-200 m from shoreline, all along the West Adriatic coast, to reduce erosion of sandy beaches [5]; these man-made structures form a kind of narrow "lagoon" (Fig. 2) that extends for hundreds of kilometers south of the Po River Delta and acts as a new suitable nursery ground for the shrimps, enhancing recruitment.

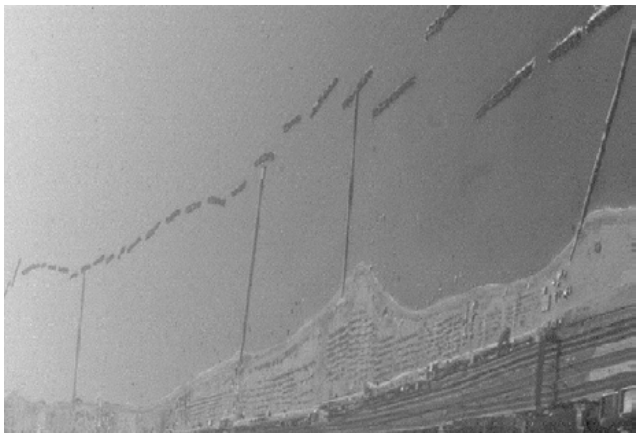

Fig. 2. Central Adriatic, aerial view of breakwaters built in front of the shoreline

20-YEARS OCCURRENCE OF THE INVASIVE ALGA *CAULERPA RACEMOSA* VAR. *CYLINDRACEA* IN GREECE

Panayotis Panayotidis [1]* and Konstantinos Tsiamis [1]
[1] Hellenic Center for Marine Research - ppanag@hcmr.gr

Abstract
The green seaweed *Caulerpa racemosa* var. *cylindracea* is one of the most aggressive and broadly distributed invasive taxa in the Mediterranean Sea. In the present study, an updated range expansion of the alga is provided for the Greek coasts, based on literature sources and recent personal collections. Moreover, invasive events hitherto reported from the Greek coasts are also cited in detail

Keywords: Algae, Aegean Sea, Alien species, Ionian Sea

The green alga *Caulerpa racemosa* var. *cylindracea* (Sonder) Verlaque, Huisman & Boudouresque (Bryopsidales, Caulerpaceae) is one of the most notorious and aggressive invaders in the Mediterranean Sea ([1]). Since the last decade of the 20th century it has exhibited a spectacular expansion in the whole Mediterranean basin ([2]). Its presence has been related with negative impacts to the native benthic communities ([3]). Nevertheless, some positive impacts have been reported from deeper un-vegetated habitats (Relini, personal communication).
In the present study an updated range expansion of *C. racemosa* var. *cylindracea* (hereafter *C. racemosa*) along the Greek coasts is presented, based on both literature records and our recent collections (years 2007-2013), as part of one of the authors (KT) PhD thesis.
After 20 years since its first report from Greece (1993 in Zakynthos Island [4]), today *C. racemosa* var. *cylindracea* can be found in the majority of the Greek seas (Figure 1), presenting an extremely high dispersion rate, possibly related with translocation in short distances through shipping (anchoring and fishing equipment). In fact, an ongoing gradual expansion from the S. Aegean towards the N. Aegean Sea can be observed (Figure 1).

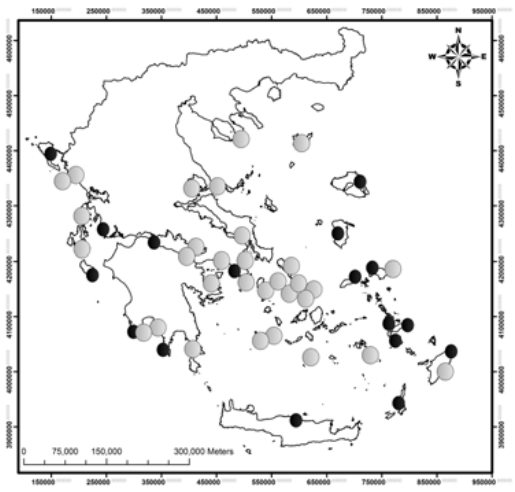

Fig. 1. Distribution records and range expansion of Caulerpa racemosa var. cylindracea in Greece. Both old (before 2007 - black dots) and new records (after 2007 - grey dots) are also given.

C. racemosa is present through the whole year, but higher abundances have been recorded during summer months. Holocarpic plants have been also recorded during summer. There is an intense polymorphism of the thallus depending on the depth and the hydrodynamism (vesicles distichously to spirally arranged on the erect fronds).
C. racemosa presents a broad ecological niche, since it has been found on both polluted and pristine sites, in hard and soft substrates, from surface level down to 70 m depth. However, more abundant populations have been found on rocky slopes with macroalgae and on dead *Posidonia* mattes ([5], [6]).
Although *C. racemosa* has been found on numerous Greek coasts, only in 5 cases invasive behavior has been reported (Table 1). During our recent deep-sea exhibition using ROVs down to 120 m depth in the Greek Ionian Sea, vast meadows of *C. racemosa* lying between 40-70 m depth on sandy and muddy bottoms were detected (Table 1). This monopolization of the sea-bottom should be related with the empty ecological niches found on those depths and substrates. On the other hand, in swallower habitats, where competition from the native flora is much higher, *C. racemosa* abundance seems to be restricted in lower values.

Abstract
Les analyses des spécimens pris par les chalutiers opérant dans la mer d'Alboran et les recherches menées à bord du bateau M.S. Meriane en 2006, dans la baie de Cadiz, ont montré la répartition des colonies coralliennes d'eau froide entre Tanger et Al Hoceima. La majorité des colonies sont observées à l'état fossile et ~5% montrent des formes de vie. Les polychètes, mollusques et crustacés observés à l'intérieur ou à proximité du corail des abysses sont menacés par les chalutiers dans l'aire marine protégée d'Al Hoceima et le reste de la côte marocaine en Méditerranée.

Keywords: Alboran Sea, Bathyal

Introduction: La rive sud de la mer d'Alboran a connu la mise en place dune aire marine protégée incorporée dans le parc national d'Al hoceima en 2004 et 4 autres sites d'intéreêt biologique et écologique en cours de réflexion pour les inclure dans les aires marines protégées : Cap des Trois fourches, Sebkha Bouareg (Lagune de nador), l'Embouchure de la Moulouya et la côte des Ghomara. Une faune importante de corail tapisse les fonds marins dans cette rive ; cependant, de nombreuses colonies ne sont connues qu'à l'état fossile dans la zone bordant Tanger au sud de la baie de Cadiz (Gardner, 2001 ; Rodrigues & Cunha, 2005 ; Depreiter *et al.*, 2005 ; Van Rensbergen, P., 2005 ; Van Rensbergen *et al.*, 2005 et Hilário et al., 2010). L'éruption des volcans de boue dans les abysses était la cause de la disparition d'un grand nombre de colonies coralliennes, ce qui a permis de classer ces habitats écologiques parmi les points chauds « hotspot » et les proposer pour des aires marines protégées. La survie de ces colonies menacées de disparition est particulièrement préoccupante chez les scientifiques.

Matériel et méthodes: Les nouvelles technologies océanographiques utilisées dans la partie sud de la baie de Cadiz a servi de base pour la découverte des volcans de boue et les récifs coralliens d'eau froide, à partir de 1999 (Gardner, 2001 ; Rodrigues & Cunha, 2005). La recherche marine menée récemment à bord des chalutiers dans la région d'Alhoceima et du cap des Trois fourches ainsi qu'à bord du bateau Maria S. Meriane en 2006 a permis d'identifier la distribution des principaux domaines de coraux d'eau froide à la frontière des profondeurs de la partie ouest méditerranéenne.

Résultats et discussion Les sédiments récupérés par le carottier multiple dans les zones des volcans de boue aux environs de Tanger, sont peuplés par une importante population d'annélides Pogonophores. Ces vers tubicoles paraissent parfaitement adaptés à la vie en surface des habitats profonds bien oxygénés que dans les strates profondes riches en méthane et en sulfure. Cette population massive de pogonophores est en mesure d'exploiter l'énergie du méthane pour le métabolisme et la croissance. En termes de mode de distribution des colonies du corail d'eau froide dans la baie de Cadiz au large des côtes marocaines, une analyse à été portée sur les *anthozoaires hexacoralliaires (Scléractinaires).* Une attention particulière a été accordée à l'interaction de l'écoulement du fluide actif des volcans de boue avec la présence spatiale des colonies de corail. Les zones parcourues par des caméras OFOS étaient Mercator MV et sa structure de crête adjacente, la crête de Vernadski, l'escarpement du Pen Duick, Renard Ridge, Meknès MV t Captain Arutyonov. En outre, les coraux ont été cartographiés et recueillies le long des pentes profondes affectées par les masses d'eau méditerranéennes. Les communautés coralliennes observées sont majoritairement mortes t à l'état fossile. Aucune trace de vie des espèces *Lophelia pertusa*, *Madrepora oculata*, *Dendrophyllia cornigera*, *D. alternata* et D. cornucopia. Une analyse minutieuse des sédiments ramenés par les carottiers à boîte donne des preuves que l'espèce de corail *Stenocyathus vermiformis* (Pourtalès, 1868) présente peu de formes vivantes dans certains sites visités. Les unités sédimentaires de surface sont dominées par *Dendrophyllia* sp. et Stenocyathus vermiformis. *Spondylus gussoni* est l'espèce de bivalve qui semble étroitement liée lié au squelette de corail. Plus bas escarpoements des volcans de boue, cet assemblage est remplacé de plus en plus par *Madrepora oculata* et Lophelia pertusa. On remarque une association formée de *Desmophyllum crista galli* et *Caryophyllia sarsiae* ou *Caryophyllia calveri*. Selon une étude sur les Hydraires des zones bathyales dans la partie sud de la baie de Cadiz, (Maura *et al.*, 2008), les auteurs se basés sur les séquences des gènes d'ARN mitochondrial et ont identifié 6 familles espèces ont été identifiées dans la zone des abysses bordant les côtes marocaines au voisinage de Tanger : Les Eudendriidae représentée par : *Eudendrium rameum ; Eudendrium* sp. 1 et *Eudendrium* sp. 2. Les Lafoeidae : *Acryptolaria conferta*, Lafoea cf. *dumos*a, *Zygophylax biarmata* et *Zygophylax levinseni marrocanum.* Nous avons observé également cette dernière espèce dans les escarpements chalutables du cap des Trois Fourches et aux environs des iles Shafarinas (cap de l'eau). Les Haleciidae : Halecium sp. 1 ; Les Sertulariidae est représentée par Sertularella gayi robusta, Sertularella polysonias Plumulariidae Nemertesia cf. antennina ; Nemertesia ventriculiformis et Polyplumaria flabellata. La famille des Aglaopheniidae avec: *Aglaophenia lophocarpa - Aglaophenia tubulifera.* Ces colonies coralliennes sont liées à l'eau froide (température allant de 4 à 13 ° C). Elles sont généralement observées à l'état fossile, et quelques localités montrent des formes de vie, à des profondeurs allant de 500 à 3500 mètres sur la baie ibéro-marocaine et au sud de la mer d'Alboran. Ces colonies de coraux d'eaux froides se développent très lentement (dix fois moins vite que les coraux tropicaux d'eau chaude) et forment des structures tridimensionnelles très fragiles et vulnérables. La faune des hexacoralliaires est moins diversifiée dans le versant sud de la mer d'Alboran selon nos observations et la menace provient particulièrement du chalutage intensif dans la région.

REGIONAL EXTINCTIONS AND INVADERS' DOMINATION: AN ECOSYSTEM PHASE-SHIFT OF LEVANT REEFS

Gil Rilov [1]*
[1] National Institute of Oceanography Israel Oceanographic and Limnological Research (IOLR) - rilovg@ocean.org.il

Abstract
The previously Atlanto-Mediterranean dominated biota of the Levant rocky reefs is showing recent major shifts in its biodiversity. Several ecologically-important species (a vermetid gastropod, sea urchins and a large predatory snail) exhibited major population collapses while several key taxonomic groups (gastropods and bivalves and to some extent fish) are completely dominated by IndoPacific invaders. I suggest that this biogeographic shift may be partly driven by global climate change. The southeastern coastal waters of the Mediterranean have warmed by 1.5-2 °C in the past two decades and may have become too hot for some indigenous species and more hospitable to tropical species. Recent lab experiments indicate that the abundant sea urchin, *Paracentrotus lividus*, is indeed dying during peak summer SST on the Israeli coast.

Keywords: Global change, Zoobenthos, Alien species, Levantine Basin, Echinodermata

The marine biota of the Levant basin was until recently dominated by Northeastern Atlantic and Atlanto-Mediterranean species. However, a major shift in the past few decades is transforming this sea into a new phase in which prevailing indigenous species are disappearing and (mostly) tropical species are taking over by their massive invasion. This has been recently demonstrated with trawl fishery data [1], and here I show that the same process is occurring on rocky reefs, a dominant ecosystem in the shallow waters of the Levant shores.

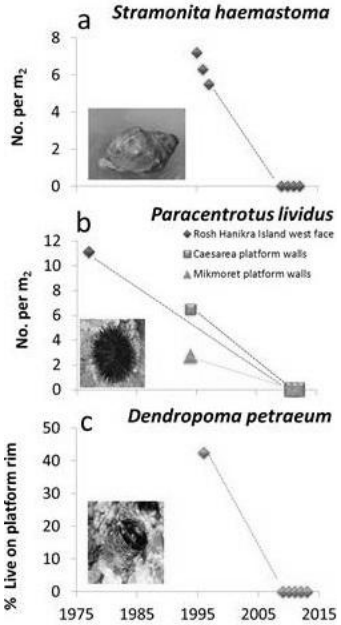

Fig. 1. Changes in (a) whelk density on intertidal rocks (a site in north Israel. The species in the 1990' showed no recruitment of juveniles), (b) urchin density at 3 subtidal reefs where anecdotal surveys were done in the past (today the species is extremely rare), and (c) percent cover of the vermetid at the edge of an intertidal reef on the central coast where the species was still abundant in the mid 1990' (the species was patchy then at both the site and coast scales). *Dendropoma* was still around in the early 2000's [5], but in the past 5 years it has been extremely rare along the Israeli coast (ecologically extinct). The dotted lines demonstrate trends; the trajectory is unknown.

Using past sporadic data and data from a current survey and monitoring program along the entire Israeli coast I show evidence for population collapses and possibly regional near-extinctions of four ecologically important and once highly abundant benthic species (Fig. 1): an ecosystem engineer (vermetid gastropod – *Dendropoma petraeum*), a predator (whelk – *Stramonita haemastoma*, [2]) and herbivores (two sea urchins – *Paracentrotus lividus*, and *Arbacia lixula*). Comparing literature species descriptions to the current surveys suggests that dozens of once abundant native molluscan species are now rare or absent along the Israeli coast. The reasons for the collapses are unknown but because the Levant represents the eastern edge of these species distribution and conditions there are already extreme, climate change (SST has increased by at least 1.5 °C in the past two decades) cannot be ruled out [3]. Recent lab experiments indicate that today's peak summer SST is indeed killing urchins, but past (1980-90's) temperatures do not.

The other side of the change is species additions through bioinvasions [4]. Recent data reveal a massive domination of subtidal rocky reefs and some intertidal reefs by (mostly) Indo-Pacific species. For example, of all benthic fishes (excluding cryptic species) that were counted underwater, more than half were invasive. Other taxonomic groups have dominant invaders, but the most outstanding result is the total domination of the gastropod and bivalve macrofauna by invasive species – 99.5% and 99%, respectfully, of all individuals from those groups counted on the rocks were aliens. The largest bivalve, the invasive oyster-like species, *Spondylus spinosus*, now forms in some areas extensive aggregations that completely change the structure of the reefs. Clearly, the ecological implications of these species collapses and invasions, including their effects on ecosystem functions, must be profound and should be urgently studied.

LES PINGERS COMME MOYEN D'ATTÉNUATION DES INTERACTIONS NÉGATIVES DU GRAND DAUPHIN AVEC LES FILETS MAILLANTS AUX ÎLES KERKENNAH (TUNISIE)

Amani Ayadi [1]*, Mohamed Nejmeddine Bradai [2] and Mohamed Ghorbel [1]
[1] INSTM (Centre de sfax) - instm.amani@hotmail.com
[2] INSTM (Centre de sfax)

Abstract
Aux îles Kerkennah, le grand dauphin entre en interaction avec les filets de pêche et engendre des problèmes socio-économiques épineux. Pour résoudre ce problème, une expérimentation de pingers Aquamark 210 a été effectuée dans le but d'atténuer ce phénomène. Avec le soutien des pêcheurs locaux, les pingers Aquamark 210 ont été expérimentés sur les filets maillant durant la saison estivale. Dans l'ensemble, les filets équipés de pingers ont été plus attaqué que les filets sans pingers. La capture par unité d'effort a été diminuée de 47.5%. Nos résultats suggèrent que les pingers Aquamark 210 testés au niveau des pêcheries artisanales aux îles Kerkennah augmentent le taux d'interaction, mais une étude plus étendue dans le temps serait nécessaire.

Keywords: Acoustics, Cetacea, Tunisian Plateau, South-Central Mediterranean, Coastal waters

Introduction
En Méditerranée, les dauphins sont impliqués dans la déprédation des poissons dans différents engins de pêche, notamment les filets maillants et les filets trémails [1, 2]. En réponse à ce problème, les pêcheurs adoptent souvent des méthodes agressives telles que l'alimentation répugnante pour maintenir les cétacés loin de leurs filets de pêche. Les dispositifs de dissuasion acoustiques tels que les pingers ont été essayés dans plusieurs régions maritimes pour faire face à ce problème: Spain [1]; Italy [3]; Greece [4]; Morocco [5], mais leur efficacité reste encore discutable. La dernière décennie a vu un effort de recherche accru sur l'efficacité de ces dispositifs de dissuasion acoustiques et les résultats montrent que l'efficacité peut varier considérablement entre les zones de pêche, les espèces et l'engin de pêche. Dans ce contexte, l'Institut National des Sciences et Technologies de la Mer (INSTM) avec le soutien financier d'ACCOBAMS (Accord sur la Conservation des Cétacés de la Mer Noire, de la Méditerranée et de la Zone Atlantique Adjacente), a entrepris une étude sur l'efficacité du dispositif acoustique Aquamark 210 conçu pour éloigner les dauphins des filets maillants.

Matériel et méthodes
Pour cette étude, 32 opérations de pêches ont été réalisées durant le mois de Juillet 2010. 16 opérations de pêche ont été équipées par des pingers Aquamark 210 et 16 ont joués le rôle de contrôle (non équipé par des pingers). Au cours des opérations de pêche, les pingers ont été fixé en haut du filet (prés des flotteurs). Au total, nous avons utilisé 27 km de filets maillants dont 12 km sont équipés par des dispositifs acoustiques. Les opérations de pêche ont été réalisées à une profondeur moyenne de 3.9 m et une durée moyenne de mouillage de 46 min.

Résultats et discussion
Etude de la capture par unité d'effort (CPUE)
La capture par unité d'effort totale (kg/50 m de filet) est de l'ordre de 0.132 kg. Cette CPUE varie selon la présence ou l'absence des pingers. Pour les filets maillants équipés de pingers, cette CPUE est de 0.098 alors qu'elle est de 0.166 kg pour les filets sans pingers; cette différence est statistiquement significative (F=4.74, p = 0.038). La figure 1 illustre la variation de la capture par unité d'effort totale en présence et en absence des pingers dans la pêche par les filets maillants à Kerkennah.

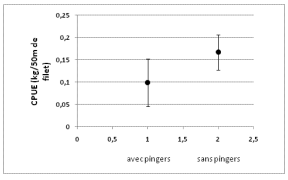

Fig. 1. Variation de la capture par unité d'effort totale en présence et en absence des pingers dans la pêche par les filets maillants à Kerkennah.

Etude de la valeur de la production
Il est à signaler que le prix moyen de poissons est plus élevé pour les pièces de filets non équipées de pinger que dans l'autre cas (43.75 DT (Dinar Tunisien) contre 20.62 DT). Cette différence est statistiquement significative (F=5.4 et p = 0.026). Dans cette étude, les filets équipés de pingers ont subi plus de dégâts, à la fois en termes de production et de pertes à gagner. Il semble que les dauphins s'approchent des pingers au lieu d'être repoussés, ce même résultat a été reporté ailleurs [7]. Il est possible que les dauphins soient alertés des filets et poissons par la présence des pingers. Dans notre cas, l'effet des pingers sur les dauphins peut confirmer l'hypothèse proposée par Kraus et Brault [8] selon laquelle les dauphins ne sont pas gênés par les sons émis par les pingers.

Conclusion
Dans notre étude, les pingers n'ont pas éloignés les dauphins des filets maillants. D'autres études prouvent que les filets maillants équipés de pingers présentent une CPUE plus importante que ceux sans pingers (0.96±0.10 kg/km/h > 0.50±0.06 kg/km/h) [9].

DISTRIBUTION OF UPPER CONTINENTAL SLOPE FISHES IN THE NORTHEASTERN LEVANTINE SEA (MEDITERRANEAN SEA)

Cem Dalyan [1]*, Emre Yemisken [1] and Lutfiye Eryilmaz [1]
[1] Istanbul University Faculty of Science, Department of Biology - dalyan_cem@yahoo.com

Abstract
30 trawl operations were carried out in the Levantine Sea with the aim to determine the distribution of upper slope fish assemblages. In total, 63 fish species were observed, as mostly composed with *C. agassizi*. The border between the upper and middle slope determined by the soft bottom communities, is at 400-500 m depths in the Mediterranean Sea. Our findings support this information for the Levantine Sea.

Keywords: Fishes, Continental slope, Levantine Basin

Introduction
The major factor on changes of faunal composition for the marine environment is the depth, especially being decisive in upper continental slope organisms that the stocks could be considered instead of exploited coastal fisheries resources [1,2,3]. Moreover, fishing activities are gradually increasing on the upper slope zone of the northeastern Levantine Sea. Yet, there isn't any comprehensive study on distribution of upper slope fishes and their stocks in the Levant Sea. The aim of the present study is to report first data on spatial and temporal characteristics of fish assemblages in the upper slope of northeastern Levantine Sea.

Materials and Methods
This study was carried out between 221 and 777 m depths, 9 – 24 nautical miles off Iskenderun Bay trimonthly (February – May – August – November) in 2010, with 30 trawl operations. Towing speed was measured by GPS as 2.5 – 2.7 knots. Towing time was between 65 and 180 min. The all specimens are identified to the lowest taxonomic category possible. The operations were performed with commercial fishing vessels. In total 63 species (13 Chondrichthyes species belonging to 9 families and 50 Actinopterygii species belonging to 33 families) were collected. Because F. commersonii is found in coastal waters, it was excluded from the analysis and was assumed as an incidental catch. Abundance data was analyzed with multivariate analysis techniques in the package Primer 6 [4].

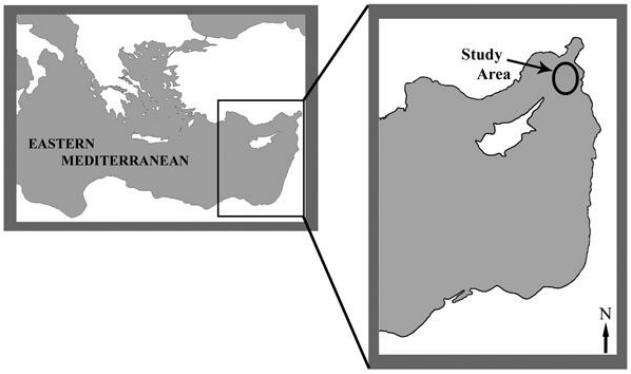

Fig. 1. Study area in the northeastern Levantine Sea.

Results and Discussion
Chlorophthalmus agassizi, Coelorhynchus caelorhynchus, Dipturus oxyrinchus, Helicolenus dactylopterus, Lepidorhombus whiffiagonis, Lophius budegassa, Merluccius merluccius, Phycis blennoides, Scyliorhinus canicula, Synchiropus phaeton were found in all depth ranges between 200 and 800 m. C. agassizi has the highest abundance and biomass per unit area and dominancy among fish species (Fig 2). H. dactylopterus was represented with the highest frequency value in sampling periods. The maximum number of species was observed at 200 – 299 m depth contour but the highest abundance score was obtained at 300 – 399 m depths. Shannon-Wiener index and Pielou's evenness index achieved the maximum values at 200 – 299 and 700 – 800 depth contours. In sampling periods, the highest average number of fish species was obtained in August with nineteen species. High abundance values were estimated in November although the Margalef diversity index and Simpson's dominance index were of lowest value.

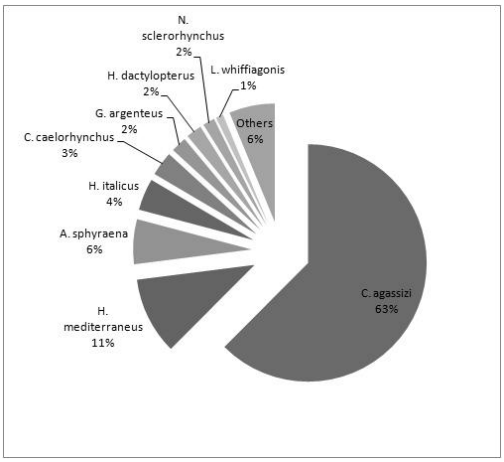

Fig. 2. The percentages of the species abundance observed in the northeastern Levantine Sea.

In the present study, spatial and temporal distribution of fish species were examined in the upper slope of Levantine Sea, ranged from 200 to 800 m depths. The lower limit of the upper slope that is theoretically adopted as 800 m, is revealed as 400 – 500 (450) m depth such as the West and Central Mediterranean Sea.

ECONOMIC ASSESSMENT OF TURKISH PURSE SEINERS OPERATED IN THE BLACK SEA

A. Cemal Dincer [1]* and Tanju Mutlu [2]
[1] Karadeniz Technical University Faculty of Marine Sciences - cdincer@ktu.edu.tr
[2] Recep Tayyip Erdogan University, Vocational School of Technical Sciences, Rize, Turkey

Abstract
To assess and evaluate the economic performance of Turkish purse seiners operated in the Black Sea, five representative commercial fishing vessels of different lengths were examined. The data related to the catches of the vessels were obtained from the two consecutive fishing seasons of 2010 and 2011 years. Economic information concerning the cost and earnings was based on the data sheets given to vessels and field surveys.Net present value (NPV) method was used as economic criteria to compare the profitability of the vessels. It was found that optimum engine power for the fishing vessels was about 3000 HP and the optimum gross tonnage (GT) was about 250.

Keywords: Fisheries, Black Sea

introduction Approximately 70% of Turkish sea fishing catch (500.000 tons) is obtained by purse seiners and based on the major pelagic species sush as anchovy**,** horse mackerel, and bonito [1]. Among these species the anchovy is the major catch component coming from the Black Sea and amounts to about 280.000 tons yearly. Fishing for anchovy is practised by purse seining with a single mother vessel [2]. Previous studies on the economic performances of the Turkish purse seiners are rather old and lack to some extent [3,4]. Since then, the occurrences of dramatic increases in the capacity of fishing fleet causes the need to re-examine the economic assessments of such vessels.

Materials and methods

Catch data were obtained from fishing experiments carried out by five commercial purse seiners in the Black Sea in years 2010 and 2011 seasons. Lengths of the vessels were 20, 28, 36, 37 and 49 m and lettered by A, B, C, D and E, respectively. Engine powers in HP varied from 400 to 4300 and the gross tonnages were also varied from 49 to 490 from the smallest to the largest one. For the economic analysis of fishing, catch was valued according to local market price. All costs were expressed in Turkish currency (1 TL = US$ 0.555=€ 0.434, 4 April 2013). The net present value (NPV) was used as a technique to evaluate the fishing investments of the vessels.

Results and discussions According to results of NPV calculations, the NPV values in 10^3 TL for the vessels A, B, C, D and E are found to be 331, 996, 1180, 1618 and 1351, respectively. Since all vessels under examination have positive NPV values, they are all considered to be profitable from the point of view of investment projects. However, with the highest NPV the Vessel D appears to be the most profitable one and because of the lowest NPV the vessel A is the least profitable investment. The variation of NPV values according to engine powers and tonnages are shown in Figure 1 and Figure 2. From these figures the optimum values for power and tonnages can be read as 3000 HP and 250 GT, respectively.

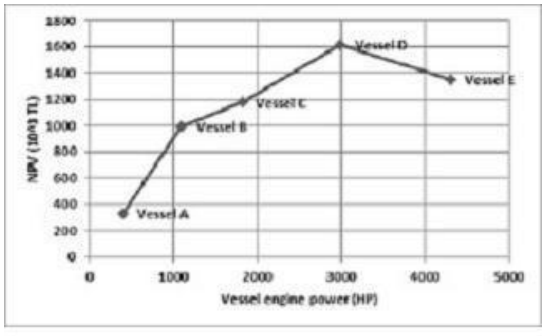

Fig. 1.

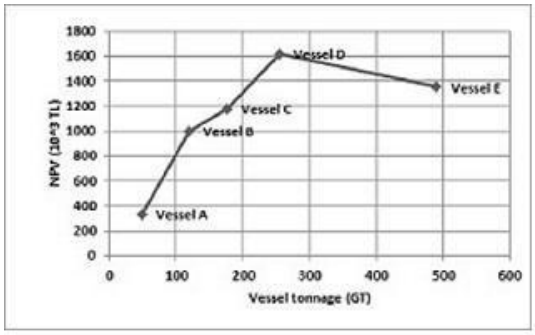

Fig. 2.

The tendency among fishers to increase the fishing capacity of the vessels by means of larger sizes and higher powers beyond the optimum points is not only meaningless for economic view point but may also endanger the fishing sustainability.

FISHERMAN COOPERATION: THE KEY FOR A SUCCESSFUL CONSERVATION.

Valentina Melli [1]*, Emilio Riginella [1], Marco Nalon [1] and Carlotta Mazzoldi [1]
[1] University of Padua, Department of Biology - valentinamelli@hotmail.it

Abstract

Artisanal fishery often offers the best opportunities for impact mitigation but it's also the most traditional and difficult to change. Trap fishery, an artisanal method that targets cuttlefish spawning adults in spring, exploits cuttlefish female attraction to traps for egg laying. The present study estimated the impact of traps on cuttlefish eggs and tested the efficacy and suitability of a management measure to mitigate this impact in the Northern Adriatic Sea. Results showed that over 3 millions of eggs, in less than 3 miles of coast, are likely destroyed by this fishery. The use of ropes, attached inside traps, allowed to collect on average 23.7% of the eggs, without affecting catch rate of adults. The efficacy of this mitigation measure is discussed considering fishermen attitude towards it.

Keywords: Fisheries, Coastal management, Conservation, North Adriatic Sea

Introduction

Overexploitation and the indirect impact of several anthropic activities has caused the decline of marine resources [1]. If, on one hand, several regulations have been introduced to protect coastal ecosystems, on the other one, social and economic factors have often compromised the efficacy and the compliance of the laws. A representative case of study in the North Adriatic Sea is the common cuttlefish, *Sepia officinalis*, an important resource traditionally exploited by the artisanal fishery [2]. In spring, when cuttlefish migrate near the coast for reproduction and egg deposition [3], artisanal fishermen take advantage of such local abundance using traps to catch the adults. Cuttlefish females use the surface of the fishing gear to attach hundreds of eggs (Fig. 1) that will need from 20 to 50 days to hatch [4]. As the eggs start accumulating on the trap they alter its functionality and need to be removed. To protect cuttlefish eggs from destruction, traps cleaning by water pressure washer has been forbidden during the reproductive period.

Fig. 1. Trap with eggs and cuttlefish.

Methods and Results

Interviewing all the 20 fishermen that perform trap fishery in the coastal area nearby Chioggia's inlet (about 3 miles in length) we were able to verify that, regardless the law, still the 80% of them use water pressure washer as the main cleaning method. Precedent studies [5] showed that this practice has an high impact on the eggs and results in their destruction. To investigate the impact of trap fishery on cuttlefish eggs, surveys were conducted on fishing boats. We assessed that an average of 947.14 ± 587.03 eggs were attached to each trap at the moment of the cleaning. Considering that each fisherman is allowed to use 250 or 400 traps (depending on the license) we estimated that every year over 3 millions of eggs, in less than 3 miles of coast, are likely destroyed by this fishery, due to trap cleaning procedures. In this study we proposed and tested the efficacy and suitability of a mitigation measure, that fishermen may easily apply. The measure consisted in the use of removable ropes attached inside traps, as additional substrate for egg deposition. Ropes allowed to recover on average 23.7% of the eggs. Besides the actual efficacy in reducing egg loss, a second result makes this mitigation measure promising: the presence of ropes in the traps did not reduce the catch. This aspect contributed to the positive attitude that fishermen showed towards the measure because it allows to both maintain their current income and preserve the future resource.

Conclusions/Significance

The case study underlines the need of dialogue with fishermen to reach the common aim of preserving fundamental resources. Considering fishermen' point of view and fishing dynamics we were able to delineate a mitigation measure that obtained considerable results in reducing the described impact and could be easily accepted. This measure, directly and actively involving fishermen in the management of their resources, could represent an outstanding step in filling the gap between fishery management authorities and stakeholders.

Abstract
Long-term changes in the fishing regime affect both the commercial target species and functionality of benthic ecosystems. The effects of short-term changes in fishing effort, were evaluated for an infaunal community from a Mediterranean fishing ground that is characterised by well-defined intra-annual trawl fleet dynamics tightly related to the main target species in the area: *Mullus barbatus*. Results suggest that, despite chronic trawling clearly modifing the infaunal community structure, changes linked to variability in the effort regime were too small to influence the *M. barbatus* population at the within-year time scale.

Keywords: North-Western Mediterranean, Fisheries, Biodiversity

Introduction: Normally, trawl fleet dynamics in the Mediterranean follow the life cycle pattern of the most important target species, which may lead to a marked variability in the fishing effort within a year. Moreover, trawling fleets can be controlled by closed seasons that aim to protect vulnerable life stages of target species. Fishing activities affects benthic communities and, consequently, demersal target species that are tightly linked to benthic habitats. Therefore, the proposed integral assessment that considers responses of the different ecosystem components to fishing pressure could be an advance in the framework of an ecosystem-based fisheries management. A trawl fishing ground located in the Catalan Sea (NW Mediterranean) with well documented fishing fleet dynamics was selected to study the effect of variable fishing effort on infaunal benthic functionality and the potential indirect consequences on M. barbatus, the most important target species in this fishing ground.

Methods: The study period was from June to November 2003 and the selected trawl fishing ground is regulated by a two month closure in summer (July and August). Two study sites were selected within the fishing ground: a fished site and an un-fished site used as a reference. In each site, infauna samples were obtained before (low effort), during (no effort) and after (high effort) the closed season. To analyse the effects of fishing effort on the community functionality, 11 biological traits were selected and split up into categories. Afterwards, these traits' categories were assigned to 25 infaunal taxa selected from a total of 147 after the criteria of abundance and frequency of occurrence. Multivariate analysis (MDS, PERMANOVA and SIMPER), based on Bray Curtis similarity matrix, were conducted to study changes on the Biological Traits composition. At the same time, daily landings of M. barbatus were available from records at the local port fish auction covering the year of the study (Fig.1).

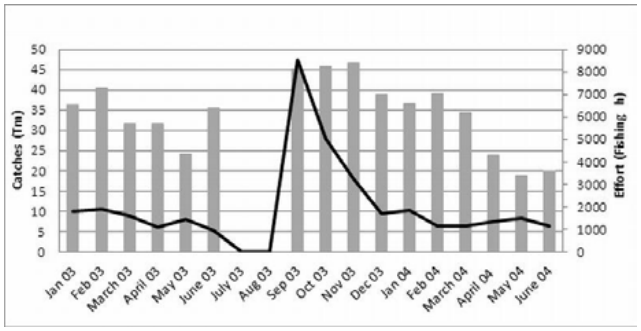

Fig. 1. *M.barbatus* catches (line) and trawling fishing hours (bars) during the study period

Results:MDS plot and PERMANOVA analysis show that infaunal Biological Traits composition from fished and reference sites were clearly different ($p< 0.001$). Significant temporal variability was also detected ($p<0.01$) and the pair-wise test showed that community composition before the closed season was different from those during and after the closed season ($p<0.01$ and $p<0.05$ respectively). However, the overall dissimilarity between groups was low (10.3% and 8.6-%) and more than 10 traits were necessary to explain 50% of dissimilarities. SIMPER (Diss/SD index >1.5) highlighted the traits' categories high flexibility, intermediate fragility, crawl, less than 1year of life span, filter feeding and 2 or more reproductive events per year as somewhat important to discriminate groups (Table 1). Catches of M.barbatus follow its life cycle, being highest during the recruitment season,from the end of August to November [1] which coincides with the highest effort period (Fig.1).

Tab. 1. Trends of the trait categories highlighted by SIMPER by Site (Control/Reference) and Time (over the year)

Trait category	Site	Time
Intermediate fragility	No differences	Decreasing during closed season in the reference site
High Flexibility	Higher in reference	Decreasing during closed season in the reference site
Filter Feeding	Higher in reference	Decreasing during closed season in the reference site
Crawl	Higher in reference	No clear pattern
>2 rep events per yr	Higher in reference	Decreasing during and after the closed season in the reference site Decreasing after the closed season in the fished site
<1yr life span	Higher in reference	Decreasing during and after the closed season in the reference site

Discussion: The effect of chronic trawling impact on the infaunal Biological Traits composition was evident [2]; however, short-term changes related with the within-year trawling fleet dynamics were not so obvious. Several traits varied over the study period, however, dissimilarities were low. Nevertheless, these are expected results considering the short duration of the closed season, while benthic communities would need longer periods to respond to changes [3]. M. barbatus, feed manly on amphipoda and polychaetes [4], might be affected by changes in any of the infaunal selected traits. For example, changes on the traits' categories less than 1year of life span and 2 or more reproductive events per year, might affect infauna productivity, leading to changes in food availability. The last trait follows a decreasing trend after the closed season in the fished site, which might lead to lower food availability in the following months.

Abstract
Data on fishing activity and landings over different types of benthic habitats are presented for the artisanal fishing fleet operating in Fourni island complex (NE Aegean Sea, Greece). Coralligène (25 %) and rocky (20.69 %) substrates were the most targeted habitat types. Both biomass and species richness of landings by fishing trip did not differ significantly between the most highly fished seabed habitat types. Such information has important implications for the development of a successful spatial management plan of fisheries resources.

Keywords: Fisheries, Aegean Sea

Introduction
Seabed habitat type and fishing pressure both largely affect the structure and function of fish assemblages [1, 2]. However, in the Mediterranean Sea, little effort has been devoted to investigating the distribution of fishing activity among different seafloor habitats and their importance in terms of catches to the fishery. Herein, we analyzed the small-scale fishing fleet landings of Fourni island complex (NE Aegean Sea) in relation to benthic habitat type. The study area is characterized by a dynamic, multi-gear, small-scale fishing community and the presence of diverse seabed habitats, consisting mainly of *Posidonia oceanica* meadows, coralligène reefs, sand and rocky substrates. Such information can be useful in the design of an adequate spatial management plan of fisheries resources in the area.

Materials and methods
Port side landings surveys were conducted daily, between March 2012 and December 2012, on artisanal fishing boats operating in the Fourni Island complex and using trammel nets or longlines. The latter two are the fishing gears used most frequently by the artisanal fishing fleet. Landings' biomass and species richness by fishing trip were recorded along with information on gear configuration (i.e. total surface area of nets and number of hooks, respectively). Fishermen were interviewed about the structure of the seabed habitat where fishing took place. In detail, fishermen were asked about the presence or absence of rocks, coralligène formations, *P. oceanica* and sand, which are the main seabed habitat types in the area. Landings were corrected for effort, expressed as kg per m^2 of net and kg per 100 hooks for trammel nets and longlines respectively. One-way Anova was used to compare landings per unit of effort and species richness over different seabed habitat types. Only seabed habitat types with a significant number of observations were used in the comparisons.

Results and Discussion
verall 62 fishing trips were sampled. Fishing occurred over various single and mixed type seabed habitats (Fig. 1). Single type seabed habitats consisted of rocks (20.69 %) and coralligène reefs (25 %), followed by mixed habitats of *P. oceanica* and sand (20.69 %). Landings per unit of effort (LPUE) did not differ significantly between the most frequently fished seabed habitat types both for trammel nets (one-way Anova, $F_{2,53} = 0.56$, $p = 0.577$) and longlines (one-way Anova, $F_{1,23} = 0.96$, $p = 0.337$). Comparison of landings' species richness between habitats also showed no significant differences for longlines (one-way Anova, $F_{1,23} = 0.187$, $p = 0.185$) and trammel nets (one-way Anova, $F_{2,53} = 0.39$, $p = 0.681$).
Rocky substrates, coralligène reefs and *P. oceanica* meadows are complex habitats of high ecological value. Coralligène reefs, in particular, are very vulnerable and not persistent to anthropogenic disturbances due to their low turnover rates [3, 4].These habitat types receive the highest fishing pressure while are equally important in terms of productivity to the fishery. The degradation of these habitats in the NE Aegean would have high socioeconomic impact on fishing communities. Hence their protecting and sustainable management is essential to achieve a degree of fisheries sustainability which will also benefit the fishing community. Such a purpose can only be achieved by the design of a Fisheries Protected Area based on detailed seabed habitats mapping data [5, 6].

SOME REMARKS ON THE BEACH SEINE FISHERY IN THE ISTANBUL STRAIT

Ugur Uzer [1]*, Taner Yildiz [1] and F. Saadet Karakulak [1]
[1] Istanbul University - uguruzer@istanbul.edu.tr

Abstract
This study aims at giving the results of the catch composition, by-catch and discard ratios in beach seine fishery in the Istanbul Strait. Samples were caught by commercial beach seine vessel from the depth interval 40-65 m, in the period of December 2009 and March 2010. The most abundant commercial species in terms of number and weight were *Mullus surmuletus* and *Trachurus trachurus*.

Keywords: Fisheries, Bosphorus Strait

Introduction
Beach seine nets have been used in fisheries for several thousand years and on every continent [1]. In Turkey beach seines were used in Aegean Sea especially in Izmir, Black Sea especially in Trabzon and Samsun, in Istanbul Strait for demersal fishes and in Marmara Sea for rose shrimp. There are a lot of studies on seine nets in the Aegean Sea [2, 3], limited studies in the Sea of Marmara [4]. However, there were no available data in the Istanbul Strait. In this study, observers were used to quantify the catches of beach seines operating in the Istanbul Strait and to evaluate the impact of this fishing gear in terms of by-catch and discards.

Materials and methods
Scientific operations were carried out on a commercial beach-seine vessel with a length of 14 m and 160 HP, totally 20 fishing trips between December 2009 and March 2010, covering the entire fishing period, in the Istanbul Strait. A beach seine net specialized for catch of bony fishes with a total length of approximately 143 m was used in the experiments. The mesh size of the cod end was 26 mm and fishing took place in depths 40-65 m. Operations were carried out in generally 60 minutes depending on the condition of the deep currents, on the towing speed and amount of yield caught in the cod-end. The total catch was sorted into the retained and discarded components by the fishermen. The total weights and numbers of each individual species were recorded.

Results and discussion
From 20 beach seine operations, 26 osteichthyes, 2 crustacea and 1 mollusca species belonging to three different taxonomic groups were obtained. It was determined that *M. surmuletus*, *T. trachurus* and *Scorpaena porcus* were most caught. Besides the red mullet which were target species, it was determined that 28 different species belonging to the three taxonomic groups were also caught. Of all the non-target species, it was seen that 13 were commercial, 14 were non-commercial, and only one was under threat species. The total catch consist of the target species, which were 77.48% in numbers and 65.90% in weight, and the non-target catch ratio was 22.52% in numbers and 34.10% in weight, respectively (Table1). In this study, it was found that the discard ratio in the beach seines together with the small-scale fleet having limited catch efforts in the Istanbul Strait was low but the ratios of the commercial species under the legal length size were high. The minimum landing size (MLS) for *M. surmuletus* was 13 cm. It was determined that the total lengths of *M. surmuletus* ranged from 6.5 to 17.30 cm (mean length 10.29±0.08 cm) and the catch ratios of both species, under MLS, was calculated as 70.70%. It was clear from the data that the growth overfishing was seen in the commercial species. It was reported that the ratios of commercial fish species under the MLS in the Aegean coasts were 75% for *Pagellus erythrinus*, 23% for *Mullus barbatus*, 7% for *M. surmuletus*, and 42% for *Diplodus vulgaris* in the beach seine fishery (with 36 mm cod-end mesh size) [5]. In another study carried out in the Aegean Sea, the ratios of non-commercial fish species under the MLS were 5.3% for *Boops boops*, 33.5% for *Spicara* sp., 39.7% for *M. barbatus*, 79.6% for *P. erythrinus*, 93% for *D. vulgaris*, and 73% for *Loligo vulgaris* in the beach seine fishery (with 32 mm cod-end mesh size) [2]. It was determined that the beach seines employed in the Aegean Sea damaged the juvenile fish stocks found in this area with the aim of protection and nutrition as well as *Posidonia oceanica* meadows especially in coastal regions. It was also found that they were not selective enough due to the fact that they caught the fish having smaller size, and when considered the high amount of by-catch and discard ratios, they were extremely harmful for the coastal ecosystem [6]. In order to protect the coastal regions as well as the juvenile fish from capture, beach seines have been banned in Turkish territorial waters (except for the Edremit Bay, the Sea of Marmara, the Istanbul and Canakkale Straits) since 2001 [7] and then the use of these nets were also banned in the Istanbul and Canakkale Straits in 2011[8]. On the other hand, all forms of trawling in the Sea of Marmara are already prohibited, so the deep-water beach seines are exceptionally allowed to catch only the pink shrimp.

USING SMALL-SCALE FISHERS' PERCEPTIONS TO FRAME KEY ISSUES OF MANAGEMENT CONCERN

Aikaterini Dogrammatzi [1], John Charalabus [1] and Vassiliki Vassilopoulou [1]*
[1] HELLENIC CENTRE FOR MARINE RESEARCH - celia@hcmr.gr

Abstract
Greek small-scale fishers' perceptions on issues of concern that need to be tackled towards achieving environmental and socio-economic sustainability are being identified through the questionnaire approach.

Keywords: Fisheries, Coastal management, Competition, North-Eastern Mediterranean

Small-scale fisheries (SSF) are an important social component of local coastal communities and are a source of high quality seafood with a low ecological impact. They dominate the Mediterranean fisheries (about 80% of units) and it is widely recognized that special attention should be paid by policy makers and fisheries managers to the territorial and flexible dimension of the sector, particularly in anticipation of the finalization of the CFP reform, as well as to the increasing complexity of coastal areas in terms of use conflicts and environmental threats (1). SSF are seriously threatened by concurrent uses of the coastal zone and the integrated management of those uses is necessary (2). In countries, like Greece, where SSF are extremely diverse, scattered geographically and employ large numbers of people, significant problems in the existing system associated with a top-down, central management regime have been highlighted (1). In the present study, Greek fishers' perceptions of the SSF sector regarding critical issues linked with management deficiencies were identified through targeted interviews.
Interviews were based on open-ended questions that encouraged interviewees, who were professional small scale fishers, to express themselves in their own way, and enabled openness since they were encouraged to talk about their major concerns in relation to the status and prevailing local conditions in SSF in their region. Interviews took place in 2012 in seven ports (Figure 1), located either in the mainland or in an Island, where SSF is considered as an important socio-economic activity. Most interviews took place in the premises of fishers' associations or at facilities in the port, had about one hour duration, and usually were attended by a few representatives of the local association (from three to twelve). Although there was a general discussion after each question, at the end they all agreed to a final statement reflecting common local issues/problems. During analysis, responses were categorized to convert a qualitative response into a quantitative one, to enable prioritization of emerging issues in the different areas.

Fig. 1. Locations where small scale fishers'interviews were conducted in Greece.

Viewpoints on issues that were discussed during the interviews were grouped into three categories (Table 1) and visualize major concerns of fishers in the seven areas under study. The first category comprises problems arising due to conflicts between human uses (both inter and intra-sectoral), the second category includes issues related to ecosystem degradation, and the third category takes account of economic constraints placed on the sustainability of fishers' livelihood. Among conflicts with human activities, competition for common resources with trawlers was highlighted in all areas as of major concern. Problems with recreational fisheries, and the need for more effective management of the sector was mentioned in certain occasions. As for intra-sectoral issues, gear (net) soak time, the need for allocation of rights to fishery resources, and discarded fishing gears were underlined in many cases (Table 1). Restrictions of fishing activities due to allocation of parts of the marine space to certain uses such as aquaculture, or to protection of priority conservation species (i.e. seals) were among complaints made in specific areas. As for ecosystem degradation, decline of the fishery resources, was cited as a key impact linked with pollution and over fishing, the latter by trawlers, in all study areas (Table 1). Then, habitat loss or damage due to pollution effects, mainly associated with agricultural runoff, as well as establishment of certain non-indigenous species raised concerns in particular localities. Finally, issues adding to the financial burden of small scale fishers were vessel operational costs linked with the high prices of petrol, gear maintenance costs due to damages caused by certain protected species, decrease of market demand and/or shift towards cheaper species as a result of the economic crisis, and unfair competition due to imported cheaper fishery products. Outcomes reveal several issues, stemming mainly from the lack of an holistic approach for effective management; important recommendations were made by fishers in terms of improving conditions and developing efficient management plans. A co-management bottom-up approach based on community cohesion founded on norms, trust, communication, commitment and respect for leaders can prevent the tragedy of the commons (3), and be a realistic solution for sustainable fisheries in complex cases like the SSF in Greece.

Abstract
A test on the restocking trial of Caramote prawns was carried out in the southwestern Sicilian coast from wild breeders. The number of specimens released was probably too low to allow for a lasting effect on the population. In the future, an higher number of nauplii must be released for several years.

Keywords: Decapoda, Aquaculture, Coastal management, Sicily Channel

The penaeid shrimp Caramote prawn, *Melicertus kerathurus* (Forskäl, 1775), is widely distributed in the entire Mediterranean except in the Black Sea [1]. This species plays an important economic role in some Mediterranean coastal regions, as in Greece ≈ 3,250 t, Tunisia ≈ 2,300 t, Spain ≈ 200 t Albania ≈100 t [2] and Italy ≈ 250 t [3]. The high demand of penaeid shrimps have stimulated, on the one hand, the developing of aquaculture activities and on the other hand, repopulation actions with the aim to support artisanal fishery in various countries worldwide [4, 5, 6, 7]. A test on the restocking trial of this species was carried out in the year 2004, in the shallow coastal area between Capo San Marco and Capo Granitola (southwestern Sicilian coast, Fig. 1).

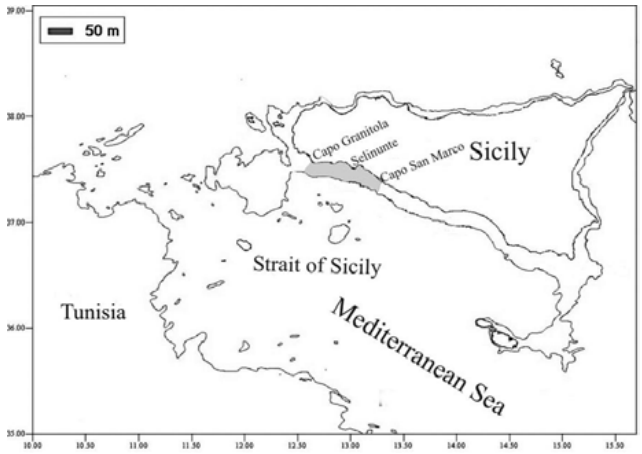

Fig. 1. Map of the study area showing the Selinunte harbour and the fishing ground where small craft catch Melicertus kerathurus (light grey).

Breeders from the restocking area were caught by trammel net throughout the entire fishing area during one night in July 2004. Females, completely intact and with spermatophore in the thelycum, were selected and transported in aquaculture plants. The restocking technique used in the aquaculture plant was that proposed by Lumare [8]. As the eggs began to hatch, the larvae (nauplii) were fed with *Chaetoceros* sp; after 5 - 6 days from their birth, the diet was integrated with *Artemia salina* nauplii. From the mysis III stage, that is after about 10 days from birth, larvae are called post-larvae. At that stage, the diet was also integrated with artificial feed for post-larvae shrimp made up of fish flour, fish oil, krill flour, wheat flour, vitamins and minerals. The post-larvae at the PL22 stage were lowered into the sea in a stretch of sandy water off-shore from Selinunte, with a depth between 50 and 100 cm, opportunely fenced and cleared of other materials and eventual predators. The post-larve were then released after about 36 hours of adaptation.

A total of 148,799 eggs were released, from which 82,888 nauplii hatched at a percentage of 56%. Only 6,000 nauplii reached the PL22 sub-stage, that is after 32 days from their birth and they were sown with success (Tab. 1).

Tab. 1. Number of specimens caught for the reproduction, mature females, females selected for the reproduction, number of breeders, eggs released, nauplii hatched and nauplii PL22.

No. of specimens caught	Mature female
156	100
Female selected and shipped	
63	
No. breeders "useful"	Eggs released
22	148,799
nauplii hatched	post-larvae PL22
82,888	~ 6,000

The number of specimens released was probably too low to allow a lasting effect on the population. In the future, an higher number of nauplii must be released for several years. Worldwide, the restocking activities with shrimps did not have great success, since they constitute the production of a common good without any real interest to the private investor. On the contrary, the shrimp production represents an important stimulus for the private entrepreneurial activity (FAO, 2008). The production of shrimps in the world aquaculture reached about 4.23 million t in 2006, compared to a production of shrimps from catch of 4.84 million t. The recent implementation of "local management plans" along the Sicilian coasts (Regulation EC No 1198/2006) allows to support measures of common interest, like restocking strategy: if these strategies will be tested systematically for some years, they could be an important opportunity to verify the real increases of natural stocks and the profitability for the artisanal fishing activity.

FISH DISCARD IN ISKENDERUN BAY TRAWL FISHERIES

Emre Yemisken [1]*, Cem Dalyan [1] and Lutfiye Eryilmaz [1]
[1] Istanbul University Faculty of Science, Department of Biology - emredy@yahoo.com

Abstract
The aim of this study is to determine the discard fish composition, abundance and biomass of trawl fisheries in Iskenderun Bay. The 44 hauls were performed by commercial trawl vessel during 2010 (May, August and October), 2011 (January) and 2012 (December). Data analysis were shown that there is no statistically significant differences between depth and discard fish rates (p=0.087, p> 0.05). *Equulites klunzingeri* dominated among discard fish species, especially between 30 – 60 m depth ranges in Iskenderun Bay.

Keywords: Fisheries, Iskenderun Bay

Introduction

Discard catch, composed of undersized marketable and unmarketable species, is an important problem in multispecies trawl fisheries, also having an influence on the dynamics of marine ecosystems. Comparison of discard rates shows variability depending on depth and season [1]. The purpose of this study is to contribute to the knowledge of discard catch and its composition in Eastern Mediterranean trawl fisheries.

Material Methods

Iskenderun Bay, located in the Levantine Sea, is an important fishing zone in the Eastern Mediterranean Sea (2) (Fig.1). The trawl operations were carried out in the Iskenderun Bay, from May 2010 to December 2012. A total of 44 hauls were performed at depths between 30 m and 110 m. Data was collected by using commercial trawl vessels (23 m length) with engine powers up to 400 HP. The stretched codend mesh sizes of trawl nets were 44 mm. Biomass and abundance data were recorded as discard and landing catch. Subsampling was performed for the most abundant species. The whole catch was stored in lab at – 20 ºC. After identification of the species, the total length (mm) and body weight (g) were measured for each individual. Sampling season and discarded fish biomass CPUE (kg/h) were compared by Kruskal Wallis (3). Pearson correlation was used to explain the relation between discard fish ratios and their haul depth.

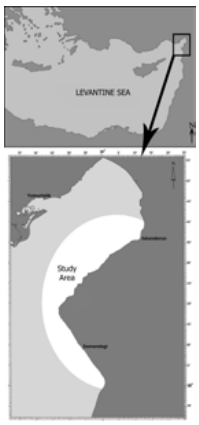

Fig. 1. Study area in and around Iskenderun Bay (Levantine Sea)

Results and Discussion

In 44 hauls 87930 individuals were obtained belonging to 101 fish species. The total fish catch was calculated as 2720 kg, 1052 kg of them were discarded. Discard catch consisted of 74 species (n=54119). The average of the total fish biomass caught per haul was 42 kg/h and the average of the discard biomass was estimated as 15.8 kg/h. 38 % (varied from 12 % to 71 % per haul) of the total fish catch biomass was constituted of discard fish. The highest seasonal discard biomass ratio was recorded in August (43.68 %) (Fig 2). A weak negative relationship between discard fish rates and depth is shown (r= -0.261, p=0.086, p>0.05). Discard fish biomass did not show any significant differences among sampling seasons (p=0.69, p>0.05). Discard catch is well studied in Mediterranean Sea. Discard fish catch was found between 34 – 44 percentages in Greek waters (4). Furthermore, Damalas and Vassilopoulou (2013) mentioned that the discard rate in trawl fisheries was between 31 % and 64 % in Central Aegean Sea (5). Kinacigil et al. (1999) reported that discard was estimated between 42.8 % and 50 % in total catch for shrimp trawl fisheries in Tasucu Bay (Northeastern Levantine Sea) (6). Our estimated data demonstrated similar rates with other fishing regions in the Mediterranean Sea.

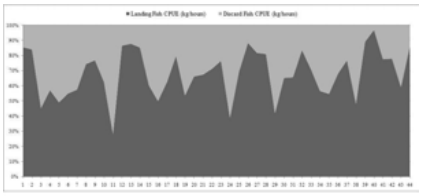

Fig. 2. Landing Fish and Discard Fish CPUE (kg/h)

Saurida undosquamis, *Nemipterus randalli*, *Sparus aurata and Mullus barbatus* were the main commercial species in the region. In the 1980's, *S. undosquamis* and *E. klunzingeri* were of highest biomass in total catch; 23 % and 14 % respectively (7). In this study, there is similar considering results in the highest biomass of the fish species; *S. undosquamis* 36 % (16,6 kg/h) and *E. klunzingeri* 10 % (7.79 kg/h) (n=1196 per hour). Discard was comprised mostly of unmarketable species such as *Equulites klunzingeri*, *Citharus linguatula*, *Champsodon sp.*. The present study might be helpful for planning an ecosystem-based management in the region.

CATCH COMPOSITION IN BOTTOM TRAWL FISHERY IN THE WESTERN BLACK SEA (TURKEY)

T. Yildiz [1]*, A. Baskaya [1], U. Uzer [1], A. E. Kahraman [1] and F. S. Karakulak [1]
[1] ISTANBUL UNIVERSITY, FACULTY of FISHERIES - yldztnr@istanbul.edu.tr

Abstract
The present study aims at giving the first results of the catch composition in bottom trawl fishery in the Western Black Sea. Samples were caught by commercial trawl from the depth interval 30-100 m, in the period of October 2010 – April 2011. The most abundant commercial species in terms of number and weight were *Mullus barbatus* and *Merlangius merlangus*. Total catch rate varied between 6.5 and 862.7 kg/h.

Keywords: Trawl surveys, Demersal, Fisheries, Black Sea

Introduction
The Black Sea is a unique sea, which is considered to be world's most isolated sea. The Black Sea is the world largest water body containing H_2S, and its hydrogen sulfide layer begins 150-200 meters below the surface [1]. Therefore, the commercial fishery is carried out mainly down to a depth of 100 m. On the other hand, considering the length of the coastal area, the amount of the fish caught, and the fishing fleet capacity, the Black Sea is the most important fishing area of Turkey and surrounding countries [2]. The aim of the present work is to assess the catch composition in commercial bottom trawl fishery in the Western Black Sea.

Material and methods
Samples were collected during 34 experimental surveys, carried out between October 2010 and April 2011 in the Western Black Sea (Turkey). A commercial trawler was used equipped with a trawl of 40 mm cod-end mesh size (from knot to knot). The duration of each haul ranged from 70 to 150 minutes and their depth varied from 30 to 100 m. For calculations and evaluations, all the catches were standardized to one fishing hour.

Results and Discussion
A total of 34 species were recorded, of which 25 were osteichthyes, 4 crustaceans, 2 chondrichthyes, 2 echinoderms and 1 molluscs. *Mullus barbatus* and *Merlangius merlangus* were the dominant commercial species. Some of the other abundant species were *Alosa immaculata*, *Gobius niger*, *Neogobius melanostomus*, and *Scorpaena porcus*. The most abundant commercial species in terms of number and weight were *M. barbatus* and *M. merlangus* (Table 1). *M. barbatus* (mean: 108.07 kg/h, min: 38.52 kg/h, max: 1220 kg/h) and *M. merlangus* (mean: 23.83 kg/h, min: 3.8 kg/h, max: 59.4 kg/h) constituted 95% of the total catch. Total catch rate varied between 6.5 and 862.7 kg/h (439 and 54785 individuals/h).
In this study, the length values obtained from the commercial species such as *M. barbatus* and *M. euxinus* caught by trawlers were compared with the minimum landing size (MLS) mentioned in Turkish Commercial Fishing Regulations numbered 3/1 published in 2012. The minimum landing size for both species is 13 cm [3]. It was determined that the total lengths of *M. barbatus* and *M. merlangus* ranged from 6.8 to 15.5 cm (mean length 9.88±0.04 cm) and from 6.2 to 20.0 cm (mean length 11.03±0.06 cm), and the catch ratios of both species, under MLS, were calculated as 93% and 87%, respectively. These findings show that the growth overfishing occurred when the commercial species were caught. Therefore, it is necessary that the minimum mesh size in the codend of bottom trawl nets should be increased, and in this way, the improvement of selectivity suppose the reduction of catch of the small size individuals.
It is indicated in the last Turkish Commercial Fishing Regulations that the minimum diamond mesh codend less than 40 mm was prohibited [3]. On the other hand, the Members and Cooperating entities of GFCM shall adopt and implement, at latest by 31 January 2012, a minimum 40 mm square mesh codend or a diamond mesh size of at least 50 mm, of acknowledged equivalent or higher size selectivity, for all trawling activities exploiting demersal stocks when operating in the GFCM Area [4]. Because Turkey is a member of GFCM, the implementation of this recommendation for the Black Sea is quite important in terms of sustainable fisheries.

URAL RIVER DELTA: A PROPOSED UNESCO-MAB BIOSPHERE RESERVE ON THE CASPIAN SEA

L. Cantelli [1]*, G. E. Marcheselli [1], F. Scarelli [1], T. Kerteshev [2] and G. Gabbianelli [1]
[1] University of Bologna - luigi.cantelli@unibo.it
[2] GEF-UNPD Kazakhstan

Abstract
The Ural River Park Project is an international collaboration aimed to support the sustainable developement and the environmental protection of the Ural delta area, on the Kazakhstan coast of the Caspian Sea. The great variety of habitats and the remarkable biodiversity hosted in these vast wetlands are endangered by pollution and environmental degradation an by the scarce environmental awareness of the local people, the project has been directed to the establishment of a Unesco-Mab Biosphere Reserve, involving directly the local Authorities and population. In this regard, the project has been focused on the proposal of a management plan for the delta area particularly focused on the interaction between the environment and the socio-economic features of the area.

Keywords: Coastal management, Conservation, Deltas, Extra-Mediterranean regions

During the past decennia, the level of water and sediment contamination in the Caspian Sea has increased as a result of anthropogenic activities, leading to a great pressure on the environment. The main sources of contaminants include untreated waste from industry and agricolture, offshore oil and gas extraction, processing and transportation, and marine dumping. The northern portion of the Caspian Sea, and more specifically the Kazakhstan coast, is particularly threatened by those negative factors impacting the environment, because of the great relevance of this area for its biodiversity. In fact, the Ural delta area is characterized by an vast wetland, covering more than 110,500 ha[1]. The site is a unique river delta, comprising a large variety of marine/coastal and inland wetland types. The specific geomorphological, sedimentological and hydrological features of these land-sea transition environments, located in close proximity to semi-desert areas and characterized by the interaction between marine and fluvial-deltaic dynamics, have created a range of marine and freshwater habitats supporting a huge amount of wildlife species of grate international and national ecological interest, notably millions of migratory birds (nesting, migrating and wintering), 13 of which are IUCN threatened bird species [2]. Moreover, the river mouth is a nesting place for two important endemic (and endangered) species: the Caspian seal and the Beluga Sturgeon (along with other species of sturgeon)[3].

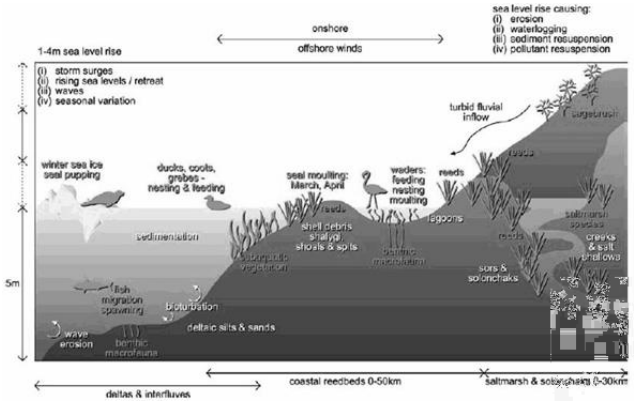

Fig. 1. habitat sensitivity in the Ural delta and adjacent coastal zone.

Therefore, in 2009 the Government of Kazakhstan has designated the Ural river and the adjacent Caspian Sea coast as Wetland of International Importance[4], part of North Caspian Nature Reserve (Ramsar Site 1856/2KZ002). In this view, under the high patronage of the Ministry of Environmental Protection, the Ural River Park Project had started, which is a collaboration between the Kazakhstan Institutions on local and national levels, the University of Bologna and the Po Delta Park – Emilia Romagna region, with the support of ENI. The URPP aims to support the national efforts in promoting the sustainable use of wetlands and coastal resources in the Ural delta area and to contribute to the progress of the area with the final goal to switch on the "Ural River Unesco Mab Biosphere Reserve", according to the program of joint work between the Ramsar Convention on Wetlands and the Unesco Mab[5]. The proposed Unesco- Mab Biosphere Reserve area, which covers about 331,000 hectares, includes the delta of the Ural River (?om the delta plain, just south of Atyrau, including the submerged prodelta area) and a significant part of the surrounding wetlands and reedbeds and will contain the existing State Nature Reserve "Ak-Zhayk", which protection status is now defined as "State Reserved Zone of the North Caspian Region", as determined by the Law of the Republic of Kazakhstan on Specially Protected Areas (15,07,97), article 48. Accordingly, an updated management plan has been prepared for the site, in total cooperation with National and local Authorities to play the important role of regulators guardians, facilitators and educators within the community; within the framework of the Integrated Coastal Zone Management (ICZM) methodology to describe and plan the complex interactions between the resource system and its potential users; using approaches and intemational procedures such as those indicated by the the UNESCO – MAB Biosphere Program. In facts, not only the environmental features, but also the interrelations among the environmental processes, the specific economical activities existing along the coast and their impact on the ecosystems have been taken into consideration, in order to achieve a complete knowledge of all the key factors involved in the sustainable developement and protection of the area, with particular attention on raising the local population awareness about the potential and the preciousness of their own land, form both the naturalistic and the economic points of view.

Abstract
Our study demonstrates that setting conservation targets for each Mediterranean ecoregion, can lead to outcomes more comprehensive in the representation of the Mediterranean biodiversity overcoming the great variability in availability of biodiversity and socioeconomic data among countries.

Keywords: Biodiversity, Conservation, Coastal management, North Adriatic Sea, Aegean Sea

Despite the agreement by most Mediterranean countries to conserve 10% of the sea by 2020 under the Convention on Biological Diversity, only 4.6% of the Mediterranean Sea is currently included in Marine Protected Areas (MPAs). Furthermore, there is a striking imbalance in MPA distribution, as 96% is located in the northern basin [1]. Consequently, current MPAs only partially protect the Mediterranean biodiversity in terms of functional and phylogenic diversity [2].

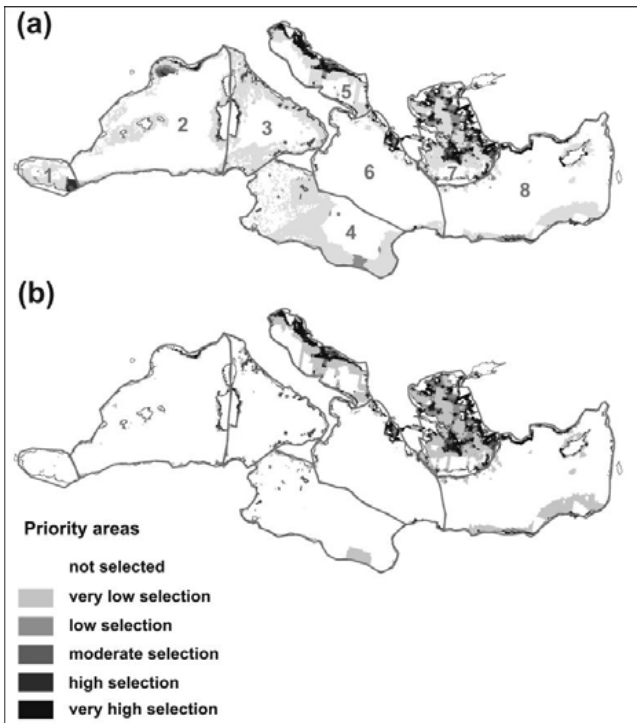

Fig. 1. Priority areas for *P. oceanica*, coralligenous formations and marine caves in the Mediterranean Sea: a) with ecoregion targets; b) without ecoregion targets. Planning units depicted in darker shades present higher selection frequency and therefore are of higher priority. The red polygons correspond to the 8 Mediterranean Ecoregions: 1. Alboran Sea, 2. Algero-Provencal Basin, 3. Tyrrhenian Sea, 4. Tunisian Plateau/Gulf of Sidra, 5. Adriatic Sea, 6. Ionian Sea, 7. Aegean Sea, and 8. Levantine Sea.

We identified priority areas throughout the Mediterranean Sea for the conservation of *Posidonia oceanica* meadows, coralligenous formations, and marine caves. To achieve this goal, we set conservation targets on the critical habitats, according to EU guidelines (60% of their distribution), as well as for each Mediterranean ecoregion (10% of the planning area) as defined by Notarbartolo di Sciara and Agardy [3], and used the prioritization software Marxan. The socioeconomic data included in the analyses, contained information on opportunity cost for fishing and aquaculture across the Mediterranean Sea.

While the spatial distribution of priority areas changed after setting ecoregional targets, the Adriatic and Aegean Seas remained high priority areas for conservation (Figs. 1a, b). The more even distribution of priority areas in our proposed network, in comparison to a whole-basin approach ignoring ecoregion representation, makes this plan more representative of the functional diversity across the basin. Moreover, it increases the resilience of the ecosystems to ongoing environmental and biological changes in the Mediterranean Sea, such as climate change and the introduction of invasive species.

FORCE' FP7 PROJECT AS A SUCCESSFUL MODEL FOR COOPERATION WITH EUROPE'S NEIGHBOURS IN THE CONTEXT OF CAPACITIES BUILDING

Suzan Kholeif [1]*
[1] National Institute of Oceanography and Fisheries - suzan_kholeif@yahoo.com

Abstract
The international competitiveness of modern economies is linked increasingly to their ability to generate, adapt and use new knowledge. S&T are considered to be key factors contributing to achieving sustainable development, prosperity and economic growth of marine resources in Mediterranean and North African. The exchange of expertise will enable scientists to carry out research aimed at supporting the implementation of the sustainable development of marine resources. In collaboration with a strong EU partnership, FORCE FP7 project considers a successful capacity building model to fill Scientific and technology gaps as means of increasing sustainable yields. Also, FORCE will promote the principles outlined in Horizon 2020.

Keywords: Fisheries, Aquaculture, South-Eastern Mediterranean

FORCE "Fishing and aquaculture-oriented research capacity in Egypt" is designed to strengthen the capacity of the National Institute of Oceanography and Fisheries of Egypt (NIOF) to carry out research activities that aim to support the implementation of sound policies based on a scientific basis for sustainable development of fisheries and aquaculture in Egypt, as well as in the entire Mediterranean North African region. The overall objectives of FORCE are; to identify the potential for more efficient collaboration between research institutions, that are focused on fisheries and aquaculture as a means of scientific and technological development and increasing sustainable yield, based in the EU and NIOF; to support NIOF in the development of a "toolbox" to assess the environmental impact of aquaculture activities; to disseminate the best practices and raise awareness among scientists, fishery inspectors and policy makers. FORCE will promote the principles and objectives outlined in the Horizon 2020 framework and EU Marine Strategies thus supporting the attainment of competent sustainable management of fisheries. FORCE will enhance the capacity building of NIOF for a comprehensive strategy and improve women's capacities to contribute effectively to a real improvement in the socio-economic conditions of the fishery community.

PRELIMINARY RESULTS

⇒ According to Law 4/94 and its amended by law 9/ 2009 every new establishments are required to carry out an Environmental Impact Assessment (EIA) before construction. The scoping EIA form B is general for all projects. As the aquaculture industry is growing fast in Egypt, there is a need to develop a special guideline for full-fledged EIA for aquaculture projects due to their potential Impacts on surrounding environment. FORCE assisted the Egyptian Environmental Affairs Agency (EEAA) and General Authority for Fish Resources (GAFRD) to amend FORM B to be specific for EIA requirements for new establishment of Aquaculture projects. Moreover, FORCE will offer the experience for improving the EIA system in Egypt through: provide a "tool box" for Environment Impact Assessment (EIA) of finish aquaculture (Fig 1); help the developers how to choose the best location (site selection) and operate the facilities; help EEAA in reviewing process; help the license authority in following up the project and improve the quality of fish specially sea bass and sea bream which can be exported to EU market

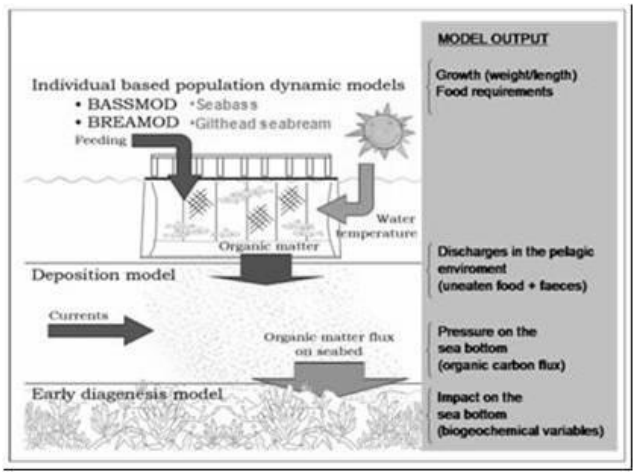

Fig. 1. Conceptual model of the impact of the release of organic matter from a fish farm on the seabed (by Roberto Pasters)

⇒ A review of the main fishing techniques and gears in Egypt, as well as of the technical properties, was carried to give a complete picture of the situation and to compare this with the current situation of other Mediterranean countries. This review implied: - an overview of the main fishing gears used in Egypt; - the main technical properties of the different fishing gears; - the characteristics of the fishing fleets in different harbours; - the characteristics of different fisheries; - the collection of information on the Egyptian legislation; - to identify the lack of information and weak points. This review made possible to initialize a technical database for Egypt by means of which it will be possible to propose new legislation with respect to gears, to propose ways how to re-structure the fleet in order to have more sustainable fishing gears and to achieve a balance between different gear types. This review should be considered as a first attempt in Egypt given that no other technical information is available for Egyptian fishing gears.

Abstract
Ce travail décrit les conditions de réapparition et la répartition de *Potamogeton pectinatus* L. (Potamogetonaceae) dans la lagune de l'Ichkeul suite à une année exceptionnellement pluvieuse (2002-2003). Ainsi, après une succession d'années sèches conduisant à une forte restriction des apports en eaux douces et par conséquent à la disparition des herbiers à *P. pectinatus* (de 1994 à 2002), une seule année était suffisante pour lessiver l'excès de sels et abaisser les salinités à des valeurs relativement faibles (salinité printanière : 8), permettant la germination des plantules à affinité dulçaquicole. L'herbier à *P. pectinatus* s'est étendu sur 18 km^2 notamment au Nord et un peu moins à l'Est et au Sud-Est de la lagune.

Keywords: Lagoons, Phanerogams, Hydrology, South-Central Mediterranean, Monitoring

Le Parc National de l'Ichkeul (Nord de la Tunisie) est inscrit sur les listes des réserves de la biosphère, du patrimoine mondial de l'UNESCO et de la convention de Ramsar. Il constitue un important site d'hivernage des oiseaux migrateurs pouvant abriter des colonies dépassant 200 000 individus. Dans le cadre de la planification hydraulique des ressources et d'utilisation des eaux du nord de la Tunisie, les aménagements projetés dans le bassin de l'Ichkeul consistent en l'installation des barrages sur six principaux oueds qui alimentent la lagune. Trois barrages ont été déjà mis en eau couvrant 46% du bassin versant de l'Ichkeul et trois autres sont prévus (couvrant 25% des surfaces du bassin versant). Cependant, les aménagements hydrauliques entrepris dans l'Ichkeul, aggravés par des conditions de sécheresse étendues sur quelques années, ont conduit à une diminution importante des apports en eau douce entraînant des modifications dans la biodiversité et dans la répartition des macrophytes ([1], [2]). Par conséquent, les oiseaux aquatiques qui sont essentiellement des phytophages ne disposent plus des ressources nutritives des herbiers à *Potamogeton pectinatus* L [3].

Nous avons effectué une campagne de mesures cartographique dans la lagune de l'Ichkeul durant la saison automnale de l'année 2003. Les observations ont été faites le long de plusieurs transects radiaux en direction du centre de la lagune. Nous avons déterminé, pour chaque station, la couverture végétale du substrat et le taux de recouvrement des espèces dominantes pour une surface de 1 m^2. Le diagnostic est fait par comparaison avec les situations antérieures observées à la même saison durant 1993, 1994 et 1998 (marquées par des saisons sèches). Les changements importants enregistrés en 2003, se résument comme suit : -une année 2003 particulièrement pluvieuse (802 mm à Tinja contre 600 mm pour une année normale) qui fait suite à trois années très déficitaires (1999-2002) ; -une chute de la salinité de l'eau suite à un lessivage de l'excès de sels. C'est la plus importante baisse enregistrée depuis 1993 (8 en mai 2003), -une extension de la limite du plan d'eau du lac entraînant l'inondation prolongée des marais, favorisant ainsi le développement des scirpes, appréciés par les oies cendrées. Malgré l'impact de la succession des années sèches, un herbier plus ou moins dense à *P. pectinatus* a été localisé (en 2003) dans le secteur Ouest, le long des berges Nord de la lagune mais également dans le secteur de Tinja, habituellement occupé par les espèces à affinité marine (Fig. 1). Le développement d'un herbier à *P. pectinatus* le long des berges nord de la lagune ainsi que dans le secteur de Tinja constitue un changement de l'aire de répartition de cette espèce qui n'a pas été observée dans cette zone depuis le début des années 1990s [1]. L'herbier à *P. pectinatus* s'ést étendu sur une surface de 18 km² alors qu'il occupait 30 km² lors de sa dernière apparition dans la lagune en 1993. Ainsi, de grandes modifications ont été relevées au niveau de la disposition des herbiers, surtout à partir de l'année 1994 [1]. *P. pectinatus* a constitué, jusqu'à l'année 1993, la principale macrophyte de la lagune. Cependant, après une succession d'années séches conduisant à une sévère restriction des apports en eau douce, la prairie à *P. pectinatus* a totalement disparu suite à l'élévation importante de la salinité de l'eau.

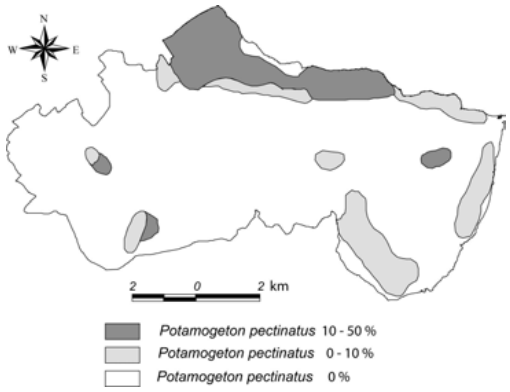

Fig. 1. Recouvrement (en %) des herbiers à *Potamogeton pectinatus* dans la lagune de l'Ichkeul (automne 2003).

Cette situation a duré jusqu'à l'année 2002, et un doute c'est instauré sur la capacité de régénération de l'herbier à *P. pectinatus*, très important pour l'équilibre de l'écosystème lagunaire. Situation qui a conduit à l'inscrption de l'Ichkeul sur la liste du patrimoine mondial en péril (en1996). A la grande surprise des chercheurs qui s'intéressent au suivi écologique de l'Ichkeul, il a suffit d'une seule année hydrologique exceptionnellement humide (2002-2003) pour que l'herbier puisse se reconstituer. Rappelant qu'une salinité <10 au début de la saison printanière est une condition sine qua non à l'apparition des jeunes pousses de *P. pectinatus* et ces conditions ont été bien établies en 2003. Le cas de l'Ichkeul est un exemple type qui montre l'importance des macrophytes benthiques comme outil d'aide à la décision. En effet, la régénération des herbiers à *P. pectinatus*, confirmée par un suivi cartographique montrant l'évolution progressive de l'herbier, a permis de reconsidérer le statut écologique du Parc National de l'Ichkeul qui ne figure plus, depuis 2006, sur la liste de l'UNESCO du patrimoine mondial en péril.

Abstract
The impact of boat anchoring on the Mediterranean endemic bivalve *Pinna nobilis* Linnaeus (1758) was assessed experimentally in the field by installing non-biological mimic units of the bivalve in the islands of Mallorca and Malta. In each of these two Mediterranean localities, two study areas having different levels of boat anchoring activities: 'control' (no anchoring allowed) and 'impacted' (anchoring allowed), were used for the field experiment. A significant number of *P. nobilis* mimic bivalves were affected by boat anchoring in the impacted areas; the impact was 3 times higher in impacted areas compared to control areas. Boat anchoring also had an adverse impact on *Posidonia oceanica* meadows, since seagrass cover was lower in the impacted areas.

Keywords: Bivalves, Endemism, Balearic Islands, Malta Trough, Coastal management

1. Introduction Anchoring by recreational boats causes an adverse impact on vulnerable and protected habitats and species. *Posidonia oceanica* seagrass meadows are the main habitat of the endemic fan mussel *Pinna nobilis*, the largest Mediterranean bivalve. Both *P. oceanica* and *P. nobilis* are under threat due to anthropogenic activities, especially in shallow coastal waters. Boating activities are increasing in Mediterranean coastal areas, especially during the summer months. Since boat anchoring causes physical damage to seagrass habitat [1], the activity can also affect the associated *P. nobilis* populations, given the large size of the bivalve. However, such direct physical adverse impact has never been assessed. Therefore, the aim of the present study was to evaluate the impact of boat anchoring on *P. nobilis* by using a field experimental approach in two Mediterranean islands that are support a high level of boating activities.

2. Materials and methods Deployment of non-biological mimic units of *P. nobilis* in *Posidonia oceanica* meadows within the 3 m to 10 m depth range was carried out during the period July to October 2012 using SCUBA diving. The experiment was conducted in two areas having different levels of boat anchoring activities: 'control' (no anchoring allowed) and 'impacted' (anchoring allowed), in the islands of Mallorca and Malta. The experimental design comprised 3 factors: 'protection' (fixed, with two levels, impacted and control), 'locality' (random and nested in protection, with 5 levels nested in control and 7 levels nested in impacted), and 'site' (random and nested within protection and locality, with three levels). For each treatment, 5 mimic bivalve units were deployed on the seabed within *P. oceanica* meadows. Statistical analysis was performed using PERMANOVA. Additionally, data on *P. oceanica* meadow cover and on the natural population of *P. nobilis*, were recorded for Mallorca.

3. Results The results indicated a significant impact of boat anchoring on the *Pinna nobilis* mimic units (Fig. 1, p value = 0.031). Of the affected mimic units, 12.09% were found leaning at an angle, 35.16% were found lying horizontally on the seabed and 52.75% were not found. The adverse impact of boat anchoring is also reflected on the *P. oceanica* habitat, since seagrass cover was significantly higher in the control areas (p-value: 0.001) in Mallorca.

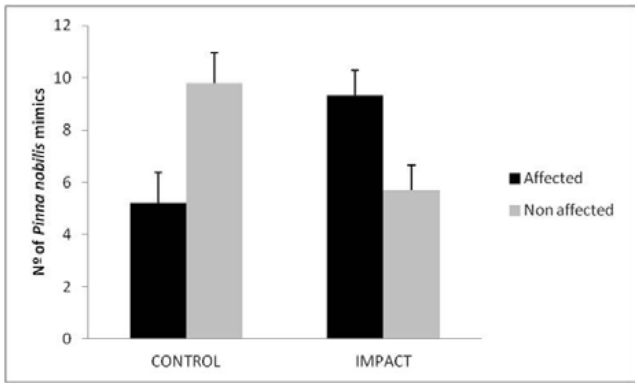

Fig. 1. Overall mean percentage affected and non affected (± standard error) *Pinna nobilis* mimic units.

4. Discussion The present results clearly indicate that *P. nobilis* mimic units were significantly affected by boat anchoring in impacted areas. Our findings highlight the importance of regulating coastal recreational activities [2] by adopting appropriate measures, for example, controlling the number of boats that enter areas where anchoring is allowed without any limitations [3]. A possible solution to minimize the impact of boat anchoring is to install mooring buoys and having environmental education programs in place to inform boat owners of the adverse effects of anchoring on *P. oceanica* and their associated biota. Such measures are important for protecting natural marine resources and improving future planning and decision making, thereby ensuring effective coastal management.

CAS D'ÉTUDE DE LA GESTION MENÉE DANS QUATRE AIRES MARINES PROTÉGÉES DE MÉDITERRANÉE

Chloë Webster [1]* and Marie Romani [1]
[1] Mediterranean Protected Areas Network (MedPAN) - chloe.webster@medpan.org

Abstract
Quatre AMP, membres du réseau MedPAN, ont fourni les éléments relatifs à différents aspects de la gestion menée depuis plusieurs années et des résultats qu'ils ont obtenus sur leurs sites. Le cas du Parc National Marin de Zakynthos en Grèce permet de mettre en avant l'importance d'une gestion intégrée de la zone côtière, le cas du Parc Naturel de Telašcica en Croatie concerne la nécessité d'impliquer les parties prenantes dans la gestion de l'AMP, le cas de la Réserve Naturelle de Bonifacio en France permet de montrer le partenariat solide mis en place avec les pêcheurs artisanaux et l'aire protégée de Kas-Kekova en Turquie expose comment développer un tourisme durable.

Keywords: Marine parks, North-Western Mediterranean, North-Eastern Mediterranean, Biodiversity, Coastal management

Parc National Marin de Zakynthos, Grèce : Gestion Intégrée des Zones Côtières

Le principal enjeu du Parc National Marin de Zakynthos est de protéger l'une des plus importantes plages de ponte de la tortue Caouanne (*Caretta caretta*) en Méditerranée, tout en maintenant et en développant des activités économiques d'une manière durable. Environ 700 000 touristes visitent Zakynthos pendant la saison estivale. Le Parc a été créé en 1999. Des actions ont été entreprises afin de sensibiliser les touristes et la population locale sur les questions environnementales et de les impliquer dans les activités de terrain, d'organiser et de contrôler l'utilisation de la plage, de limiter les déchets, de mettre en oeuvre des codes de conduite et la certification des opérateurs locaux et plus généralement de limiter l'impact négatif des activités humaines sur les espèces protégées et les écosystèmes. Les intrusions des visiteurs et de la population locale dans les zones réservées ont été considérablement réduites, tandis que les délimitations de la zone marine et terrestre ont progressivement amélioré le contrôle des activités touristiques. A titre d'exemple, la délimitation des zones marines du Parc, en collaboration avec la police portuaire, a contribué à appliquer la réglementation sur la vitesse et l'accès des bateaux, et a permis de diminuer les risques pour les tortues et de protéger les habitats marins uniques de la zone. Le système d'ancrage sur bouées choisi a aussi évité la destruction des herbiers de Posidonia oceanica. Les conflits avec les populations locales et les parties prenantes ont diminué et le Parc est de plus en plus intégré dans le contexte socio-économique local. Le Parc National Marin de Zakynthos est régulièrement cité comme référence par l'Union Européenne pour la mise en oeuvre de la directive Habitat en Grèce et comme un exemple de gestion intégrée des zones côtières efficace.

Parc Naturel de Telašcica, Croatie : participation des parties prenantes dans la gestion de l'AMP

Le Parc Naturel de Telašcica a été créé en 1988, mais ce n'est que depuis peu qu'il est activement géré. Couvrant environ un tiers de l'île de Dugi Otok, le Parc concerne directement un millier de résidents locaux. Les populations locales se sont montrées au départ méfiantes à l'égard des mesures de gestion qui pourraient être imposées par le Parc. Au cours de ces dernières années, Sunce, une ONG locale, et le WWF se sont appliqués à démontrer les avantages d'une coopération étroite avec toutes les parties prenantes, pour une meilleure gestion de la zone. Une grande attention a été accordée à la communauté des pêcheurs. Malgré la baisse constante des stocks de poissons, le concept de pêche durable était difficile à accepter. Certains représentants de la communauté ont finalement pris part à des séances d'information et à des ateliers pour discuter du plan de zonage et du nouveau règlement de la pêche. Les autorités de gestion du Parc ont été formées à une gestion efficace des AMP, à la fois en termes de conservation mais également de concertation avec les parties prenantes. Historiquement perçu comme une menace par la population locale, le Parc gagne jour après jours de nouveaux partisans et les principes de protection de l'environnement progressent.

Réserve Naturelle de Bonifacio, France : préserver la pêche artisanale

L'Office de l'Environnement de la Corse (OEC) qui gère la réserve collabore activement depuis 1999 avec la Prud'homie des patrons pêcheurs de Bonifacio dans le cadre de la gestion du stock halieutique des Bouches de Bonifacio. Les suivis réguliers effectués sur les îles Lavezzi depuis 1992 puis étendus à l'ensemble de la réserve en 2000, jouent un rôle primordial dans la compréhension du fonctionnement des écosystèmes et permettent de prendre des mesures de gestion adaptées pour leur préservation. En 1982 déjà, les pêcheurs de la prud'homie de Bonifacio ont mis en place 2 cantonnements de pêche et une limitation du maillage restrictive. Ils ont par la suite largement participé au long processus de la création de la Réserve en 1999. Depuis 2000, ce partenariat se concrétise avec la participation des patrons pêcheurs aux différentes études menées sur la réserve en termes de gestion de la ressource halieutique. En retour, les pêcheurs sont indemnisés pour la mise à disposition de leurs navires et de leurs engins de pêche ainsi que pour les contraintes imposées par les suivis. Aujourd'hui les suivis scientifiques menés en partenariat avec les pêcheurs ont identifié un indice de biomasse moyen 6 fois plus élevé dans les zones protégées, ce qui engendre des revenus plus importants pour les pêcheries.

Aire de Protection Spéciale (SEPA) de Kas-Kekova, Turquie: développer le tourisme durable

L'Aire Spécialement protégée de Kas-Kekova est un hot-spot de la plongée en Méditerranée. Cet afflux de touristes doit cependant être géré pour limiter les dommages comme la détérioration des herbiers marins, la pêche illégale et les pollutions. La gestion du tourisme est un chapitre essentiel dans le premier plan de gestion de Kas-Kekova. L'Association sous-marine de Kas, KASAD, qui fédère la plupart des clubs de plongée de la région, a contribué à la définition du plan de zonage. Ensemble, ils ont identifié l'emplacement des sites de plongée et se sont mis d'accord sur l'installation d'un système de bouée afin d'éviter l'utilisation d'ancres et de protéger les herbiers sensibles. A ce jour, 5 sites de plongée sont équipés en tant que projet pilote.

Les sessions d'information et de consultation intensives avec les acteurs locaux, tels que KASAD ou les opérateurs de bateaux touristiques, ont conduit à d'importants engagements informels, qui sont appliqués avant même l'adoption officielle de la législation.

DESIGN OF AN ECONOMIC AND ENVIRONMENTAL GIS-DATABASE TO ASSESS THE ECONOMIC IMPACT OF COASTLINE EROSION TO TOURISM. THE CLIMATOURISM DATABASE.

George Alexandrakis [1]* and Nikolaos Kampanis [1]
[1] Institute of Applied and Computational Mathematics, Foundation for Research and Technology, Hellas - alexandrakis@iacm.forth.gr

Abstract
A novel database, functioning as a supporting tool for the estimation of the economic impact of beach erosion to tourism, is described. The conceptualization, design and implementation of the database are discussed. The proposed database aims to provide realistic data to estimate the economic value of the beach, through a hedonic pricing econometric model.

Keywords: Erosion, Economic valuation, Gis, Cretan Sea

1. Introduction
Tourism is one of the principal sectors for the economy, especially in the Mediterranean countries. With the majority of the touristic activities concentrated around coastal areas, coastal erosion, among others, poses a significant threat to coastal economies that depend heavily on revenue from tourism. The ClimaTourism Database focuses on the identification of the vulnerability of the coast to sea level rise and associated erosion, in terms of expected land loss and economic activity. To achieve this, a database with environmental and economic data has been developed, as a supporting tool for economic impact to tourism. This multipurpose database needs to consider social, economic and environmental factors, whose interrelation will be better comprehended after being distributed and analyzed within the geographical space. The conceptualization, design and implementation of a regional GIS database, and its application to the Cretan Isl. in Greece, are presented.

2. Conceptual Model
The ClimaTourism database modeling combines environmental and economic data, under a multipurpose approach. The estimation of the vulnerability of the coast is implemented in two scales. The larger scale estimates the vulnerability in a regional level, with the use of the CVI method [1]. Subsequently, a smaller scale focuses on highly vulnerable beaches with high touristic and economic value. For this, the BVI method [2] is used, in order to identify the key factors that result to beach erosion. Finally the economic value of vulnerable beaches is estimated with the use of a hedonic pricing method [3]. There are three types of data that are used: (a) Raw data, derived from maps and remote sensing products, field observations, laboratory analyses, and social and economic features. (b) Analytical data, that are produced by analyzing the previous groups and (c) thematic data, created by interpreting the various types of data. In order to analyze large amounts of data -in a variety of formats, produced by numerous methods, and with different levels of accuracy- the database has been developed in a GIS form, organized in four levels. The first level concerns the gathering of raw data. In the second level the organization of the data is made. In level 3, new thematic data can be generated for further utilization. The applications of the database are implemented in level 4. The database flow chart and the conceptual model are illustrated in Figure 1.

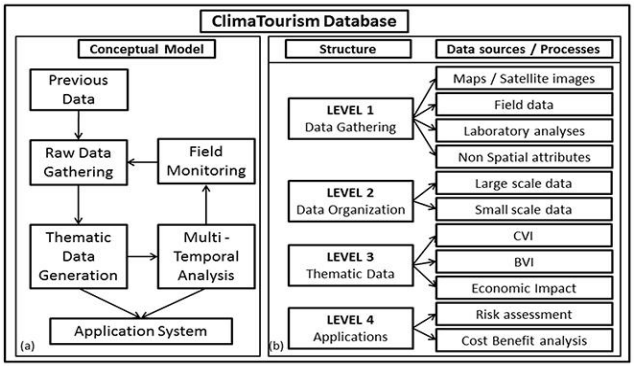

Fig. 1. Database flow chart and conceptual model.

3. Database design, implementation and geographical coverage
The geographical coverage of the large scale dataset covers the area of the Cretan shoreline and the area offshore which is included in the coordinates (Upper left 35.43N 24.69E, Low Right 34.91N 26.31E). At this scale, data about elevation, geomorphology, sea level trends, shoreline displacement, tide ranges, and wave heights are used. The small scale data set covers the areas of the beach zones. These data are derived by the numerical estimation of the processes that control beach evolution. This estimation depends on the calculation of other important variables, such as granulometry, wave characteristics, the geomorphology of the beach zone (e.g. beach slope), and, analytical data derived from these variables (e.g. wave run up). The socio-economic data that will be used for the database applications are included in this dataset. Details of the relational database, such as entities, relationships, tables, maps and, glossary of terms for data surveying, can be found in D1.4 deliverable, in the ClimaTourism WEB page (http://www.iacm.forth.gr/Climatourism).

4. Econometric model
A hedonic pricing model [4] is used to estimate the value of beach width that is capitalized in tourism income:

$$\ln(BL_{ij})=a_1(A_{ij})+ a_2(T_{ij})+ a_3(P_{ij})+ a_4(W_{ij})$$

where Beach Land value (i) in location (j) (BL_{ij}), is a function of Accommodation facilities (A_{ij}), number of hotels, Cafes, restaurants, hotel beds in a 200m from the beach buffer zone; Tourist activities (T_{ij}), number of enterprises that use the beach (e.g. water sports), beach area used for touristic activities; Property values in the proximity of the beach (P_{ij}); width of the beach at the property location (W_{ij}).

5. Expected results and conclusions
The expected outcome of the database is the identification of the most vulnerable and under high risk touristic coastal areas, and the estimation of the economic impact from beach land loss. Research of the economic implications of beach erosion were mainly focus in the cost of coastal protection measures and less in the income losses from tourism. A join environmental and economics approach of the problem can provide a management tool to mitigate the impact of beach erosion in tourism, through a realistic cost-benefit analysis for planning protection measures.

PRELIMINARY STUDY OF THE MANAGEMENT OF *POSIDONIA OCEANICA* BANQUETTES IN SPANISH COASTAL BEACHES.

Juan Eduardo Guillén Nieto [1]*, Joaquín Martínez Vidal [1], Alejandro Triviño Pérez [1] and Gabriel Soler Capdepón [1]
[1] Instituto de Ecología Litoral - j.guillen@ecologialitoral.com

Abstract
We performed a preliminary study on the management of *Posidonia oceanica* banquettes in various Spanish Mediterranean beaches. The biomass based on dead leaves that reaches the shorelands was estimated in 1,975 tonnes/year/km. Its annual removal cost exceed 100,000€ per municipality in 7.7% of the cases studied. There is a public ignorance about the environmental role of the banquettes residues. Thus, most people do not identify this biomass as natural; it is considered waste and its presence in the beaches responsibility of the administration.

Keywords: Posidonia, Coastal management, South-Western Mediterranean

Introduction:
Accumulations of leaves and debris from the seagrass *Posidonia oceanica* are commonly found along the Mediterranean coast. They form structures from a few centimeters to several meters thick, which are defined as "banquettes", consisting of leaves, rhizomes and sediments (Jeudy de Audoly Grissac & 1985; Boudouresque and Meisnesz 1982; Jeudy de Grissac, 1984). Although the banquettes often have been cited as having a role in the protection of beaches against erosion (Mateo *et al*., 2003, Boudouresque and Jeudy de Grissac, 1983), these are usually removed from beaches and coves to promote the exploitation of tourism in the Mediterranean region (Duarte, 2004). De Falco *et al*. (2008) estimate in 19-44 m^3 the sediment loss in 1,000 m^3 of banquettes disposed.

Material and Methods:
It has been studied for 13 areas in the Spanish Mediterranean coast (Formentera, Menorca, Benidorm, El Campello, Orihuela, Pilar de la Horadada, Santa Pola, Villajoyosa, Jávea, Vinaroz, Xilxes, Torreblanca and Lorca), using waste data and surveys focused on participation of beach users and local technicians.

Results:
In all cases, residues are principally composed of *Posidonia oceanica* banquettes (76.92%), the rest are various algae or other seagrasses (*Cymodocea nodosa*, mainly). The amounts of *P. oceanica* which are removed in the study areas have an average value of 1,975.11 tonnes/year/km, but this value is subject to high variability (sd 2,649.96), depending on each beach and year. Thus, the data obtained evidences a direct relationship between sea storms and tons of *P. oceanica* collected. In 2011 there was a high frequency of sea storms, higher than annual average, with an exceptional episode (March 2011) where the waves reached 4 meters high, coinciding with the maximum amounts given in the study. The residues of *Posidonia oceanica* collected were transferred to waste landfills in the 55% of the cases, to be treated as household waste, only 10% was used for environmental purposes, such as dune restoration, other uses were: farming (18%) , agriculture (11%), and other (6%). Another highlight of the study was the public perception of the residues, with results of 92.8% identified the presence of banquettes as waste, compared to the rest that considered as natural. Citizens likewise considered to local administration responsible for the presence of residues of *P. oceanica* on beaches (53.8%), compared with 15.4% who point out the ocean currents or other natural causes. Regarding the economic cost that municipalities expended for treatment of *Posidonia oceanica* residues, the survey revealed that the majority annual cost per municipality is less than 25,000€ (53.8% of cases), 7.7% intended between 25,000 and 50,000€, 15.9% expended between 50,000 and 100,000€, and 7.7% expended more than 100,000€ to treat the residues.

Acknowledgments:
The study is part of the project Seamatter financed by the European LIFE Programme (LIFE11 ENV/E/000600). We thank the municipalities of El Campello, Benidorm, Lorca, Orihuela, Pilar de La Horadada, Santa Pola, Torreblanca, Villajoyosa, Vinaroz, Xàbia, Xilxes, and the Island Councils of Formentera and Menorca, for providing their data for this study.

Abstract
The present paper presents the analytical and empirical aspects of an integrated vulnerability index for fishing/small ports based on the IPCC methodology for coastal vulnerability assessment. Six corresponding steps were adopted in order to assess the fishing ports vulnerability index (VIP-F). Geo-physical and socio-economic parameters are taken into account. The proposed index consists of three sub-indices: a physical index, a social and an economic index, all depending on differentially weighted variables. The development and a primary application of the proposed index were implemented in 47 fishing and small commercial ports of Lesvos Island, Greece. The proposed methodology can be adapted for vulnerability assessment of larger ports.

Keywords: Global change, Coastal systems, Aegean Sea

Introduction
Vulnerability in a broad sense defines the magnitude of the threat posed by climate change to humans. That includes both the degree to which an ecosystem service is sensitive to global change plus the degree to which the sector that relies on this service is unable to adapt to the changes. Thus, in a quantitative sense vulnerability is considered to be a function of exposure, sensitivity and coping capacity. [1] Both geo-physical and socio-economic indicators are accordingly used to quantify vulnerability to climate change impacts and prioritize policy responses. Coastal zones have attracted major investments which are susceptible to hazards such as storm surges and coastal erosion. Fishing ports (i.e. small ports for professional and amateur fishing boats) are among those investments. Climate changes along with the projected mean sea level rise, increases pressures to the coastal areas and consequently is expected to affect their economic growth [2]. The aim of this study is the development of a composite vulnerability index mainly for fishing ports but also for small island ports and the empirical application of this index to the fishing and other commercial small ports of Lesvos Island.

Methodology
Based on the IPCC methodology [3], [4], as adapted within CLIMSAVE project [5], for coastal vulnerability assessment, six (6) interlinked steps were adopted in order to assess the VIP-F.These steps are: (i) delineation of the study areas and identification of local climate change impacts through local data collection. (ii) production of an inventory for the fishing ports' characteristics (construction materials, size, orientation, sea-level sign etc). Data collected and analyzed referred to wind intensity/ direction, frequency of extreme wind observations, the incident wave's characteristics (height, period) and the effective fetch length at the fishing port entrance. (iii) identification of relevant stakeholders: professional and amateur users of the ports. (iv) calibration of physical changes through fishermen observations and corresponding impacts on the fishing ports (effects on the construction and the vessels). (v) Calculation of fishing ports adjustment costs according to two SLR scenarios. The engineering adaptation measures examined are: pier lifting, pier extension, deepening and enrichment with boulders. The required volumes of material, as well as the appropriate prices were also calculated. (vi) Estimation of the fishing ports' vulnerability through the adopted vulnerability index. The suggested VIP-F consists of three sub-indices: the physical, the social and the economic, dependent on differentially weighted variables. Each variable was introduced into a calibrated table, where 1 corresponds to the worst case and 6 to the best. The calibration was based on the maximum and minimum value of each variable, multiplied by a corresponding weighting factor. The VIP-F is finally given by the following formula:
VIP-F = [(Physical sub-index x 0.5) + (Social sub-index x 0.25) + (Economic sub-index x 0.25)].

Results and conclusions
The first results show that from a total of 47 fishing and small ports in Lesvos, 83% has VIP-F values higher than 3 (with a range between 3.1 and 3.9), implying medium vulnerability. 17% of the examined small ports shows a VIP-F value lower than 3 , being thus the most vulnerable. Mytilini (the islands' capital city) port has a value of 4.6, indicating that it is the less vulnerable port in the whole island. Nevertheless due to its importance for social/economic activities on the island, it still must be considered for adaptation measures to future climatic changes. Since the cost of protecting measures seems to be very high for all fishing ports, this index will help ranking the investment opportunities of the highest importance to the society. This in turn will support a cost effective allocation of investment funds for climate change adaptation measures for small or bigger ports.

AQUATIC GENETIC DIVERSITY: ASSESSING ECONOMIC VALUE

A. Issari [1], S. Matsiori [1]*, A. Exadactylos [1], G. Ekonomou [1] and D. Vafidis [1]
[1] Department of Ichthyology and Aquatic Environment School of Agricultural Sciences University of - steriani@uth.gr

Abstract
This study explores the factors influencing people's Willingness To Pay (WTP) for protecting aquatic genetic diversity. WTP was derived from a face-to-face survey of 350 respondents randomly selected residents of Volos city. Significant relationships are found between environmental people's WTP and its age and functional uses of genetic resources.

Keywords: Economic valuation, Biodiversity, Aegean Sea

Introduction
Economic valuation of biological resources supports conservation policies of these resources [1] and also recognises the importance of them valuation [2]. The objective of this paper was to investigate people's WTP for aquatic genetic diversity conservation by exploring the determinant factors that affect respondents' WTP. According to [3] the majority of previous studies have quantified genetic diversity measuring direct use benefits of biological resources in terms of inputs to the production of market goods [4,5,6].

Materials and methods
A CV survey was carried out to 350 randomly selected residents of Volos city. Volos is a coastal port city in Thessaly situated in the middle of the Greek mainland and is built along the Pagasitikos Gulf. A questionnaire was constructed and tested according to guidelines established by the NOAA panel [7]. Respondents were asked whether they would support a conservation program of aquatic genetic resources. Implementation of the program would cost them a specified amount of money (in €) in a one-time payment. In the second phase respondents were asked if they were willing to pay a specific amount of money to confirm their participation. The discrete choice model has become the most used approach for determining whether people are willing to pay for a non-market good [8]. Follow-up a Principal Components Analysis (PCA) was used as a tool for measuring different public perceptions and preferences with regard to importance of aquatic genetic resources.

Results and Discussion
The results revealed that most respondents (53.4%) were males. Mean age was 30.93 years, while mean monthly income was 942.57 €. Most respondents were formally educated (13.3 years) and all the respondents were engaged in at least one economic activity. PCA was used to measure different public perceptions with regard to importance of aquatic genetic resources (Table 1).

Tab. 1. Importance of aquatic genetic diversity

Factors Identi-fication	Variance Explained (%)	Cronba-ch's a	Total Cronba-ch's a	KMO	Bartlett's Test of Sphericity
Species Tolerance	30.59	0.82	0.87	0.82	App. χ^2 (1376,44) df = 190 p = .000
Functional Uses	12.88	0.75			
Pharmacy Production Services	7.78	0.81			
Conserva-tional Uses	5.99	0.71			
-	5.39	0.52			

Collected data, in the form of a binary variable (1=Yes and 0=No), on the amount that the respondents were willing to pay as well as a number of explanatory variables were used in a logistic regression model formulation (Table 2). The results of PCA indicate that the populations' ability to resistance, tolerance is the most important service provided by aquatic genetic diversity. Next, with the help of the extracted factors we explore how the level of importance may yield additional insight to explain individuals' WTP for its protection. Our empirical analysis illustrates that non one of socio-economic characteristics (e.g., age, household size, and income), except age, had significant effect on people WTP. On the other hand our results linked aquatic genetic resources with its functional uses (indirect use values).

Tab. 2. Description of explanatory variables and logistic regression results

Variables' description	b	Wald
Constant	1.367 [0.013]	1.415

LANDSCAPE APPROACH TO THE ASSESSMENT OF MPA ECOSYSTEM SERVICES

Tatyana V. Pankeieva [1]* and Natalya A. Milchakova [1]
[1] Institute of Biology of the Southern Seas - tatyanapankeeva@yandex.ua

Abstract
The design procedure of ecosystem services are given for marine protected areas (MPA) on the basis of landscape and resources of macrophytes (using the example of the National natural park, Tarkhankut Peninsula, Crimea). Use of this technique allows identification of priority areas for the creation and organization of marine protected areas in the coastal zone of the Black Sea.

Keywords: Conservation, Black Sea, Ecosystem services

Anthropogenic pressure on the coastal zone in many areas of the Black Sea have led to the degradation and decrease in areas of natural habitat, reducing biological and landscape diversity, reducing their ecosystem services. Giving the value of ecosystem services with application towards MPA, the landscape approach and resource data for macrophytes could be one structural form of the economic calculation. Despite the extensive range of the scientific research on this topic, some aspects remain poorly explored by the government, including the assessment of ecosystem functions of seascapes. Coastal ecosystems, including estuaries, coastal wetlands,seagrass beds and algae, coral reefs and the continental shelf were disproportionately high in value. They cover only 6.4% of the world's surface but are responsible for 43% of the estimated value of the world's ecosystem services [1]. The coastal zone is defined as the economic valuation of ecosystem services MPA that can be given through the evaluation of services including macrophyte data resources and benthic landscape structure. As major primary producers, macrophytes provide the normal functioning and stability of the coastal ecosystem and, therefore, a sustainable environment, including the MPA. Coastal landscape structure reflects patterns of distribution of benthic landscapes with their features of geology, geomorphology, hydrology and biota. For the valuation of ecosystem services, calculation of macrophytes by subdivisions shall possess a natural property of integrity, which is typical of benthic landscapes. The developed method of valuation for ecosystem services, based on MPA landscape structure of the seabed and macrophytes resources, provides performance in few stages: physical and geographical characteristics of the area, structure and resources of bottom vegetation, to create the landscape map of the coastal zone, ecosystem services assessment of macrophytes including benthic landscape structure, mapping of the of bottom landscapes for ecosystem services assessment, and analyses of the full sets of data. Taken as a basis for mapping the coastal landscape sector of the coastal zone, the territorial unit for the assessment of ecosystem services is the bottom benthic landscape with bottom vegetation and macrophytes communities. For each floor of the landscape, the following parameters are calculated: area (ha), stocks (t, wet weight) and biomass of macrophytes (t/ha, wet weight). According to published data, the value of ecosystem services is estimated at $34,000 per ha per year for the bottom vegetation [2, 3]. Since stocks and biomass of macrophytes within landscaped boundaries have different values, the recommended method is to calculate the value of the ecosystem services to all areas of the coastal zone, including MPA. For this, calculate the ratio of ecosystem services (K) of macrophytes as a function of their biomass (t/ha), which is calculated on a peer review from a regional perspective. Valuation of ecosystem services, taking into account the landscape structure and bottom vegetation parameters, is carried by the following formula:

$$V = S \times D \times K \quad (1)$$

where V - the value of ecosystem services within the macrophyte landscape contours (in $); S - area of the landscape contour (km^2); D - a certain value of the ecosystem services of bottom vegetation, with 1 hectare = $34000 [2,3], K – the calculated coefficient, taking into account the biomass of macrophytes (t/ha). This technique has been tested for the bottom vegetation and landscapes of the Tarkhankut Peninsula coastal zone, which is a National natural park of Ukraine with a high level of landscape and biological diversity. This is confirmed by the high value of ecosystem services, benthic landscape and vegetation, and is designed by the proposed method (see Fig. 1).

In conclusion, the necessity of costing the benthic landscapes and bottom vegetation has taken into account their high ecological value. This technique can be applied to estimate the value of MPA ecosystem services along the Ukrainian part of the Black Sea coastal zone where full sets of data for macrophytes resources and bottom landscape structure exist to promote friendly and sustainable of natural resources, aimed at preserving the most valuable natural complexes. The advantage of this approach is not only the ability to characterize the unique landscape and biological diversity and ecosystem services for MPA, but also to give them an economic assessment, to determine the benefits and losses, to develop ways and means of preserving these services of the coastal ecosystems.

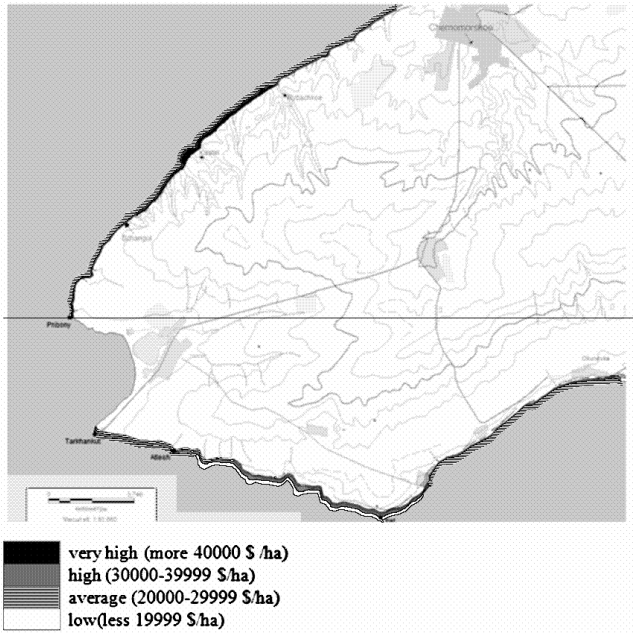

Fig. 1. Value of ecosystem services of the benthic landscape of the Tarkhankut Peninsula

IMPACTS OF OFFSHORE WIND FARMS ON MARINE ECOSYSTEM (A REVIEW)

Lilija V. Bondareva [1], Vladimir V. Alexandrov [1] and Valentina G. Riabohina [1]*
[1] Institute of Biology of the Southern Seas, Sevastopol, Ukraine - valryabog@yandex.ru

Abstract
The environmental impact of offshore wind farms (OWF) is reviewed to consider possible threats for the Black Sea ecosystems due to the wind power development planned in this region. The physiological and biochemical responses of marine species to vibrations created by OWF are poorly investigated and thus are important subject for future research.

Keywords: Black Sea, Coastal management, Wind

At present the successful development of wind energy, especially in the coastal zone, gradually led to the construction of Offshore Wind Farms (OWF). This is due to the fact that the wind speed reaches higher levels around offshore areas of the sea than on land. Usually the shallow areas (depth up to 30 m), with a distance from the coast of 30–90 km are selected for OWF. There are no OWF in the Black Sea yet, but wind power development is considered for this region [1], so it is necessary to study possible threats from OWF. There are many publications on evaluating the effect of Wind Farms (WF) on the biota and environmental conditions especially on climate. Because of the wind energy development in offshore areas the number of studies describing the effect of OWF on environment is rising. It is proposed to perform an analysis of the WF environmental impact during all the main phases of their life cycle, which includes the production of power equipment, construction of the facilities, operation, dismantling and disposal of obsolete and worn-out elements [2]. It is obvious that direct impact of the OWF production and disposal on marine ecosystems is excluded.

Environmental impacts during the WF construction do not differ from those in other capital construction projects. Construction works disturb and destroy benthic communities and substrate; the noise of construction machinery is an additional source of animal disturbance, but the impact of WF construction process is limited in time [2]. The estimated lifetime of modern WF is about 25 years [2]. During the stage of their operation WF impact human, flora and fauna, air, water and land use through various types of noise, vibration, electromagnetic radiation, optical effects, mechanical effects and waste [2]. For minimizing the environmental impacts technical characteristics and location of WF are of a large value; for example reduced vibration, design features protecting birds, WF placement far away from birds migration routes, especially from the stopover points [2,3].

Erecting of OWF in the sea leads to the emergence of new sources of noise and vibrations. Propagation of sound in air and water mediums differs, so effect of sound on biota in these mediums considered to differ too. The harmful influence of noise on human activity is well-known, noise is also the main component of disturbance to wildlife. Acoustic vibrations can affect living organisms directly, because of the resonance phenomenon: vibration at resonant frequency of an organ would cause organ damage [4,5]. Low-frequency mechanical vibration is a factor of strong influence for marine animals and for humans [4]. It impacts all biological objects negatively even at the molecular and biochemical levels; this impact depends on specific conditions [4,6]. Mechanical vibrations have a destructive effect on the conformation of enzymes (e.g. catalase), reducing their functional activity. This effect depends on the amplitude and the frequency range of vibration; the degree of the enzyme inactivation is proportional to the vibration intensity [6]. Experimentally proven that the joint action of noise and vibration results in an increase of sugar, cholesterol and lipoprotein content in rat's blood [4]. Acoustic safety of OWF is very important for fish because their mechanoreceptors provide successful foraging, defense and recognition of the individuals of the same species; mechanical vibrations can influence the shoal formation and the reproduction of fish. The perception of mechanical vibrations is species specific; high sensitivity to low frequency vibrations was found for four species of Black Sea fish: sea snake, rass goby, rock bass and sea ruff [4].

The OWF have specific effect on the marine environment that result from fouling of underwater structures; the OWF potential for new habitats creation is discussed. Usually, the artificial reefs are regarded as means to improve ecosystems of the Black Sea, although the hydrotechnical constructions can have neutral or even negative effect on aquatic ecosystems [7]. This is due to species composition of fouling communities in the Black Sea, their productivity and development can vary significantly depending on the substrates, the location of the object, eutrophication and other factors [8].

The impact of WF on birds and bats is well-known [3] and depends on the location of WF, especially on their proximity to the birds migration routes. It is clear that OWF will be perceived by birds as a place to rest. Identifying the influence of OWF is especially important for the Black Sea, because this basin is a part of main bird migrations routes [9]. Bats are often victims of WF on land; apparently this is a genuine problem for OWF as well. The migration path of bats often coincides with the migration routes of birds; there is evidence of finding bats in the open sea. Several papers discuss the impact of WF on some climatic characteristics: change in wind speed, humidity, air composition (CO_2) and near-surface air temperature. The rotation of the turbines results in vertical mixing of heat in the atmosphere, which affects the temperature and can slightly change the evaporation [10].

Thus, possible negative impacts on biota and environment are possible as a consequence of the wind power development in the Black Sea. They have to be considered during the planning such an activity in this region taking into account their influence on the MPA network to be created. The physiological and biochemical responses of marine species to mechanical vibrations in aquatic environments are poorly investigated and thus are important subject for future research.

Abstract
Oil pollution of the Marmara Sea was investigated at 17 stations during February 2013. Total hydrocarbons were determined against chrysene standard using spectrofluorophotometer. The highest oil pollution was found as 11,9 µg/L at Station 7 in Dardanelles and 2,71 µg/L at station 3 in Istanbul Strait. According to results oil concentrations in some stations are much higher than limit value. Long term monitoring is necessary on pollution due to busy traffic of Marmara Sea.

Keywords: Coastal waters, Surface waters, Petroleum, Marmara Sea

Petroleum hydrocarbons are usually introduced into the environment as a result of anthropogenic activities which increased dramatically in the last two decades and they are also released into the aquatic environment through wastewaters, from coke and petroleum industries, vehicle traffic, and oil spills [1]. In Marmara Sea oil pollution is mostly caused by the inflow from Black Sea, as well as heavy shipping traffic and the Izmit refinery. The Dardanelles was also affected by the pollution carried from the Sea of Marmara and shipping/tanker traffic [2,3,4]. In this study oil pollution was determined in the coastal surface water of the Marmara Sea at 17 stations in 2013 February. The seawater samples were taken in 2,8 L amber glass bottles and 15 ml dichlormethane (DCM) was immediately added for preservation. The samples were extracted with DCM and distilled. The residue was taken with hexane and analyzed by spectrofluorophotometer (Shimadzu RF 5301) at 310/ 360 nm (ex/em). Chrysene was used as reference according to suggestion (Aldrich) [5-8]. Names of the stations are listed as 1- Garipce, 2- Rumeli Kavagi, 3- Kumkapi, 4- Büyükçekmece, 5- Tekirdag, 6- Gallipoli, 7- Karakova Cape, 8- Seddülbahir, 9- Kumkale Cape, 10- Gocuk Cape, 11- Lapseki, 12- Erdek Bay, 13- Marmara Island, 14- Kinaliada, 15, Kadikoy, 16- Anadolu Hisari, 17- Anadolu Feneri. Sampling stations are shown in Figure 1.

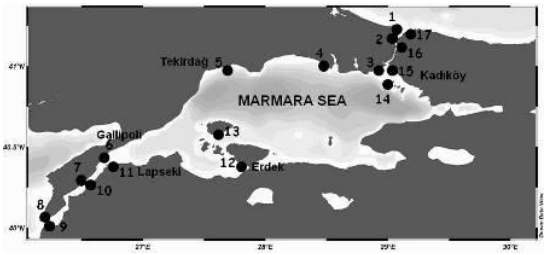

Fig. 1. Sampling Stations in Marmara Sea

The equation of calibration curve for Iraq crude oil: for chrysene:
y= 2134,05*C – 3,5469 r = 0,99.
The oil pollution levels examined in sea water are shown in Figure 2. Oil pollution was investigated at various regions in Marmara Sea by Güven et al., 2005 [2], Güven et al. in 2001-2002 [3], Güven and Ilgar in 1996-1997 [4], in Golden Horn by Cumali and Güven, 2008 [5]. Güven and Ilgar indicated that coastal areas were more polluted than mid-points of Dardanelles and also Sea of Marmara in1996 [4]. Limit value of oil in sea water is reported as 2,5 µg/L by WHO. We found the highest oil level at station 7 as 11.9 µg/L. This case is related to location of shipyard being close to station 7 in Dardanelles. Besides other higher concentrations were found as 10,2 µg/L at Gallipoli and 9,4 µg/L at Lapseki stations in Dardanelles. Gallipoli and Lapseki stations are located at the enterence of Dardanelles and these high concentrations are related to waiting of ships at the enterence. In Istanbul Strait the highest level was found as 2,71 µg/L at station 3 (Kumkapi) where is fishing vessels and yachts station. According to findings oil concentrations in some stations are much higher than limit value indicated by WHO. This study showed that oil pollution had varied among the stations and long term monitoring is necessary on the pollution to understand change in pollution level in Marmara Sea having busy traffic.

Abstract
The concentrations of trace metals (Fe, Mn, Cu, Cd, Cr, Ni, Al, Pb) were measured in two marine organisms of environmental relevance: red algae (*Corallina sp*.) and mollusk limpet (*Patella caerulea* Linnaeus, 1758). The samples were collected at two coastal stations located in the north coasts of Tunisia (Bizerta Channel: CB and La Goulette harbour: LG). These areas are influenced by anthropogenic activities (harbour, industrial and urban wastes). Metal concentrations measured in the limpet indicate that the area of Bizerta Channel was the most polluted. We found high variability of metal bioaccumulation among the two species analysed. The order of metal accumulation in the red algae was Al>Fe>Mn>Pb-Cu>Ni>Cr>Cd, while in the limpet the order was Fe>Al>Mn>Cu>Pb-Ni>Cr>Cd.

Keywords: Algae, Mollusca, Metals, Tunisian Plateau

Marine organisms can be used as monitors to give information on concentrations of trace metal in the surrounding environment. Especially, macroalgae and limpet species are usually used to indicate heavy metal levels in coastal waters throughout the world [1].There have been made numerous studies on the trace metal concentrations of the bivalve and gastropod molluscs in the Tunisian marine environment, but limited information exists on the content of the trace metals in algae of the Tunisian coastal waters. In benthic food webs, marine algae are key links and they act as time-integrators of pollution [2]. Their sedentary nature is another reason why marine algae species are well fitted as monitor organisms in heavy metal monitoring.
The aim of the present study was to determine the levels of Fe, Mn, Cu, Cd, Cr, Ni, Al, Pb in red algae *Corallina sp.* and the limpet *Patella caerulea*, sampled seasonally during 2006-2007, from two different stations in the north coasts of Tunisia (Bizerta Channel: CB and La Goulette harbour: LG). Algal samples and between 30 and 40 specimens of *P. caerulea* were handpicked in the tidal zone from the two studied sites. Organisms were depurate and soft tissues were dried, pulverized and mineralized. Heavy metals analyses were performed in the limpet and algae samples according to the methods described by AOAC [3] and Riget et al. [4].

Tab. 1. Mean concentrations of metals in tissues of *P. caerulea* and *Corallina sp*. collected from the north coasts of Tunisia since summer 2006 until the spring 2007. [a] $mg.g^{-1}$

	Fe[a]	Mn	Cu	Cd	Cr	Ni	Al[a]	Pb
Stations	The mean metal concentrations in *P. caerulea* ($\mu g.g^{-1}$ dry weigh)							
CB	2.59±0.18	5.14±0.83	5.59±0.47	1.63±0.27	2.78±0.59	3.43±0.8	0.40±0.03	3.51±0.67
LG	1.86±0.17	10.76±2.49	9.29±1.43	0.78±0.24	1.00±0.36	3.00±1.12	0.35±0.06	3.61±0.8
	The mean metal concentrations in *Corallina sp.* ($\mu g.g^{-1}$ dry weigh)							
CB	2.29±0.96	36.55±12.68	8.43±3.17	0.76±0.2	2.21±0.92	2.90±0.6	2.53±1.41	7.79±5.68
LG	2.52±1.14	60.80±16.16	13.15±9.62	0.78±0.27	1.28±0.7	2.51±1.49	4.11±1.55	9.26±5.41

The mean heavy metal concentrations determined in *P. caerulea* and *Corallina sp*. are shown in Table 1. Results revealed that in CB station, concentrations of Fe, Cu, Cd, Cr and Ni are significantly higher (ANOVA, $P<0.05$) in soft tissues of *P. caerulea* than in *Corallina sp*., otherwise, in *Corallina sp.*, the rates of Mn, Al and Pb are significantly higher than in *P. caerulea* (ANOVA, $P<0.05$). However, in LG station, except the Cd and the Ni, the mean concentrations of all metals are significantly higher than the rates found in tissues of *Corallina sp*. than in those of *P. caerulea* (ANOVA, $P<0.05$).
In the present study, comparison between stations for the concentrations for all metals revealed that the highest values of the heavy metal in *Corallina sp*. were found at LG station for Fe, Mn, Cu, Cd, Al and Pb (Table 1). However, the highest values in the limpet were found at CB station for Fe, Cd, Cr, Ni and Al.
High concentrations of trace metals registered in CB and LG stations are probably related to the degree of water contamination. High levels of heavy metals in the limpet registered in CB station are caused by wastewater discharges and by the important maritime activities in this area. This zone is also submitted to the impact of industrial activities which cause atmospheric and chemical aquatic pollution [5]. In LG station, the high concentrations in Fe, Mn, Cu, Cd, Al and Pb in tissues of the red algae could be explained by the fact that this station is located at the trade fishing harbour characterized by the important port activity. Besides, this station receives wastes from ships, industrial, urban and agriculture effluents from closed areas via Medjerda Wadi, Khlij channel and Meliane Wadi [6].
The patterns of heavy metal accumulation rates in decreasing order were Al>Fe>Mn>Pb-Cu>Ni>Cr>Cd in the red algae and Fe>Al>Mn>Cu>Pb-Ni>Cr>Cd in The limpet, where Pb, Cu and Ni were changeable in their order at different stations. The observed variation in metal levels in these marine organisms at different stations may be related to the environmental conditions of the area and to the physiological conditions of biota regarding the metal.

IMPACT D'UN REJET D'UNE CENTRALE ELECTRIQUE SUR LE PEUPLEMENT MICROZOOPLANCTONIQUE AU NIVEAU DE LA COTE EST DE LA TUNISIE

Meher Bellakhal [1]* and Mouna Bellakhal Fartouna [1]
[1] Institut Supérieur de Pêche et d'Aquaculture - meher2976@yahoo.fr

Abstract
Des proliférations massives et fréquentes de méduses au niveau de la baie de Sousse, située à l'est de la Tunisie, ont conduit à la suspicion du rejet d'une centrale électrique implantée dans cette zone. En effet, ce rejet provoque une élévation de la température de l'eau jusqu'à 36°C susceptible de perturber la prolifération du phytoplancton puis celle du zooplancton via le réseau trophique. 5 groupes microzooplanctoniques ont été identifiés. A l'échelle saisonnière la densité moyenne la plus importante (2814 cellules/L) a été enregistrée en automne alors qu'à l'échelle spatiale les densités les plus élevées ont été enregistrées au niveau des stations les plus proches du rejet où elles ont atteint 4883 cellules/L.

Keywords: Coastal systems, Thermal pollution, Zooplankton , Tunisian Plateau

Introduction
Le littoral, interface entre la terre et la mer, est un milieu complexe, riche sur le plan écologique et très convoité. Actuellement, 60 % de la population mondiale vit à moins de 60 km des côtes et l'urbanisation littorale risque de s'amplifier, puisqu'on attend 75 % de la population mondiale sur les côtes en 2025 [1]. Selon le PNUE (Programme des Nations Unies pour l'Environnement), 80 % des pollutions marines sont d'origine terrestre et anthropique [2]. La pollution thermique présente un danger néfaste pour l'équilibre écologique des écosystèmes côtiers [3]; [4]; [5]; [6]; [7]. C'est dans ce cadre que la Baie de Sousse a été au cours de ces dernières décennies exposée à des activités anthropiques assez intenses qui ont provoqué une pollution à l'origine de plusieurs problèmes d'ordre environnemental. Parmi ces problèmes on cite la prolifération massive et inhabituelle de méduses qui touche cette zone de plus en plus fréquemment au cours de la saison estivale. La centrale d'électricité, implanté dans cette zone a été soupçonnée dans cette perturbation par son effluent d'eau chaude qui provoque une élévation de la température de l'eau dans la zone limitrophe. L'objective de ce travail est donc d'étudier l'impact de ce rejet sur la répartition spatio-temporelle de quelques groupes microzooplanctoniques.

Matériel et méthodes
A proximité d'une centrale électrique, au niveau de la baie de Sousse située sur la côte Est de la Tunisie (35°50' N ; 10°50' W), 20 stations d'échantillonnage, réparties sur 5 radiales séparées l'une de l'autre de 2 Km et dont chacune comprend 3 stations selon les isobathes : 2 m, 5 m et 10 m, ont été prospectées saisonnièrement durant 2 ans. De plus, 2 stations ont été choisies à proximité des canaux d'amené d'eau de mer pour la centrale électrique, 2 autres au niveau du rejet et une station de référence en amont du site selon le sens du courant, ont été également choisies. Les échantillons ont été récoltés à l'aide d'un filet à plancton de 70 µm de mail et fixés au formol neutralisé au Borax (4 à 5%). L'identification et le dénombrement du microzooplancton a été effectué selon la méthode d'Utermöhl.

Résultats et discussion
Les fluctuations saisonnières du microzooplancton ont été assez hétérogènes. En effet, il a été relativement le plus abondant au printemps avec une abondance relative de 5% par rapport au microplancton total tandis que sa densité était la plus importante en automne avec 2814 cellules/L. Durant l'été elle a été de l'ordre de 1646 cellules/L, 227 cellules/L en hiver et 1217 cellules/L au printemps. A l'échelle spatiale, le microzooplancton a été relativement le plus abondant au niveau de la station 42, située dans la 4ème radiale et à l'isobathe 2 m, avec une abondance relative moyenne de 9.64%. La densité moyenne la plus élevée a été enregistrée au niveau de la station 22, très proche du rejet, et elle a été de l'ordre de 4883 cellules/L. Les observations de terrain ont montré que les proliférations de méduses suivent bien l'évolution spatio-temporelle de ces densités et sont plus fréquentes en automne et en été notamment au niveau des stations proches du rejet. Durant la période d'étude, ce sont les Ciliés non loriqués qui ont dominés le peuplement microzooplanctonique avec les valeurs d'abondance relative et de densité moyenne les plus importantes. En 2ème rang on trouve les Tintinnides. Nous trouvons par la suite, selon un ordre décroissant de leurs abondances relatives : les nauplii de Copépodes, les larves de Lamellibranches, les larves d'Annélides, les larves de Gastéropodes et les Rotifères. Les Ciliés ont été omniprésents au niveau de la Baie de Sousse durant la période d'étude. Ils se sont de même imposés sur le plan quantitatif avec une densité moyenne de 829 cellules/L ce qui correspond à l'abondance relative la plus importante de l'ordre de 52.55%. A l'échelle spatiale, les Ciliés ont dominé le peuplement microzooplanctonique surtout au niveau de la station 45 où on assiste à une abondance relative maximale de l'ordre de 84.82%. En revanche, la densité moyenne a été maximale au niveau de la station 22 avec une valeur de 2310 cellules/L. Au niveau de la station OH1, située à l'embouchure du rejet, cette densité a été la plus faible avec une valeur de 140 cellules/L. Les Tintinnides ont représenté le groupe microzooplanctonique le plus important sur le plan qualitatif en étant omniprésents marquant leur présence au niveau de toutes les stations et durant les 4 saisons d'étude. Sur le plan quantitatif, ils représentent le deuxième groupe le plus important avec une abondance relative annuelle de 40.68% et une densité moyenne de 533 cellules/L. Les nauplii de Copépodes ont été classés parmi les taxa omniprésents en étant assez fréquentes et ubiquistes. Sur le plan quantitatif, ils ont présenté une densité moyennes annuelle de l'ordre de 87 cellules/L ce qui correspond à 5.30% du microzooplancton total. Les larves de Lamellibranches ont présenté un rôle secondaire aussi bien sur le plan quantitatif que sur le plan qualitatif. Elles ont été absentes pendant le printemps et n'ont fait aucune apparition au niveau de 11 stations. Les larves d'Annélides sont à leur tour classées parmi les taxa secondaires aussi bien sur le plan quantitatif que qualitatif où elles se trouvent au cinquième rang avec une densité moyenne de l'ordre de 8 cellules/L ce qui correspond à 0.34% du peuplement microzooplanctonique.

LONG TERM FLUCTUATIONS AND TRENDS OF METALS IN SARONIKOS GULF (GREECE) AS RECORDED BY THE MUSSEL WATCH PROGRAMME

Vassiliki-angelique Catsiki [1]* and Evangelia Strogyloudi [1]
[1] Hellenic Centre for Marine Research - cats@hcmr.gr

Abstract
Bioaccumulation of metals was studied in mussels from Saronikos gulf during the period 1986-2012 in order to investigate temporal trends and control the effectiveness of the wastes treatment. Results showed a decreasing metal gradient towards the open sea. The temporal evolution comprises important variations. It was found that the operation of the wastes treatment unit caused a temporal reduction in metal bioavailability, followed by an increase, as the quantity of wastes increased too.

Keywords: Monitoring, Bio-accumulation, Saronikos Bay

Introduction
The worldwide increase of marine pollution requires control strategies based on regular monitoring of contaminants, frequently performed through the analysis of sessile marine organisms [1]. The present paper aims to describe long term fluctuations and temporal trends of metals in Saronikos gulf (Central Aegean Sea, Greece) by the means of *Mytilus galloprovincialis* in order to control the effectiveness of the wastes treatment and the measures taken. Note that the municipal and part of the industrial wastes are treated since 1996.

Materials and methods
Mytilus galloprovincialis samples were collected from 4 coastal stations seasonally during 1986 to 2005 and scarcely till 2012. During each sampling occasion 4 to 6 replicates of composite samples from the soft parts of 20 specimens of similar size were analysed by AAS for Cu, Cr, Ni, Zn, Fe, Mn and occasionally for Cd and Pb. The accuracy was tested with reference materials.

Results and discussion
Metal levels in the 1537 samples showed that, with some exceptions, Saronikos Gulf's mussels are generally moderately contaminated by metals [2]. Results showed a decreasing metal gradient towards the open sea; Elefsis' bay mussels being the more contaminated [3]. In addition bioaccumulation was elevated during the cold periods of the year.
The Locally Weighted Regression smoothing technique, used to reduce temporally limited changes, showed that most metal levels maintained relatively constant during the period 1985-89, followed by an increasing period till 1993 for Cr & Mn and till 1997 for Zn. During 1997, with the exception of Cr, metals either reach their higher levels (Cu, Fe, Zn), or they have a secondary pick (Ni, Cd, Mn). The year 1997 coincides with one year of operation of the wastes treatment unit, time probably necessary for a first sign of the effectiveness of the Athens' wastes treatment. However during 1993-94 important industries ceased to function. Especially Cr presents its minimal levels during 1997, fact showing that all metals have not the same origin. After 1997 the concentrations temporally return to their previous levels of 1985 and either continued to decrease or start to increase again.
Regression analysis showed that Cu, Cd, Ni and Mn levels present a statistically significant decrease in relation to 1985. On the contrary Fe & Zn (metals especially related with domestic sewages) have a statistically significant increase, while for Cr the observed fluctuations mask the overall trend.
Although the sewages treatment and the reduction of industrial activity in the area had obviously result to decrease trends, we can not neglect the significant gradual augmentation of the quantity of the treated sewages released into Saronikos gulf, that probably cause the observed increase trends.
In conclusion although a reduction is observed for most metals, the increasing trends of Fe and Zn should be taken into consideration by the decision makers since the actual sewage treatment only indirectly removes metals.

TOXIC BANKS: ENCYSTED RESTING STAGES IN HAIFA PORT, ISRAEL

Fernando Rubino [1], Manuela Belmonte [1] and Bella Galil [2]*
[1] Institute for Coastal Marine Environment, CNR, Talassografico "A Cerruti", Via Roma 3, 74123 Taranto, Italy
[2] National Institute of Oceanography, Israel Oceanographic and Limnological Research, POB 8030, Haifa 31080, Israel - bella@ocean.org.il

Abstract
Shipping-mediated introduction and transfer of alien and harmful biota increase with fleet and port expansion. The Mediterranean is a key world maritime route but only voluntary arrangements for ballast water management. Encysted resting stages in the sediments in the port of Haifa, Israel, were sampled on the eve of a major port enlargement project, with the aim of recording the diversity and abundance of the assemblages. Our findings reveal among the cysts present the potentially toxic bloom-forming *Scrippsiella trochoidea*, and the potentially toxic *Alexandrium minutum* and *Gymnodinium uncatenatum* associated with Paralytic Shellfish Poisoning.

Keywords: Plankton, Levantine Basin, Biodiversity, Sediments, Toxic blooms

Studies of benthic resting stages of marine plankton provide information of past and present environmental conditions such as eutrophication, pollution loads and blooms of toxic species. Accumulation of encysted resting stages in ports, form "seed banks" for certain taxa of marine plankton. Haifa port, enclosing the Kishon estuary, Israel's most polluted river, is impacted by nutrient enrichment and industrial waste water, physically altered by construction and frequent dredging, and prone to establishment of ship-transported alien species. The present survey, the first such survey in Israel, was conducted on the eve of a major port enlargement project, with the aim of recording the diversity and abundance of encysted resting stages produced by plankton in surficial sediments and examining the relationship between their structure and different environments within the port. Considering the small number of samples (8 stations, 3 replicates each), species richness (80 cyst morphotypes, 55 produced by dinoflagellates) is remarkably high when compared with results elsewhere in the Mediterranean: in Thermaikos Gulf, Greece, only 36 dinocysts were recorded [1], though 76 dinocyst types were identified from a one year study in Mar Piccolo, Gulf of Taranto, Italy [2]. In addition, we report the highest number of ciliate cyst types recorded from marine sediments. Ciliate cysts were particularly abundant at the Kishon zone where *Strombidium conicum* dominated the ciliate community. The finding in all our samples of *Alexandrium minutum* cysts, a well-known toxin-producer dinoflagellate, responsible for paralytic shellfish poisoning [3] represents a risk potential, as well as *Gymnodinium uncatenatum*,another causative of PSP[4],reported for the first time in the Mediterranean Sea. The cyst assemblages were dominated (44%) by the calcareous cysts of the peridiniacean cosmopolitan bloom-forming species *Scrippsiella trochoidea*, which lethal effects have been unambiguously demonstrated [5]. Cyst assemblages respond to changes in nutrient levels and pollution: in oligothrophic environments, species richness and abundance increase with nutrient enrichment, only to decline with rising eutrophication and pollution, whereas the percentage of heterotrophic and mixotrophic dinoflagellates and ciliates increases [6]. Our results support this: in the Kishon estuary ciliates were more abundant than elsewhere in the port, whereas dinoflagellates' abundance is diminished. These trends hold true both for full and empty cysts. The autotrophic/heterotrophic ratio (A/H) (including ciliate species) reveals that heterotrophic species are more abundant where environmental conditions are extreme. The presence of potentially toxic species, together with many new records of dinoflagellates and ciliates, underscore the need to improve our knowledge of ports' cyst bank assemblages, including stratigraphic analyses, in order to estimate the potential risk of shipping-mediated introduction and transfer of alien and harmful bloom-forming taxa. This is particularly critical as the Mediterranean is a key world maritime route with 30 % of worldwide traffic, 25 % of oil transport, and 450 ports and terminals. Long-term demographic trends and the introduction of larger vessels are driving factors of port development and expansion, yet until the time that the Ballast Water Management Convention enters into force, only voluntary ballast water management are in effect in the Mediterranean.

Abstract

The pressure for more energy demand is a strong driver for the construction of offshore oil and gas platforms. This also applies to the Adriatic Sea where, since 1960 several gas field were commissioned. The continuous expansion of the gas industry may potentially produce detrimental effects on marine communities, especially in such a peculiar semi-enclosed basin like the Adriatic sea which contains ecosystems that are subject to intensive anthropic pressures, like unsustainable fishing and inputs of environmental pollutants. To date, the environmental effects of gas platforms are poorly understood. Thus, a multidisciplinary approach based on chemical, biological and ecological investigations was performed to evaluate the ecological status as well as the water column and the sediments quality near a gas platforms.

Keywords: Monitoring, Bio-indicators, Sediments, Biodiversity, North-Eastern Mediterranean

The rapid expansion of the gas industry may potentially produce detrimental effects on marine communities, especially in deep-water ecosystems [1]. During perforation, drilling fluids are used to assist perforation, and their discharge often increases pollutants in sediments close to platforms and/or changes the sedimentation rates and grain size composition [2]. On the other hand, the platform production phase is characterized by the discharge of large quantities of a complex mixture of organic and inorganic chemicals named produced water (PW) which comes from the routine separation of water present in the oil and gas reservoir. Impacts of offshore oil and gas activities have reduced around some installations, but the evidence base for environmental impacts is limited. Benthic communities can be used to monitor the effects of gas and oil drilling activities since many organisms are sessile or have limited mobility and respond quickly to mechanical and chemical disturbances [3]. Hence, an in situ monitoring data using biological effects methods with endpoints reflecting long term, ecological, effects would support a comprehension of the oil and gas production related adverse effects on acquatic ecosystem. On this context, biological indicators or markers (biomarkers) can be used to measure the biological responses related to the exposure to environmental pollutants [4]. Common for all of the methods is the capability of performing time-integrating response assessment to complex mixtures over extended periods of time, which is often required in environmental monitoring Since most of these sub lethal stress index are highly sensitive and responses occur at lower concentrations and/or prior in time to more adverse effects at a higher organization level, they have become convenient early-warning tools for assessing the potential for long term effects. In our work we tested whether changes in soft-bottom communities were associated with changes in the sediment chemistry as well as to monitor the quality of the water column thought the assessment of marine organisms health status. 24 sampling sites were selected at 5, 30, 60, 120 and 1000 m from two orthogonal transects centered on the gas platform. Samples were collected using a Van-Veen grab for benthic community and ecotoxicological investigation and by a box-corer for physical– chemical analyses. Total content of Al, Cd, Cr, Ba, Cu, Hg, Ni, Pb, Zn and PAH_{16} were estimated in sediments and mussels. To assess the ecotoxicity of sampled sediments the Microtox assay, the *C. orientale* mortality test and the mortality and bioaccumulation rate in *Hediste diversicolor* ragworm were performed. Two seasonal surveys, one in summer and one in winter, were carried out on native mussels (*M. galloprovincialis*). Bivalves were hand-collected by scuba divers at 5–10 m depths close (CA) to and far (FA) from the galvanic anodes placed on the submerged parts of the rig and in the Portonovo Bay (middle Adriatic Sea). The survival on air, the micronucleus test, the comet test, the catalase activity, the citosolic content of malondaldeide, the metallothionein levels, the real-time quantitative PCR on Mt_{10} (III), Mt_{20} (IV) as well as the levels of lipofuscin, neutral lipids and the lysosomal membrane stability on cryo sections of mussel's digestive glands were measured. AFM and SEM microscopy ultra structural analysis were performed on samples of mussels digestive glands and gonads.The composition and abundance of macrofauna communities was assessed. The Clarke "W", the AMBI and the BENTIX index were estimated and compared following Teixeira *et al.*, [5]. An overall evaluation of results confirmed the absence of marked biological effects caused by the activities of the model platform. Even if a chemical contamination and to a lesser extent biological disturbance in these areas is recorded in the first phases of platform's set up, the area of contamination and biological disturbance is decreasing in space within few years. Biomarkers also showed the same gradient from the discharge point, but it is still uncertain how the specific biomarkers affect the individual organisms, the populations or the ecosystems. Future research activity is addressed to find a better link between biomarkers and ecological risk. Further positive aspects of these structures need to be better studied in the future as pipelines, platform legs and subsea templates may act as shelter for fish and other mobile marine organisms, also offering greater food availability and provide a habitat for benthic organisms usually associated with hard substrates [6], [7].

ASSESSMENT OF THE TROPHIC STATUS OF THE MERSIN BAY WATERS (NORTHEASTERN MEDITERRANEAN)

Mehmet Salih Kaptan [1]*, Süleyman Tugrul [1] and Mustafa Koçak [1]
[1] Institute of Marine Sciences Middle East Technical University - mkaptan@ims.metu.edu.tr

Abstract
The eutrophication related biochemical biochemical parameters were measured seasonally in the Mersin Bay located in the Northeastern Mediterranean Sea between 2008 and 2011. The results showed 5-10 fold spatial and seasonal changes were observed in nutrients (DIN, TP), Chl-a and Secchi disc depth (SDD) in the shelf waters of the bay. The assessment of trophic conditions of the bay surface waters by cluster analysis, TRIX and UNTRIX approaches show that the inner bay water reached "eutrophic" conditions compared to the offshore properties.

Keywords: Eutrophication, Mersin Bay, North-Eastern Mediterranean, Nutrients

Introduction:
Land-based inputs (river + domestic waste discharges) have enhanced eutrophication in the NE Mediterranean coastal waters [1]. In the present study, the spatial and temporal variability of eutrophication related indicators (DIN, TP, Chl-*a*, DO%, SDD) were studies to assess trophic levels of Mersin Bay surface waters polluted by the major rivers (Seyhan, Ceyhan, Berdan) and discharges of domestic wastewaters from the Mersin city. Different classification methods were applied to determine the tropic status of the water bodies in the bay [2,3].

Materials and Methods:
Data were collected seasonally by R/V-Bilim-2 at 50 stations (Fig. 1) between September 2008 and February 2011 (funded by TUBITAK Grant #: 107G066). Nutrients and DO were measured on board by a multichannel autoanalyzer and the Winkler titration method. TP and Chl-a samples were kept under deep freeze until their analysis in the laboratory.

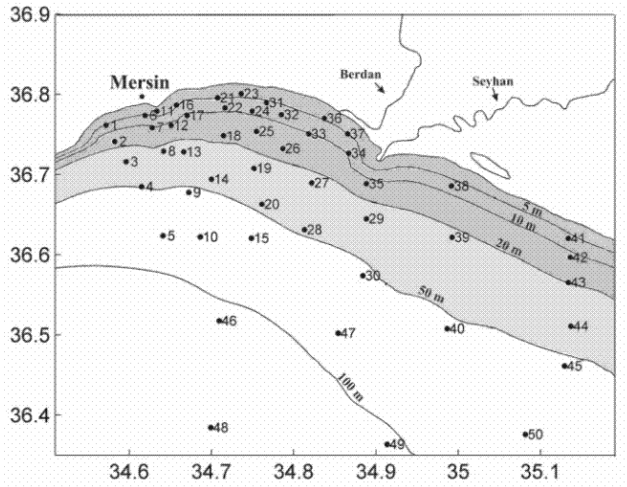

Fig. 1. Locations of sampling stations visited in the Mersin Bay shelf zone

Results and Discussion:
The surface water concentrations of TP, DIN and Chl-*a* in the bay increased 5-10 times from the oligotrophic offshore (Average TP: 0.1 µM; DIN: 0.36 µM, Chl-*a*: 0.09 µg/L, SDD:15 m) to the eutrophic nearshore waters (<20 m) (Table 1), which were very consistent with similar changes in primary productivity and algae abundance. The classifications methods of Cluster Analysis, TRIX and UNTRIX consistently show that the inner bay was occupied by eutrophic water body (boundary ~ 20 m depth counter), where the outer bay (>40m deep) waters exhibited oligotrophic properties. The water body in between was classified as "mesotrophic" (Fig. 1). Comparison of the results of original TRIX, UNTRIX and modified TRIX (TRIX-IMS having modified "a" and "b" coefficients) showed that the TRIX underestimates the impacts of excessive nutrient loads on the oligotrophic water bodies. The inner bay with an annual average TRIX value of ~4.5 remains at "mesotrophic" level. Therefore, the modified TRIX (TRIX-IMS) and UNTRIX approaches explicitly categorized the inner bay water body as "eutrophic" compared to the "oligotrophic" waters of the outer bay.

Tab. 1. Annual averages of eutrophication related parameters determined by different classification methods in the 3 different water bodies of the Mersin Bay.

		Cluster Analysis	TRIX	TRIX-IMS	UNTRIX
TP (µM)	E	0.45		0.41	0.37
	M	0.20	0.45	0.18	0.17

ESTIMATION OF THE SOURCES OF PCDD/F POLLUTION IN THE SEDIMENTS OF IZMIT BAY

Aykan Karademir [1]* and Halim A. Ergul [2]
[1] Department of Envronmental Engineering Kocaeli University - aykan@kocaeli.edu.tr
[2] Department of Biology, Kocaeli University

Abstract
The study presents an evaluation of the possible sources of PCDD/F pollution in the surface sediments of the Izmit Bay (Turkey) based on a mass balance model for PCDD/F congeners. The model was applied for the estimation of the effect of atmospheric deposition, soil erosion and wastewater discharges on the PCDD/F levels in the sediments. The model results suggested that OCDD levels in the sediment samples could be explained mainly by the effect of atmospheric deposition processes. The differences between the modeled and observed levels of highly-chlorinated PCDFs indicated that the industrial discharges in the past could be a significant contributor to the PCDD/F pollution in the sediments.

Keywords: Sediments, Marmara Sea, Models

Introduction: Izmit Bay (Fig.1), has been subjected to substantial pollution problems since 1960s. The bay has been receiving wastewaters of more than 400 industries in different sectors including the largest petroleum refinery of Turkey, several metallurgical and chemical plants, automotive and tyre factories etc., together with the untreated or inadequately treated domestic wastewaters from 2 million inhabitants living around the bay. Karademir et al. [1] gives an assessment of the PCDD/F levels in the surface sediments of Izmit Bay. The study presents a modeling approach applied to estimate the impact of atmospheric deposition and surface runoff on the PCDD/F levels of surface sediments in the Izmit Bay. The main object of the modeling study is to assess the role of industrial wastewaters in the PCDD/F pollution in the bay, which is unknown due to the lack of data related to discharges in the past.

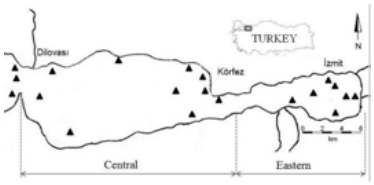

Fig. 1. The study area

Modeling Approach: For modeling, the algorithms and assumptions given in USEPA [2] were used. The principal assumption is that PCDD/F inputs to the bay result from (a) atmospheric deposition, (b) erosion of soil from watershed area of the bay by surface run-off, (c) municipal wastewater discharges, and (d) industrial wastes; while PCDD/F output from the bay takes place through the outflows to the Marmara Sea. The mass balance statement: [Net mass of contaminant entering the water body] = [An amount which remains sorbed to suspended materials] + [An amount which remains as dissolved in the water column] + [An amount which remains sorbed to particles settling to the bottom]. Atmospheric PCDD/F concentrations and deposition rates (DR_a) in Kocaeli were taken from Bakoglu et al. [3]. Total surface area of the bay (W_{aw}) was considered as 310 km^2. Wastewater inflow was computed as 240 000 m^3 per day, while the PCDD/F concentrations (C_{ww}) of wastewater were taken from Yee et al. [4]. Due to the lack of data related to the industrial inputs of PCDD/Fs, M_{ind} was not included in computations. Computations were performed for PCDD/F concentrations in bottom sediments and the model results were compared to the observed levels.

Results: Fig. 2 shows modeled and observed PCDD/F concentrations in the sediments of Izmit Bay. It shows that there is a good agreement between estimated and measured PCDD/F concentrations except for three highly-chlorinated furans: 1,2,3,4,7,8-HxCDF, 1,2,3,4,6,7,8-HpCDF and OCDF. The model explains nearly all the OCDD presence in the sediments, suggesting that OCDD levels are related to atmospheric deposition (97%), erosion of contaminated soils (2%) and municipal wastewater discharge (1%). On the other hand, the high differences between observed and modeled concentrations of 1,2,3,4,7,8-HxCDF, 1,2,3,4,6,7,8-HpCDF and OCDF are obvious (observed values are 10-20 times higher than the modeled ones), which may be attributed to the industrial discharges not included in the model. On the contrary, model overestimates the level of 1,2,3,4,6,7,8-HpCDD, which was measured in substantial levels both in the air and the soil samples collected in the area [3]. The dominance of OCDF in some sediment samples taken from the central section was related to the production of VCM in the past, while that of 1,2,3,4,6,7,8-HpCDF was attributed to the unknown use of a chlorophenol-based fungicide in the region. Additionally, the sediments with a congener profile characterized by the dominance of OCDD were explained by the effect of pentachlorophenol releases and their subsequent transfer to the sediments as the final sinks, through different processes took place after the deposition of airborne PCDD/Fs to water and soil surfaces. The results show that the atmospheric deposition is the main contributor of the PCDD/F pollution in the bay, with an average contribution about 98% both in total concentration of toxic PCDD/Fs and in WHO-TEQ basis, while the rest is related mainly to the erosion of contaminated soils. The contribution of municipal wastewaters is estimated as very low (lower than 1%). Total PCDD/F inputs by atmospheric deposition, soil erosion and municipal wastewater discharges are computed as 3.88 g WHO-TEQ per year, 0.05 g WHO-TEQ per year, and 0.005 g WHO-TEQ per year, respectively.

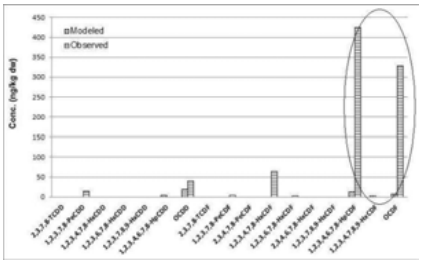

Fig. 2. Modeled and observed PCDD/F concentrations

LEVELS AND DISTRIBUTION OF CHLORINATED PESTICIDES AND PCBS IN WILD MUSSELS COLLECTED ALONG THE ADRIATIC COAST OF CROATIA

Vesna Milun [1]*
[1] Institute of Oceanography and Fisheries - milun@izor.hr

Abstract
Levels and distribution of chlorinated pesticides and PCBs were investigated in wild mussels *Mytilus galloprovincialis* collected from the Adriatic coast of Croatia in 2003 and 2011. The accumulation pattern of organic contaminants in mussels was characterized by much higher PCBs levels in relation to chlorinated pesticides. Moreover, the most contaminated mussels were collected from the areas where industrial, harbour and urban wastewaters have been released.

Keywords: Bivalves, Bio-accumulation, Monitoring, Pcb, Central Adriatic Sea

Introduction
Mussels have been successfully used for decades as indicators of chemical contamination in coastal areas [1]. As filter feeders, mussels bioaccumulate contaminants through their food revealing essentially the fraction that is available in the environment. This study presents the results of monitoring levels and distribution of PCBs and chlorinated pesticides in the Croatian coastal area using *M. galloprovincialis* as indicator species in 2003 and 2011. The data was expected to indicate temporal differences in organic contamination level.

Materials and Methods
Wild mussels were collected at 12 sites in the pre-spawning period (during March) from the coast in 2003 and 2011 (Fig. 1). Freeze-dried samples were Soxhlet extracted, cleaned-up and passed through a florisil column for OCs separation. Concentrated fractions were analyzed for CPs (HCB, lindane, aldrin, dieldrin), DDTs (p,p'-DDE, -DDD,-DDT) and PCBs (IUPAC No. 28, 52, 101, 118, 138, 153, 180) by Agilent GC-μECD using HP 5 capillary column. Internal standards and reference material IAEA-432 were used to assure data quality.

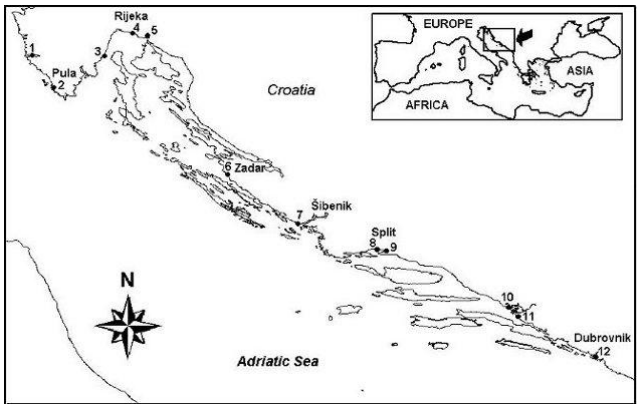

Fig. 1. Study area with sampling locations.

Results and Discussion
The accumulation pattern of OCs in mussel tissue indicated a decreasing concentration trend in the order of PCBs>DDTs>CPs at all locations both in 2003 and 2011 (Fig. 2). PCBs values varied spatially in range of 6.1-99 ng g^{-1} dw (2003) and 4.6-75 ng g^{-1} dw (2011). Elevated concentrations were found in areas with high discharge of wastewaters from on shore local sources. Mussels revealed spatially and temporally similar PCB congener accumulation profile (PCB 153>138>101>118>52>28) with predominant PCB 153 and PCB 138 contribution. The content of DDTs varied in the range of 4.8-18.8 ng g^{-1} dw (2003) and 2.0-11.2 ng g^{-1} dw (2011). The accumulation profile of DDTs indicated a decreasing concentration trend in order of DDE>DDD>DDT. High percentage of more stable and accumulative DDE metabolite reflected a decreased use of DDTs in the study area. The low levels of CPs (HCB, lindan, aldrin, dieldrin) with 52% data below DL reflected low exposure to these compounds, probably as result of their prohibition in the Mediterranean region.

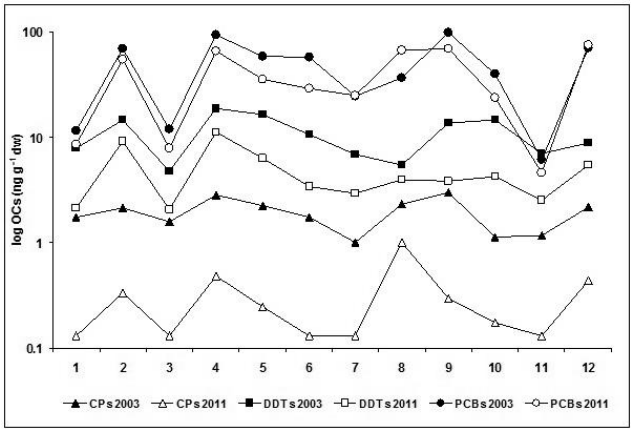

Fig. 2. Levels and spatial distribution of organochlorine compounds.

Statistical comparison of OCs concentrations found in mussels in 2003 and 2011 showed significant difference for lindane and DDTs but no difference for PCBs. Furthermore, anthropogenically impacted sites were separated by PCA factor scores analysis from sites away from known source of pollution. Due to the low statistical correlation between environmental (temperature, salinity) and biological (condition index, lipids) parameters and contaminants level, OCs differences found in mussels were primarily influenced by local pollution sources. However, values obtained for the eastern Adriatic coast are within the range (or even lower) of values published for the Mediterranean coast [2]. Evaluation of the potential risks to human health associated with consumption of analysed mussels indicated that measured OCs concentrations are less likely to pose a significant health risk (RQ<1) for shellfish consumers in Croatia [3].

Abstract
The copper pollution in the marine environment is determined by measuring its concentration in sediment and mussel. This study performed between May 2008 and August 2009 in the *Mytilus galloprovincialis* and sediment from Foça (Aegean Sea).The coasts of Foça remain heavily impacted by a number of pollutants originating from different sources such as shipping activity, tourism activities, municipal wastewaters, population growth and unplanned urbanization,sewage etc. The Cu levels in the sediment and mussel samples are not higher in the coast of Foça (Aegean Sea). On the other hand, the Cu concentration in mussel and sediment will be significantly higher in the present results than other coast. The construction of the new port and the increase in tourism activities will consist of coastal pollution.

Keywords: Bio-indicators, Mollusca, Metals, Sediments, Aegean Sea

Introduction
From an environmental point of view, the coastal zone can be considered as the geographic space of interaction between terrestrial and marine ecosystems that is of great importance for the survival of a large variety of plants, animals and marine species (1). The pollution of the marine ecosystem by heavy metals is a world-wide problem. Heavy metals can be classified as potentially toxic (cadmium, lead, mercury, etc.), probably essential (nickel, vanadium, cobalt) and essential (iron, manganese, copper, zinc). The essential metals can also produce toxic effects when the metal intake is excessively elevated (2). Bivalves, a marine organism, have been used as a kind of metal concentration ''detector'', as metal concentrations found in their soft tissue are known to reflect the concentrations of the same metals in the aquatic these mussels could be exposed to sub-lethal or even lethal levels of specific toxins (3).

Materials and Methods
The copper pollution in the marine environment is determined by measuring its concentration in sediment and mussel. The common Mediterranean mussels *Mytilus galloprovincialis* were collected from the coasts of Foça (Aegean Sea) from May 2008 and August 2009. Immediately after collection, the samples put into an ice compartment and transported to the laboratory, and then the samples were frozen at −21ºC for metal analysis. Before dissection, the mussel samples were thawed at room temperature (27ºC) with the posterior margin facing downwards in order to allow excess water to drain away. The total soft tissues were dried in an oven at 105ºC to constant dry weight. The surface sediment samples were taken by using a Van Veen type grab from the Foça coast stations (6 stations), respectively. The collected sediment samples were homogenized and stored in plastic cups that were cleaned by 1:1 HCl and 1:1 HNO_3 before analysis. About 100 g of sediment samples were dried at 85 ºC for 48 h, crushed and homogenized prior to the analysis. The mussel samples (0.5 g) were digested with 7 ml of HNO_3, (65%), 2 ml of H_2O_2 (30%) and the sediment samples (0.5 g) were digested with 2 ml of HNO_3 (65%), 6 ml HCl (37%) in a microwave digestion system (CEM Corporation, MARS-5) for 30 min and diluted to 25 ml with deionized water and stored in polyethylene bottles until analysis. A blank digest was performed in the same way. The prepared samples were determined for Cu by ICP-OES. The accuracy of the analysis was verified by analyzing the Europeancertified reference material (ERM-C278, mussel tissue), by the same procedure used for the samples.Certified Referrence Materials NCS DC 74301 (marine sediment) was used for calibration. The results showed good agreement between certified and analytical values. Values are expressed as the mean of three analyses for each sample (2,3,4).

Results
A comparison of the metal concentrations for the investigated elements in mussels and sediments at the Foça costal area for sediment and mussels different locations and and six seasons (May 2008 to August 2009) showed differences clearly associated with anthropogenic impact. Cu concentration changed between 0.009-0.112 mg/kg d.w mussel, respectively. The concentrations of the copper ranged from 0.008 to 0.394 (mg/kg dw) in sediment.

Observed seasonal changes due to the increase in population.mussel directly was affected such as rainfall, wind factors. Mussels have been effective uptake of the copper of sexual maturity.

Conclusion
Copper levels in the sediment and mussel samples are not higher in the coast of Foça (Aegean Sea). On the other hand, the Cu concentration in mussel and sediment will be significantly higher in the present results than other coast. the construction of the new port and the increase in tourism activities will consist of coastal pollution.

Abstract
In Psittalia –Keratsini strait the outfall sewer of Athens discharged untreated sewage for a period of over 40 years. As a result a surface layer of organic mud has been formed covering the seafloor. Copper, Zn, Mo, Ag, Cd, Pb, Cr, As, Ni, Fe and Co are highly enriched in the organic mud layer compared to underlying natural sediments.

Keywords: Sewage pollution, Metals, Sediments, Gulf of Saronikos

Introduction
North Saronikos gulf receiving sewage from the industrial area of Elefsina and Piraeus port is a heavily polluted marine environment. In particular, the area between the island of Psittalia and Keratsini, was receiving the urban and a large part of the industrial waste of the city of Athens through the main sewer (MSA) in Keratsini for many decades. In 1994, a biological treatment plant was installed in Psittalia Island [1]. Until then, the sewage through MSA was flowing without any treatment, directly to the sea through a diversion channel from the Keratsini outlet works. In 2001 an integrated marine remote sensing survey revealed the presence of a surface layer of organic mud covering the natural seabed [2]. The present paper presents the geochemical data from the area aiming to the evaluation of the spatial and temporal distribution of metal contaminants in the seabed. The dataset includes the results of analysis of grain composition, organic carbon content (Corg) and metal concentrations from six sediment cores selected from the area (Fig. 1).

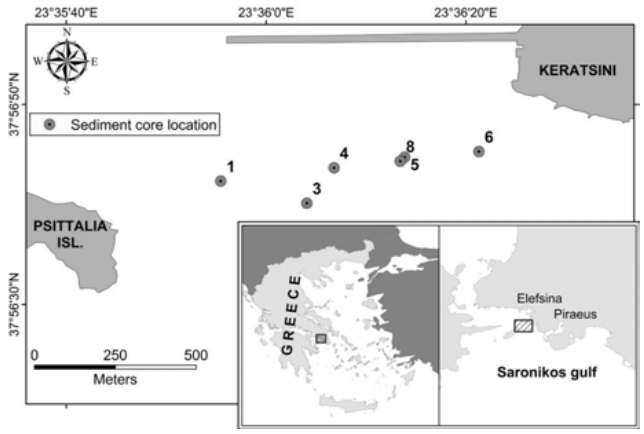

Fig. 1. Map showing the sediment cores locations in Psittalia - Keratsini Strait.

Material and Methods
The collected sediment cores were transferred to the laboratory and stored vertically at 4°C. Prior to analyses, the cores were gently cut longitudinally using a Plexiglas sheet. The sediment of the uppermost 2 cm of all cores together with sediment samples of about 2 cm in thickness taken along the sediment core, were used for the elemental analyses. A quantity of each sediment sample was digested using a mixture of acids (HNO_3, $HClO_4$, HF, HCl) (conventional method - open system) for elemental total concentration measurements by ICP-MS [3]. Grain size analysis was carried out by dry and wet (pipette method) sieving methods.

Results and Discussion
The organic mud surface layer which is associated with the untreated sewage discharges has a thickness ranging from 0.6 to 2.0m. Macroscopic and granulometric study of the sediment cores showed that the thickness of the organic mud layer decreases with increasing distance from the sewage outfall. In all the examined sediments the surface layer consists of high percentages of Corg and silt/clay size particles (Table 1). On the contrary, the underlying natural sediments are characterized by increased percentages of sandy particles and low organic carbon content (Table 1). The mean metal concentrations in the organic mud layer are among the higher reported in marine sediments collected from other harbours, gulfs and coastal areas in Greece and Mediterranean Sea [3, and references within]. Enrichment factors obtained from the results follow the order: Cu>Zn>Mo>Ag>Cd>Pb>Cr>As>Ni>Fe>Co>Mn. Metal concentrations are positively correlated with the fine fractions of organic mud and their spatial distribution presents a clear decreasing trend with increasing distance from the sewage outfall. The natural seabed sediments just beneath the organic mud appear to be affected by the metalliferous organic mud. These elevated metal concentrations are probably attributed to the effect of fine-grained organic mud soaking on the underlying coarse-grained natural sediments. Moreover, the metal concentrations present a general downcore decreasing trend. This probably reflects the gradual growth of urban population and thus the increase of urban and industrial pollution in Athens metropolitan area and accordingly in the seabed of north Saronikos gulf.

Tab. 1. Gravel, sand, silt, clay, organic carbon (%) and metal concentration (ppm) in organic mud and natural sediments in the study area.

	Organic mud	Natural sediments		Organic mud	Natural sediments
	Mean	Mean		Mean	Mean
Gravel	4.6	7.7	**Co**	19.0	8.8
Sand	22.6	54.4	**Mn**	178.6	76.2
Silt	56.4	25.8	**Ni**	85.0	14.5
Clay	16.4	12.1	**As**	63. 4	21. 7
Corg	5.70	0.93	**Ag**	12.0	0.4

Abstract

On the night of 13 January 2012, the cruise ship "Costa Concordia", collided with a submerged rock close to the Giglio island harbour (Tuscany, Italy) causing 32 victims and a potential environmental disaster, the extent of which is still to be evaluated. After the emergency on the research and passengers safety, a monitoring plan to assess the environmental status in the environment affected by the wreck has been implemented. As part of a more complex and articulated monitoring plan, the preliminary results obtained from the analyses of sediments and biota (*Mytilus galloprovincialis*) are described.

Keywords: Chemical analysis, Bio-indicators, Monitoring, Pollution, Tyrrhenian Sea

Introduction

Immediately after the Costa Concordia wreck, a plan to avoid a more severe environmental impact and to monitor the impact of substances spilled from the boat, has been activated. First of all, the ship tanks were emptied for preventing fuel spill at sea. The Department of the Italian Civil Protection commissioned to ISPRA (National Institute for the Environmental Protection and Research) and ARPAT (Regional Agency for the Tuscan Environmental Protection) the development of a multidisciplinary monitoring plan, in accordance with current legislation [1,2,3]. According to this plan, an integrated approach was followed, examining chemical, biological and ecotoxicological parameters. Among planned activities, chemicals released from the boat have been monitored through active mussel watch methodology and sediment analysis. Concentrations of PAHs, aliphatic hydrocarbons, PCBs and halogenated pesticides, organotin compounds were measured in mussel tissues and sediments. These data were further complemented with ecotoxicological responses measured as both biomarkers and toxicity bioassays.

Results and discussion

Sediment The analyses on sediments sampled during the two campaigns (February and October 2012) showed low levels of contamination from organics xenobiotics (organotins under limit of quantification; low concentration of aliphatic hydrocarbons, PAHs and some PCB congeners; pesticides mostly absent except for traces of DDT and its metabolites). Levels of organic compounds were under the values fixed as EQS [2] and in accordance with literature data [4,5]. Metals (As, Cd, Cr, Cu, Hg, Ni Pb) concentrations were found below the EQS, except for lead measured in two sites of the second sampling campaign; however, concentration are in accordance with monitoring data for the region [5]. Biological responses (biomarkers) were measured on the polychaete *Hediste diversicolor* exposed to sediment collected on April 2012 in proximity of the ship. Results did not evidence any relevant toxicity and organisms maintained a "good physiological condition": beside the high survival rate (> 80%), no effects were detected in terms of oxidative stress biomarkers, damages to structural integrity of DNA, or specific responses to metals, organophosphorus and carbamates pesticides).

Mussel watch Water column contamination has been assessed through an active mussel watch approach with translocated *Mytilus galloprovincialis* as organism bioindicator of the bioavailable contaminant fraction. This strategy has been successfully applied in national monitoring plans to assess level of chemical contamination of marine coastal water [6]. Six cages containing mussels were placed in each of the three sites at two different depths, approximately 2 m from the surface and 1m from the bottom; one site was selected far from contamination source as blank, one in proximity of the poop and one between the prow of the wreck and the harbor. After a period of 4-6 weeks, mussels have been recovered and replaced, for a total of 8 translocation experiments carried out between February and December 2012. Results from the first four campaigns, showed low concentrations of organotins compounds, organics xenobiotics (PCBs, pesticides, PAHs and aliphatic hydrocarbons) and metals in tissues of translocated mussels. Bioaccumulation levels were almost comparable to those found in the reference area. Slightly higher values have been seldom found in mussels near the harbor.

Conclusion

Preliminary results did not highlight particularly critical conditions in terms of chemical and toxicological disturbance due to the shipwreck. Further investigations are still in progress and will continue during 2013 for a better and comprehensive evaluation, which will also consider the possible impact caused by the activities related to the wreck removal. This work, as well as the ISPRA monitoring Plan was financially supported by the Civil Protection Department.

FINGERPRINTING STUDY OF AN OIL SPILL CASE ALONG THE SARDINIAN COAST (MEDITERRANEAN SEA)

G. Romanelli [1]*, M. Matiddi [1], M. Amici [1], S. Di Muccio [1], P. Giordano [1], M. Mannozzi [1], R. Parravano [1], V. Perini [1] and L. Alcaro [1]

Abstract

A contamination coastal survey was conducted to assess the environmental impact of oil spillages from a submerged pipeline of the E.on power plant of Porto Torres (North west Sardinia) during the draining operation of the France tanker M/C Emerald.Samples taken from different coastal areas and offshore stations were analyzed on GC/FID and GC/MSD for aliphatic and polycyclic aromatic hydrocarbons, terpanes and steranes (fingerprinting). Results were compared with profiles of the spilled oil (IFO 380), of which it was estimated that a total of approximately 50 tons was lost at sea. The comparison of the oil fingerprint revealed a different type of oil beached in close proximity to the power plant and confirmed the same source of oil beached in an area far from the spill point.

Keywords: Chemical analysis, Coastal systems, Petroleum, Pollution, Tyrrhenian Sea

Introduction

In January 2012 the tanker "M/C Emerald" was transferring fuel through a submerged pipeline to the electric power plant in the mainland at Porto Torres, North-West Sardinian coast. Few hours later, a petroleum slick was seen at sea off the harbor, and along the nearest coast. The event was caused by the weld's breakage of a pipeline in the submerged side along thebreakwater,during the draining activity from the tanker to the Power plant. In the following days, the marine current and winds brought the product along the east coast with a patchy distribution, at different areas. Weathering factors affecting petroleum and the occurrence of previous spills on involved coasts, mixed with chronic anthropogenic sources of oil at sea, makes very difficult to identify the origin of contamination. Fingerprinting analysis has been conducted to verify the source of the pollution, in this specific case.

Materials and methods

Samples were taken from the pipeline inside the Power plant, from the tanker and from several beaches involved from the pollution event. Oil samples were analyzed applying the CEN methodology. According to this methodology, the identification of an oil spill has to be proved, by fingerprinting analysis of some "diagnostic" substances (biomarker, PAHs, alkanes, etc.) in the samples to be compared. At this purpose, the two samples to be compared are first analyzed by GC chromatography with FID detector and results are critically evaluated. In fact, if the chromatographic pattern shows differences that cannot be explained by chemical weathering, then the samples cannot have the same origin. On the contrary, if the two chromatograms obtained by GC FID are similar or differences can be explained by weathering, further analysis by GC MSD need to be performed. The GC/MSD analysis allows to compare the chemical composition by fingerprinting of a selected "diagnostic" set of compounds indicative of type and origin of the oil. If there are not significant differences between the diagnostic compounds of the two samples compared, then the conclusion is that the two samples have the same origin (Positive Match). If there are few differences that can be explained by weathering, it can be assumed that the two samples have probably the same origin (Probable Match). If the differences are more evident and cannot be explained by chemical weathering, then the conclusion is that the two samples have different origin (Non-Match).

Results

In this case, the source causing the pollution event was corresponding to the point of the rupture of the pipeline. Oil samples to be compared were taken along the shoreline east and west of Porto Torres, where according to the forecasting models the product would have been beached. In the first campaign conducted in February 2011 five sites were selected for sampling: the beach of Stintino "la Pelosa", the beaches of Santa Teresa di Gallura "Santa Reparata" and "Santa Teresa", the beaches of Marina di Sorso "Eden beach" and "Marritza". Samples treated were first analyzed by GC/FID. The sample from "la Pelosa" showed chromatographic differences so clear that was excluded by further analysis. For the other samples the GC/FID results showed that further analysis on GC/MSD were necessary. Conclusion based on the fingerprinting analysis of these samples showed that the sample from "Santa Reparata" and that from the pipeline have the same origin. For the other three samples results suggest that one ("Eden" beach) is clearly different, whereas "S. Teresa" and "Marritza" are probably derived from the suspected source. The analytical approach has been supported by field observations on the features and appearance of the petroleum product found on the coast line inspected. Fingerprinting analysis showed to be a necessary technique to the identification of oil spill source, also in this case.

THE USE OF MULTIVARIATE AND GEOSTATISTICAL ANALYSES FOR THE EVALUATION OF QUALITY OF COASTAL MARINE ENVIRONMENT

Fani Sakellariadou [1]*
[1] University of Piraeus, Dept of Maritime Studies - fsakelar@unipi.gr

Abstract
Marine sediments from the Elefsis bay (West Attica, Greece) were analyzed for the determination of metal content. Results were treated with multivariate statistical analyses, such as cluster analysis and principal component analysis to facilitate data interpretation. It was found that metal groups are associated mainly with industrial activities and to a lesser extent with local geological features. Inter-element correlation coefficients were produced, indicating a common metal origin at the inner part of the bay. Also, the spatial distribution of sediment contaminants was constructed applying the Simple Kriging interpolation method. Spatial distribution patterns showed the significant influence of anthropogenic pollutant sources.

Keywords: Coastal systems, Metals, Pollution, Sediments, Saronikos Bay

Introduction Environmental status is influenced by man-made and natural disturbances. As seabed sediments are physical traps for many environment pollutants [1, 2], the evaluation of sediment quality gives significant information related to the consequences of the contamination of marine systems. As chemical analysis of sediment samples provides a large data set, multivariate statistics are considered as powerful tools making easier the interpretation task. Hierarchical cluster analysis forms dendograms that provide a relative percentage measure of the magnitude of difference between clusters. The PCA technique enables data reduction and description of a given multidimensional system by means of a smaller number of new variables. It is used to detect sample patterns, groupings, similarities or differences, to identify metal sources and to distinguish between natural and anthropogenic inputs. Furthermore, the production of inter-element correlation coefficients gives useful information on metal similarities and sources. In addition, the construction of spatial distribution patterns for sediment contaminants shows the pollution trend. The generation of pollution dispersion surface needs the application of a data interpolation method, like the Simple Kriging approach that predicts unknown values from data observed at known locations using variograms [3, 4].

Material and Methods Thirteen sediment samples were collected from various sites of the Elefsis bay (Fig.1), located in west Attica, in Greece. The bay is connected to the Saronikos gulf via two natural channels. Elefsis is characterised by the presence of important heavy industries at the north-eastern coastline and the use of its ports for transportation of raw material and goods.

Fig. 1. Elefsis bay with sampling sites.

Samples were digested with a mixture of concentrated HNO_3, $HClO_4$ and HF in screw capped Teflon beakers, on a hot plate [5]. Metal contents were measured by AAS; the relative standard deviation of the measurements was <5%. Data set was treated with cluster analysis, principal component analysis and the Simple Kriging geostatistical method. Inter-element correlation coefficients were produced.

Results A metal enrichment occurs at the inner part of the Elefsis Bay while lower metal values correspond to its western edge. The dendogram resulted from the metal cluster analysis gives the (Mn, Ni, Cr, Cu, Pb, Zn) and (Fe, Al) groups. Principal component analysis (Fig. 2) shows that sediments collected close to the industrial activities have high positive scores for (Cu, Zn, Pb) and (Al, Mn, Sn). Inter-element correlation coefficients correspond to values greater than 0.65 for the pairs (Mn, Al) and (Sn, Mn), greater than 0.75 for the pairs (Pb, Mn) and (Cu, Pb) and greater than 0.85 for the pairs (Cu, Zn) and (Zn, Pb). All anthropogenic metals correspond to higher correlation coefficients for the sediments collected from the inner part of the bay. Spatial patterns of sediment contaminants show enrichment in anthropogenic metals close to industrial activities while areas of lower pollutant content occur at the western edge of the bay.

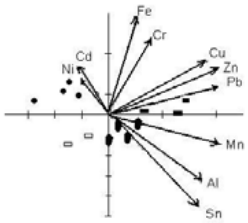

Fig. 2. PCA analysis: sediment samples and relative metal contents.

Discussion Metal clusters correspond mainly to man-made (industrial) activities and to a lesser extent to the local geology characterised by the presence of feldspars, clays and ophiolites. The lower metal content at the western edge is attributed to the drop in anthropogenic pollution sources, the presence of strong subsea currents, the calcareous type of the seabed and the grain size (coarse) of the material covering it. Correlation coefficient values at the inner part of the bay indicate a common metal origin.

Conclusion Industrial activities have strongly influenced the sediment contamination at the Elefsis bay. It is concluded that Elefsis bay seabed acts as physical metal trap and secondary pollution source.

Abstract
Concentrations of Cd, Co, Cu, Fe, Ni, Pb and Zn were determined in the marine algae. Certain macroalgae species were chosen among the green, brown and red algae species at 7 stations in the Turkish coasts of the Black Sea, Marmara Sea and Mediterranean Sea in 2009. The concentrations of the heavy metals Fe, Zn and Cu in the present study are higher, but Ni and Co are lower when compared with previous studies in the same region. Also, The highest Fe accumulation was determined in red algae *Ceramium rubrum* (Black Sea) and *Corallina officinalis* (Mediterranean Sea).

Keywords: Algae, Trace elements, Black Sea, Aegean Sea, Marmara Sea

INTRODUCTION
The Black Sea, Marmara Sea and Mediterranean Sea have been subject to very high levels of pollution due to industrial activity, municipal waste waters, agricultural chemicals, oil pollution and airborne particles(1,2). Marine algae species are usually used to indicate heavy metal levels in both estuary and coastal waters throughout the world (3). The macroalgae species are usually used to indicate heavy metal levels in both estuarine and coastal waters throughout the world. In benthic food webs, macroalgae are key links and they act as time-integrators of pollutants (3). Some papers have been published concerning heavy metal concentrations measured in macroalgae species collected from Turkish Seas (1,2,4,5,6). The objectives of this paper are to examine the concentration selected heavy metals in marine algae at different stations of Turkey coasts in the year of 2009.

MATERIALS AND METHODS
To determine the concentration of Cd, Co, Cu, Fe, Ni, Pb and Zn in the marine algae, samples were collected from 7 different stations of the Black Sea, Marmara Sea and Mediterranean Sea during the year of 2009. The marine algae species were in Black Sea; Enteromorpha intestinalis, Enteromorpha linza, Ulva lactuca (green algae) Corallina officinalis, Ceramium rubrum (red algae), Cystoseira barbata (brown algae) in Marmara Sea; U. lactuca, C.officinalis, C.barbata and in Mediterranean Sea; Corallina elongata (red algae). About 500 g of the fresh weight were harvested at low tide. The samples were rinsed to remove sand and epiphytal materials in the sea water and then with top water and distilled water. They then were dried at 85 oC and homogenized. All procedure of the method was similar to that previously described (1). The concentration of the heavy metals were determined by ICP-MS. Certified Reference Material BCR-279 sea lactuca (Ulva lactuca, powder) was used for calibration. The results showed good agreement between certified and analytical values (recovery rates 90-110 %).

Fig. 1. Average heavy metal concentrations (mg kg^{-1} dry weight) in marine algae samples of all sampling stations in Black Sea, Marmara Sea and Mediterranean Sea

RESULTS
The heavy metal concentrations in marine algae are shown in Table 1. Accumulation levels of heavy metals in marine algae have been detected in the order Fe> Cu> Zn> Ni > Co at all stations respectively. The highest uptake in marine algae species at the sampling sites were as follows: Fe and Co in C. rubrum and C. officinalis, Cu in U. lactuca and C. elongata, Zn in U. lactuca and C. officinalis, Ni in E. linza and C. officinalis. The heavy metals accumulated in different algal taxa were: in green algae Cu, Zn and Ni; in red algae Fe and Co. The Cd and Pb concentrations in tested marine algae samples were found to be below the lower limit detection (<0.01). Heavy metal levels of C. rubrum and C. officinalis were significantly higher than those in other marine algae species.

Abstract
This study aims to assess the inputs of chemical contaminants to the coastal environment from direct urban discharges of Marseille area. The measurements allow to rank the various sources (sewage network, urban watercourses,...) both in concentrations and fluxes and to compare to similar values available for big rivers like the Rhône.

Keywords: Monitoring, Trace elements, Sewage pollution, Pcb, North-Western Mediterranean

Marine pollution is one of the priority issues of the Mediterranean environment. The Mediterranean Action Plan has shown that few large cities were responsible for a major fraction of the inputs from urban areas and should be considered as hot spots. Pollutant inputs to the sea come form different sources; besides sewage treatment plants and industrial effluents, it is important to consider intermittent flows from rivers and diffuse runoff from the coastal urban areas.

The present study aims to assess the inputs of chemical contaminants to the coastal and marine environments derived from direct urban discharges (sewage network, urban watercourses) of Marseille area (France). The contaminants of interest are metallic (Cd, Pb, Hg) and organics (PAHs, PCBs, PBDEs), distinguishing the dissolved and the particulate fractions. The method for the fluxes determination is based on (i) the determination of contaminant concentrations by collecting water samples in Marseille study area, and (ii) the hydrological (water discharge) data provided by the territorial managers. The collection of water and particles samples started in 2009 and finished in 2011 under various weather conditions (dry/rain periods) and different sampling sites : outfall of water plant, coastal rivers, torrents (rain period), overflow (storm). Data were compared to those available for rivers [1,2,3].

The results show that urban water displays relatively high concentrations for metallic contaminants, both for the dissolved fraction (Hg: 0.04-62.35 ng.L^{-1}) and the particulate fraction (Hg: 4-6235 ng.g^{-1}). These concentrations are 10 to 20 times higher than the concentrations measured in the Rhône river. For organic contaminants, concentrations are particularly high for PAH (eg fluoranthène : 0.21 – 156 ng.L^{-1} dissolved fraction, 4.2 –2256 ng.g^{-1} particulates fraction) and PBDE (0.01- 21 ng/L dissolved fraction, 1.4 – 674 ng/g^{-1} particulate fraction). These concentrations are 50 to100 times higher than measured values in the Rhône river (fig 1).

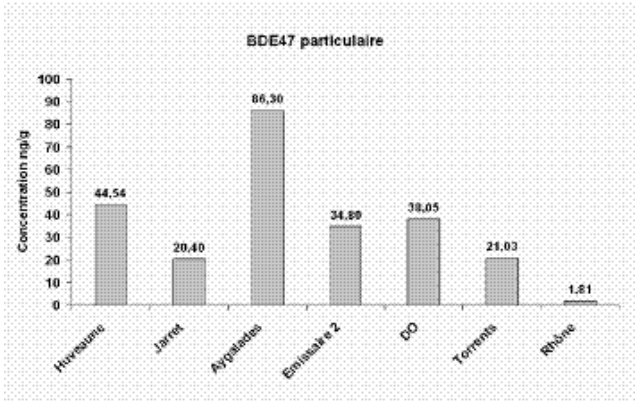

Fig. 1. Figure 1 : Mean concentrations of PBDE particulate fraction. Coastal river (Huveaune , Jarret, Aygalades) – waste water treatment plant (emissaire2), overflow (DO).

Results show that concentrations of pollutants are greater in coastal rivers (Hg and PCBs) and overflow (Pb, PBDE and PAH). By dry weather, variability of concentrations is generally strong. By rain period, concentrations are constant with lower values (dilution by run off water).

The estimation of fluxes shows that the first contributor is the waste water treatment plant of the city (due to the amount of water discharge) by dry or rain period. The second contributor are the coastal rivers. The small coastal rivers are not relevant, neither the sewer outflows. Estimated fluxes for Hg and Pb are 100 to 1000 times lower than in the Rhône river. For PAH, the fluxes are 10 000 times lower. Finally for PCBs and PBDE, the values are 100 to 5000 times and 300 to 10000 times higher in the Rhone and in the Saint Laurent rivers than in this study (fig 2).

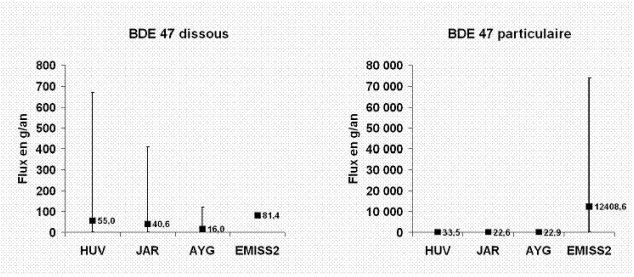

Fig. 2. Figure 2 : BDE 47 fluxes in coastal rivers(HUV, JAR, AYG) and waste water treatment plant (EMISS2). Mean (¦), maximum and minimum values (I).

To optimise the estimation of the polluting flows, a better understanding of factors influencing the variability of the concentrations, longer sampled periods and larger number of sampled floods are necessary. The fate of dissolved and chemicals from the coastal area to the open sea can be further assessed using dedicated numerical models.

PRELIMINARY STUDIES ON THE EFFECTS OF HEAT PUMP DISCHARGES ON SHALLOW BENTHIC LITTORAL COMMUNITIES IN MONACO

Abstract
Among renewable energies, seawater heat pumps (HP) represent useful technology which uses oceans thermal energy needed for air conditioning and heating systems. However, the outflow of these systems consist of thermally altered brackish or seawater which is discharged directly into the sea, thus potentially impacting local benthic communities.
We measured the effects of HP discharge along spatial gradients east- and westward of an outflow in the Ligurian Sea, assessing the composition of upper sublittoral benthic assemblages. The combined effect of temperature and salinity alteration did not seem to affect the structure of macrolaglal assemblages, while *C. compressa* was absent close the outflow.
These preliminary results showed a limited effect of HP in artificial zones characterized by tolerant species-dominated assemblages.

Keywords: Thermal pollution, North-Western Mediterranean

Heat pumps (HP) represent relatively new technology based on a renewable source of energy, namely ocean's heat, and have potential for future energy supply in coastal developed areas. HP are thermodynamic plants which, based on the differences of surface and deep seawater temperature, extract the energy necessary for domestic cooling or warming [1]. However HP outflow consist of thermally altered brackish or seawater discharges, which could impact the local meso- and sublittoral benthic communities.
Thermal pollution has mainly been studied at the outflows of nuclear or thermal power plants in the past, showing alteration of seaweeds communities and pattern of invertebrate recruitments ([2], [3]).
The project OPTIMA-PAC (OPTImisation des performances énergétiques et MAitrise des impacts sur le milieu marin des PAC eau de mer : vers une nouvelle filière industrielle compétitive), aimed at evaluating the impacts of such discharge is being carried out in the North-Western Mediterranean along the coast of the Principality of Monaco, where HP are utilized since more than 30 years.
In an early stage of the project, the impact of a brackish HP outflow was studied in Summer 2012. Temperature dataloggers were placed at the discharge point and 5, 10 20 40 and 60/80 m east- and westward, respectively, to quantify the entity of thermal disturbance due to the HP on such spatial gradient. Salinity measurements along the gradient were carried out as well. Photographic sampling quadrates were carried out at each station to analyse possible differences in benthic communities' structure and composition and the distribution of the mesolittoral brown alga *Cystoseira compressa* was mapped along the two spatial gradients.
The largest thermal effects were recorded mainly within the first 5-10 m apart from the outflow. The main effect seems to be a widening of the daily temperature range compared to extreme positions (Fig.1). Salinity alteration followed a similar spatial pattern to temperature, with a minimum average value of 29‰ at the outflow.
A preliminary analysis of the benthic assemblages, strongly dominated by coralline and turfs of filamentous algae, revealed significant differences among stations in the gradient, however without any clear relation with the distance to the discharge point. Other environmental factors are potentially affecting the structure of artificial reefs assemblages more that the combined effect of temperature and salinity alteration recorded. The strong anthropization of the study area, chracterized by algal communities dominated by relatively tolerant species, could account for the lack of a clear effect of HP discharge on assemblages structure. On the contrary, *C. compressa* patches were distributed only starting from 27 and 40 m from the outflow, westward and eastward respectively.
These preliminary results suggest that the effects of HP rejects may be limited in highly impacted artificial zones, but the response of benthic communities may be very different on natural substratum, where sensitive species (i.e. *Cystoseira* species) are thriving. Future investigations should consider biological indicators potentially more sensitive to the observed alteration of the environmental parameters, like early life stages, reproduction and physiological traits of benthic organisms.

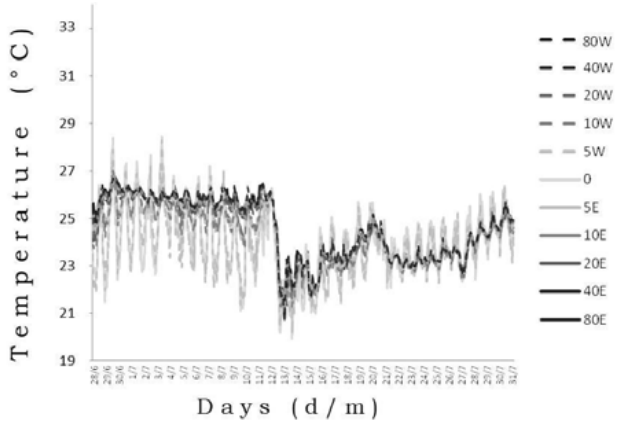

Fig. 1. Recorded temperature from 28/06 to 01/08/2012 along spatial gradients (0-80, E-W) from the HP discharge.

Acknowledgements
The present work was funded by the project Otpima-PAC, supported by the PACA marine competitivness cluster and selected by DGCIS under the 11th FUI (Fonds unique Interministériel) call for proposal. Authors wish to thank the other partners of the project for the constructive discussions during the meetings and in particular the Environment Direction and the Maritime Affairs of Monaco Principality that supported the field activities.

Abstract
This work describes the fate of coliform bacteria in the near-shore coastal waters of Civitavecchia and S. Marinella bathing areas (Latium, Italy) integrating mathematical models and in situ data. The modeling approach was used to determine the accumulation and the dynamics of spreading and transport of potentially infectious microorganisms coming from input loads.

Keywords: Bacteria, Pollution, Models, Tyrrhenian Sea

Most of coastal areas are affected by high population density, mainly in the summer season, and by industrial activities which can cause the uncontrolled discharge of polluted waters into the sea. The investigated area is characterized by the presence of several local inputs which produce a surplus of wastewater when the sewage overflow condition is reached. The use of mathematical models plays a key role to analyse the dispersion of potentially dangerous substances to human health and marine ecosystems.In summer 2012, four intensive field surveys were undertaken to measure bacteria load concentration in two selected areas (Civitavecchia and S. Marinella beaches) according to the following criteria: (a) presence of sewage effluents, (b) large number of bathers and (c) low hydrodynamism (e.g. due to the presence of coastal protection barriers). In each bathing area samples were collected every three hours (from 7 a.m. to 8 p.m.) at local inputs and control stations to validate mathematical model results.

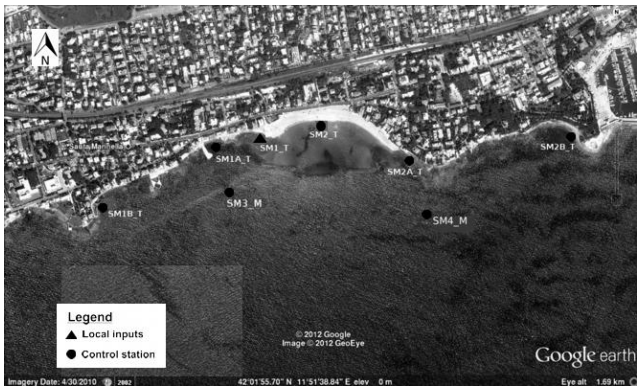

Fig. 1. Sampling stations in Santa Marinella bathing area

Collected samples were analysed according to the standard culture method [1] and the new fluorescent antibody analysis proposed by Caruso et. al, 2000 [2], in order to evaluate the pathogen cells concentration. In addition to the water quality indicator measurements, current speed and direction, temperature and salinity were also measured. Moreover solar radiation and wind speed and direction were available from weather station of Port Authority of Civitavecchia while wave parameters were collected from Capo Linaro wave-buoy of RON (Italian Data Buoy Network).Wind and wave data were used to calculate coastal marine currents by three dimensional models with high spatial-time resolution. The resulting hydrodynamic field was obtained by the steering module that couples the DELFT3D-FLOW [3] and the SWAN models [4]. The dispersion of coliform bacteria was simulated by the Delft3d-WAQ [5] model that takes into account their decay rate (due to solar radiation, salinity and sea temperature) and the flow calculated by the steering process. Predictions for fecal coliform distributions were successfully verified in the study areas, identifying the temporal evolution of potentially pathogenic bacteria in the next 24 hours. The comparison between model and in situ data showed a positive correlation (R2= 0.88) especially at higher concentrations and until a distance of about 200 meters.

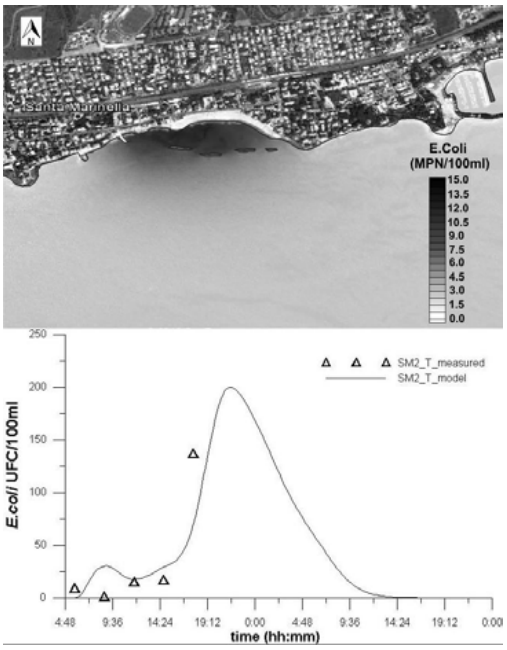

Fig. 2. Faecal coliform (FC) dispersion simulated by Delft3d-WAQ (above) and related comparison between predicted and measured FC concentration at SM2_T station (below).

Abstract
Soumise à la pollution anthropique, la baie d'Alger a fait l'objet d'une étude de contamination par les métaux traces. Deux carottes montrent que les sédiments côtiers sont plus contaminés que ceux profonds et présentent des anomalies pour certains métaux. Des perturbations dans la distribution verticale de certains métaux sont observées. Celle du Mn ne permet de définir la limite entre la couche d'oxydation et la couche de réduction que dans la carotte des sédiments profonds qui est de l'ordre de 3 cm.

Keywords: Pollution, Metals, Sediments, Algerian Sea

1. Introduction : La baie d'Alger est soumise à plusieurs sources de pollution. La zone industrielle d'Alger, via l'oued El Harrach, constitue une source potentielle. Le présent travail, réalisé en mars 2009, a pour objectif de déterminer le niveau de contamination de quelques métaux dans le sédiment et son évolution en fonction de la profondeur du sédiment et de la bathymétrie.

2. Matériels et méthodes : Deux carottes de sédiment ont été prélevées dans la baie d'Alger (fig.1) : l'une de 33 cm de longueur à 30 m de profondeur en face l'oued El Harrach (C-1) et l'autre de 27 cm de longueur à 116 m de profondeur (C-2). Les métaux étudiés sont le Cu, le Zn, le Cr, le Ni, le Mn et le Fe. La détermination des concentrations a été faite par spectrophotométrie d'absorption atomique selon les méthodes décrites par [1], [2], [3] et [4].

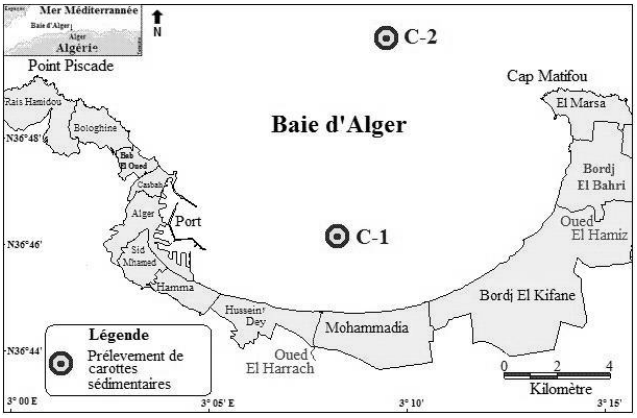

Fig. 1. Positions des deux carottes sédimentaires dans la baie d'Alger.

3. Résultats : Les résultats obtenus montrent des concentrations modérées pour tous les métaux étudiés. En outre, les moyennes des concentrations des métaux de la carotte (C-1) sont relativement plus élevées que celles de la carotte (C-2), sauf pour le nickel où les moyennes sont comparables. Ceci dénote l'influence des apports continentaux, probablement d'origines anthropiques. Dans la distribution verticale des métaux en fonction de la profondeur, la carotte (C-1) manifeste des concentrations anomales pour le Zn, le Cu et le Cr (fig. 2). En effet, les profils verticaux de ces métaux montrent des anomalies qu'on n'observe pas dans la carotte (C-2). Ces anomalies sont entre 0 et 10 cm de profondeur dans le sédiment avec deux pics : le premier avec la concentration maximale se localise à 6 cm de profondeur et le deuxième avec une concentration modérée se situe à une profondeur de 1,5 cm. L'essai de datation évoque que ces anomalies sont assez récentes (années 80). En dehors de ces anomalies, la concentration moyenne (µg/g) le long du profil est de : Zn=124,16; Cu=29,56 et Cr=23,49. Cette moyenne peut correspondre au fond géochimique de l'élément chimique considéré. Dans les deux carottes, à l'exception des anomalies observées, si le Zn, le Cu, le Cr et relativement le Fe de la carotte C-1 montrent une distribution verticale assez stable, le Ni, le Mn et le Fe de la carotte C-2, par contre, présentent des perturbations. Ces dernières peuvent être en rapport avec les conditions de sédimentation, la nature des sédiments et leur évolution diagénétique. La distribution verticale du Mn au niveau de la carotte C-2 permet de définir une épaisseur de l'ordre de 3 cm à la couche d'oxydation (de bioturbation). Cette limite n'est pas définissable au niveau de la carotte (C-1). La moyenne des concentrations relevées pour le Zn et le Cu dans la présente étude sont supérieures à celles du sédiment superficiel de la baie d'Alger au voisinage du site de la carotte C-1 [5]. Cependant, ces auteurs relèvent, pour les mêmes éléments, des concentrations supérieures à celles observées au niveau de la zone de C-2.

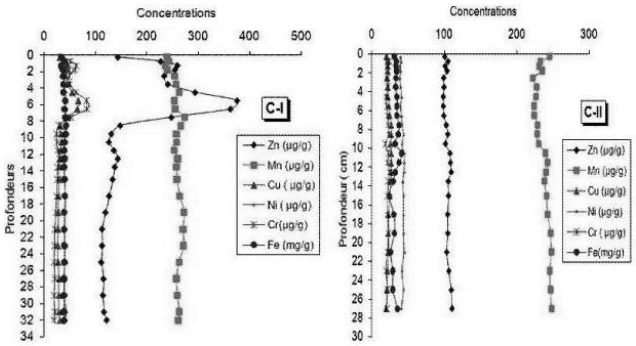

Fig. 2. Profils de distribution verticale des métaux dans les sédiments de la baie d'Alger

4. Conclusion : Les concentrations relevées pour les métaux étudiés ont un niveau modéré. Celles de C-1 sont nettement plus élevées que celles de C-2. Trois éléments (Zn, Cu et Cr) présentent des concentrations anomales dans C-1 entre 0 et 10 cm de profondeur. Ces anomalies sont assez récentes, cependant, l'origine reste à déterminer. La distribution verticale du Mn dans la carotte C-1 ne permet pas de définir l'épaisseur de la couche d'oxydation. Par conséquent, une perturbation dans le comportement du Mn et dans la sédimentation au niveau de la zone de cette carotte peut être évoquée.

Abstract
The highly contaminated sediments from Toulon bay (NW Mediterranean Sea) were deeply studied to investigate their potential threat toward the seawater quality. A seasonal variation of diagenetic tracers and of inorganic contaminants was then revealed, with high intensity in early autumn and spring (November and March), probably linked to "fresh" organic matter input (e. g. plankton bloom). Within this significant variation, a coupling of contaminants and diagenesis -sensitive carrier phases was demonstrated (As/Fe oxides, Co/Mn oxides...). A similar behaviour was evidenced for oxyanion/oxycation, and also for metals. Theirs dynamics seemed to be closely related to that of the sedimentary organic matter.

Keywords: Sediments, Trace elements, Geochemistry, North-Western Mediterranean

Introduction
The sedimentary dynamic of diagenesis tracers and inorganic contaminants was investigated in Toulon bay (NW Mediterranean Sea), previously demonstrated to be hugely polluted by numerous species (metals/metalloids, PAH …) [1]. Such dynamics influence the role of sediments: only a sink or also a source of contamination for the surrounding ecosystem. Few studies on the diagenesis variations were realized, and they were maily dedicated for some tracers in subsurface sediments [2, 3]. In such context, analytical and modelling approaches were used to better understand the dynamic and fate of diagenesis tracers and inorganic contaminants in coastal sediments.

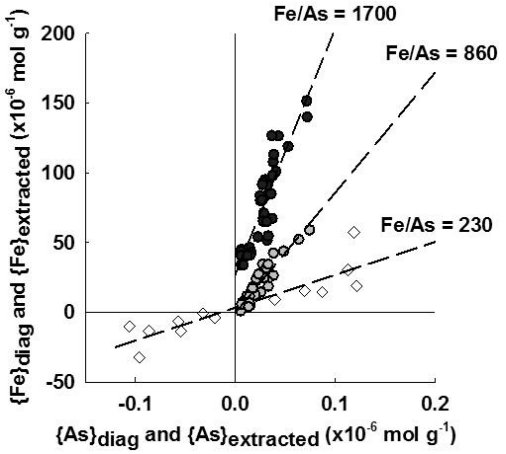

Fig. 1. Fe and As contents gained or lost by diagenesis activity (PROFILE calculations, *open diamond*), and measured on sediment extracts (ascorbate pH 8.2 (*grey circle*) and 1 M HCl (*black circle*)).

Materials and methods
Core sediments were sampled through the bay every 2 months, during 1.5 years to characterize porewater (physical/chemical parameters, diagenesis tracers and major/trace concentrations …) and solid sediments (major/trace contents, selective extractions and carrier phase identification). A 1D steady-state modelling approach (PROFILE [4]) was used to fit the elements' profiles, estimating depth reaction intervals and reaction rates. Thermodynamic simulation (PHREEQC [5]) was also performed to (1) calculate elements' chemical speciation and (2) simulate the dissolved/particulate element fractionation, by implementing in the database the main geochemical reactions and processes occurring in sediments.

Results and discussion
The diagenesis dissolved profiles (C_T (DOC+DIC), N, P, Mn, Fe, S...) showed significant seasonal variations. The highest diagenesis activity was recorded in November and March, suggesting a link with the varying input of "fresh" organic matter (e.g. plankton bloom). Diagenetic products (DIC, NH_4^+, PO_4^{3-}) ratio appeared to be constant through the seasonal variation (C_T/PO_4^{3-} = 280, R^2 = 0.75 (n = 200); C_T/N_T=11, R^2 = 0.90 (n = 200)). Otherwise, the coupling of experimental (selective extractions) and modelling approaches demonstrated the strong link between contaminants and the diagenesis-sensitive phases in subsurface sediments. The most recurrent examples were the coupling of As/Fe oxides and Co/Mn oxides. Precisely, the estimation of the Fe and As quantity lost or gained through different diagenetic processes (mineral dissolution/precipitation or adsorption...) demonstrated a correlation with a Fe/As ratio of 230 (Fig. 1). Selective extractions have also shown that As was mainly linked to amorphous iron oxyhydroxide. The relationship between As and this diagenetic-sensible mineral explained the high As remobilization in subsurface sediment. In the sulfidic sediments, similar profiles were recorded for oxyanion/oxycations (As, Sb, U, V...), apparently following a covariation with the dissolved organic matter profiles. A similar observation was found for different metals (Cu, Pb, Ni ...). It seemed that the organic matter quality (aromaticity) control their dynamics.

Conclusion
The monitoring of the diagenetic activity showed a significant seasonal modification of the behaviour of numerous elements, either diagenetic tracers or inorganic contaminants. Such variation could impact on the diffusive flux of pollutants from sediments to the water column. Numerous diagenetic processes involved in the dynamics of different inorganic contaminants were also identified and the role of sedimentary organic matter needs further investigations.

Abstract
Quantification and characterization of chronic inputs of trace metals and organic carbon in coastal Mediterranean area (the city of Marseille) during contrasted seasons (dry and raining periods) was carried out. During dry season, the impact of Treated Wastewater (TWW) on trace elements fluxes to the sea was clearly evidenced. In the freshwater/seawater mixing zone, most of the studied elements presented non-conservative behaviors, partly due to a non-equilibrium in the dissolved/particulate metals distribution in the effluents [1].

Keywords: Coastal waters, Geochemistry, Metals, Sewage pollution, North-Western Mediterranean

Study site:
Only a few studies have dealt with the Mediterranean area despite its rapid anthropization due to present-day heliotropism from Northern Europe and despite its climate specificities. Among all the possible sources of marine pollution, large coastal cities are among the most worrying, especially in the Mediterranean Sea. A typical example is Marseille, the largest Mediterranean French city, with over 1.7 million inhabitants. Two small rivers, the Huveaune and the Jarret, run through the agglomeration and join before their outlet to the sea. The uniqueness of this system is that the river waters are mixed with the city waste water treatment plants (WWTP) effluents and then rapidly discharged into the open sea without passing through an estuary, so that the WWTPs' contribution to the water characteristics at the outlet is most likely predominant during baseflow periods. These inputs have a certain impact on the local coastal ecosystem, however, a high number of such anthropized sources along the coast is likely to impact the whole Mediterranean Sea.

Material and methods:
Nine sampling campaigns (2010 to 2012) were conducted during dry and wet periods, under contrasting conditions with regard to season, wind and waves. One of this campaign was performed during an abnormal event, characterized by very high DOC and metal concentrations, probably due to the WWTP dysfunction. Water samples were systhematically collected in rivers, effluents and along the salinity gradient to cover the whole freshwater/ seawater miwing zone. Samples for DOC/POC analyses were filtered through 0.7 µm glass filters. Particulate organic carbon (POC) was quantified using these filters. DOC and POC concentrations were analyzed using a TOC-meter. Samples for dissolved/particulate metal analyses were filtered through 0.45 µm cellulose nitrate filters. The filters were dissolved by microwave digestion in aqua regia for further analysis of particulate metals by HR-ICP/MS. Dissolved trace metals were analyzed after acidification and UV irradiation by DPASV and DPCSV [2]. For a better understanding of the mechanisms that operate in the salinity gradient, remobilization experiments were performed in lab to simulate the outlet effluent/seawater mixing. Unfiltered effluent water was mixed with filtered seawater to cover a range of salinity: 1, 2.5, 5, 10 and 25. At 15 min, 1, 6 and 24h of contact time, water aliquots were filtered and analyzed for DOC and dissolved trace metals. To simulate flood conditions, a second set of experiments was performed after addition to the effluent water of flood deposit particules from the outlet, reaching a final SPM concentration of 800 $mg.L^{-1}$.

Results and discussion:
During baseflow conditions, dissolved and total organic carbon and metal concentrations in the rivers considered were comparable to values observed for other small coastal Mediterranean rivers, surpassing the world average river values. Concerning the trace metal dynamics in the plume salinity gradient (Fig. 1), Cu, Cd, Co, Pb and Zn are desorbed from the SPM, increasing the potentially bioavailable fraction of these metals. It was clearly demonstrated that the release of metal ions can occur at low salinity with fast kinetics followed by partial re-adsorption onto SPM; a behavior especially observed for Cu. Other metals (e.g. Ni) can undergo a fast adsorption onto SPM followed by slower desorption. Such unusual behaviors make mandatory the practice of filtration immediately after sampling to avoid under- or over-estimation of dissolved metal concentrations.

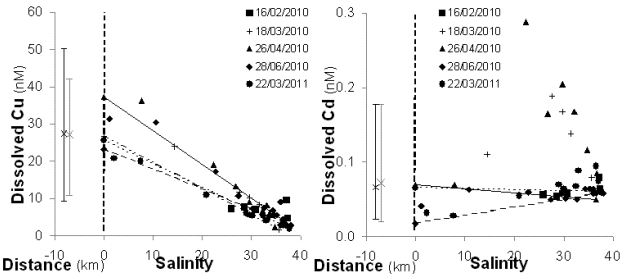

Fig. 1. Variation of dissolved Cu (left) and Cd (right) concentrations, during dry season, in rivers (as a function of the distance until the outlet) and from outlet to seawater (as a function of the salinity).

A second important point of this study is that, at the outlet, the river signatures were hidden by the WWTP anthropogenic input for most elements or compounds. The anthropogenic input was higher than 90% of the total input to the sea for particulate Cd, Pb and Cu and higher than 65% for particulate Zn, Co and dissolved Zn and Pb. The daily variation of these inputs followed the fluctuations of the TWW issued from WWTP. Although most likely not frequent, the observed abnormal event linked to a WWTP malfunction or by-pass can temporally strongly enhance the impact of an urbanized area on the coastal zone. Similar phenomena all around the Mediterranean are more than probable, especially in countries without wastewater treatment plants. This underlines the need for such treatment facilities for an improvement of local coastal water quality, but most likely also at a more global scale. Such chronic fluxes of pollutants require better study in comparison to other main sources (large rivers, aerosols, etc.). During wet conditions, trace metals fluxes increased, with a main contribution from rivers (compared to WWTP). Considering the high anthropogenic organic matter and trace element contents of the output to the sea, a detailed study of their chemical speciations, which are known to be strongly influenced by dissolved organic ligands, must be performed to evaluate their bioavailability for marine biota.

ORGANOCHLORINE CONTAMINATION (OCPS AND PCBS) IN SEDIMENTS FROM THE CANDARLI GULF (EASTERN AEGEAN)

Idil Pazi [1]*, Filiz Kucuksezgin [1] and Lutfi T. Gonul [1]
[1] Dokuz Eylul University Institute of Marine Science and Technology - idil.erden@deu.edu.tr

Abstract
The residual levels of organochlorine pesticides (OCPs) and polychlorinated biphenyls (PCBs) were determined in surface sediments collected from Candarli Gulf. Total concentrations of OCPs and PCBs in sediments ranged from 10.2 to 57.3 and 2.8 to 205 ngg^{-1} dwt, respectively. DDTs in sediments (8.0 to 37.4 ngg^{-1} dwt) were originated weathered agricultural soils and recent DDT inputs. Their concentrations appeared to be relatively low according to sediment quality guidelines except for Bakircay River estuary and petrochemical industry area.

Keywords: Pesticides, Pcb, Sediments, Aegean Sea

Introduction
Organochlorines (OCs), such as PCBs and OCPs, represent an important group of persistent organic compounds (POPs) that have caused worldwide concern as toxic environmental contaminants. An investigation of the distribution of OCPs and PCBs in sediments can provide valuable data about sediment contamination in a marine environment.Although the production and usage of many organochlorinated compounds were completely banned in Turkey in the 1990s, pesticide usage increased by 270% between the years of 1979-2007 [1]. In this study, OCswere measured in Candarli Gulf sediments to provide a better understanding of recent distribution, possible sources as well as potential biological risk of these compounds in this area.

Materials and Methods
In the framework of MEDPOL Phase IV Project, sediment samples were collected from 18 stations in 2009 covering the entire Candarli Gulf, using box corer to detect organchlorine residues. The sampling sites were shown in Fig.1. Sediment samples were analysed according to [2]. Quantitative analysis was performed with GC–MS. The OCPs and PCBs were analyzed in the sediments. Sediment (IAEA-417) sample was used as a control for the analytical methods.

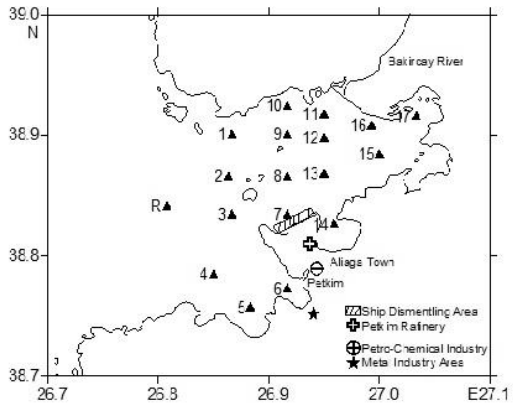

Fig. 1. Location of stations

Results and Discussion
Concentrations of sum nine OCPs in surface sediments from Candarli mean value of 34± 3.03 (Mean±SE) ng g^{-1} (based on dry weight). The highest value was found close to the Bakircay Estuary, while the lowest value of OCPs occurred in the middle part of the Gulf, corresponding to the lowest content of total organic carbon. Aldrin, dieldrin were found below detection limit (bdl) and endrin was found at low concentrations in most of the samples (bdl-2.9 ng g-1). Aroclor 1254 and 1260 in Candarli Gulf sediments ranged from 1.4 to 141 and 1.4 to 64.2 ngg^{-1}, respectively (Fig. 2). The higher levels of PCBs can be attributed to localized source of contaminants from Petkim petro chemical industry. In the Bakircay River estuary reported that OCPs and PCBs in sediments were 3-4 orders of magnitude higher than those in the reference station.

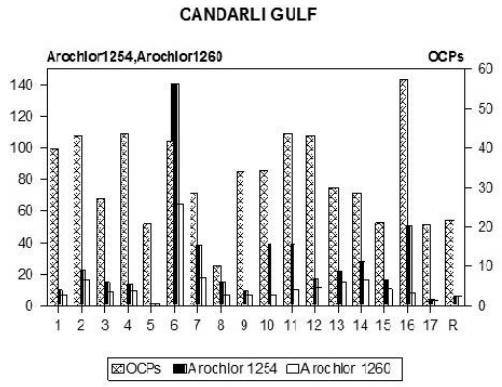

Fig. 2. Total concentrations of OCPs, Arochlor 1254 and Arochlor 1260 (ng g^{-1} dry weight) in the Candarli Gulf

Conclusion
This study first documented the composition and distribution of OCPs and PCBs in sediments collected from the Candarli Gulf. The results indicated that the DDTs were the predominant contaminant in sediments of the Eastern Aegean coasts. The recent DDT inputs in the Candarli Gulf mainly from the agricultural activity. Highest concentrations of PCBs were found in samples collected near the petrochemical industry. Based on the sediment quality guidelines, ΣPCB concentrations of the samples collected for this study did not exceed the ERM (Effect Range-Median value) or PEL (Probable Effect Level) values, other than the station near the petrochemical industry.

Abstract

In the framework of sustainable development, the anthropogenic impact of large coastal cities on the marine ecosystem is a key issue. This project aimed to improve our knowledge in marine ecosystem response to the anthropogenic supplies (from rivers, sewage outflows and atmosphere) from large cities. In particular, the goal is to underline how the physical forcing decreases or increases the anthropogenic impact on the coastal ecosystem and the assessment of the chemical contaminant (PCB) inputs (from city to sea) and exports (from mid-sea to open sea).

Keywords: North-Western Mediterranean, Coastal models, Coastal processes, Eutrophication, Pollution

The density of contaminant-generating industries of the city of Marseille is highly representative of large modern Mediterranean cities. Marseille was thus chosen for the development of numerical tools, based on the coupling of a hydrodynamic model [1], a sedimentary model, a biogeochemical model [2] and a model of chemical contamination (PCB). The coastal area off Marseille is characterized by numerous physical and biogeochemical forcing, as shown on Figure 1. The physical forcing are: wind induced upwelling and downwelling, eddies, intrusion of the Northern Current, wind vertical mixing or stratification by heat fluxes. The biogeochemical inputs come from the Rhone River, the urban rivers in case of rainfall, the Waste Water Treatment Plant (WWTP) inputs, the sediment and atmospheric inputs and the biogeochemical characteristics of large-scale waters surrounding the Marseille area.

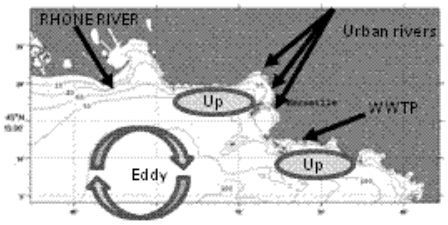

Fig. 1. Study Site of the Massilia Project - Physical processes and Anthropogenic and Natural Inputs

The approach was to study realistic typical and extreme events observed during the years 2007 and 2008. The status of typical or extreme of each event was determined in comparing with statistics on the 2001-2008 period. We used numerical tools to address following questions: i) what are the respective contributions of the physical forcing in the modulation of the oligotrophic level of this coastal ecosystem submitted to strong anthropogenic supplies? ii) What is the influence of extreme events, which frequency increases with global warming (floods, storms, heat events), on the changes in the first trophic level (phytoplankton) in the Bay of Marseille? iii) Are the chemical contaminant (PCB) inputs from the city to the sea off Marseille, stocked inside the coastal marine area or exported to the open sea?

Mistral wind events induced two spots of upwelling with a strong upwards vertical velocity (maximum of 5 $m.s^{-1}$ during an upwelling event in 2008's November) [1]. The area impacted by ascent of deep water was characterized by low temperature and high nutrient concentrations. These nutrient concentrations induced an increase in chlorophyll-a concentrations in the upwelling spot and at the front between the upwelled water and the Rhone River plume water. This phytoplankton production could be potentially associated with chemical contaminant (PCB). In addition, sediment erosion occurred in the South part of the Bay of Marseille, where the fetch for Mistral wind was the largest. The suspended particulate matter and the adsorbed chemical contaminant (PCB) were exported offshore by currents.

South-Easterly wind events induced strong intrusion of large-scale waters inside the domain and a downwelling at the coast, inducing a vertical mixing of the whole water column. This wind was associated with waves, which induced sediment erosion near the WWTP inputs. The suspended particulate matter and the adsorbed chemical contaminant (PCB) were transported nearshore by currents, in the South part of the Bay of Marseille. The end of summer rainfall had a weak impact on hydrodynamics, but induced significant nutrients, suspended matter and PCB inputs in the Bay of Marseille by urban rivers and in the South area by the WWTP. The nutrients did not promote a significant phytoplankton production, which was limited by light and temperature in fall.

The intrusion events of Rhone River diluted water in the Bay of Marseille induced a decrease in salinity and an increase in nutrients, suspended matter and PCB. This nutrient enrichment induced a phytoplankton production and an increase in chlorophyll-a concentrations, potentially associated with PCB adsorption. These events could be associated with an anticyclonic eddy located off the Rhone River mouth [3].

Abstract
Large coastal cities are a significant source of marine pollution in the Mediterranean Sea. Metals and organics are brought to the marine environment through the sewage system and the surrounding catchments. Based on measurements of contaminants concentration in urban rivers and city outflows, a hydrosedimentary model of the bay of Marseilles was applied to study the transport of dissolved and particulate contaminants, their dilution and potential accumulation area for several circulation pattern and weather conditions. Examples are shown for Lead and CB153. This work is part of the METROC, MASSILIA, MERMEX and PERSEUS projects.

Keywords: Coastal models, Metals, Pcb, Pollution, Gulf of Lyon

Studies dealing with monitoring networks [1] and process studies [2] showed environmental disturbances in the coastal zone of the Mediterranean Sea by ecosystem damage, chemical contamination or ecotoxicological effects. The Mediterranean marine system differs from the Atlantic system in its impulsive behaviour triggered by meteorological events. Indeed, events like wind and rain drive both the coastal circulation and the particulate flow.

Inputs from big Mediterranean cities contribute to coastal contamination through urban wastes and leaching of coastal catchment. In the framework of the IFREMER METROC project, a team aimed to assess chemical contaminant raw inputs (from city to sea) and exports (from midsea to open sea) in the bay of Marseilles, a city whose geomorphology and density of contaminant-generating industries is highly representative of large modern Mediterranean cities. A modelling strategy was therefore developed. The hydrodynamical and hydrosedimentary MARS3D model [3,4] coupled to the WW3 wave model were applied to the area of Marseilles to assess the dispersion of chemicals. The potential area of contaminants' accumulation in sediments and their export to the open sea were further studied depending on the meteorological conditions.
The model takes into account the various forcing and hydrodynamical processes (wind, general circulation, waves, vertical mixing, surface heating) as well as hydrosedimentary processes (advection of particles, deposit, resuspension). Inputs from the city have been previously studied [5] and were used to simulate the urban discharges from small rivers and outflows. Sea measurements were used to calibrate and validate the hydrodynamics and the particulate transport reproduced by the model.

In a first approach, the model was applied to reproduce the dynamics of conservative dissolved substances in order to compute residence times and dilution rates encountered in the area during a long period. Floods are totally evacuated from the bay of Marseilles in a few days (<1 to 11 days depending on the flood and meteorological situation). The area of influence for each discharge source is described through its dilution rate.
The model was then applied to particulate substances : local accumulation or export depend on the kind of particles associated with contaminants, and on the discharge. An application to a metal contaminant (Lead) is shown in Figure 1 and the influence of each input (waste water treatment plant, coastal river, storm-water drains, atmospherical input) was investigated. An application to CB153 was also performed in the framework of the MASSILIA EC2CO project [6]. The CB 153 model simulates processes of adsorption/desorption and volatilisation, using results of DOC and detrital and algal POC from the coupled biogeochemistry model ECO3M-MASSILIA.
From this study, the bay of Marseilles appears as a transit area and not as a storage area even if non negligible deposits are found in the northern and southern part of the bay and off the Cortiou outflow. Deposits are more important in the case of contaminants being hydrophobic, less desorbable and associated with high fall velocity particles.

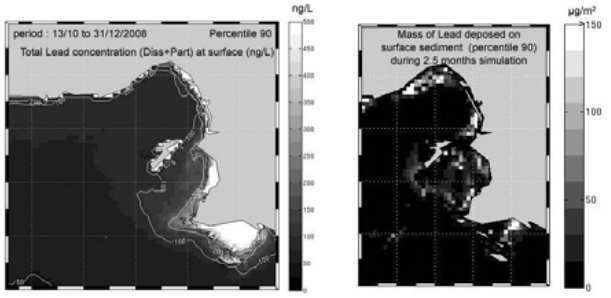

Fig. 1. **Map of total Lead concentration (dissolved plus particulate) at the water surface in the bay of Marseilles, percentile 90 (left panel) and map of lead deposal (µg/m2 - percentile 90) at the surface sediment (right panel) during the period October- December2008.**

Abstract
L'objectif de cette étude est d'appréhender les facteurs qui influencent la contamination du réseau planctonique proche d'une grande métropole. Des échantillons de plancton ont été récoltés dans la baie de Marseille à sept dates entre septembre 2010 et octobre 2011 Les résultats montrent l'importance des conditions météorologiques (fort mistral ou forte précipitation) des jours précédant l'échantillonnage sur les teneurs observées.

Keywords: Pcb, North-Western Mediterranean, Plankton, Bio-accumulation

Introduction
Le milieu marin méditerranéen est soumis à de fortes contaminations organiques et métalliques. . Cette étude présente une évolution temporelle de la contamination en PCBs du plancton et identifie les facteurs environnementaux qui favorise les teneurs observées de contamination en PCBs du réseau planctonique de la baie de Marseille, soumise à de forts rejets de polluants attribuables principalement aux activités domestiques et industrielles.

Matériels et Méthodes
Des échantillons de plancton ont été récoltés à l'aide de coups de filets (60µm) horizontaux au maximum de chlorophylle dans la baie de Marseille à sept dates (septembre, novembre, et décembre 2010 et janvier, avril, juin et octobre 2010). Plusieurs paramètres ont été mesurés sur différentes classes de taille (60-200, 200-500, 500-1000 et 1000-2000µm) : pigments chlorophylliens, contenu en isotopes stables du carbone et de l'azote et concentration de 7 congénères des PCBs (CB 18, CB 52, CB 101, CB 118, CB 138, CB 153, CB 180).

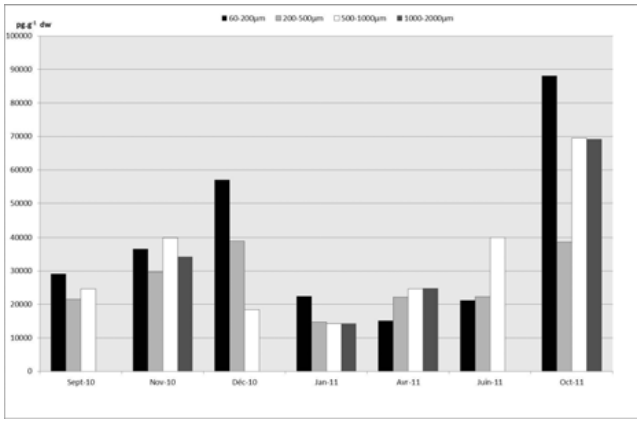

Fig. 1. Somme des concentrations de 7 PCBs (CB28, CB52, CB101, CB118, CB138, CB153, CB180) pour chaque classe de taille à chaque date d'échantillonnage.

Résultats
L'évolution saisonnière des contenus en PCBs (figure 1) et en isotopes stables (^{13}C, ^{15}N) dans les différentes fractions de taille du zoo de la baie de Marseille (septembre 2010 - octobre 2011) seront présentées et analysées. Une analyse de covariance (ANCOVA) à plusieurs facteurs : la force du vent (modérée ou faible), les précipitations, le débit de l'Huveaune, les classes de taille du plancton, et la concentration en chlorophylle a été réalisé pour chaque variables : concentration en PCBs, les ratios des isotopes stables du carbone et de l'azote (tableau 1).

Tab. 1. Résultat des analyses de covariances (ANCOVA) sur la concentration en PCB, δ13C et δ15N des différents facteurs environnementaux : saison, force du vent, débit de l'Huveaune et les précipitations, et facteurs biologique : classe de taille et concentration en chlorophylle. En gras les valeurs significatives.

Facteur	PCB		$\delta^{13}C$		$\delta^{15}N$	
	F	P	F	P	F	P
Saison	5.65	**0.015**	52.41	**<0.001**	1.21	0.325
Vent	14.64	**0.002**	12.19	**0.003**	47.76	**<0.001**
Taille	0.31	0.817	0.67	0.585	1.59	0.234
Débit Huveaune	0.14	0.718	0.80	0.386	16.74	**0.001**
Chlorophylle	0.13	0.723	9.14	**0.009**	0.31	0.586
Précipitation	8.15	**0.012**	3.22	0.093	26.96	**<0.001**

Discussion
Le plancton, premier maillon du réseau trophique, semble être très impacté par les facteurs environnementaux tels que le vent que par l'effet de la bioamplification liée aux interactions trophiques. Les fortes teneurs en contaminants observées après un fort Le Mistral, s'explique par la remise en suspension des sédiments fortement contaminés de la rade nord [1]. Cela est confirmé par les teneurs en δ13C et δ15N des mêmes échantillons présentant une signature proche de celle des sédiments chargé en détritus de Posidonia oceanica [2]. Cette contamination pourrait provenir du transport par le courant sud de la baie de matière du bassin septentrional vers le lieu d'échantillonnage, comme observé par Castelbon [3].

FINGER PRINT ANALYSIS OF PETROLEUM HYDROCARBONS AND THEIR DERIVATIVES FOR THE IDENTIFICATION OF ILLEGAL DISCHARGES: CASE STUDY TURKISH COASTS

Fatma Telli karkoç [1], Hakan Atabay [1], Leyla G. Tolun [1]* and Ersan Kuzyaka [1]
[1] TUBITAK MAM ENVIRONMENT INS - leyla.tolun@tubitak.gov.tr

Abstract
An increasing traffic of over 55,000 ships a year in Turkish seas are producing an average of 12 illegal oil spills a year. Fingerprint analysis is initiated by comparison of fluorometric spectra of polluted sea water sample and suspected source sample. 'Matching' is confirmed or rejected by subsequent comparison of FTIR, HPLC and GC-FID. In this study, 39 clean sea waters, 41 polluted sea waters and 111 suspected samples were analysed. 76 suspected samples were spectrofluorometrically analysed and categorised as "*Non-match*". Finally, 28 suspected samples were classified as a "Match".

Keywords: Petroleum, Marmara Sea, Pollution

Introduction
Oil is the black blood that runs through the veins of the modern global energy system (Höök, 2009). Oil spills discharges could be "mystery spills" or "known-source spills" (Stout. and Wang, 2007). Normally, determination of the mysterious spill method is based on direct comparison of matching peaks among chromatograms/spectra. The aim of this paper is to identification of the spilled oil pollution source coming from illegal discharges.

Material and Method
Clean sea water, polluted sea water and suspected vessel samples were analysed according to the fingerprint procedures explained in ASTM methods (ASTM, 2011a; ASTM 2011b; ASTM 2006; ASTM, 1996). For each occasion/event, at least three samples were taken from clean water (sea/fresh) as a reference site, polluted waters from polluted site and samples from different tanks/section of suspected sources like sludge, bilge, slope, bunker tanks etc. Collecting samples were scan by using synchronous spektrofluorometer between 200-600 nm. Samples scan patterns were compared between polluted sample and suspected sample. If polluted sample and suspected samples pattern were similar than further analysis were done by using, HPLC, GC-FID and FT-IR methods.

Results and Discussion
For present study, samples were collected from 38 illegal discharges events from Turkish Coasts. 39 clean sea water, 41 polluted sea water and 111 suspected samples were analysed (Table 1). 76 samples of them were syn-spektrofluorometrically analysed and polluted samples spectral results were not similar with suspected samples. They were classified as "*Non-match*", so there were no need for further analysis (Table 1). Other 35 suspected sample were classified as "*Match or Probable Match*", and they were required further analysed by using other methods such as FT-IR, HPLC and GC-FID. Finally, 28 samples were classified as a "Match" .

Case 1; Non match: Samples were compared for the similarities and analysis was started with syn-spectrofluoromety. (Figure 1). Figure 1 showed that polluted samples and suspicious sample were completely different each other (Non-match) and clean sea water spectrum was also behaving differently.
Case 2; Match: In second case, since, syn-spectrofluorometric results were matched with either polluted sample or suspicious samples, finger printing analysis should be continued with other methods by using HPLC, FT-IR and GC-FID

Conclusion
Finger print analysis is a qualitative method and consists of four different methods were used for the comparison of the chromatogram/spectra. In addition to this, expert judgement is another important step for the assessment of the results. Although, achieve the highest success rate in terms of the correct result, sometimes, specific cases, the finger print method could not show one source or sometimes shows more than one sources. If the source sample and polluted sample outputs were not the same, finger print analysis were ended and legal proceedings were completed in a short time.

DISTRIBUTION OF PHTHALATE ACID ESTERS (PAE_S) IN SURFACE SEDIMENTS FROM THE SEA OF MARMARA, TURKEY

Selma Ünlü [1]*, Bedri Alpar [1] and Hülya Özaltin Günday [1]
[1] Istanbul University Institute of Marine Sciences - su@istanbul.edu.tr

Abstract
Surface sediments from 35 sampling sites of the Sea of Marmara were analyzed for 6 phthalate acid esters (PAEs), namely diethyl phthalate (DEP), dimethyl phthalate (DMP) di-n-butyl phthalate (DBP), benzylbutyl phthalate (BBP), di-(2-ethylhexyl) phthalate (DEHP) and di-n-octylphthalate (DnOP). In all samples, concentrations of the DBP and DEHP were found to be higher than the other four PAEs. DBP and DEHP concentrations in sediment samples ranged from <MDL to 1.18 µg/g dry weight (dw), and 0.01 to 4.52µg/g dw, respectively. The analytical results showed a direct relation of PAEs levels with the input of urban and industrial treated waste waters near the sampling point. As compared to the results from other studies, the Sea of Marmara exhibited relatively low pollution by the PAEs.

Keywords: Pollution, Plastics, Sediments, Marmara Sea

Introduction

Phthalate acid esters (PAEs) are widely used as non-reactive additives in plastics, particularly polyvinyl chloride, but also in rubber, cellulose and styrene production, to improve their softness and flexibility. The global production is approximately 6.0 million tones [1]. As PAEs do not chemically bind in the polymeric matrix, they can enter the environment directly and/or indirectly, during the production of plastic and plastic material or after disposal. Because of the large and widespread application, PAEs are ubiquitous in the environment and have been widely detected in air, water, soil and sediment. Since some phthalate esters have low water solubility and high octanol partition coefficient, they can become concentrated in suspended matter and sediment. In the 1980s, only six phthalates (DMP, DEP, DBP, BBP, DnOP and DEHP) have been classified as priority pollutants by the US Environmental Protection Agency (EPA). The main objectives of the present study are to investigate the PAEs concentrations in the sediments from the Sea of Marmara and discussing their possible sources and ecological effects.

Material and Method

The sediments were taken from 35 stations by using a grab sampler on board of R/V ARAR in December 2010. The sampling depths vary between 11 and 150 m. The samples (0-5 cm depth) were collected using a pre-cleaned stainless steel scoop into pre-cleaned aluminium foil envelopes. Then they were stored in a freezer at -20°C until analysis.The methods used in this study have been described in detail [2] and will only be summarized here. Extraction of samples with a Soxhlet apparatus and analyses by a Gas Chromatography/Mass Spectrometry (GC/MS, Finnigan (Thermo) Trace DSQ) were given in detail by Zeng [2]. Background contamination due to various sources in the laboratory constituted a major problem, which was controlled by performing blank analysis with each sample series. All solvents were tested regularly for PAE contaminations. Only glass, teflon and stainless steel were used. All hardware was cleaned with tap water, distilled water and acetonitrile, then stored at 150°C and rinsed with hexane before use. A mixture of six PAEs, including DEP, DMP, DBP, BBP, DEHP and DOP were obtained from Dr. Ehrenstorfer GmbH Inc. (Germany). For the six PAEs standards, the recoveries of spiked blanks (n=3) varied from 78.2 to 108.2% (relative standard deviations <12.7). The organic carbon content of sediment samples were measured by a Carlo Erba NC2500 model CHN analyzer after removing the inorganic carbonate fractions.

Results and Discussion

The $\sum_6$PAEs concentrations ranged from ND to 5.7µg/g-dw, with the median concentration of 0.9µg/g-dw of the 6 PAEs, DEHP and DBP dominated the PAEs, with the maximum concentrations of 1.18 and 4.52µg/g-dw respectively, and accounted for 37 and 59% of the $\sum_6$PAEs concentrations. It has been reported that DBP and DEHP are the most commonly used plasticizers worldwide [3]. The concentrations of PAEs in sediments were substantially lower than most reported in other locations over the world [e.g. 2, 4, 5]. The statistical analyses indicated that ∑PAEs concentrations, especially DEHP concentrations, had a significant positive relationship with TOC in the sediments. The correlation coefficients were 0.72 ($p<0.01$) for total PAEs concentrations, and 0.76 ($p<0.01$) for DEHP. Based on the ecotoxicology and environmental chemistry of DnBP and DEHP, median concentrations of DnBP (0.30 µg/g) and DEHP(0.52 µg/g) measured in sediments of the Sea of Marmara; which were lower 2.5 and 2 times than the ERLs of 0.7µg/g and 1µg/g, respectively [6]. As no data were available representing the past levels of PAEs in the study area no conclusion can be made concerning temporal changes in PAEs levels in the sediments of the Sea of Marmara. These results can be used as reference levels for future monitoring programs of pollution from PAEs.

Abstract
The aim of this study was to evaluate heavy metal (Cr, Fe, Ni, Cu, Zn, As, Cd, Hg, Pb) and selenium levels in digestive gland and gill tissues of wild Mediterranean mussel *Mytilus galloprovincialis* (Lamarck, 1819) collected from Izmir Bay. The highest values (mg kg^{-1} dry weight) of these metals for digestive gland and gills were revealed. Statistically significant differences ($p<0.05$) between digestive gland and gills were found for Cr, Ni, Zn, As, Se and Cd. The low levels of toxic metals (Cd, Hg, Pb, Cr, Ni) found in tissues of *M. galloprovincialis*, comparing with the other studies including taken place in the Inner of Izmir Bay. *M. galloprovincialis* can be used as a sensitive biomonitor for the availabilities of studied elements in the Inner Bay of Izmir, Turkey.

Keywords: Bio-accumulation, Izmir Bay, Metals, Bivalves

Introduction
Mussels are sedentary organisms filtrating large amounts of water allowing them to accumulate the substances from the environment. This characteristic makes it possible to use them as "bioindicators" in an aquatic environment. *M. galloprovincialis* is a very sensitive 'early warning' tool for heavy metals contamination of a marine environment [1, 2, 3]. The aim of this study was to quantify and compare heavy metals and selenium in digestive glands and gill tissues of *M. galloprovincialis* caught four locations in Izmir Bay.

Material and Method
Izmir Bay is located in the eastern Aegean Sea between latitudes of 38°20' and 38°42' N and longitudes of 29°25' - 27°10' E. A total of 180 samples of the wild mussel *M. galloprovincialis* with shell length of 50-60 mm were collected from four locations in the Izmir Bay in early spring 2010 (Fig. 1). Drying and digestion processes of the samples were carried out with the procedure used by Licata et al., (2004) [3]. Inductively coupled plasma-mass spectroscopy (ICP-MS) was used to determine heavy metals in mussel samples. Statistics were performed using SPSS software version 15.0. The data obtained by the values of studied elements were subjected to one-way analysis of variance (ANOVA) followed by *post-hoc* test analyses based on the Tukey test.

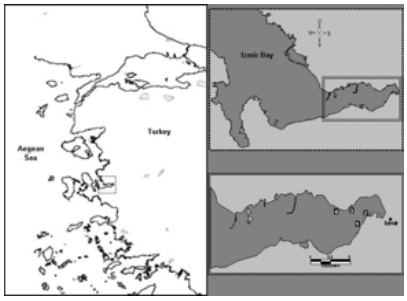

Fig. 1. The study area and sampling stations (1: Pasaport, 2: Alsancak, 3: Karsiyaka, 4: Bostanli).

Results and Discussion
Fe has the highest concentrations both in the gill and digestive gland while Cd and Hg have the lowest values. Generally, content of concentrations in the digestive gland were lower than concentrations in the gill. The magnitude of element concentrations in digestive gland was determined as Fe>Zn>Cu>As>Se>Ni>Cr>Pb>Cd>Hg. The data obtained showed that accumulated metal concentrations in gills in the following sequences: Fe>Zn>As>Cu>Se>Ni>Cr>Pb>Cd≈Hg. Considering all data, there is a statistically positive significant correlation between Cu-Pb, Ni-Cd, Se-Cd, Ni-Se, Fe-Cu, Cr-Cd, Ni-Cu, Ni-Pb, Fe-Ni, Cr-Se, Zn-Pb, Zn-Cd, and Zn-Se (from higher to lesser), while negative relationships were found As-Se, Ni-Hg, Fe-Hg, Zn-Hg, Ni-As, Cu-Hg, As-Cd, and Hg-Pb. Especially, Hg and Ag showed negative relationships with the other heavy metals and Se. Among the correlations of measured elements in gill, the correlations between Ni-Cu, Cu-Pb, Ni-Pb, Fe-As were significant. In the same tissue, the negative significant relationships between Cr-Cu, Cr-Ni, Cr-Pb, Ni-Hg, Fe-Hg were found. The significant correlations between Fe-Cu, Fe-Ni, Cu-Pb, Ni-Cu, Zn-Pb, Zn-Cd, Cu-Zn, Cd-Pb, Cu-Cd, Cr-Pb, Ni-Zn, Cr-Cu, Fe-Zn, Fe-Pb, Ni-Cd, Ni-Pb, Cr-Cd, Fe-Cd, Cr-Ni, Cr-Fe, Cu-Se, Se-Pb, Ni-Se, Fe-Se, Cr-Zn, Zn-Se were determined in the digestive gland, while Hg showed the strongly negative relationships with Cu, Fe, Ni, Zn, Pb, Cd, Cr, Se. Among the three correlation matrices, the correlation matrix obtained from the digestive gland has stronger and significant relationships relatively. According to ANOVA, there were no statistical significant differences between the studied tissues in terms of Fe, Cu and Hg but Cr, Ni, Zn, As, Se, Cd, Pb. The results of ANOVA also indicated that the significant differences weren't found among sampling stations in terms of Cr, As, Se, Cd. However, the other elements have shown significant differences in the stations. Tukey *post-hoc* analysis separated station 1 and 3 in terms of these elements. Also, no significant differences were found between station 1 and 2, except for Zn. Finally, in comparison to data reported in other studies, our findings for in *M. galloprovincialis* indicated that most of the data were lower in the literature.

Conclusions
As a conclusion, with a detailed statistical analysis we obtained following results; •*M. galloprovincialis* samples collected from different locations have significantly different heavy metal concentrations. •Gills had higher concentrations for Cr, Fe, Ni, Zn, Cd, Pb, and Se compared to digestive gland. •Fe and Zn contents are high both digestive gland and gills at all sites. •Se shown a significant negative correlation with Hg, and a weak negative correlation with As but the other measured heavy metals. •The low levels of toxic metals (Cd, Hg, Pb, Cr, Ni) found in tissues of *M. galloprovincialis*, despite urbanization and vessel traffic in the Izmir Bay, comparing with the other studies done in the Inner of Izmir Bay. This situation might be a consequence of waste water treatment activities during the last decade in the bay.

THE CALYPSO HF RADAR DATA INTERFACE

Joel Azzopardi [1]*, Raisa Tarasova [1], Adam P. Gauci [1] and Aldo Drago [1]
[1] Physical Oceanography Unit, University of Malta - joel.azzopardi@um.edu.mt

Abstract

Within the ambit of the CALYPSO project, a network of HF-radars with installations on the northern coast of the Maltese Islands, and on the southern Sicilian coast is intended to provide real-time sea surface currents in the Malta Channel. This paper describes the web interface developed to provide users with viewing, selection and downloading of the measured data. Value-added services targeting the general public as well as specialised professional users provide a means to maximise benefits through the use of the data for different applications.

Keywords: Remote sensing, Currents, Malta Channel

The HF radar network set up within the CALYPSO project [1] provides synoptic maps of currents in real-time every hour and with a high resolution and coverage in space. It consists of multiple radars at different locations and with an overlapping beam pattern; the same patch of water can be viewed from different angles, and the surface current radial velocity components can be summed to determine the total surface current velocity vector. Data measured simultaneously at the different points can be combined to produce hourly maps of current vectors within a regular grid.

The real-time data produced by the HF-radar network is of interest not only to researchers but is also useful to national authorities during the undertaking of crucial activities such as Search-and-Rescue and Oil Spill Response. However, such users would require the data to be in an enhanced format that is readable and understandable to them and their systems. For this reason the CALYPSO web data interface was developed to provide such users with the required value-added services derived from the original data gathered by the radars.

The data interface is composed of two main sections, namely: the Public Interface – targeting the public users by showing plots and statistics over nine different sub-regions in the Malta Channel; and the Professional Interface – targeting the professional users by the presentation of quick-view plots, and allowing the download of data, and the handling of special data requests.

The products available on the CALYPSO Data Interface are derived from nowcast sea surface currents data generated by the HF-radar system, and forecast currents data generated by the ROSARIO-6420 [2] Malta shelf forecast. The domain of data coverage has a spatial resolution of 0.03° (approx. 3Km) in the case of the observation nowcasts, and 0.0163° (approx. 1.6 Km) for the forecast fields. Data is provided with a temporal resolution of 1 hour.

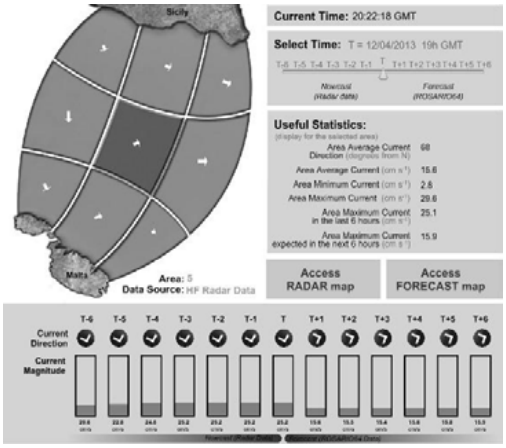

Fig. 1. A screen-shot of the Calypso Public Data Interface

The Public Data Interface synthesises the hourly data fields by spatial averaging over 9 sub-regions and presenting the information on sea surface currents averaged for each sub-region for a time span of 13 hours, namely: the present hour conditions; the previous 6 hours generated from HF radar observations; and the next 6 hours generated by ROSARIO 6420 forecast. The information displayed for each selected sub-region includes: the average current magnitude and direction in that sub region; the maximum and minimum current magnitude; the maximum current magnitude over the last 6 hours; and the maximum current magnitude expected in the coming 6 hours.

The Calypso Professional Data Interface consists of four main components. It allows the viewing and downloading of data for the entire domain. The user selects the date and time of interest, and is presented with an image of the currents for the selected date-time, along with the necessary links to download the data in ASCII or in NetCDF formats. The user can also submit a request to aggregate the data over a period of interest. The system performs the required aggregation and 'pushes' the user-selected aggregated dataset in the pre-selected format. The user can alternatively select a point and period of interest, and the system prepares a time series of the sea surface currents hourly data at the selected geographical location and time span; apart from the data time series, the system also presents the user with an interactive plot of the time series using Google Charts [3]. The user has also the option to select an area of interest, and the system outputs to the user time series of the mean, minimum and maximum currents within the selected area. The online interface further allows the user to submit a special data request; the user requests an area and period of interest, and the system returns a pdf report describing the evolving sea surface circulation conditions. This reporting function is especially relevant for oil spill emergencies where such a report can then be uploaded to the European CECIS Emergency Response system [4] in case of an oil spill emergency.

Abstract

A new method for assessing anchoring pressure is proposed. It is based upon an automatic high frequency digital photography (AP-AP system). The autonomous equipment is working from sunset to sunrise.

Keywords: Posidonia, North-Western Mediterranean, Monitoring, Mapping, Marine parks

Introduction

Leisure boating is an activity in the increase in the Mediterranean. Anchoring of boats on e.g. *Posidonia ocenica* meadows and the coralligenous assemblages is a source of bottom degradation and an issue of growing concern [1, 2]. Up until now, leisure boat frequentation, anchoring and carrying capacity were tackled on the basis of inaccurate data, e.g. a few aerial photographs and boat counts. Within the framework of the research program 'Liteau III FHUVEL', the anchoring pressure issue was addressed through automatic high frequency digital photography (AP-AP System: Anchoring Pressure by Automatic Photography).

Material and methods

The method was successfully implemented in Sormiou and Frioul-Crine Coves, two sites of the recently established 'Parc national des Calanques' (Calanques National Park, Marseille-Cassis, Provence, France), during respectively 19 months and 7 months.

The camera was installed in a waterproof shelter, 200 m and 60 m respectively, above the sea level, depending on the site and programmed to take a picture every 10 min from sunrise to sunset (Figure 1).

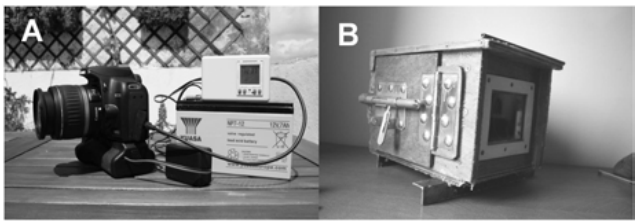

Fig. 1. AP-AP system: A - Camera with electronic dispositive; B - protective case.

The battery and memory card of the camera ensured an autonomy of 15 to 21 days. Photos, which were taken at an oblique angle, were transformed to a vertical format (Figure 2), in order to match the maps, using a set of 150 GPS marks. Spatial data analysis was performed under GIS Arc View 10.2®. The exact anchoring location of every boat, every day, every 10-min, was manually geo-referenced.

Photo analysis makes it possible to assess the pressure location within the site, the time of arrival, the departure and the anchoring duration, the day of the week (weekday vs weekend), the month, the boat category (e.g. sailing boat, motor boat) and the weather.

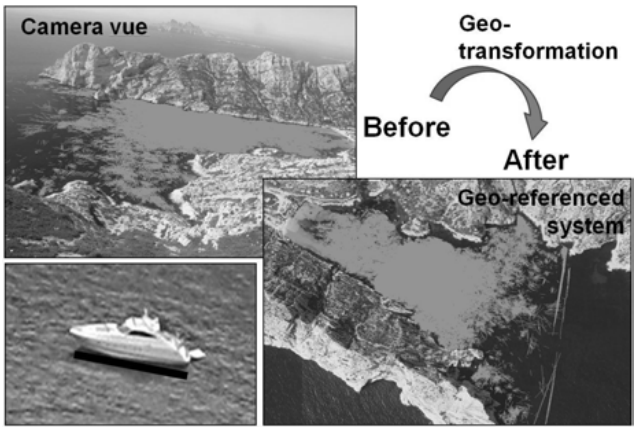

Fig. 2. Geo-transformation of identified anchored boats from the camera vue to a georeferenced system. The gray area is the enveloppe area of the position of boats every 10 min, over the study period. In the vignette, the black line plotted from the prow to the stern of the boat allows to get the size and the orientation of the boat.

Abstract

Anchoring pressure was precisely evaluated with the AP-AP system in Sormiou Cove (Provence, France, NW Mediterranean Sea). The image analysis (30 000 pictures) under GIS allowed to georeference anchored boat position and determinate the anchoring density per hectare and per day, during an annual cycle.

Keywords: Posidonia, North-Western Mediterranean, Monitoring, Mapping, Marine parks

Introduction

Ecological importance of *Posidonia oceanica* meadows makes their decline particularly worrying [1]. The regression of *P. oceanica* meadows in the NW Mediterranean is therefore an issue of growing concern. A variety of human activities threaten *P. oceanica* meadows, e.g. pollution, water turbidity, trawling, invasive species and anchoring. Beyond a given level of anchoring pressure (number per hectare, frequency), the rhizome growth cannot compensate for shoot and rhizome losses. Breaks then develop within the matte. The anchoring pressure was assessed by the AP-AP system (Anchoring Pressure by Automatic Photography) developed during the research program 'Liteau III FHUVEL' [2]. The goal was to compare spatialized maps of the anchoring pressure and of the status of the *P. oceanica* meadow.

Material and methods

The study site was Sormiou Cove, a popular site for leisure boating and anchoring, mostly covered by *P. oceanica* [3], close to the city of Marseilles. Sormiou Cove is included within the recently established 'Parc national des Calanques'. 30 000 pictures taken by the AP-AP system (May 2010 through April 2011) were georeferenced under GIS.

Results and discussion

During the one-year study period, 5 920 boats anchored over the 25.5-ha surface area where anchoring is authorized. Anchoring occurred mostly (95%) during the high season (May through September). The highest recorded daily frequentation was 255 boats (July 11th) while the highest recorded simultaneous frequentation was 101 boats (August 22nd, 15:14). Sailing boats constituted the dominant category (44%), followed by motor boats less than 10 m long (30%), with conspicuous fluctuations according to the day of the week, the month and the wind strength (Figure 1).

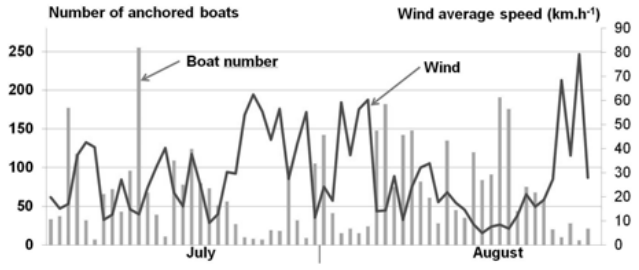

Fig. 1. Number of anchored boats per day according to wind strength (July and August 2010).

The anchoring process began at 9:00 and peaked from 12:00 to 14:00. The mean duration of the stay at anchor was 6 h 18 min, the record being 9 days. The sailing boats were concentrated in the centre of the cove, close to the line of marker buoys delimiting the area of unauthorized anchoring. The highest local density of anchored boats was observed in the centre of the cove, 6 boats/ha/d (annual average) and 22 boats/ha/d (August average) (Figure 2).

The thresholds of maximum sustainable anchoring pressure on *P. oceanica* meadows are 2 boats/ha/d (annual average) and 10 boats/ha/d (at peak periods) [4]. Though the validity of these recommendations requires confirmation, it is worth noting that the Sormiou Cove anchoring pressure locally exceeds the above mentioned thresholds (upon 2 ha of meadow). The monitoring of the *P. oceanica* meadow will allow to confirm, to invalidate or to adjust the thresholds proposed by the authors above mentioned.

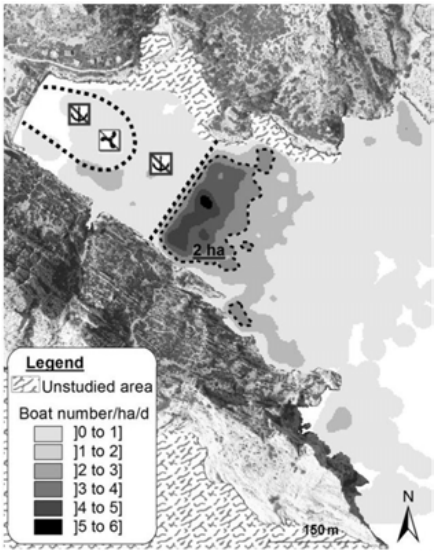

Fig. 2. Anchoring pressure (boat number/ha/d)(May 2010 through April 2011).

MAPPING NATURAL AND CULTURAL MARINE HERITAGE SITES IN LEROS ISLAND GREECE

M. Geraga [1], E. Katsou [1], D. Christodoulou [1], M. Iatrou [1]*, S. Kordella [1], G. Papatheodorou [1], V. Mentogiannis [2] and K. Kouvas [3]

[3] Hydrovius Dive Center, Leros, Greece

Abstract

Mapping of natural and cultural marine heritage sites is substantial to national and regional inventories aiming to conservation and protection and the management of coastal and offshore resources. Within this concept this study presents the results of a marine geophysical survey in conjunction with visual inspection, conducted at Leros Island, Greece. The acquired data designated wrecks of the World War II (WW II) and mapped in detail the marine protected habitats of the studied area.

Keywords: Aegean Sea, Coastal management, Posidonia, Remote sensing

Introduction

The battle of Leros island, located in the south-eastern Aegean Sea marked the history of the island during the second world war [1]. The island was occupied by British forces since 15th September 1943, after the surrender of Italy on 8 September 1943. The location of the island and the coastal geomorphology revealed Leros as strategically vital for Allied and German forces. The battle began with German air attacks on 26 September. All forces involved suffered heavy casualties during the battle which lasted 52 days and ended with the capitulation of the Allied forces. Today wrecks lay on the seabed keeping the memory of that battle. Furthermore, the island of Leros hosts ecosystems which are of great importance in marine environments. A marine remote sensing survey was carried out in the coastal zone (up to depth of 100m) of Leros Island between 10 and 18 June 2011. The objective of this survey was twofold: (i) to map *P. oceanica* meadows and coralligene formations and (ii) to detect and identify targets which are probably related to Leros Battle during the WW II.

Methods and Results

The remote sensing survey of Leros Island was organized into two phases. First a systematic survey of the sea floor was carried out using side-scan sonar. The second phase consisted of visual inspection based on the results of the first phase. This methodological approach provides a cost-effective tool to rapidly survey areas of ecological and historical interest [2,3]. A total area of 54.1 km^2 around the island insonified by a side scan sonar system consisting of a dual frequency (100 and 500 kHz) towfish 272TD, following standard methods for relative studies [2,3]. Visual inspection and confirmation of sites of interest achieved by dropping and towing of digital camera and scuba diving by experts. All the acquired data were imported and georeferenced into the GIS environment (Fig 1).

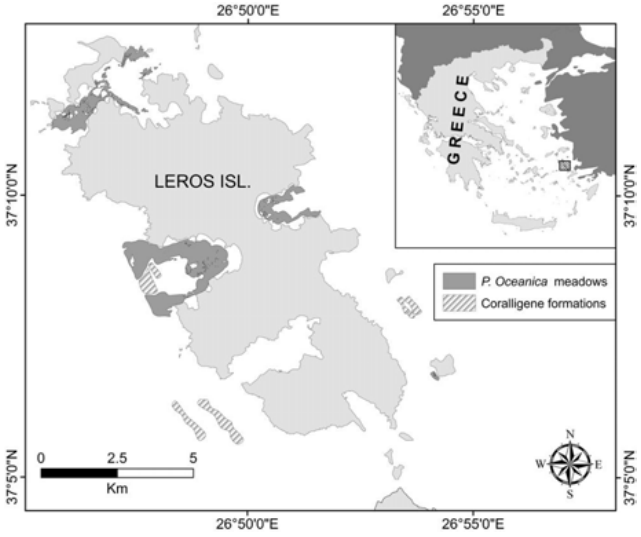

Fig. 1. Map showing the area of the marine protected habitats around Leros island.

The analysis and interpretation of the results showed that a total area of 5.5 km^2 and 1.5 km^2 is covered by prairies of *Posidonia oceanica* and coralligene formations, respectively (Fig. 1).

According to European Union regulations, both of them are included in the list of marine protected habitats. Furthermore the study detected several targets as potential wreck sites. Selective visual inspection among the targets confirmed the existence of debris of two barges (in Lakki and Partheni bays), one landing ship (in Lakki bay), two aircrafts (close to Blefoutis bay and at the entrance of Lakki bay) and anti-submarine nets (in Lakki and Partheni bays). One of the targets was the debris of the flagship *Queen Olga* (Fig. 2).

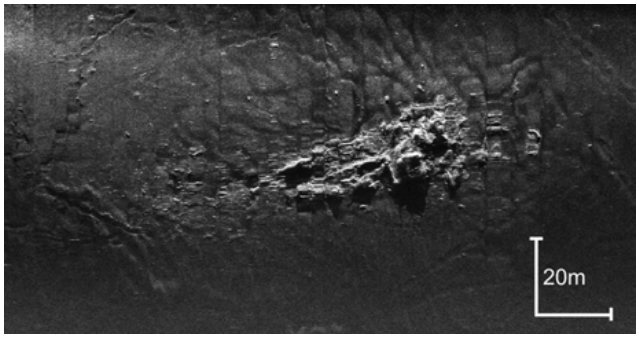

Fig. 2. Sonograph from Lakki Bay, presenting the remains of the flagship *Queen Olga.*

Abstract
This paper presents the acoustic image of various types of habitats identified during the scanning performed for seabed habitat mapping, and emphasizes the correlation between the type of habitat, its relation to the sediments on the seafloor, and the corresponding acoustic facies.

Keywords: Black Sea, Acoustics, Instruments and techniques, Swath mapping, Sediments

There are six Natura 2000 sites on the Romanian Black Sea coast. Mapping of seafloor habitats was performed using an IXSEA Elics 400-1250 side-scan sonar, coupled with ground truthing by sampling and diving. Similar approaches were done by [1], [2] and [3].

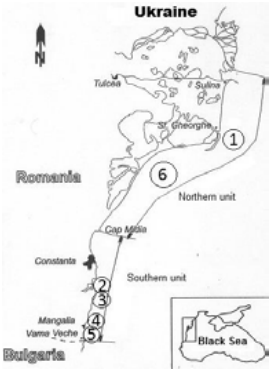

Fig. 1. The Romanian coast with locations of Natura 2000 site: 1- "The submarine metanogenic structures Sf. Gheorghe", 2- "Eforie N-S submerged beach", 3- "Cape Tuzla marine area", 4- "Mangalia submarine sulphurous springs", 5- "Vama Veche- 2 Mai" and 6- "Danube Delta- marine area"

The sonograms were processed and into a mosaic. Seabed classification using backscatter properties was done and helped in the identification of acoustic facies and corresponding sedimentary facies. An exemple is in Figure 2 for Mangalia site. Four main types of habitat were identified, according to the European Commission's Directive [4], divided into subtypes according to their particularities. We have analyzed them and characterized them based on their acoustic features:

Sandbanks which are slightly covered by sea water all the time (1110) are characterized by a relatively intense backscatter and, as the sand grains are smaller than the resolution of the sonograms, they are seen as plain light gray. They show typical sedimentological features such as current ripples. They appear in all Natura 2000 sites.

Reefs (1170). There are two acoustic facies identified that belong to this main type of habitat. The first is represented by mussel beds, Mytilus galloprovincialis reefs, and the second by various types of rocks. The mussel beds show intense backscatter, the sonar facing clams powerfully reflecting the sound. They look like low mounds or blankets of shells on the seafloor, appearing in a linear orientation transverse to the nutrient bearing currents. They appear in the deeper areas of the Vama Veche- 2 Mai, Tuzla, Sfantu Gheorghe and Danube Delta- marine area sites. Also, on Mangalia, Tuzla and Eforie sites, areas containing a large amount of broken, disarticulated shells and shell debris were found. The acoustic facies resembles the mussel beds but show a different morphology, their architecture being controlled by water movement and not by the living and development of the organisms that produce them.

The rocks show distinctive characteristics on the sonograms. Some of their features are large enough to be seen, like the orientation of fissures. The level of backscatter varies as sonar-facing surfaces and boulders reflect very well the sound, returning the signal with great amplitude, and cast shadows, from where the returned amplitude is close to zero. They appear in the southern unit.

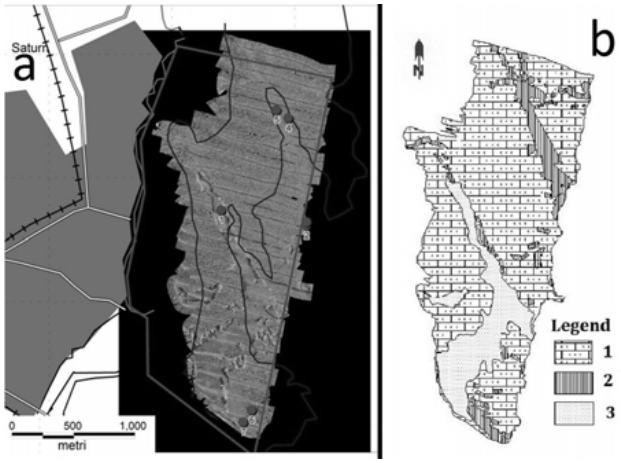

Fig. 2. A) Mosaic of the Mangalia Natura 2000 site; the dots mark ground truthing location; B) The distribution of habitats associated to the main acoustic facies: 1- habitat 1170, rocks; 2- broken, 3- habitat 1110, sand;

Submarine structures made by leaking gases (1180). Carbonate chimneys are seen on sonograms in the muddy areas in front of Sfantu Gheorghe, but do not appear on habitat maps due to their small size.

The mud with Mellina, although not assigned to a specific type of habitat according to the Habitat Directive covers important areas in Vama Veche and Sfantu Gheorghe sites. It shows a small level of backscatter and appears dark gray on sonograms.

The Mudflats and Sandflats not covered by water at low tides (1140) was identified near the shore in areas where sonar scanning was not appropriate because low water depth.

A clear correlation can be done between the acoustic and sedimentary facies. Based on the relation between the type of seabed and living organism, sonar scanning is a valuable tool for assessing habitat distribution. However, the level of details regarding the types of species living on the seafloor is limited.

IMPACT OF ATMOSPHERIC CYCLONES ON THE PRODUCTIVITY OF THE MEDITERRANEAN AND ARABIAN SEAS

Sergey Piontkovski [1]* and Saud Al-Jufaili [1]
[1] Sultan Qaboos University - spiontkovski@mail.ru

Abstract
Remotely sensed parameters of 7 atmospheric cyclones were analyzed to estimate the range of fluctuations of chlorophyll-*a* concentrations induced by the passage of these cyclones through waters with different biological productivity (the low productivity of Mediterranean Sea versus the highly productive Arabian Sea). The annual mean of chlorophyll concentration in the western Arabian Sea exceeded the Mediterranean concentrations by ten times. Amplitudes of chlorophyll peaks initiated by propagating cyclones were associated with the phase of the chlorophyll seasonal cycle.

Keywords: Remote sensing, North-Eastern Mediterranean

Phytoplankton communities of the upper layer of the ocean respond to propagating atmospheric cyclones by increasing biological productivity (Subrahmanyam et al., 2002). The variety of this response in waters with different biological productivity is poorly understood however. The goal of this study was to compare biological footprints of cyclones in poorly productive versus highly productive waters, exemplified by the Mediterranean and Arabian Sea correspondently.

Satellite-derived (4-km spatial resolution SeaWIFS and MODIS-Aqua) daily and weekly chlorophyll-a concentrations (Level-2 and Level-3 products) available from the NASA Ocean Color Group (http://oceancolor.gsfc.nasa.gov) were used to retrieve time series for the Arabian Sea and the Mediterranean Sea for the period of 1997-2013. Data on seasonal concentrations of nitrates were retrieved from the WOD database (http://www.nodc.noaa.gov/OC5/indprod.html). Characteristics of cyclones were retrieved from global and regional databases (the PO-DAAC ftp site- ftp://podaac.jpl.nasa.gov/ocean_wind/quikscat/NRT/; http://hurricane.accuweather.com;
http://iridl.ldeo.columbia.edu/docfind/databrief/, and others).

Seasonal cycles of nitrates and chlorophyll-a concentration may be treated as the background processes mediating potential response of the phytoplankton community to propagating cyclones (Figure 1).

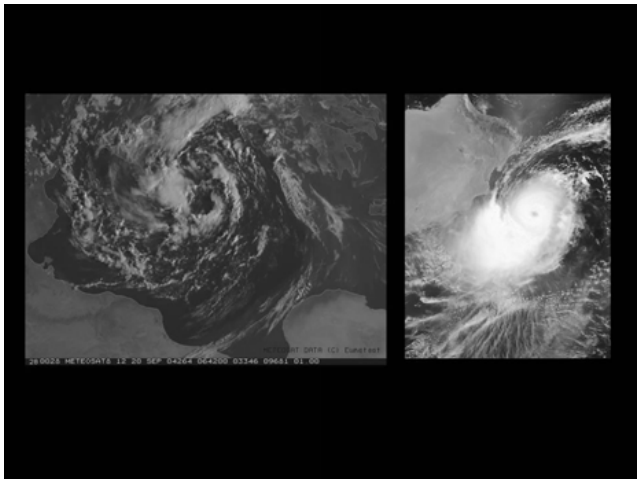

Fig. 1. Cyclone # 040920 in the Mediterranean Sea (left panel) and cyclone "Phet" in the Arabian Sea (http://in.reuters.com/article/idINIndia-49106920100607).

In the western Arabian Sea, seasonal amplitudes of chlorophyll-a exceeded the eastern Mediterranean amplitudes tenfold (Figure 2). In terms of development and duration, seasonal peaks of the Arabian Sea time series have a sharp (pulse-type) form versus a smoothed sinusoidal type typical for oligotrophic Mediterranean waters. In the western Arabian Sea, in 2002-2013, the annually averaged chlorophyll-a concentration exceeded the eastern Mediterranean one by 10 times.

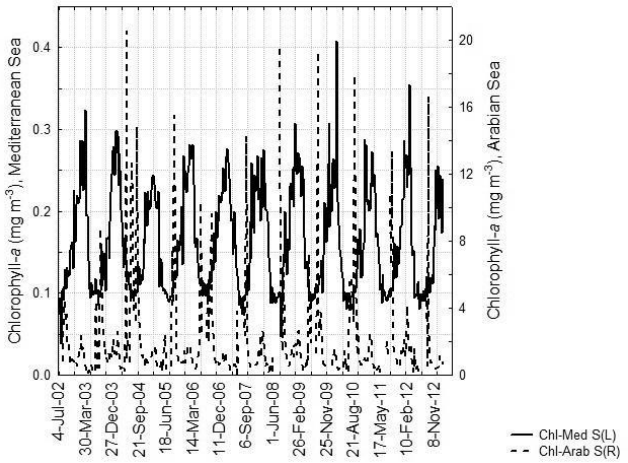

Fig. 2. Seasonal cycles of chlorophyll-*a* concentration in the Mediterranean and the Arabian Seas.

The concentration of nitrates at 100m depth at the time of seasonal chlorophyll peaks was twice as high in the western Arabian Sea compared to the eastern Mediterranean waters. In the Arabian Sea, tropical cyclone #01A has induced gradual amplification of the chlorophyll concentration, with up to a twentyfold increase. This cyclone matched the time of low chlorophyll concentration observed in May. ??The other two cyclones ("Gonu" and "Phet") matched the time of maximal chlorophyll concentrations of the seasonal cycle (in June). The response of the phytoplankton community to these two cyclones was much less pronounced (with about a 1.5 fold chlorophyll increase). In the Mediterranean Sea, the passage of cyclones #071018 and #040920 matched the time of low concentrations (in September-October). The phytoplankton community has responded to propagating cyclones by about a 1.6 fold increase in chlorophyll-a concentration. The cyclone which hit the Gulf of Lyons on March 26 1999, matched the time of high seasonal concentration of chlorophyll. A minor (1.3 fold) chlorophyll increase was observed during the cyclone's passage. The above cases pointed out that presumably, the phase of the chlorophyll seasonal cycle might be one of the important factors mediating the phytoplankton community's response to propagating cyclones. In terms of chlorophyll peaks induced by cyclones, the response might be minimal when cyclones match the time of seasonal chlorophyll peaks in the region, because these peaks reflect the maximal response to the physical-chemical environment the community is capable of producing.

Abstract
This work presents the integration of the *Posidonia oceanica* distribution model (PoDM) for the North African coasts, developed within the MEDINA FP7 Project, in GEOSS (Global Earth Observation System of Systems). It is shown how this implementation represents a contribution in facilitating the use of remote sensing data and ecological models for coastal ecosystem evaluations and monitoring.

Keywords: Posidonia, South-Central Mediterranean, Remote sensing, Models

Posidonia oceanica (L.) Delile is an endemic seagrass species of the Mediterranean sea and the most-widespread and most important species in this region. Moreover, the distribution and population conditions of this species are considered important biological indicators of coastal water quality and coastal ecosystem status [1]. Considering the importance of *P. oceanica*, and the regression of its distribution recorded in recent years [2], the management and conservation of its sensitive habitats is required. The aim of this work is to present the integration of the *P. oceanica* distribution model (PoDM), developed within the MEDINA FP7 Project, in GEOSS (Global Earth Observation System of Systems) – a public infrastructure which connects tools of Earth Observation with monitoring and global changes information systems. Species distribution models are tools that allow relating species distribution to environmental conditions. The model developed within MEDINA, a project aimed at enhancing Northern African Countries capabilities of monitoring coastal areas, was developed using *P. oceanica* distribution data from 5 Mediterranean areas on one side, and bathymetry and chemical-physical data (SST, Chlorophyll, Organic Matter, light *Kd*, Irradiance), derived from satellite observations (AVHRR/MODIS and MERIS) on the other side. The user, after connecting to the server (*http://medina.dais.unive.it:3838/PoDM/*; fig. 1) should take care of gathering the necessary data and all variables need to meet certain characteristics in terms of formats, time and space resolution and extent. All input data should be raster layers and share homogeneous cartographic characteristics. Moreover, all variables, with the exception of bathymetry must be supplied as yearly average, in order to meet model assumptions.

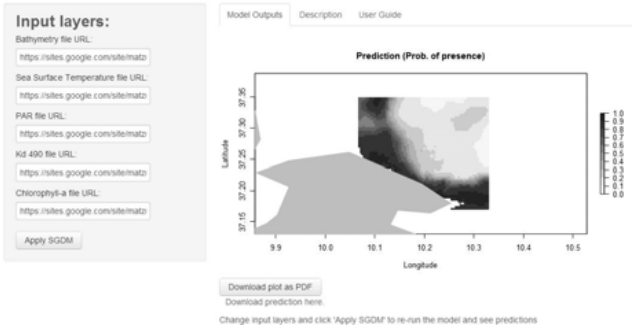

Fig. 1. Screenshot of the web application interface.

In order to override these drawbacks, the integration between the PoDM web application and GEOSS has been developed. In this way, the required input data can be searched, accessed and ingested into the model leveraging the brokering framework of the GEOSS Common Infrastructure (GCI). This framework is comprised of a set of middle-ware components (Brokers) that are in charge of implementing the needed interoperability arrangements to interconnect the heterogeneous and distributed capacities contributing to GEOSS [3, 4]. Figure 2 depicts the architecture of the integration. The MEDINA Spatial Data Infrastructure is integrated with the GEO Discovery and Access Broker (DAB) of the GCI. This allows to transparently discover and access the resources (data and model implementation) which are required to run the model. A high-level description of the steps needed to execute the model is provided using a Business Process Modeling Notation (BPMN) v. 2.0 document. This will be transformed to an executable workflow by a new experimental component, the BP Broker [5], and submitted for execution to a workflow engine. The BP Broker is linked to the GEO DAB for the discovery and access of data. The generated forecasts are then published back on GEOSS through the service bus of the MEDINA SDI which is brokered by the GEO DAB.

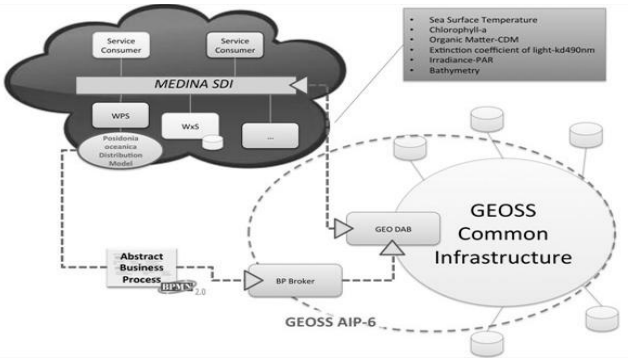

Fig. 2. PoMD web application and GEOSS integration architecture.

The integration between a remote sensing-based species distribution model and GEOSS represents a potentially useful tool open and easily accessible to every users for mapping and evaluating the potential distribution of *P. oceanica* by using satellite data. This could represent an important contribution in support, ease and enhance capabilities of using and integrating remote sensing products and numerical models for coastal ecosystem evaluations and monitoring.

ETUDE DES MACROPHYTES DU GOLF D'ANNABA

Mounia Aouissi [1]*, Hocine Frehi [1] and Farid Derbal [1]
[1] Université Badji Mokhtar Annaba, Laboratoire Bioressources Marines, Algérie - aouissi_m@yahoo.fr

Abstract
Selon l'étude des macrophytes du golfe d'Annaba, on a pu enregistrer la présence de trois groupes d'algues: les Chlorophycées (avec 15 espèces), les Rhodophycées (avec 33 espèces), les Phéophycées (avec 20 espèces) et une Phanérogame représentée par une espèce: *Posidonia oceanica*. Parmi ces espèces, deux sont invasives pour la méditerranée :*Caulerpa racimosa et Asparagopsis armata*.

Keywords: Phanerogams, Posidonia, Infralittoral, Algerian Sea, Supralittoral

Introduction

Les algues jouent un rôle primordial dans le maintien de l'équilibre écologique du milieu aquatique et sont un indicateur de l'état des milieux marins [1]. Leur étude est donc un enjeu majeur et c'est dans ce cadre que s'insère la présente étude. Notre travail consistera à établir un recensement de la flore algale qui se développe dans le golfe d'Annaba (Cap de Garde) et d'essayer de les identifier en établissant un alguier. Elle tend à contribuer à la connaissance des algues marines benthiques (Chlorophycée, Phéophycées et Rhodophycées) du golf d'Annaba et de recenser les différentes espèces qui y vivent [2]. Mais nous n'avons pas la prétention d'établir un inventaire précis car de nouvelles algues sont régulièrement découvertes.

Matériel et Méthodes

Pour nos sorties, nous avons utilisé une embarcation, du matériel de plongée (vêtements de terrain, bouteilles de plongée, lestes, palmes, masque, tuba, gilet stabilisateur) un système GPS ainsi que d'un appareil photographique numérique avec caisson pour les prises de vues. Un quadrat carré en métal galvanisé de côté de 25cm a été utilisé pour délimiter les zones d'échantillonage, des récipients divers, sachets, grattoir. Un multiparamètre type HANA pour mesurer les différents paramètres physiques (Température, salinité, oxygène dissous, pH).

Résultats et Discussion

L'étude des algues marines benthiques (Macrophytobenthos) a mis en exergue une richesse spécifique de 69 espèces: ** 15 *Chlorophyceae* (Algues vertes) ** 33 *Rhodophyceae* (Algues rouges) ** 20 *Phaeophyceae* (Algues brunes) **01 *Phanérogam : Posidonia oceanica* (Tableau 1)

DINOFLAGELLATE CYSTS IN RECENT MARINE SEDIMENTS FROM GULF OF GEMLIK (TURKEY)

N. Balkis [1]*, M. Balci [2], A. Giannakourou [3], A. Venetsanopoulou [3] and P. Mudie [4]

Abstract
In coastal waters, many planktonic organisms produce resting cysts and they have an important ecological role in semi-enclosed areas such as bays and gulfs where they can be a source of algal blooms. The accumulation of harmful algal cysts in the sediments can explain the frequent outbreaks of HABs. The aim of the study is to describe recent dinoflagellate cysts in surface sediments from the Gulf of Gemlik, in eastern Marmara Sea. Approximately 25 different dinoflagellate cyst types were found in sediment samples, collected between August 2010 and May 2011, from 5 stations in the Gulf. These 25 dinoflagellate cyst types were transferred to f/2 culture medium for germination in laboratory studies. This is the first study on cultivation of recent dinoflagellate cysts in Turkish marine waters and this work is ongoing.

Keywords: Dinoflagellates, Sediments, Toxic blooms, Marmara Sea

Ocurrence of HABs influence the marine ecosystem in several ways as they cause structural changes in natural food webs and their effect on aquaculture is of primary economic concern in terms of availability of healthy stocks and in maintaining the local economy [1]. In the last decade, scientific papers have highlighted the use of cyst signals as indicators of eutrophication and industrial pollution. Cysts can rest in the the surface sediments for decades [2], being a reservoir of potential biodiversity. The study of dinoflagellate cysts is one of the important subjects for understanding blooming mechanisms and the oceanographic conditions associated with harmful algal blooms. Cyst banks are not only the witness of past blooms, but also show the potential of what a given basin can produce in the future and are of strategic importance for prediction of red tide events [3,4]. There are very few studies about microalgae resting cysts in recent marine sediments from the Marmara Sea [4]. The Gulf of Gemlik which is located in the south-eastern part of Marmara Sea is a 15 km wide and 35 km long semi-enclosed basin. The maximum depth is 110 m in the middle of a small northwest-trending elliptical central trough which is a fault-controlled depositional area.

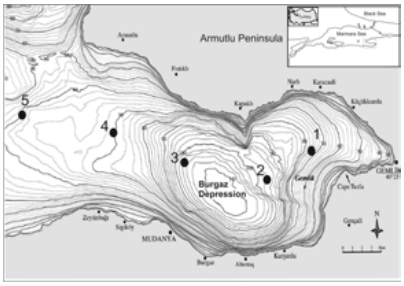

Fig. 1. Sampling stations in the Gulf of Gemlik

Twenty-five different dinoflagellate cyst types were found in sediment samples collected between August 2011 and May 2012 from 5 stations at the Gulf. The study will be an attempt to answer a question of practical interest: could the presence of cysts in the sediments eventually provide an inoculum, leading to the appearance (or initiation) of blooms. The information that will be gained would be a highly valuable contribution to the study of HAB development. Cyst cultures also germinate benthic resting cysts and link them with thecate plankton species, contributing to knowledge of theca-cyst taxonomy.

SUMMER PICOEUKARYOTIC DIVERSITY IN THE GULF OF GABES

A. Bellaaj zouari [1]*, M. Bel Hassen [1], B. Baccouch [1], F. Akrout [1] and A. Hamza [1]
[1] INSTM Salammbô, Tunisie. - amel.zouari@instm.rnrt.tn

Abstract
The investigations of picoeukaryotic diversity, hydrographical water properties and nutrient contents were carried out during June 2008 in the Gulf of Gabes (south-western Mediterranean Sea). Denaturing gradient gel electrophoresis (DGGE) analysis revealed a spatial and vertical diversity of the eukaryotic picoplankton community. The diversity is more important in offshore stations than in coastal area, notably at the thermocline. The vertical distribution of nutrients is almost homogeneous whereas an increasing surface gradient toward the offshore area was detected for both temperature and salinity. Eukaryotic sequences affiliated to picoeukaryotic organisms and to Metazoans were obtained and results suggest that the picoeukaryotic assemblages in the Gulf of Gabes were influenced by the hydrographical water structure.

Keywords: Plankton, Gulf of Gabes, Biodiversity

Introduction

Eukaryotic picoplankton organisms are important players in global carbon cycling. They contribute significantly to both phytoplankton biomass and primary production. Exploration of picoeukaryotic diversity is essential to understand their community structure and distribution patterns. In recent years, the introduction of molecular biology methods, such as Denaturing Gradient Gel Electrophoresis (DGGE), provided a new insight on the genetic diversity of the picoplankton [1]. The DGGE approach offered a reasonably detailed view of marine picoeukaryotic assemblages and allowed a direct analysis of gene sequences in natural samples leading to the phylogenetic identification of the dominant members [2,3]. In the Gulf of Gabes, different studies on the composition and the variability of phytoplankton organisms in relation to hydrographical properties and water masses nutrient contents have been conducted using CHEMTAX analysis of HPLC pigment data [4,5,6]. However, composition of picoeukaryotic community has not yet been examined with molecular biology approaches. The object of this study is to investigate the diversity of picoeukaryotic organisms in the Gulf of Gabes using DGGE approach; and to analyze the physico-chemical water properties and the availability of nutrients to determine their effect on the structure and distribution of picoeukaryotic community.

Material and methods

Sampling was conducted in the Gluf of Gabes (33-35°N and 10-11°E) at different depths of 15 stations with Niskin bottles attached to a rosette and a conductivity, temperature and depth probe (Seabird 9). To collect the picoplankton biomass, seawater was pre-filtered through a GF/D membrane (whatman) and then filtered on a 47 mm diameter membrane filter with a 0.45µm pore size; which is transferred immediately into a cryovial tube containing 3 ml of DNA lysis buffer [7]. Cryovials were then stored in liquid nitrogen. DNA extraction was achieved by a phenol chlorophorm protocol [8]. DNA yield was quantified by NanoDrop (Thermo). PCR amplification with the primers Euk1A and Euk 516r-GC and DGGE analyses were carried out according to Dièz et al. [2]. DNA bands were cut and transferred to microcentrifuge tubes that contained 80 µl of MQ water. They are incubated firstly at 37°C for 4h with stirring and secondly at 4°C overnight. A sample of 20µl was used as PCR template for PCR reamplification with Euk1A and Euk 516r primers. PCR products were purified and then subjected to sequencing. For nutrient analysis, seawater was stored at -20°C and then analyzed with an automatic analyzer type 3 (BRAN + LUEBBE).

Results and Discussion

The vertical temperature distribution exhibited a decreasing gradient with depth. Whereas, the density, particularly influenced by the temperature gradient, showed a high surface to bottom increasing. Both the surface temperature and salinity surface increased toward the offshore area. The vertical distribution of nutrients is almost homogeneous throughout the water column. The low detected concentrations of phosphorus suggested that this nutrient could be the first limiting factor for phytoplankton growth. This finding is consistent with reports of P limitation in the Mediterranean Sea [9]. The Comparison of the obtained DGGE fingerprints revealed that the diversity of picoeukaryotic community in offshore stations is more important than that in coastal water. At offshore stations, an important diversity is distinguished at the thermocline. The important diversity detected at the offshore stations could be related to distinct water masses described in the Gulf of Gabes [5]. The dendrogram analysis showed that the samples are grouped according to their positions in the water column. These results are similar to those of Diez et *al*., [2]. Sequences obtained from extracted gel bands were affiliated to Metazoans and to picoeukaryotic organisms. Metazoa sequences corresponding to Crustacea, Mollusca and Cnidaires groups could originate from sperm cells [3]. Our results revealed a spatial and vertical diversity of the picoeukaryotic community in the Gulf of Gabes and suggested that the environmental factors control their composition and distribution.

RELATIONSHIPS BETWEEN OTOLITH SIZE AND MASS VERSUS FISH SIZE AND WEIGHT IN *GNATHOPHIS MYSTAX* (DELAROCHE, 1809) FROM THE SIGACIK BAY (SOUTHERN AEGEAN SEA)

Gökçen Bilge [1]*, Halit Filiz [1] and Anil Gülsahin [1]
[1] Mugla Sitki Kocman University Faculty of Fisheries - gbilge@mu.edu.tr

Abstract
Length, height and weight of the sagittal otoliths versus fish length and weight relationships of the *Gnathophis mystax* specimens were investigated. Fish specimens were collected during the period July-September 2007 throughout off the Sigacik Bay using bottom trawls. Calculated regressions were displayed a high coefficient of determinations ranging between 0.910 - 0.986. The linear and non-linear functions provided the best fit for %44 and %56, respectively.

Keywords: Deep sea ecology, Fishes, Aegean Sea

Introduction
Gnathophis mystax (Thinlip conger) is a demersal fish species living on the shelf and on upper slope, on muddy bottoms between 80 - 800 m and it's distributed in eastern Atlantic and Mediterranean [1]. *G. mystax* is also known from the Aegean Sea and the Mediterranean coasts of Turkey [2]. The otoliths are one of the most important tools for understanding the life of fish and fish populations for the fisheries biologists [3]. They are widely used in stomach content analysis because they are one of the last species-specific features to be digested in the digestive systems of piscivorous predators and they are important tool for prey classification. The aim of this study is to fill in the missing data concerning otolith and fish size relationships of the species in the Aegean Sea, thereby providing researchers studying food habits of top predators to determine the size and weight of prey fish from length or weight of recovered otoliths.

Material and Methods
Specimens (n= 205) were collected via commercial bottom trawl vessels from the upper slope of the Sigacik Bay at depths between 296-603 meters during the year of 2007. Fishes were weighted (W in g) and measured (TL, in mm). Sagittae (Fig. 1) were removed to expose them then cleaned and stored dry in glass vials and left and right otolith were considered separately. Each sagitta was placed with the sulcus acusticus oriented through the observer and otolith length (OL, in mm) was determined [4]. Otolith height (OH, in mm) was measured. Individual otolith weight (OW-in mg) was determined. The paired t-test was used to check any differences between left and right otolith pairs. When significant differences ($p<0.05$) were not found, a single regression was used for each parameter (OL, OW and OH). Linear ($Y = ax+b$) and exponential ($Y = ax^b$) regression equations were fitted to determine what equations (TL-OL, TL–OH, TL–OW, W–OL, W–OH, W–OW, OW–OL, OH-OL and OW-OH) best described various relationships between otolith and fish size [5].

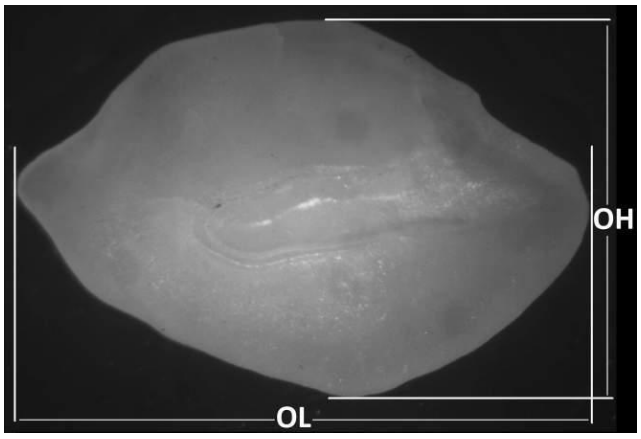

Fig. 1. Sagittal otolith and measurements of *Gnathophis mystax* (342 mm TL, 7.8 mm OL).

Results and Discussion
Minimum, maximum, average (± SD) values were found for total length as 191, 349, 269.4 (± 40.3) mm; for fish weight as 5.79, 53.77, 22.89 (± 11.27) g; for otolith length as 4.92, 8.01, 6.47 (± 0.71) mm; for otolith height as 3.12, 5.23, 4.23 (±0.52) mm and for otolith weight as 0.0228, 0.1405, 0.0700 (± 0.0300) g, respectively. No significant differences (t-test for paired comparisons, $P>0.05$) were found between left and right otolith size and weight data. Left sagittae measurements were used for the calculation of equations. Relationships between fish and otolith measurements were given in Table 1. Although, there are some identification guides for western Mediterranean and Atlantic Ocean, data about sagittal otolith morphometrics are limited with some species specific papers for eastern Mediterranean. Morphometric data of the sagittal otoliths of two *G. mystax* specimens (TL= 270 and 380 mm) were reported (in ratio of OL/TL= 2.3-2.8 and OH/OL= 62.1-64.2) from the western Mediterranean [6]. In the present study, these ratios were calculated between 2.1-2.8 and 58.0-79.2, respectively. Larger sample size and length intervals samplings may affect the results.

Tab. 1. Intercept values (a), regression slope (b) and coefficients of determination (r^2) for linear (L) and exponential (E) relationships between otolith morphometric parameters, fish length and weight of *Gnathophis mystax*.

	Relationship	Regression	a	b	r^2
Fish Length	TL vs. OL	L	54.33	- 81.851	0.922
	TL vs. OH	L	76.778	- 55.679	0.967
	TL vs. OW	E	721.39	0.3567	0.941
Fish Weight	W vs. OL	E	0.0068	4.2976	0.910
	W vs. OH	E	0.0672	3.9769	0.956
	W vs. OW	L	410.74	- 4.4178	0.986
Otolith	OW vs. OL	E	9E-05	3.5345	0.923
	OH vs. OL	L	0.6993	- 0.2871	0.931
	OW vs. OH	E	0.0006	3.2609	0.963

DIFFÉRENCIATION MORPHOLOGIQUE ET OTOLITHOMÉTRIQUE D'*ATHERINA BOYERI* (RISSO, 1810) DANS TROIS HABITATS CÔTIERS DE L'EST DE L'ALGÉRIE.

Ahmed Sofiane Boudinar [1]*, Lamya Chaoui [1] and Mohamed Hichem Kara [1]
[1] Laboratoire Bioressources Marines, Université Badji Mokhtar-Annaba, BP 12, 23000 Annaba, Algérie. - boudinar-2009@live.fr

Abstract
L'analyse de la morphologie somatique et de la forme des otolithes (sagittae) de l'athérine *Atherina boyeri*, issue de 3 habitats des côtes Est de l'Algérie, permet d'identifier 3 groupes distincts. Ces résultats vont dans le même sens que les connaissances antérieures qui montrent l'existence de 2 ou 3 espèces au sein de ce complexe et permettent, en plus, d'identifier un autre morphe rattaché à l'Oued Ziama.

Keywords: Biometrics, Algerian Sea, Lagoons, Fishes, Estuaries

Introduction
Atherina boyeri (Risso, 1810) est un petit poisson euryhalin vivant dans les eaux côtières, les estuaires et les lagunes et peut former des populations denses dans les eaux douces. Il est commun en Méditerranée et dans l'Atlantique Nord-Est. *A. boyeri* constitue un complexe subdivisé en 3 espèces, une lagunaire (*A. lagunae*) et deux marines (ponctuée *A. punctata* et non ponctuée *A. boyeri*) (Trabelsi, 2002a et 2002b). Cette étude utilise la morphologie somatique et la forme des otolithes pour comparer les athérines issues de 3 sites de nature différents dans l'Est algérien: la lagune Mellah, le golfe d'Annaba et l'embouchure de l'Oued Ziama.

Matériels et méthodes
La morphologie de 754 spécimens appartenant à quatre populations d'*Atherina boyeri* provenant de trois sites est décrite en utilisant 14 paramètres métriques et 9 autres numériques: lagune Mellah (n = 269; 2,0 ≤ Lt ≤ 8,3 cm), Golfe d'Annaba (n = 194 individus non ponctuée; 4,6 ≤ Lt ≤ 13,1 cm et 144 individus ponctués; 5,4 ≤ Lt ≤ 10,7 cm), embouchure Oued Ziama (n = 147; 2,9 ≤ Lt ≤ 10,2 cm). Une analyse factor discriminante est appliquée pour différencier les 4 échantillons. La forme des otolithes a aussi été utilisée comme outil de différentiation de ces populations. Les contours de 452 otolithes (sagittae) (69 lagunaires, 51 marins non ponctués, 40 marins ponctués, 66 estuariens) ont été numérisés et analysés en utilisant le programme TNPC (5.0). Une analyse factorielle discriminante a été également appliquée en utilisant les descripteurs de Fourier (Shape V 1.3). La comparaison des caractères numériques est basée sur l'utilisation du coefficient de différence CD de Mayr-Lynsley-Usinger qui permet de déterminer le niveau taxonomique des échantillons.

Résultats
Un test du succès de la classification de la discrimination indique un bon taux de reclassification en utilisant les caractères métriques (71,9%) ou les descripteurs de Fourier (84,3%). Les résultats de l'analyse discriminante, basés sur les caractères métriques, montrent que ces populations ne sont pas homogènes (Wilk's lambda = 0,194, p < 0.001) et peuvent être séparées en trois groupes distincts (fig. 1).

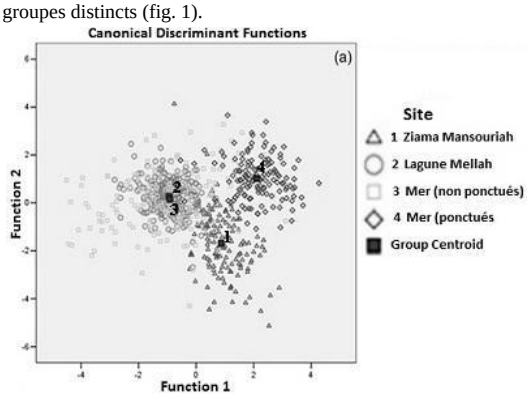

Fig. 1. Représentation graphique de l'analyse factorielle discriminante utilisant les caractères métriques.

Le premier contient les individus de la lagune Mellah et ceux non ponctués du golfe d'Annaba, le second contient les poissons ponctués du golfe d'Annaba et le troisième est formé des athérines de l'oued Ziama.L'analyse de la forme des otolithes confirme cette structure en trois groupes (Wilk's lambda = 0.062, p < 0.001) (fig. 2), exprimée en particulier par la différence de rondeur des otolithes. Enfin, l'analyse des caractères numériques distingue 4 groupes en séparant, en plus, les individus de la lagune Mellah de ceux non ponctués de la mer adjacente.

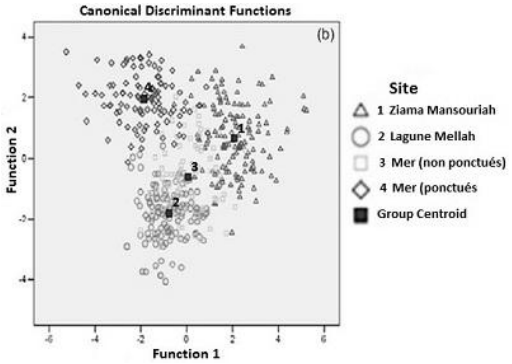

Fig. 2. Représentation graphique de l'analyse factorielle discriminante utilisant les descripteurs de fourrier.

Discussion
Les caractères somatiques, métriques et numériques, associés à la forme de l'otolithe sagittae d'*Atherina boyeri* des côtes de l'Est algérien nous ont permis de reconnaitre trois groupes distincts. Ces différences peuvent être attribuées à la grande plasticité morphologique reconnue de cette espèce en fonction de son environnement, mais pourrait aussi correspondre aux résultats des travaux de Trabelsi *et al*. (2002a et 2002b)et Klossa-Kilia *et al*. (2007) qui reconnaissent la complexité du taxon *Atherina boyeri* et son organisation en 2 ou 3 espèces. Cependant, l'occurrence d'un autre groupe issu de l'embouchure de l'Oued Ziama mérite notre attention. Les analyses génétiques en cours sur ces populations nous permettraient d'en savoir davantage.

MORPHOLOGIE ET CROISSANCE RELATIVE DE QUELQUES LABRIDAE (TÉLÉOSTÉENS) DES CÔTES EST ALGÉRIENNES

Naima Boughamou [1]*, Farid Derbal [1] and Mohamed Hichem Kara [1]
[1] Laboratoire Bioressources Marines, Université Badji-Mokhtar, Annaba, Algérie. - boughamounaima@gmail.com

Abstract
Cette étude fournit les premiers résultats sur la morphologie et la croissance relative de quelques Labridae communs sur les côtes est algériennes. Chez *Symphodus tinca*, l'allométrie majorante concerne 13/14 paramètres. Seul le diamètre orbitaire (Do) présente une allométrie minorante. Chez *Xyrichthys novacula*, un total de 11/14 paramètres présentent une isométrie de croissance seulement 2/14 paramètres montrent une allométrie majorante et un seul paramètre présente une allométrie minorante (Ls). La croissance relative est isométrique chez *S. tinca*, *Labrus merula* et *X. novacula* et majorante chez *S. ocellatus*.

Keywords: Fishes, Biometrics, Growth, Algerian Sea

Introduction
Les Labridae sont des téléostéens côtiers qui habitent les herbiers à Zostère et à Posidonie ainsi que les fonds mixtes (rochers-algues) [1, 2]. *Symphodus tinca, S. ocellatus, L. merula* et *X. novacula* sont des espèces assez communes sur les côtes orientales d'Algérie [3] mais qui ne sont pas connues. Nous fournissons ici les premiers résultats sur la morphologie de *S. tinca* et *X. novacula* et la relation longueur-masse de *S. tinca, S. ocellatus, L. merula* et *X. novacula* des côtes est d'Algérie.

Matériel et méthodes
Les échantillons de Labridae (245 *S. tinca* pour la biométrie et 556 pour l'étude de la relation longueur-masse, 74 *S. ocellatus*, 61 *L. merula*, 147 *X. novacula*) proviennent de la pêche artisanale et expérimentale pratiquée dans le golfe d'Annaba (est, Algérie). La caractérisation morphologique s'est effectuée à partir de 8 paramètres numériques et 15 paramètres métriques. La longueur et la masse totales ont été respectivement exprimées en centimètre et en gramme.

Résultats et discussion
Les nageoires dorsales et anales de *S. tinca* comportent respectivement 14 à 16 et 3 rayons durs, et 11 à 12 rayons mous. Le nombre d'écailles de la ligne latérale est compris entre 33 et 38. Le nombre de branchiospines inférieures et supérieures varie respectivement entre 9 et 13 et entre 0 et 3. Le nombre de vertèbres est égal à 34. Chez *X. novacula*, les nageoires dorsales et anales comportent respectivement 9 et 3 rayons durs, et entre 12 et 13 rayons mous avec un nombre de 25 vertèbres. Le nombre d'écailles à la ligne latérale varie 24 et 29. Le nombre de branchiospines inférieures et supérieures varie respectivement entre11 et 12, et entre 6 et 7. Ces valeurs des caractères numériques observées chez *S. tinca* et *X. novacula* des côtes est algériennes sont proches ou égales de celles rapportées en Méditerranée [4].Une corrélation très hautement significative a été observée chez *S. tinca* ($0,832 \leq r \leq 0,997$; $P \leq 0,001$) et *X. novacula* ($0,579 \leq r \leq 0,988$; $P \leq 0,001$) pour l'ensemble des paramètres morphométriques examinés en fonction de la longueur totale ou celle de la tête. Chez *S. tinca*, l'allométrie majorante concerne 13 paramètres métriques et elle est minorante pour le diamètre orbitaire. Chez *X. novacula* les paramètres suivants : longueur pré-dorsale, diamètre orbitaire, longueur pré-orbitaire, longueur post-orbitaire, longueur pré-pectorale, longueur post-pectorale, longueur pré-anale, hauteur du corps, épaisseur du corps, diamètre inter-orbitaire et hauteur du pédoncule caudal, présentent une isométrie de croissance, alors que les longueurs céphalique et du maxillaire supérieur montrent une allométrie majorante. La longueur standard présente une allométrie minorante. La croissance relative est isométrique chez *S. tinca* (r = 0,956 ; b = 2,97 ; tobs = 0,791 ; N = 556), *L. merula* (r = 0,924 ; b = 3,082 ; tobs = 0,547 ; N = 61) et *X. novacula* (r = 0,923 ; b = 2,945 ; tobs = 1,504 ; N = 147), alors qu'elle est majorante chez *S. ocellatus* (r = 0,948 ; b = 3,251 ; b = 2,159 ; N = 74). La croissance relative est respectivement minorante, isométrique et rapide chez *S. tinca* (b = 2,875), *S. ocellatus* (b = 2,966) et *L. merula* (b = 3,186) dans les zones ouest de la Méditerranée [5], tandis que la masse croit au même rythme que la taille chez *X. novacula* dans les zones centrales du même bassin [6]. Ce changement des valeurs de b dépend de plusieurs facteurs, aussi bien biotiques (forme du poisson, quantités de graisse stockées, nourriture, sexe, stade de maturité) qu'abiotiques (température, salinité) [7, 8, 9].

SHELL SHAPE DIFFERENTIATION IN THE THREE MORPHOTYPES OF THE MEDITERRANEAN LIMPET *PATELLA CAERULEA* (LINNAEUS, 1758)

Jihen Boukhicha [1]*, Oum Kalthoum Ben Hassine [1] and Sabiha Tlig-Zouari [1]
[1] Faculty of sciences of Tunis University of Tunis El Manar, Tunis,Tunisia - boukhicha.jihen73@gmail.com

Abstract
Shell shape differentiation in the three *Patella caerulea* morphotypes was studied along the Tunisian coastline. Statistical analysis revealed morphometric variability mainly associated to shell height and radula length. Both var. *subplana cognata* and var. *subplana stellata* showed a partial morphometric overlap.The study indicated that in addition to external shell architecture, the three *P. caerulea* morphs also exhibited different shell shapes. Therefore, morphometrics seems to be efficient to distinguish different *P. caerulea* morphotypes with enough precision.

Keywords: Gastropods, Biometrics, Mediolittoral, Mediterranean Ridge

Introduction
Patella caerulea (Linnaeus, 1758) is endemic to the Mediterranean. It has a wide vertical distribution and colonizes different types of micro-habitats, this feature results in high morphological diversity. Two forms were reported for this species ([1]): the classic morphotype with regular thin ribs and smooth edge and *subplana* morph with large protruding ribs and irregular angular edge. The latter presents two forms: *cognata* characterized by slightly vertically curved ribs around the peristome (*P. caerulea* var. *subplana cognata*) and *stellata* characterized by a flat star-shaped shell due to the angular extensions of the ribs (*P. caerulea* var. *subplana stellata*). In order to highlight the possible shell shape variations between these three morphs, a comparative morphometric study was performed.

Material and methods
A total of 391 specimes of *P. caerulea* was collected from 10 rocky stations covering the entire Tunisian coastline (from Algero-Tunisian (Tabarka) to Tuniso-Libyan (Zarzis) frontiers). The classification adopted by [1] was used to identify each specimen's morph. Shell length (SL), shell width (SW), shell height (SH), shell length from apex to anterior end (SAA) and from apex to posterior end (SAP) and radula length (RL) were measured to the nearest 0.01mm using a digital caliper.
All parameters were Log transformed in order to increase linearity and multivariate normality ([2]). Size dependent variation was removed using an allometric approach ([3]). Data were transformed using the following formula: Mtrans = logM – β (log SL - log SLmean), where Mtrans is the transformed measurement, M the original measurement, β the within-group slope regressions of the log M vs. log SL, SL the shell length, and SLmean the overall mean of the shell length.
A discriminant function analysis (DFA) on transformed data was performed to estimate the contribution of each shell character to group separation and illustrate the spatial separation between the centroids of the three morphs. Wilks' lambda was subsequently estimated to test the significance of the difference between the identified groups means. In order to discern the possible overlap between the morphology of the three studied morphs, percent classification success (PCS) was evaluated, for each morph, as the percentage of correct re-classification of individuals in discriminant analysis.

Results and discussion
Based on the observation of the external shell architecture, 149 individuals of the classic form, 122 *P. caerulea* var. *subplana cognata* and 120 *P. caerulea* var. *subplana stellata* were identified.
The contributions of the morphometric variables to group separation are shown in Fig.1. The two first discriminant functions explained 79% of inter-group variability. The DFA plot (Fig.2) showed discrimination between the three studied morphs which was proved by wilks' lambda (Wilks' lambda = 0.0526, F=6.4165, p<0.001). Morphometric differences were mainly related to shell height and radula length which were more important in the classic morph. However, a partial overlap between the two morphs of the var. *subplana* was observed.
91% of the classic form, 64% of var. *cognata* and 67% of var. *stellata* were cross-validated correctly into their putative groups, confirming the classic morph distinction and the overlap between var. *cognata* and var. *stellata*. Morphometric differentiation between the two latter morphs was mainly associated to shell width and the anteroposterior position of the apex.

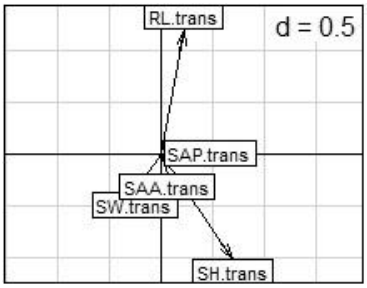

Fig. 1. Transformed variable contribution in the discrimination of groups.

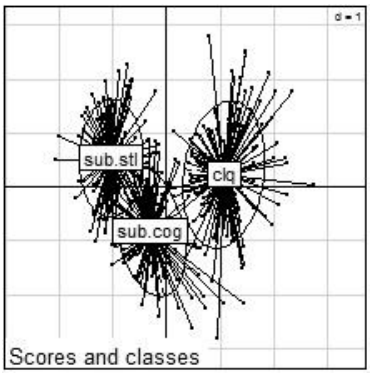

Fig. 2. Discriminant function scores for the three morphs.

The results suggest that in addition to the variations in the shell radial ribs architecture ([1]), the three morphotypes of *P. caerulea*, also exhibit shell shape differences. Therefore, morphometrics seems to be efficient to distinguish different *P. caerulea* morphs with enough precision. Shape variability in these three morphotypes can be considered as an expression of phenotypic adaptation to the extremely diverse intertidal rocky shore environments and reinforces the morphological plasticity reported in limpets. These morph specific phenotypic traits seem to confer physical advantages for the survival of each morphotype in its respective niche.

ETUDE SYSTÉMATIQUE, PHYLOGÉNÉTIQUE ET PHYLOGÉOGRAPHIQUE DE QUELQUES ESPÈCES DE PATELLES

Zoheir Bouzaza [1]* and Karim Mezali [1]
[1] Faculté des sciences Exactes et Sciences de la Nature et de la Vie - riskemall@yahoo.fr

Abstract
Une étude phylogénétique et phylogéographique sur quelques espèces de Gastéropodes prosobranches a été réalisée sur la côte algérienne afin de comprendre le patron de connectivité entre leurs populations, en expliquant par les données paléontologiques les causes de leur divergence. Ceci nous a donné une idée sur la plasticité morphologique des patelles étudiées puisque l'aspect morphologique ne pouvait pas toujours être un critère de raprochement intraspécifique. Aussi, nous avons pu constater que la divergence et la répartition géographique entre les espèces de patelles étudiées concordait avec certains bouleversements paléontologiques, ce qui pourrait être la cause des divergences des espèces étudiées.

Keywords: Biogeography, Algerian Sea

Introduction: le but de ce travail est d'étudier la phylogénie et la phylogéographie de deux gastéropodes Prosobranches [*Patella rustica* (Pr) et *Patella ferruginea* (Pf)] pour comprendre les models de connectivité entre leurs populations, en expliquant, par les données paléontologiques , les causes de leurs différences, leur répartition et leurs réponses aux changements environnementaux.
Matériel et méthodes: l'échantillonnage a été fait dans quelques stations de la côte Algérienne. Après avoir identifié les espèces morphologiquement, nous avons effectué le travail moléculaire (extraction d'ADN, PCR, séquençage de l'ADN ...) en utilisant le marqueur mitochondrial « COI ». Les résultats de séquences de l'ADN mitochondrial obtenus ont été traités à l'aide de quelques logiciels telque « codon code Aligner 3.7.1 » disponible en (http://www.codoncode.com/aligner) pour l'alignement de séquence, "MEGA 5.03" (Tamura et al., 2011) pour la construction d'un arbre phylogénétique suivant la méthode du maximum de vraisemblance "ML" en utilisant le modèle de "Juke-Cantor (1969)" et «Network 4.6 » (Polzin & Daneschmand, 2011) pour la construction d'un réseau d'haplotypes en utilisant le procédé « Median Joining». Nous avons utilisé le modèle de «l'horloge détendue » avec une distribution log-normale du taux de substitution en utilisant deux valeurs différentes (0,6% et 1,2% par million d'années "MA") Hellberg & Vacquier (1999).
Résultats et discussion: les données génétiques nous ont montré que certains individus morphologiquement identifiées autant que *Patella rustica* appartiennent en fait à l'espèce *Patella caerulea* (Pc) (Fig. 1).

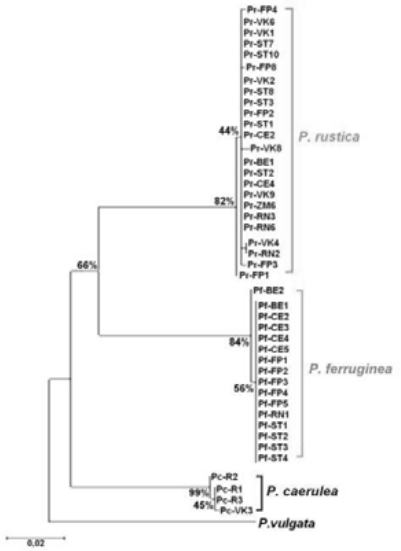

Fig. 1. Arbre phylogénétique des espèces étudiées établi par la méthode « ML » avec un nombre de réplicas bootstrap de 100.

L'arbre phylogénétique (Fig. 1) nous montre que les deux formes de *Patella ferruginea* (Rouxii et Lamarkii)
(J. Christiaens, 1973) sont situées dans un même clade avec des morphotypes appartenant à la même espèce. Le réseau d'haplotypes (Fig. 2) montre qu'il existe une distribution en étoile des espèces étudiées qui peut être expliqué par une récente explosion démographique après le dernier maximum glaciaire.

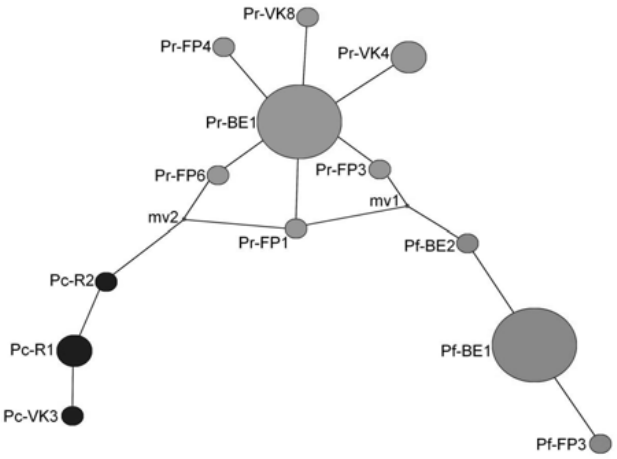

Fig. 2. Réseaux d'haplotypes représentant les espèces de patelles étudiées. Pf, *Patella ferruginea* ; Pr, *Patella rustica* ; Pc, *Patella caerulea*.

La divergence entre les espèces *Patella ferruginea* et *Patella rustica* étudiées se situe entre 8. 25 et 4,125 MA, cela aurait pu être produit pendant l'ère Messinien où le niveau de la mer avait diminué considérablement, ce qui a donné lieu à un isolement génétique créant une spéciation allopatrique.

THE ROLE OF FISHERY IN THE ENERGY BUDGET OF BURULLUS LAKE: INSIGHTS FROM A FOOD WEB MODEL AND LINKS WITH ECOSYSTEM STATUS MONITORING AND ASSESSMENT

Daniele Brigolin [1]*, Fabio Pranovi [1] and Roberto Pastres [1]
[1] Università Ca' Foscari Venezia - brigo@unive.it

Abstract
This work aims at investigating the role played by fishery in the energy budget of the Burullus lake (Nile Delta, Egypt). The food web was reconstructed by means of an inverse methodology of linear estimation, based on an extensive review of published field studies performed during the early 2000s. A subsequent network analysis allowed to derive a set of measures which could be of interest in the context of the implementation of the UNEP-MAP approach for ecosystem status monitoring and assessment. Results pointed out that the detrital path can play a significant role in sustaining catches, and the relevant export of organic matter associated to fishery is important for maintaining the system around its equilibrium.

Keywords: Food webs, Fisheries, Models, Nile Delta

Introduction: Burullus, located in the Kafr El-Sheikh Governorate, is the most central of the Nile delta lakes. The wetland, which extends for about 410 km^2, is an important spot for breeding and wintering of different waterfowl populations, and was designated as a Ramsar site in 1988. After the Aswan high dam completion the lake became subjected to strong inputs of drainage waters, experiencing very few exchange with the sea, limited in time, and restricted to the area nearby the Bughaz canal. The constant load of inorganic nutrients from the drainage basin stimulated an elevated trophism of the site, and was capable to sustain a relevant increase in fishery landings, mostly Mugilidae and Cichlidae, which started in the eighties and peaked in the early 2000s, at about 60000 tons (GAFRD statistics; Rahman, 2011). The estimation of mass and energy fluxes in fishery exploited systems is a topic of high applied interest, since these fluxes are the basis to calculate integrated measures, which can contribute to the monitoring and assessment of the ecosystem status. In particular, in the framework of the Ecosystem Approach implementation proposed by the Mediterranean Action Plan of the United Nations Environment Program (http://www.unepmap.org), these indexes could contribute to Ecological Objective 4 ("Alterations to components of marine food webs caused by resource extraction or human-induced environmental changes do not have long-term adverse effects on food web dynamics and related viability"). The model study here presented was carried out in the framework of the MEDINA project "Marine Ecosystem Dynamics and Indicators for North Africa" (EU 282977). A steady-state model for lake Burullus was balanced by means of an inverse methodology of linear estimation. Model application was specifically focused on the role played by fishery in the energy budget of the lake food web, and compares the energy resources provided by primary producers and organic detritus for sustaining consumers and fishery.

Methods: species were aggregated in compartments on the basis of the similarity in size and feeding ecology. The resulting lake food web included 15 living compartments, and 1 dead dissolved and/or particulate organic matter, see Table 1. Data, which main references are summarized in Table 1, were collected between 2000 and 2004. The resulting linear system of 16 mass-balance equations was under-determined, and was therefore solved using the inverse methodology by van Oevelen et al. (2009). Model constraints were set on the basis of general eco-physiological knowledge of system functioning (growth, assimilation and ecotrophic efficiencies), and site-specific information on fishery landings, primary productivity and gut contents.

Preliminary results:results suggest that a relevant fraction of the synthesized organic matter is not directly conveyed to higher trophic levels through grazing, but first accumulates in detritus. This detrital path seems to play a significant role also for sustaining the declared catches. In such a situation, the high export from TL2 (on an integer scale representation), associated to fishery, could induce a positive feedback on the system, preventing from a potentially dangerous accumulation of organic matter which could lead to dystrophic crises. This could represents an interesting case study within the context of the ecosystem based management, in which typical negative effects due to the exploitation activities are in some way counterbalanced by positive feedbacks. The set of ecosystem functioning indexes, derived by estimated fluxes, could provide an useful basis to assess the Burullus lake status in the early 2000s, constituting also a base for future comparison with different states reached by the system as a consequence of changes in the human induced pressures.

INFESTATION STATUS OF GNATHIID ISOPOD JUVENILES PARASITIC ON *MULLUS BARBATUS* (L. 1758) OFF THE NORTHERN SICILIAN COAST (MEDITERRANEAN SEA)

B. Busalacchi [1]*, T. Bottari [1], R. Forzano [1], E. Armeli Minicante [1] and P. Rinelli [1]
[1] Istituto per l'Ambiente Marino Costiero - CNR - barbara.busalacchi@iamc.cnr.it

Abstract
The host-parasite relationship between the gnathiid isopods and the red mullet (*Mullus barbatus*) was studied off the northern Sicily coast. The relationships between parasitic prevalence and sex and age of host have been evaluated.

Keywords: Fishes, Parasitism, Tyrrhenian Sea

Introduction
Gnathiid isopods are temporal parasites of teleosts and elasmobranchs as well. The larvae are hematophagous feeding on the blood of the host through attaching to their fins, nostrils, lips, eye rims, oral cavity, and especially gills. Adults live freely on sandy-muddy bottom. Recently gnathiid larvae on *Mullus barbatus* gills in the Southern Tyrrhenian Sea have been reported (1). The aim of the present study is to describe the relationships between parasitic prevalence and sex and age of *M. barbatus.*

Methods
Three experimental trawl surveys were conducted on May 2011 and 2012 and October 2011 along the northern Sicily coast. A total of 308 specimens of *M. barbatus* were caught, frozen on board and sent to laboratory. Fish were measured (mm) and dissected to identify their sex. The sagittal otoliths were extracted, cleaned and stored dry. The entire gills were removed and examined under a stereomicroscope for the presence of ectoparasites. Two readers aged the otoliths twice using a stereomicroscope under reflected light (2). The prevalence of infestation, mean intensity and mean abundance, with relative 95% confidence intervals, were calculated using the software 'Quantitative Parasitology 3.0' (3).

Results and discussion
Gnathiid larvae with full and empty stomach were observed on *M. barbatus* at the same time. The parasite prevalence was 19.3 and 9.1 in host males and females, respectively. This difference was statistically significant (Fisher's exact test, $p < 0.05$). The prevalence by age class ranged from 0 to 26.3% (Table 1). The III age class showed the highest prevalence (26.3%). Prevalence and abundance were higher in October than in May (Table 2; Fisher's exact test, $p<0.01$; Bootstrap 2-sample t-test, $p<0.01$). Apparently the gnathiid isopods are not host specific being described in a large number of species. The values of prevalence and intensity reported in this study are lower than reported for *Dentex dentex, Epinephelus aeneus* and *E. marginatus* (4, 5). No relationship between age and prevalence and intensity was revealed.

RP-HPLC DETERMINATION OF CAFFEIC ACID IN *ZOSTERA NOLTII* FROM TURKISH COASTLINES

Levent Cavas [1]*, Hakan Alyuruk [2] and Gamze Topcam [1]
[1] Dokuz Eylül University, Faculty of Science Department of Chemistry - levent.cavas@deu.edu.tr
[2] Dokuz Eylül University, Institute of Marine Sciences and Technology, Izmir, Turkey

Abstract
Zostera noltii biosynthesizes important bioactive compounds such as caffeic, zosteric and rosmarinic acid.In the present work, seasonal variation of caffeic acid in *Zostera noltii* detritus from Turkish coastlines was determined by reverse phase HPLC.

Keywords: Biotechnologies, Chemical analysis, Detritus, Aegean Sea

Introduction:
Zostera noltii (Hornemann, 1832) is a dwarf eelgrass species widely distributed along Turkish coastlines. This species is generally located at the shallow coastal waters and at the entrances of the estuaries. Biosynthesis of protective and defensive bioactive metabolites, especially antioxidant compounds like caffeic acid (CA), zosteric acid and rosmarinic acid, could be altered due to the variability of different environmental stress factors like temperature, salinity and epiphytic grazers [1]. On the other hand, these regions also affected from tides that result in loss of bioactive compound resources. Caffeic acid is one of the greatly studied natural compound for its hepatoprotective effects against t-BHP-induced oxidative liver damage [2], suppression of UV-B induced skin carcinogenesis [3], suppression of COX-2 expression [3], antioxidant activity [4], anti-hepatitis B virus activity [5], peripheral analgesic effect in mice and rats [6], inhibition of cancer cell metastasis [7], anti-inflammatory and anti-coagulatory activity [8] in the literature. In this study, it was aimed to determine seasonal variation of caffeic acid levels in *Zostera noltii* detritus from Turkish coastlines by reverse phase HPLC.

Materials and Methods:
Zostera noltii detritus were collected from Dikili coastlines, Turkey. The samples were washed by using tap water to remove epiphytes and then they were allowed to dry at room temperature. The samples were powdered and 20 g of dried sample was extracted with HPLC methanol by soxhlet extraction for 8 h. The chromatographic separations were performed with Shimadzu LC-20 HPLC system connected to SPD-20A UV detector. Separation of caffeic acid was obtained on Inertsil C8 HPLC column (GL Sciences), (250 mm x 4.6 mm, 5 µm). The analytes were eluted by using linear gradient of 0.1% TFA (v/v) in water (A) and 0.1% TFA (v/v) in methanol (B) (0 min, 1% B; 20 min 99% B) at a flow rate of 1 mL/min. Caffeic acid concentration was determined by using calibration curve of a caffeic acid standard at 360 nm. Statistical analysis of results was performed with one-way Anova followed by Tukey's test in Minitab 16.

Results:
HPLC chromatogram of *Z. noltii* detritus was given in Figure 1.

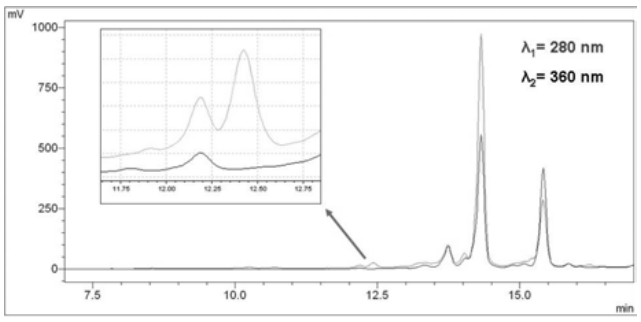

Fig. 1. A sample HPLC chromatogram of *Z. noltii* detritus at 360 nm (λ_1: grey, λ_2: black).

According to the results, caffeic acid was clearly separated from other eluents by simultaneous detection at two wavelengths, 280 and 360 nm. The concentration of caffeic acid was determined from a five point calibration curve (R^2=0.9916) at 360 nm. The seasonal variation of caffeic acid content in *Z. noltii* detritus was given in Table 1.

Tab. 1. Seasonal change of caffeic acid levels in *Z. noltii* detritus from Turkish coastlines. Small letters indicate seasonal changes for each sampling area at significance level of $p<0.05$ according to One-Way Anova.

Season	Caffeic acid concentration (µg CA/g DW)
Spring	275 ± 15^{b}
Summer	161 ± 14^{c}
Autumn	19 ± 1^{d}
Winter	332 ± 17^{a}

According to the Table 1, highest caffeic acid contents in detritus samples from Dikili was determined as 332 ± 17 CA/g dry weight (DW) and it was maximum in winter season.

Conclusion:
Caffeic acid is an important bioactive metabolite that has so far been shown as one of the strongest drug candidate against cancer in the literature. Therefore, *Z. noltii* detritus from Turkish coastlines could be potential bioresource for isolation of caffeic acid.

RÉGIME ALIMENTAIRE DE L'ANGUILLE *ANGUILLA ANGUILLA* DANS LES EAUX DE TRANSITIO DE L'EST DE L'ALGÉRIE.

F. Derbal [1], S. Hamdi [1], L. Rouag-Laouira [1], L. Chaoui [1]* and M. Kara [1]
[1] Université d'Annaba, Algérie - chaouilamya@hotmail.com

Abstract
Le régime alimentaire est étudié chez l'anguille européenne *Anguilla anguilla* de l'embouchure de l'oued El-Kébir et de la lagune du Mellah, dans le nord-Est de l'Algérie. Les valeurs moyennes annuelles de la vacuité digestive sont respectivement de 38,1% et de 53,1%. Elles fluctuent sensiblement en fonction des saisons, du sexe et du stade de développement. Dans les deux sites, *A. anguilla* est opportuniste et se nourrit préférentiellement de crustacés (%IRIOEK = 95,38, %IRILM = 89,86).

Keywords: Fishes, Lagoons, Brackish water, Diet, North-Western Mediterranean

Introduction
En Méditerranée, l'anguille européenne *A. anguilla* est en danger critique d'extinction [1]. Malgré ce statut, sa biologie et son écologie restent très peu connues, tant en Algérie que sur les côtes nord-africaines [2]. Cette étude vise à fournir les premières données sur le régime alimentaire de deux populations d'A. anguilla vivant dans l'oued El-Kébir et la lagune du Mellah, deux hydrosystèmes en communication directe et permanente avec la mer.

Matériel et méthodes
La composition taxonomique et les variations du régime alimentaire de 1120 anguilles, pêchées à l'embouchure de l'oued El-Kébir (position géographique : 07°15'E - 36°59'N, effectif : 495, Lt = 23,5 - 83 cm, Wt = 23 - 1470 g) et dans la lagune Mellah (position géographique : 08°20'E - 36° 53'N, effectif : 625, Lt = 24,3 - 75,8 cm, Wt = 23 - 842 g) au moyen de verveux, ont été étudiées entre décembre 2008 et novembre 2009. Chez chacune des 2 populations étudiées, les coefficients de vacuité digestive (CV%) ont été déterminés en fonction des saisons, du sexe et du stade d'argenture (jaunes, argentés, intermédiaires). Le statut des proies ingérées (préférentielles, secondaires, accidentelles) a été aussi recherché en utilisant le pourcentage indiciaire du IRI [3].

Résultats
Les valeurs moyennes annuelles respectives de la vacuité digestive chez *A. anguilla* de la lagune du Mellah et de l'oued El-Kébir sont de 53,1% et de 42,9%. Il en est de même pour la vacuité digestive des mâles (CvLM = 44,6% ; CvOEK = 37,6%) et des femelles (CvLM = 24,5% ; CvOEK = 28,6%), les individus indéterminés étant absents dans l'oued El-Kébir (CvLM = 60,2%). Dans les deux sites, les valeurs du coefficient de vacuité chez les anguilles jaunes et intermédiaires sont inférieures à 50% alors que celles des anguilles argentées est presque de 90% dans le Mellah et nulle dans l'oued El-Kébir. L'anguille du Mellah se nourrit principalement de crustacés décapodes (%IRI = 89,86) et accidentellement d'ostéichtyens, de mollusques et de macrophytes (%IRI < 10). Les principales proies identifiées dans les contenus digestifs appartiennent à 12 espèces : *Palaemon adspersus*, *Penaeus kerathurus*, *Carcinus aestuarii*, *Microdeutopus gryllotalpa*, *Aphanius fasciatus*, *Atherina boyeri*, *Gobius niger*, *Abra ovata*, *Cardium glaucum*, *Mytilus galloprovincialis* et Ruppia sp. Nous avons identifié un total de 464 proies pesant 633 g, soit un nombre et un poids moyens par tube digestif plein de 1,6 et 2,1 g, respectivement. Dans l'oued El Kébir, les crustacés décapodes constituent aussi la base de son alimentation (%IRI = 90,48) avec une préférence pour la petite crevette P. adspersus (%IRI = 66,48). Les ostéichtyens, les mollusques et les macrophytes sont faiblement représentés (%IRI < 5). Au total, 12 taxons entrent dans la composition de son alimentation dont : 3 crustacés (*P. adspersus*, *C. aestuarii*, *Sphaeroma* sp.), 1 insecte (*Libellula quadrimaculata*), 5 ostéichtyens (*Mugil cephalus*, *Liza saliens*, *L. ramada*, *Chelon labrosus* , *Atherina sp.*), 1 phanérogame (*Ruppia* sp.) et 1 mollusque (*Hydrobia* sp.). Chaque anguille échantillonnée ingère en moyenne 2 proies pour un poids total de 4,4 g.

Discussion
Les variations de la vacuité digestive dans la lagune du Mellah et dans l'oued El-Kébir seraient dues non seulement à l'effet de la température [4], mais à la conjugaison avec d'autres facteurs environnementaux, comme la photopériode et la pluviosité [5], ainsi que la turbidité (facteur causant les crises dystrophiques en milieux confinés) [6]. L'importance des crustacés dans leur alimentation de base, notamment de *P. adspersus* et de *C. aestuarii*, s'expliquerait par la disponibilité de ces proies dans ces milieux. Ce régime à base de crustacés est décrit aussi dans les estuaires de la Severn [7] et du Tage [8] ainsi que dans la lagune de Mauguio [6]. Dans les 2 sites étudiés, les petits poissons, notamment les muges et les athérines, sont consommés accessoirement, alors qu'en milieu dulcicole la tendance alimentaire des anguilles est plutôt l'ichtyophagie [9], avec un spectre alimentaire qui peut s'étendre à d'autres proies, comme les crustacés, les mollusques, les annélides et les larves d'insecte [4]. Nous pouvons ainsi supposer que cette hétérogénéité alimentaire aussi bien qualitative que quantitative observée dans les 2 hydrosystèmes étudiés est attribuée probablement à l'adaptation exceptionnelle de l'anguille à coloniser divers biotopes, ce qui leur permettrait d'acquérir ce comportement nutritionnel de type opportuniste.

ETUDE DES MYXOSPORIDIES ET DES MICROSPORIDIES DES POISSONS DES CÔTES NORD-EST DE LA TUNISIE

Kalthoum Chourabi [1]*, Lamjed Mansour [1] and Oum Kalthoum Ben Hassine [1]
[1] Faculté des Sciences de Tunis - chourabi.kalthoum@gmail.com

Abstract
Les poissons sont fréquemment les hôtes de divers protozoaires parasites, en particulier les Myxosporidies et les Microsporidies. Nous avons consacré nos investigations à certaines espèces de poissons des côtes Nord Est de la Tunisie pour la recherche de ces parasites. Sur l'ensemble des poissons examinés nous avons récolté deux Myxosporidies sur *Trachurus trachurus* et sur *Symphodus tinca* et une Microsporidie sur *Sardinella aurita*.

Keywords: Fishes, Parasitism, Tunisian Plateau

Introduction
Les poissons constituent un biotope extrêmement favorable au développement d'un grand nombre de protozoaires parasites, notamment les Myxosporidies et les Microsporidies. L'impact de ces parasites dans les élevages de poissons a relancé l'intérêt de leur étude. Ces parasites sont caractérisés par la formation de kystes et la présence d'une forme de propagation: la spore.

Matériel et Méthodes
La recherche des Myxosporidies et des Microsporidies a été réalisée sur des poissons frais: *Trachurus trachurus*, *Sardinella aurita* et *Symphodus tinca*, provenant des côtes Nord-Est de la Tunisie. L'observation à la loupe binoculaire intéresse toutes les parties du corps du poisson afin de détecter la présence éventuelle de kystes et de caractériser les spores en microscopie photonique.

Résultats et Discussion
Sur l'ensemble des poissons examinés, nous avons récolté une Myxosporidie du genre *Kudoa* repérée chez *Trachurus trachurus.* Elle est signalée pour la première fois dans les ovules. Nous notons que deux autres espèces de *Kudo*a ont été déjà décrites chez ce poisson au niveau des muscles et la vésicule biliaire [1].

Chez *Symphodus tinca*, nous avons rencontré une Myxosporidie du genre *Henneguya*. Cette dernière a déjà été retrouvée sur ce Crénilabre [2]. Récemment une nouvelle espèce *Henneguya tunisiensis* a été mentionnée sur les branchies de ce même poisson en provenance des îles Kerkennah [3].
Sardinella aurita est parasitée, pour la première fois, par une Microsporidie appartenant au groupe Microsporidium.

Conclusion
Les données préliminaires supportent l'idée qu'il s'agisse d'une nouvelle espèce de *Kudoa*.
L'analyse moléculaire comparative d'*Henneguya* sp. et *Henneguya tunisiensis* permettra de confirmer s'il s'agit ou non de la même espèce.
Nous avons placé la microsporidie dans le groupe polyphylétique de *Microsporidium* sp. en attendant la caractérisation ultrastructurale et éventuellement moléculaire.

SEASONAL VARIATIONS OF THE LEVELS OF TOTAL AND CULTURABLE HETEROTROPHIC BACTERIA AROUND GOKCEADA ISLAND (THE NORTHERN AEGEAN SEA), TURKEY

Pelin Saliha Çiftçi Türetken [1]* and Gulsen Altug [1]
[1] Istanbul University Fisheries Faculty - pciftci@istanbul.edu.tr

Abstract
The aim of this study was to investigate total and culturable heterotrophic bacteria levels at the sea water samples taken from 19 stations determined around Gökçeada Island, Northern Aegean Sea. The highest total and culturable heterotrophic bacteria level was recorded at St-10 (Cape of Kömür) in summer sampling survey.

Keywords: Bacteria, Coastal waters, Surface waters, Temperature, Aegean Sea

Introduction
Heterotrophic bacteria which have important roles on the food chain and live as a part of marine ecosystem. Determination of their levels has an importance to use as alarm symptoms for the environmental pollution and sudden changes in the marine environmet, understanding of the marine ecosystem functioning [1]. Gökçeada which is situated in the North Aegean Sea is the largest island of Turkey. In this study, the variations of heterotrophic bacteria levels were investigated seasonally around Gökçeada Island coastal and off shore areas.

Materials and Methods
Seawater surface samples were taken seasonally from 19 stations that selected open sea stations, Gökçeada coastal area stations and referance station during February 2012- September 2012. The samples were taken to the sterile bottles under aseptic conditions and have been analysed at Istanbul University Fisheries Faculty Aquatic Microbial Ecology Laboratory. Marine agar and spread culture method was used in order to determine total culturable bacteria levels [2]. Then the bacteria colonies were counted and recorded. DAPI and CTC staining method was used to determinate total (living and dead) bacteria count. Epifluorescent microscope was used to estimate abundance of heterotrophic bacteria [3].

Results and Discussion
The changes of bacteria levels at 19 stations have shown in Figure 1. Maksimum culturable heterotrophic bacteria level has recorded as $11x10^{10}$ CFU/100 ml at St 10 (Cape of Komur) in summer sampling period. Maksimum total bacteria level was found $27x10^{12}$ CFU/100 ml at the same station and the same sampling period. While maximum values of heterotrophic bacteria haver reported in summer period, minimum values have recorded in winter sampling period. According to the results shown above bacteria levels were all positively correlated with seasonal sea water temperature changes.

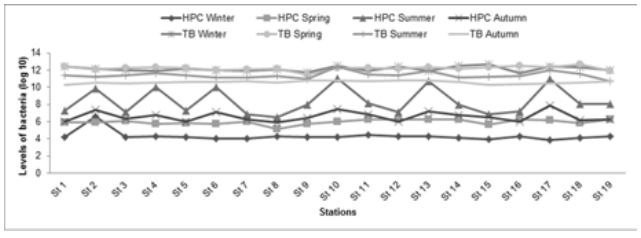

Fig. 1. Levels of total and culturable heterotrophic bacteria (Log_{10})

ÉTUDE BIOCHIMIQUE DE CINQ SOUCHES ALGÉRIENNES D'ARTEMIA (CRUSTACÉ : BRANCHIOPODE)

Abdelkader Amorouayeche [1], Mounia Amarouayache [1], Farid Derbal [1]* and Mohamed H. Kara [1]
[1] Laboratoire Bioressources Marines, Université Badji-Mokhtar d'Annaba - mfderbal@yahoo.fr

Abstract
Nous comparons ici la biochimie (lipides, protéines et glucides totaux) de cinq souches algériennes d'*Artemia*, petit crustacé d'intérêt aquacole, (*A. salina* et populations parthénogénétiques) et une américaine (*A. franciscana*). La souche américaine et la souche parthénogénétique d'El-Bahira sont les plus riches en lipides. La souche d'Ez-Zemoul (*A. salina*) est particulièrement riche en glucides. *Artemia* de Bathioua est la plus riche en protéines. Les populations parthénogénétique et mixte d'El-Bahira et de Bathioua respectivement ont une composition globale proche de la souche commerciale américaine *A. franciscana*.

Keywords: Crustacea, Biotechnologies, Aquaculture, South-Western Mediterranean, Algerian Basin

Introduction
En Algérie, l'*Artemia* (Leach, 1819) existe dans au moins 10 sites, dont certains ont fait l'objet d'études éco-biologiques [1]. Les travaux sur la biochimie ne concernent que le Chott Marouane et portent sur l'analyse des acides gras [2]. Ce travail est complémentaire et a pour objectif la connaissance de la qualité nutritionnelle des souches algériennes d'*Artemia*, en vue de leur exploitation en aquaculture.

Matériel et méthodes
Les souches étudiées appartiennent à 5 populations algériennes d'Artemia et une américaine: *A. salina* (Chott Marouane, Sebkha Ez-Zemoul), population parthénogénétique (Lac El-Bahira), populations mixtes parthénogénétique + *A. salina* (salines de Bathioua et Rélizane) et *A. franciscana* (Grand Lac Salé, Utah). L'extraction des métabolites a été réalisée sur des cystes décapsulés. Nous avons dosé les protéines [3], les lipides [4] et les glucides totaux [5] et recherché d'éventuels groupes de populations analogues (Minitab 16).

Résultats et discussion
Les résultats des taux de protéines, de lipides et de glucides sont présentés dans la figure 1. La souche la plus riche en lipides est celle d'*A. franciscana* d'Amérique (14,32%), suivie de celle d'El-Bahira (12,16%). Le taux le plus élevé de protéines est observé chez *Artemia* de Bathioua (58%), suivi de celle du Chott Marouane (51,65%). Le taux le plus bas est observé chez *A. salina* de la Sebkha Ez-Zemoul (35,14%) qui est particulièrement riche en glucides (31%).

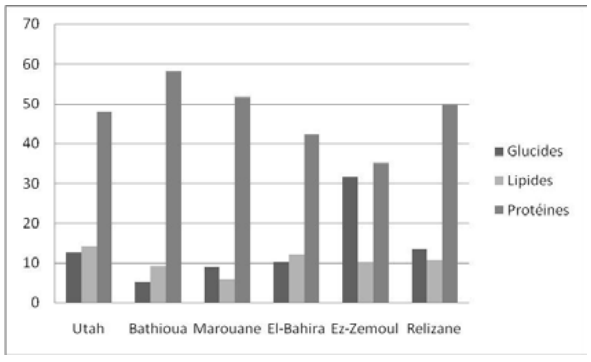

Fig. 1. Concentration des différents métabolites (% du poids sec) dans les six souches étudiées.

Dans le monde, les études portant sur la biochimie des cystes et des nauplii d'*Artemia* concernent essentiellement les acides gras [2, 6] pour leur intérêt en aquaculture. Les métabolites totaux ont été moins étudiés, particulièrement chez les cystes décapsulés, bien que cette forme soit fréquemment utilisée en larviculture [7]. L'analyse hiérarchique comparant les six souches étudiées met en évidence trois grands groupes distincts (Fig. 2): le premier groupe englobe les souches d'*A. franciscana*, parthénogénétique d'El-Bahira et mixte de Bathioua, le second groupe est composé de la population mixte de Rélizane et d'*A. salina* du Chott Marouane. La souche d'*A. salina* d'Ez-Zemoul est très différente des autres et forme un groupe à part. Du point de vue de la composition biochimique totale, les populations algériennes les plus proches de la souche américaine, la plus utilisée en aquaculture, sont celles parthénogénétiques ou mixtes.

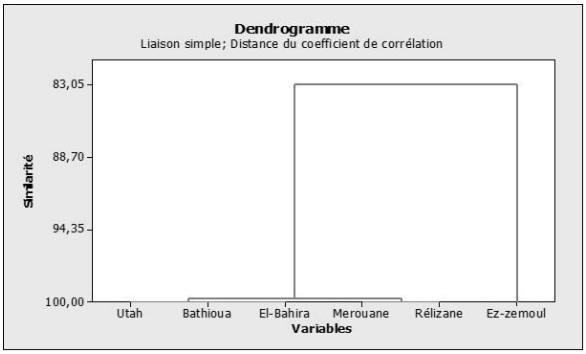

Fig. 2. Résultats de l'analyse de similarité entre les six souches étudiées.

Abstract
The yellowmouth barracuda *Sphyraena viridensis* is a termophilic fish species, now very common in the Ligurian Sea. In the available literature, information on this species is very scanty. In particular the early stages of the life cycle (e.g. settlement) are virtually unknown. An analysis of this crucial phase can be very important to understand the dynamics of the species, since the study of the characteristics of the settlement, post-settlement and recruitment is crucial to obtain information on the supply of the local population. A Visual Census survey was carried out in some locations of western Ligurian coasts between April and November 2011. Uni and multivariate analyses were used in order to evaluate the preferential habitat types and other information on these early life stages of the species.

Keywords: Fish behaviour, Ligurian Sea, Fishes

Introduction
Yellowmouth barracuda, *Sphyraena viridensis* is one of the two species reported in the waters of the north-western Mediterranean Sea (the other is *Sphyraena sphyraena*) [1, 2]. Visual Census has allowed us to collect the necessary data for the analysis of the habits and distribution, during the important stages of settlement, post-settlement and recruitment, so far little known.

Materials and methods
To investigate the habits and distribution of juveniles of *S. viridensis*, we applied a sampling design with four habitats (semi artificial pier, gravel beach, artificial ballast, semi submerged cliff), replicated in two areas along the western Ligurian coast. 3-way ANOVA, with the factors time (orthogonal and random), area (orthogonal and random) and habitat (fixed and orthogonal), and 2-way with the factors time (orthogonal and random) and habitat (orthogonal and fixed), incorporating the two areas in a single series of replicates, were used to determine whether the juveniles of *S. viridensis* show a preference for specific habitat types among those taken into consideration and to show how their abundance varied over time. Further investigations on the differences among habitats and among times were made taking into account also the species that have are known to be preyed upon by juveniles of *S. viridensis* and could affected their distribution (juveniles of *Diplodus sargus*, *Oblada melanura* and *Atherina sp*.). An MDS plot was produced using the Bray-Curtis index to measure the similarity between the different visual transects collected at different times and in different habitats. PERMANOVA was used to assess the differences between the tested factors**.**

Results
Boyh 3-way and 2-way ANOVA results have shown that the factor habitat does not influence significantly the settlement of juveniles, whose density varies rather significantly in time. This result is confirmed by the MDS plot and PERMANOVA, for which also those fish species preyed upon by *S. viridensis* have been taken into account. Furthermore, these species seems not to affect the distribution of juveniles of this species, as demonstrated by the low correlations obtained with correlation plots.

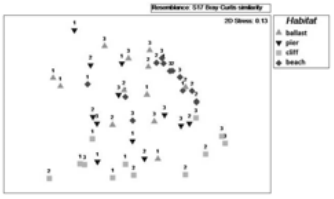

Fig. 1. MDS plot developed to investigate the differences among habitats and among times taking into account the distribution of juveniles of *S. viridensis* and their main preys

Other studies have been done in this framework regarding the mortality of small *S. viridensis* and their growth rate, that were never conducted earlier for this species. In particular, growth seems quite rapid (almost 2 mm per day, achieveing recruitment at a length of about 20 cm).

Discussion
From all the results we can affirm that *S. viridensis* can establish without distinction in all the considered habitat types, when their length is 5 or 6 cm, showing a variation of abundance that, after an initial period of settlement, which occurs in early summer, is decreasing to settle on values rather constant during the remaining summer months. The fact of not having spotted juveniles of *S. sphyraena* leads us to think that probably the settlement for this species occurs in habitats different than those used by juveniles of *S. viridensis*. This could be an example of segregation between juveniles of congeneric species [3], in this case spatial. The information obtained from the literature [4] could reinforce this conclusion: it is shown that the habitats suitable for settlement of juveniles of *S. sphyraena* are mainly sandy bottoms, an habitat type that is not between those sampled in the study. Finally, the high growth rate recorded, which allows to reach a larger size before winter, makes it possible to accumulate a good amount of lipids and to face more successfully the cold season [5].

ORGANISATION FONCTIONNELLE ET VARIABILITÉ SPATIALE DE LA MACROFAUNE BENTHIQUE DE LA LAGUNE D'ELBIBAN ET DU PORT DE ZARZIS (SUD-EST TUNISIEN)

Hanem Djabou [1]* and Ahmed Afli [1]
[1] INSTM salammbo, tunis - hanem.djabou@laposte.net

Abstract
Deux zones côtières tunisiennes, la lagune d'El Biban et le port de pêche de Zarzis plus ou moins exposés aux activités anthropiques, ont été étudiées. Le sédiment a été prélevé par plongée autonome, les descripteurs statistiques et les indices de diversité ont été déterminés. Les résultats montrent que les deux écosystèmes présentent des signes d'eutrophisation. L'organisation trophique révèle une dominance des organismes déposivores dans le port, alors que la lagune est dominée par les herbivores. Une analyse des correspondances effectuée sur les valeurs des paramètres physico-chimiques enregistrées montre des différences notables entre les deux sites étudiés, et aussi entre les stations du même site.

Keywords: Coastal systems, Eutrophication, Trophic relations, Zoobenthos, South-Western Mediterranean

Très productifs, les écosystèmes paraliques subissent des perturbations fréquentes et brusques pouvant provoquer des variations considérables dans les facteurs physico-chimiques ainsi que dans l'organisation fonctionnelle de la macrofaune benthique [1]. Elément clé des écosystèmes côtiers, les communautés benthiques jouent un rôle essentiel dans la décomposition des détritus, le cycle des nutriments et le flux d'énergie vers les niveaux trophiques supérieurs [2]. Elles représentent également un outil biologique important pour l'évaluation de l'état écologique des écosystèmes puisqu'elles montrent des réponses différentes en fonction de la nature et de l'ampleur des perturbations naturelles et anthropiques [3]. Les travaux sur la macrofaune benthique du sud de la Tunisie sont rares et se limitent généralement à l'étude d'une ou de quelques espèces seulement sans évoquer l'état général des communautés [4]. Dans ce travail, on se propose d'étudier l'état écologique de deux milieux du Sud-Est tunisien, la lagune d'El Biban et le port de pêche de Zarzis. Il s'agit d'étudier la structure et l'organisation fonctionnelle des communautés en réponse aux principaux facteurs anthropiques et environnementaux. Au total, 21 stations ont été échantillonnées, quatorze lagunaires et sept portuaires. L'échantillonnage a été réalisé par plongée et un total de 0,50 m² a été prélevé à raison de deux prélèvements par station. Les échantillons ont été tamisés sur une toile de 1 mm² de vide de maille et les macro-invertébrés ont été prélevés et identifiés. Les données de base considérées sont le nombre d'espèces ou richesse spécifique S, l'abondance A qui peut être exprimée en densité moyenne ou totale par unité de surface (N/m²), l'indice de diversité de Shannon-Wiener H' (Shannon & Weaver 1963) et l'indice d'équitabilité J' (Pielou 1966). Les principaux paramètres physico-chimiques ont été étudiés. Il s'agit de la température, de la salinité, de l'oxygène dissous, de la granulométrie et des éléments nutritifs, à savoir les nitrites, les nitrates, l'azote ammoniacal et les ortho-phosphates. Une analyse des Correspondances (CA) a été établie sur les valeurs de similarité de Bray-Curtis entre les groupes trophiques et les principaux paramètres physico-chimiques. Au total, 53 espèces ont été identifiées dans la lagune d'El Biban dont plus de 32% sont communes avec le port de pêche de Zarzis. La richesse spécifique moyenne ***S*** dans la lagune est deux fois celle du port, et l'abondance ***A*** est en moyenne douze fois plus importante dans la lagune. Ces paramètres ne présentent pas de forte variation spatiale. L'organisation trophique révèle une dominance des organismes déposivores dans le port, alors que la lagune est dominée par les espèces herbivores. L'analyse (Figure 1) montre des différences notables entre les deux milieux ainsi qu'au sein des stations lagunaires. Trois groupes peuvent être identifiés par cette analyse.Le premier regroupe les stations portuaires (les SDF et l'élément PO^3). Le deuxième groupe est composé des groupes trophiques SF, DF, NSDF, C et µB et la plupart des stations lagunaires, hormis la station BIB13 qui forme un groupe à part ayant une forte corrélation avec la fraction sédimentaire fine. Les autres paramètres physico-chimiques sont situés au milieu du graphique et semblent avoir presque la même influence sur les différentes stations.

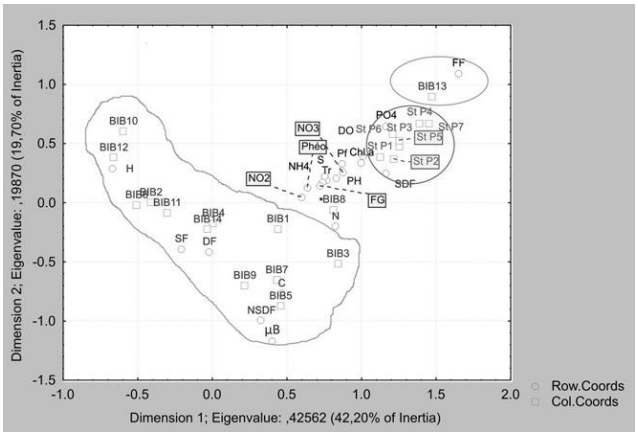

Fig. 1. Analyse des correspondances établie entre les groupes trophiques et les paramètres physico-chimiques

LEVELS OF BACTERIAL POLLUTION IN SURFACE WATERS OF MARMARIS BAY IN TURKEY

M. Didem Ercan [1]*, Canan Ontas [1] and Nedim Ozdemir [1]
[1] Mugla Sitki Kocman University, Fisheries Faculty, Kotekli, Turkey - dican@mu.edu.tr

Abstract
Indicator bacteria and V. cholerae levels were investigated in water samples from 18 stations in the Marmaris Bay, Mugla, between May 2011 and April 2012. As a result total and fecal coliform contamination in the water was found over the limit.

Keywords: Bacteria, Aegean Sea

Introduction
Marine pollution is an event of mixing the water with concentrate of unwanted harmful substances that may impair the quality of water can be measured. Logarithmic growths of microorganisms in nature occur rarely. In this way for a rapid reproduction and abundant presence of nutrients as well as the physicochemical conditions must be optimal. If pollution reaches serious level, environment can become toxic that aquatic life is limited [1]. Also, changes in the natural levels of bacteria, depending on environmental pollution factors, affect adversely the ecosystem and public health [2]. In this study, indicator coliform bacteria and *V. cholerae* levels were investigated in water samples in the Marmaris Bay. This is the first study about investigation of bacterial pollution of the Marmaris Bay that place is touristic.

Materials and Methods
Surface (0-30 cm) sea water was sampled in to the sterile bottles monthly, between May 2011 and April 2012. Membrane filtration and streak plate method were used for bacterial analysis. In streak plate method, ENDO agar for coliforms and TCBS for *V. cholerae* were used. Determination of indicator bacteria were carried out according to described method [3]. For *V. cholerae* identification, biochemical tests [4] and API20E kits were used. Nitrite, nitrate, phosphate and Cl-a levels were measured by spectrophotometrically [5].

Results and Discussion
Monthly results of coliforms analysis were given in figure 1 and 2. Our findings were evaluated according to European Union Blue Flag Project Standards; total coliform limit value is 500 cfu/100 mL (base on log10 is 2,7/100 mL), fecal coliform limit value is 100 cfu/100 mL (base on log10 is 2/100 mL).V. cholerae suspected colonies, growth on TCBS, was identified non V. cholerae by biochemically tests. In the summer, total and fecal coliform levels were high in the beach and marina. Mugla city has increased the number of tourists every year more and more. Marmaris, town of Mugla, covers about 40% of the foreign tourists. According to the findings, in the stations 1,4,6,8,9,11,13,15,16,17 were polluted with fecal contaminant in the summer. But, number 6 and 8 were found below the limit values. Also, open water stations affected by sea shore with currents and sea vessels. All this results were observed in the tourism season, it exceeds the limit values to be associated with the input of organic matter revealed by analysis of the nutrients. The areas which exceeds the limits were not suitable for use recreational aims. The Marmaris Bay is under the effects of biological pollution due to the fact that heavily populated with dwelling and hotel guests, and blue cruises. If measured bacterial contamination in the summer increase in the coming years that is expected to be led to the emergence of infectious diseases.

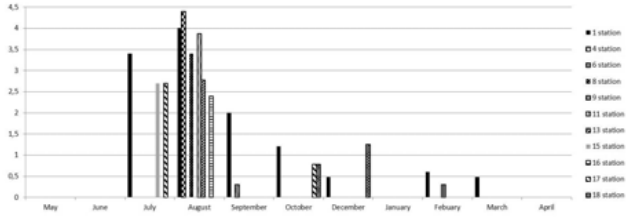

Fig. 1. Levels of Fecal Coliform in water samples collected from Marmaris Bay, Turkey, during one year(2011)

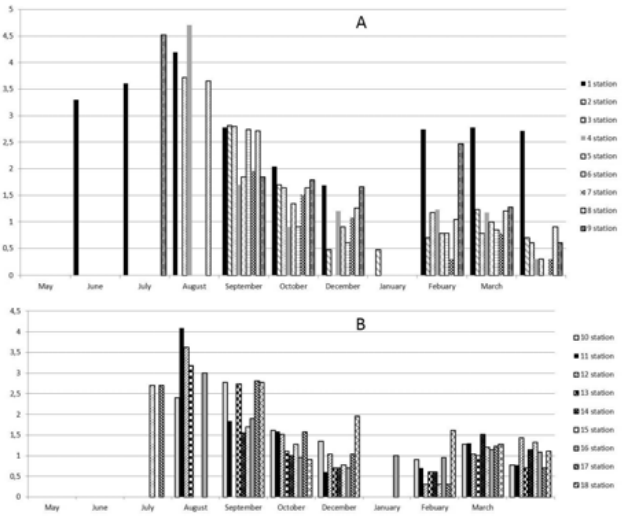

Fig. 2. Levels of Total Coliforms, in water samples collected in Marmaris Bay, TURKEY. log10 CFU/100mL A.1st sampling, B. 2nd sampling.

Abstract
Earthen pond aquaculture is one of the parts of marine aquaculture of Turkey. Wintering the juveniles of the marine fish in the earthen ponds is the general trend for fish farmers in Mugla region. In this study, we would like to determine the effects of salinity to the growth performance after wintering conditions on sea bream fry. Three different salinity rates (‰10-18-24) used in thisstudy which were produced by reverse osmosis system. The best growth performance is found at ‰ 18 salinity.

Keywords: Aquaculture, Aegean Sea

Introduction
Sea bream is one of the benthic species, which lives at 5-50 ‰ salinity and between 5-32 ° C temperatures [1]. Having this kind of a big tolerance to the environmental conditions, sea bream have a very good market for many years. Today, many studies are continuing on this species. Because of the rapid development of the aquaculture, we need larger number of studies for wider spectrum of economic fishes [2, 3]. Physiological and biological studies on sea bream are relatively less than other aquaculture species. Difficulties in culture of this species make the studies on the species difficult and the main challenges are to acclimatize the species to laboratory and culture conditions [2, 4, 5 ,6]. In Turkey, most of the studies accomplished on the larval stage of this species aimed to increase the survival rate, growth performance, artificial feeds, larval rearing protocols and treatment of diseases of the species. Salinity is one of the most important environmental factors affecting growth rate. The relationship between salinity and growth has substantial effect on the cultivation methods of many important fish species. The osmoregulation mechanism in fish is for osmotic balance and balanced energy required for growth. For example, osmotic balance on energy consumption for marine fish, cultured water is considered to be the most suitable in the iso-osmotic salinity (12 ‰) for the growth [7]. In this study, we aim to find the wintering effects on the growth performance of sea bream fries in three different salinity levels (‰ 10, ‰ 18, ‰ 24).

Material and Methods
Three different salinity levels (‰ 10 ‰ 18 ‰ 24) were generated by using reverse osmosis system. Paralleled groups were placed with 15 individuals. Each fish was anesthetized with 0.5 mL/L ratio phenoxyethanol to take the biometric measures then they were placed into the tanks. The system was heated by aquarium heaters, aerated with aquarium pumps. The volume of the each tank was 70 L. Each day, half of the system water was renewed. Fish were fed twice in a day with ad libitum. At the end of 15-day trial growth of sea bream, weight and length were examined and the growth rate, specific growth rate (SGR), feed conversion rate (FCR) and condition factor (CF) values were calculated and the results are given in Table 1. Also water quality parameters were measured during the study (Table 2).

Results and Discussion
The results of this study suggested that the best growth rate, weight gain, SGR, FCR and CF were in the group of 18‰. As it is well known, water quality is the most important factor affecting fish growth. The results of this study also showed that the water quality in 18‰ salinity level had the best as is the growth rate.

Tab. 1. The growth parameters of the groups.

Salinity	Time		Inital	Final	Mean Gain	SGR	CF Initial	CF Final	FCR
‰10	15 days	L(cm)	9,26	9,55	0,29	0,21	1,42	1,31	3,5
		W(g)	11,24	11,7	0,45	0,26			
‰18	15 days	L(cm)	8,44	8,68	0,24	0,19	1,34	1,31	3
		W(g)	8,05	8,6	0,55	0,44			
‰24	15 days	L(cm)	8,6	8,77	0,17	0,13	1,4	1,34	4,6
		W(g)	8,9	9,01	0,11	0,08			

Tab. 2. The water quality parameters of the study.

Water Quality Parameters			
Salinity	‰9	‰18	‰24
O_2(mg/lt)	5	5.3	5
pH	8	8.07	8.17
NH_4(mg/lt)	0.09	0.07	0.1
NO_2(mg/lt)	0.41	0.20	0.91
NO_3(mg/lt)	3.89	3.06	14.4
PO_4(mg/lt)	0.65	0.51	0.55
Temperature(°C)	20.6	20.6	20.6

Our findings on weight gain, specific growth rate, condition factor values overlapped with the results found in other studies on sea bream [8,9,10]. However, our study indicated higher feed conversion ratio compared to other studies. This result is important for the earthen pond farmers that prefer to take their sea bream larvae before the winter time. This kind of a value of FCR rate means loss of money for the farmers.

UTILISATION DES PARASITES COMME MARQUEURS BIOLOGIQUES POUR LA DISCRIMINATION DE STOCK DE *SCOMBER JAPONICUS*

Mariam Feki [1]*, Lobna Boudaya [1] and Lassad Neifar [1]
[1] faculté de sciences de sfax - feki_mariam@yahoo.fr

Abstract
Des analyses discriminantes non paramétriques, utilisant neuf taxons parasites comme marqueurs biologiques de Scomber japonicus, ont permis de séparer les maquereaux en provenant de quatre localités des côtes tunisiennes (Bizerte au Nord, Kélibia et Mahdia à l'Est et Zarzis au Sud) en trois stocks. Les parasites, essentiellement les Monogenea seraient de bons marqueurs biologiques pour discriminer les stocks.

Keywords: Fishes, Parasitism, Stock assessment, Tunisian Plateau

La production de *Scomber japonicus* en Tunisie a atteint 4725 tonnes en 2011 [1]. Ce poisson, pêché le long de la côte tunisienne, présente une biomasse variable selon les localités [2]. Pour une gestion durable de cette ressource, l'identification d'éventuels stocks est indispensable. Dans ce travail, les parasites sont utilisés comme marqueurs biologiques pour la discrimination des stocks. Ils présentent l'avantage d'être plus faciles à manipuler que les marqueurs artificiels et plus efficaces pour l'étude des petites et délicates espèces comme les Scombridae [3]. 369 individus de *S. japonicus* ont été échantillonnés aux des points de débarquement de 4 localités, Bizerte, Kélibia, Mahdia et Zarzis. Les coordonnées de pêche ont été soigneusement prélevées avec la collaboration des pêcheurs.

Fig. 1. Localisation des stations d'échantillonnage

Chaque poisson a été examiné afin de rechercher tous les macroparasites. Pour chaque espèce parasite, la prévalence et l'abondance moyenne ont été calculées [4]. Les variations géographiques de ces paramètres ont été testées par les tests statistiques X^2 et ANOVA. Une analyse discriminante a été réalisée pour séparer les maquereaux des différentes régions. Trois Monogenea *Grubea cochlear*, *Kuhnia scombri* et *Kuhnia minor* ont été récoltés au niveau des branchies. Six endoparasites : 4 Digenea, *Prodistomum orientalis*, *Opechona bacillaris*, *Monascus filiformis* et *Lecithocladium excisum*, un Acanthocephala *Rhadinorhynchus* sp. et un Nematoda Anisakidae ont été identifiés au niveau du tube digestif. Les 3 Monogenea et deux Digenea *M. filiformis* et *O. bacillaris* sont totalement absents au niveau de Bizerte. La comparaison de la prévalence et de l'abondance moyenne entre chaque deux régions a montré des différences significatives entre Kélibia et Bizerte pour *P. orientalis* (χ^2=8,51 ; d.d.l=1; p<0.05), (F=14,94 ; d.d.l=1 ; p<0.05) et *L. excisum* (χ^2=20,06 ; d.d.l=1 ; p<0.05), (F=36,82 ; d.d.l=1 ; p<0.05). La prévalence et l'abondance des 3 Monogenea ne présentent aucune différence significative entre Kélibia et Mahdia (p>0,05). *O. bacillaris* (χ^2=4,55 ; d.d.l=1 ; p<0.05), (F=6,42 ; d.d.l=1 ; p<0.05), et *Rhadinorhynchus* sp. (χ^2=5,36 ; d.d.l=1 ; p<0.05), (F=6,25 ; d.d.l=1 ; p<0.05) sont plus prévalents et abondants à Mahdia. *G. cochlear* (χ^2=17,05 ; d.d.l=1 ; p<0.05), (F=21,73 ; d.d.l=1 ; p<0.05) est plus prévalent et abondant à Mahdia qu'à Zarzis. L'analyse discriminante a pu séparer les *S. japonicus* des 4 régions en trois stocks (lambda de Wilks=9,34 ; p<0,01).

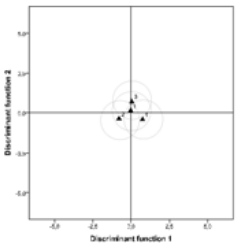

Fig. 2. Analyse discriminante séparant les maquereaux des différentes localités 1Kélibia, 2 Bizerte, 3 MAhdia et 4 Zarzis

Un au niveau de Bizerte (Nord de la Tunisie), un rassemblant les individus de Kélibia et Mahdia (Est de la Tunisie) et un au niveau de Zarzis (Sud de la Tunisie). Les parasites, essentiellement les Monogenea à cycle direct et spécifiques de leurs hôtes seraient de bons marqueurs biologiques pour discriminer les stocks.

OPTIMISATION ET CARACTÉRISATION DE L'ACTIVITÉ PROTÉOLYTIQUE CHEZ LA SOUCHE *SALICOLA* SP. ISOLÉE DE LA SALINE DE SFAX EN TUNISIE

D. Frikha [1]*, S. Masmoudi [1], H. Trigui [1], F. Ghanmi [1] and S. Maalej [1]
[1] Faculté des sciences de Sfax - fdonyez@yahoo.com

Abstract
Salicola sp. (Souche ETR14) est une bactérie halophile extrême isolée des eaux de la saline de Sfax en Tunisieau niveaude la table de cristallisation du sel. Cette souche, identifiée par la méthode polyphasique a été criblée en termes d'activités hydrolases. Nos résultats montrent cette souche dispose d'une forte activité protéolytique. L'activité protéase a été optimale en présence de 4% de glucose, 1% de tryptone et 1% de $MgSO_4$. De plus, elle était optimale à une température de 60°C et à un pH de 9, alors que la dénaturation thermique à 70°C, n'affecte que 13 % de cette activité après 1 h d'exposition.

Keywords: Bacteria, Tunisian Plateau

Introduction
Les bactéries et les archées halophiles ont émergé en tant que sources possibles et importantes d'hydrolases résistantes à la salinité et à la dénaturation thermique [1]. Parmi ces hydrolases, les protéases produites par des bactéries halophiles extrêmes présentent un intérêt biotechnologique considérable [2]. Quelques travaux sur la saline de Sfax en Tunisie ont montrés que les bactéries du genre *Salicola* dominent dans les eaux des tables de crsitallisation du sel [3]. Dans ce travail, l'activité protéase de la souche ETR14 a été optimisée et caractérisée.

Matériel et méthodes
ETR14 a été isolée sur milieu R2A à pH 7,4 et à une température de 37°C puis identifiée par amplification et séquençage du gène codant pour l'ARNr16S. L'activité protéolytique a été détectée sur milieu solide DSC additionné de 20% de lait écrémé [4] et l'activité a été dosée selon la méthode de Kembhavi en 1993 [5]**.** Pour améliorer l'activité protéase, différentes sources de carbone (glucose, maltose, amidon, sucrose et xylose) et d'azotes (urée; peptone; tryptone; NH_4Cl) ont été testées à une concentration finale de 1 % (w/v). De plus, d'autres cations comme le Ca^{2+} ; Mg^{2+} ; Mn^{2+} ; Zn^{2+} ont été testés en ce qui concerne leur aptitude à améliorer l'activité protéase. La stabilité de l'activité protéolytique a été testée vis à vis du pH en utilisant un tampon phosphate (0,1M) pH 6 ; 6,4 ; 7,4 et 8, un tampon Tris-HCl (0,2M) pH 8,5 et un tampon Glycine-NaOH (0,1M) pH 9 et 10. Pour déterminer la stabilité face à la dénaturation thermique, l'extrait enzymatique a été exposé 15 min à 30, 40, 45, 50, 55 et 60°C et l'activité protéolytique résiduelle a été estimée par rapport à un contrôle non traité.

Résultats
La souche ETR14 isolées des eaux de la table de cristallisation du sel TS18 est capable de supporter des concentrations en sel comprises entre 100 et 250 g/l, avec une vitesse spécifique de croissance maximale en présence de 200 g/l de sel. Ces résultats suggèrent que ETR14 est une souche halophile extrême. L'identification de cette souche par l'analyse de l'ARNr 16S montre qu'elle est affiliée au genre Salicola, famille des *Halomonadaceae*, classe des *Gamma-Proteobacteria*, phylum des *Protobacteria* et domaine des *Bacteria*. Salicola sp. montre une activité protéolytique importante sur milieu solide DSC-97 contenant 20 % de lait écrème alors qu'elle est protéasenégative sur le milieu R2A. Le meilleur halo de l'activité protéolytique a été détecté sur milieu solide à 200g /l de sel ce qui nous a permis de classer cette protéase parmi les halophile extrêmes.La production enzymatique a été optimale en présence de 4% de glucose en tant que source de carbone, 1% de tryptone comme source d'azote et 1% de $MgSO_4$. De plus, l'activité protéolytique était optimale à une température de 60°C et à un pH de 9, alors que la dénaturation thermique à 70°C, n'affecte que 13 % de l'activité protéolytique après 1 h d'exposition.

BIOMASS DISTRIBUTION OF NORWAY LOBSTER, NEPHROPS NORVEGICUS, OFF CATALANO-LEVANTINE MEDITERRANEAN COAST OF SPAIN (CGPM-GSA 06).

Mariano Garcia Rodriguez [1]* and Jose luis Perez Gil [1]
[1] INSTITUTO ESPAÑOL DE OCEANOGRAFIA - mariano.garcia@md.ieo.es

Abstract
The Norway lobster, a demersal species found on muddy bottoms, is a sedentary lobster that inhabits borrows built in the mud, and is present at depths ranging from 20 to 800 m. We analysed its biomass distribution in the Mediterranean coast of Spain (GSA06), and the influence of some abiotic factors in such distribution, using survey data from 2006 to 2012. Our results reveal that, during this time interval, Norway lobster biomass distribution was shaped by the temperature and, more clearly the salinity of the water masses. Depth was the most important factor, negatively affecting the species biomass, which decreased dramatically below 500 m depth.

Keywords: Decapoda, Biomass, South-Western Mediterranean

Introduction
The Norway lobster (*Nephrops norvegicus*) is a demersal species found on muddy bottoms in the North-Eastern Atlantic and the Mediterranean, being common in the coasts of the Iberian Peninsula. It is a sedentary lobster that inhabits borrows built in the mud and is found at depths ranging from 20 to 800 m. This species is among the most valuable resources for the trawl fleets in the studied area (GSA06), with landings reaching an average of 470 t per year (2007-2012) and showing some stability along time. Patchiness of the species populations seems to be related to both heterogeneity in the characteristics of the sediments [1] and variations in fishing effort [2]. In addition, it is often argued that marine organisms may respond to a combination of depth-related factors such as availability of food, light, temperature and pressure [3]. Here we present an exploratory study on the influence of some of these abiotic factors on the biomass distribution of the Norway lobster.

Material and Methods
Sampling took place in the Catalano-Levantine coast of Spain (FAO-GFCM Geographic Sub Area 06, GSA 6). All samples were collected during the course of seven consecutive MEDITS_ES International Spring Trawl Surveys (from 2006 to 2012) according to the international standard methodology [4]. Depth, temperature and salinity were recorded with a CTD SBE-37 probe located in the mouth of the gear. For each of these variables, the average of the data recorded during the effective trawl (when the gear is in contact with the bottom) was estimated for each haul and included in the analyses. Time period (from 2006 to 2012) and latitude were also considered as factors. Species biomass per haul was calculated as the catch in weight per swept area and expressed as kg/km^2. G.I.S. was used to generate a distribution map by kriging. Data were normalised by logarithmic transformation, and the relationship between the different factors and species biomass was analysed by linear and multiple regressions (GLM), applying a simple model without interactions. Analyses comprised data from 145 hauls.

Results and Discussion
Nephrops norvegicus biomass values ranged from 0.113 to 230.0 kg/km^2, with an average of 16.22 kg/km^2. The average biomass of the species seemed to be stable along time, showing overall lower abundances in Southern (Levante) than in Northern (Catalonian coasts) latitudes, with the highest biomass values found in some locations (Gerona, Barcelona, and Ibiza channel). The species was present in almost all the depth range studied, occurring from 76 m to 819 m, although the maximum biomass values were concentrated in the 200-500 m depth interval. Average length of individuals was significantly smaller in Catalonian coasts, being related with a more intensive exploitation [5]. In the area of study, both salinity and temperature are positively correlated with depth, showing a gradient on both the continental shelf and the upper slope. These gradients correspond to the Modified Atlantic Water (MAW) and to the Levantine Intermediate Water (LIW), in the shelf and the slope respectively, and to the Western Mediterranean Deep Water (WMDW) in the Ibiza channel [7]. In this sense, the species biomass appeared distributed in ranges of temperature and salinity 1.241 C^o and 0.618 psu wide, respectively, with averages of 13.180 C^o (±0.166 S.D.) for temperature and 38.423 psu (±0.133 S.D.) for salinity. These values are closely related to the LIW. Overall, our model explained 26% of the observed deviance. Biomass increased, although not significantly, with temperature, which explained 1.8% of the deviance (F=3.3257; p= 0.070). It also increased, in this case significantly (F=16.397; p= 0.0000865), with salinity, which coped with 9.1% of the deviance. On the other hand, bathymetric distribution (depth) explained 12.3% of the deviance, being negatively correlated (F=22.149; p= 0.0000062) with biomass, which decreased as depth increased, especially below 500 m depth.

EVALUATING QUALITY OF CORALLIGENOUS ASSEMBLAGES: PRELIMINARY RESULTS OF THE RAPID VISUAL ASSESSMENT METHOD

Giulia Gatti [1]* and Stéphane Sartoretto [2]
[1] Department of Hearth, Evironmental and Life Sciences, University of Genoa, corso Europa 26 - 16132 Genoa, Italy - giulia.gatti@unige.it
[2] Ifremer - Centre de Méditerranée, Zone Portuaire de Brégaillon - BP 330 - 83507 La Seyne sur Mer cedex, France

Abstract
The Rapid Visual Assessment (RVA) method, proposed for the evaluation of coralligenous quality, was applied on assemblages differently affected by human pressures. Result showed that RVA is able to reveal the health status of the assemblages. Future activities will compare the RVA with an index under development (INDEX-COR).

Keywords: Coastal systems, Monitoring, Sampling methods, North-Western Mediterranean

Introduction
Despite the great importance of coralligenous habitat [1], due to its large distribution and specific richness, standardised methods for its study are still lack. Thus, the health status of coralligenous remains scarcely broached. Since the European Marine Strategy Framework Directive (MSFD, 2008/56/EEC) required to reach a good environmental status of coastal ecosystems, different approaches aimed to assess the health status of coralligenous assemblages started to be developed [2, 3]. Here we present the preliminary results obtained by the application of the Rapid Visual Assessment (RVA) method proposed by Gatti *et al*. [4] and based on a seascape approach. The final aims of this study are the improvement of the methodology and the intercalibration with another index under development (INDEX-COR).

Materials and Methods
The RVA was applied between Marseilles and Toulon (France). Six sites differently affected by human pressures were selected:
· Marseilles - Low pressure: Cap Caveau (Frioul Island); reference: Moyade; high pressure: Northern Plane Island (sewage outfall)
· La Ciotat - Low pressure: Bec de L'Aigle; high pressure:Figuerolle (sewage outfall)
· Toulon - Reference: Eastern "Sêche des pêcheurs".
We considered three layers to describe the structure of assemblages [5]: Basal layer (0-1 cm height), Intermediate layer (1-10 cm) and Upper layer (> 10 cm). Several descriptors were considered to characterise the geomorphology and to evaluate the quality of the coralligenous. A score comprised between 1 (low quality) and 3 (high quality) was given for each layer and finally a mean global score was computed in order to obtain the quality value of each site.

Results and Discussions

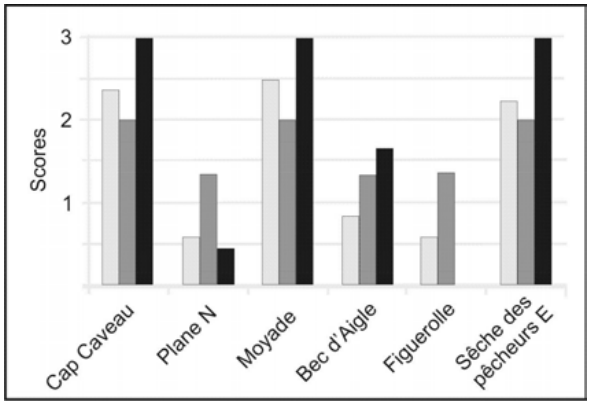

Fig. 1. Quality Scores per layer. Light gray: Basal layer; dark gray: Intermediate layer; black: Upper layer.

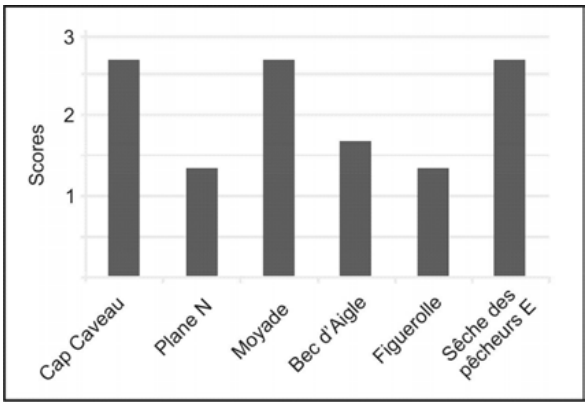

Fig. 2. Global Quality Scores (= mean value of layers Quality Scores).

The RVA approach revealed that, even in the same site, the three layers can show different dynamics. Anyway, global scores disclosed that RVA distinguished well the lower quality of high impacted sites from low or non-impacted ones. The next step will complete these preliminary results and will compare the RVA method with the INDEX-COR approach.

[2] The University of Tokyo Atmosphere and Ocean Research Institute

Abstract
We conducted research of the movements and behavior of the smooth hound shark (*Mustelus mustelus*) using biologging method in the Edremit Bay, Turkey. During the pool experiments two sharks were attached with accelerometer, and it was observed that one of the sharks was trying to remove the accelerometer by swimming on its back and rubbing it to the pool bottom. The behavior of sharks were identified by acceleration data and video records. This paper, aims to report the unexpected reactions of the shark, and to present the importance of monitoring experiments at captive conditions.

Keywords: Fish behaviour, Edremit Bay

Introduction: Assessing animal behavior is essential to understand life history (1). Using the animal-borne devices is crucial for marine and fisheries studies. Bio-logging methods are being used for a wide variety of species such as sea birds, fishes, marine mammals, and sea turtles. To obtain behavioral data of the animal, or to proper analyze the information contained by loggers, not only the effect of attaching logger on animal, but also reaction of the animal to the attaching logger should be investigated. Sharks are the target species for the fisheries in Turkey. Although not being used as food, the extended amount of export and selling of the smooth hound shark to aquariums.. Therefore the smooth hound shark is being caught by fisherman in the Edremit Bay. In this region, there is less information regarding the movements and behavior of this species. Bio-logging study on the *Mustelus mustelus* to understand the movements and behavior has started in in August 2012. In this study, we are explaining that how the shark has tried to remove the logger during pool experiments.

Material and Methods: We caught two female Smooth hound sharks (113cm and 4 kg, 105 cm and 4.3 kg, respectively) by demersal longline in Edremit Bay and kept in 19 tons pool. We attached the accelerometer W190-PD3GT (21 mm in diameter, 116 mm in length, 60 g in air; Little Leonardo, Japan) between 18 and 21 August 2012. Sampling rates were 32 Hz for acceleration. After anesthesia the accelerometer were attached on the back front side of the first dorsal fin using plastic cable ties through two tiny holes. The sharks were put back into the pools and left for them to come out from the anesthesia. After 17 hours, we placed video camera (550HDRX, Sony) with waterproof housing was placed into the corner of the pool, and audio-visual recordings obtained during day time in 2 different periods (around between 10:00 -12:00 and 14:00-16:00). Total 9 hours footage were recorded during 3 days. Acceleration data were analyzed using Igor Pro 6.2. To identify the specific behaviour, we used dorsoventral and lateral acceleration data throuth 0,59 Hz low pass filter and extracted the specific events automatically with these acceleration data (Mask analysis). Finally we make sure the time wen extracted events occured and checked shark behavior when occured in same time by observing video records.

Results: Video records show 4 rolling and rubbing events. Analysis of acceleration of behaviors determined 13 rolling events which includes rolling events observed by video record (Fig 1). All events occured at daytime and in the first 36 hours. After detach the accelerometer, the attachment points had become even more injured, probably because of rubbing. Additionally, video records showed one more different type of rolling and rubbing behavior of the sharks. The shark changed its body position upside down and hit accelerometer to bottom twice with half rolling at the same side of the body.

Discussion: Pool experiment helped us to determine that reaction of shark and leads us to think about alternative attachment place and technique. That kind of behavior can be harmful for animal and also for devices, and can affect success of logger recovery. Similar behavior of shortnose sturgeon (*Acipenser brevirostrum*) that rubbed external transmitters along tank sides and bottom were reported. According to the reports express that, externally attached transmitter loss began at second day because rubbing (1,3). By using video records, we could identify that unexpected behavior more easily. The use of video is a good means of capturing uncommon or previously unknown behavior of captive animals (2). In conclusion, before release animal attached logger, pool experiments is important. During that period, continuously audio-video recordings can help to identify unexpected behavior of animals.

Abstract
L'impact du copépode parasite *Peroderma cylindricum* sur la composition lipidique et la qualité nutritionnelle de la sardine a été étudié. Les résultats obtenus ont montré que le parasite détourne un pourcentage non négligeable d'acides gras notamment polyinsaturés à son profit. En outre, il entraîne une élévation de la teneur en acides gras saturés et en acides gras monoinsaturés et détériore de ce fait la qualité nutritionnelle de la sardine.

Keywords: Parasitism, Fishes, Tunisian Plateau, Copepoda

Introduction
La sardine héberge de nombreux parasites dont le plus pathogène est le crustacé copépode *Peroderma cylindricum* [1]. Ce parasite inflige à son hôte des dégâts considérables sur les plans morpho-anatomique, physiologique et comportemental [1-3]. Dans le présent travail, nous avons abordé l'effet de la copépodose sur la qualité lipidique du poisson-hôte.

Matériel et méthodes
Les sardines ont été prélevées sur les débarquements de pêche au feu du port de Kélibia (Nord-Est de la Tunisie). Au total, 48 spécimens de sardines de longueur totale comprise entre 16 et 18 cm ont été collectés. L'extraction des lipides a été effectuée selon la méthode de Folch [4]. Les esters méthyliques des acides gras ont été obtenus par une trans-estérification selon la méthode de Cecchi et al. [5].

Résultats et discussion
Les résultats de l'analyse de la composition lipidique ont révélé que le copépode *P. cylindricum* entraîne (I) une élévation da la teneur en acides gras saturés (AGS) suite à l'augmentation de celles du C14:0, du C15:0 et du C17:0, (II) une élévation de la teneur en acides gras monoinsaturés (AGMI) touchant le C16:1n-9, le C18:1n-9 et le C20:1n-9 et (III) une réduction de la teneur en acides gras polyinsaturés (AGPI) surtout le DHA (C22:6n-3). Le calcul de paramètres lipidiques a permis d'étudier la qualité nutritionnelle du gras du poisson parasité. Les résultats ont révélé que le parasite entraîne une élévation des rapports AGS/AGPI et EPA/DHA et une réduction du rapport oméga-3/oméga-6. Le parasite induit également une élévation de la valeur de l'indice d'athérogénicité et de thrombogénicité. L'élévation de ces indices témoigne de la détérioration de la qualité nutritionnelle bénéfique pour la santé humaine. La modification de la composition lipidique des sardines parasitées témoigne du détournement sélectif de certains acides gras au détriment du parasite. Des résultats similaires ont été enregistrés chez le copépode *Lepeophtheirus salmonis* parasite du saumon atlantique *Salmo salar* [6]. L'impact très sévère des parasites sur leurs hôtes caractérise certaines espèces de copépodes de la même famille (Pennellidés) de *P. cylindricum* telle que *Lernaeocera branchialis* [7].

Abstract
The most common important biological pressures in the Ionian Sea and Romanian Black Sea coast (presence of alien species, fishery, relationships between fishery and cetaceans) are studied, among others, in the frame of the project "Investigation and application study of the ecosystemic approach to fishery in the Ionian Sea and Black Sea (Romania)"

Keywords: Ionian Sea, Black Sea, Alien species, Fisheries, Cetacea

Introduction
The goals of ecosystemic approach to fishery (EAF) are ''to balance diverse societal objectives, by taking into account the knowledge and uncertainties about biotic, abiotic, and human components of ecosystems and their interactions and applying an integrated approach to fisheries within ecologically meaningful boundaries'' [1]. The biotic compartment, including the most important biological pressures (target fish resources, other species associated and dependent species – alien, cetaceans - the living habitat) could actually offer a valuable assistance for the description of the fishery interaction within the ecosystem.

Material and Methods.
In the frame of the project all the needed data-indicators will be collected (a) describing the state of the marine environment in the two research areas as well as (b) all the human activities will be reported in details (for example fisheries, aquaculture and pollution) that can affect environment (pressure indicators). The indicators which describe the state of the environment in areas relating to the abiotic and biotic parameters (e.g. marine organisms, marine protected areas), fisheries (e.g. fleet, fishing effort, spawning and nursery areas) and the legislative framework related to the environment. Regarding the record of anthropogenic impacts on the environment (pressure indicators) will be analyzed the impact of the fishery in the marine environment (e.g. impact to the fishery resources, interactions between cetaceans-fishery), the climatic changes, as the alien species, the aquaculture data in both areas and all the recorded cases of marine pollution from land and water resources. Finally we provide the first guidelines for the application and future use of the Ecological Approach to Fisheries in both regions. The above data will be processed in a comparative manner for both regions, taking into account differences in geomorphology, oceanography, fisheries and social synthesis. Very useful results to be exported will be used in the future as useful tools for the implementation of the Ecological Approach to Fisheries in both regions. The aim of the present study is to present some of the most important anthropogenic pressures (the situation of the fishery sector, the interactions between cetacean-fishery and the alien species) in both marine ecosystems of the study areas (Ionian and Romanian Black Sea coast .

Results and Discussion
Most of the alien species (60 species) found in the Ionian have an Indo-Pacific origin and belong to fishes, phyto- zoobenthos plankton. Their mode of introduction is mainly by shipping and via Suez [2]. Most invasive species at Romanian coasts (totally 70 species) were accidentally introduced from ships' hulls, ballast water, aquaculture. These species are mainly cosmopolite planktonic (43%), Atlantic and Indo Pacific species [3]. The monitoring of alien species in both areas, which does not exist, should be one of the priorities of any strategy to protect biodiversity. The number of fishery vessels during the period 2000-2012 (mean number: 4432) in the Ionian has decreased and the main gears used are trawlers, purse seines, beach seines, nets. The most common species in the landings are: anchovy, pilchard, anchovy, picarel, bogue, hake. The small size of the fleet and the traditional fishing techniques are the most important characteristics of the Romanian fishery. There are different types of fishing gears in this country (like trawls, point net, gillnets, long and bottom lines, specific gillnets, sea pound nets, other). During the period 2000-2011, the level of total catches declining from 2476 tons to 258 tons. In general, values of Good Environmental Status (GES), in the frame of the MSFD 2008/56/EC, concerning some of the assessed fishing stocks in the Ionian are within safe limits (deep waters rose shrimp, red and striped red mullets)having acceptable values of fishing pressure and biomass indicators. Other species (hake, anchovy and sardine) present slight departures from the safe limits [4]. In the last years (2005-2011) the stock biomass for the main Romanian fishes (sprat, whiting, turbot, dogfish) presented some variations comparing the period 2005-2008. The fishing effort continues the trend of reduction reported since 2000. Resource overlap between common dolphins and fisheries in the Inner Ionian differed, being higher for purse and beach seiners [5]. The illegal fishery and the specific use of the turbot gill nets cause often the dolphin's death in the Romanian coasts [6]. Since fisheries can have often several by-catch problems with other vulnerable species (turtles, birds, elasmobranches, cetaceans) would be advisable to adopt a multi taxon strategy of mitigation in both countries.

Conclusions
Concluding, the deep knowledge of the most important biological pressures in the environment, alien species, target fishery species and interaction between fishery-cetacean, will absolutely contribute to the fishery management in both countries taking into consideration all the ecosystem's characteristics for the application of the ecosystemic approach to fishery

Abstract
In this study, the effectiveness of hydrogen peroxide as a treatment for disinfecting goldfish (*Carassius auratus auratus, L.*) eggs were investigated, considering hatching success and embryo survival in various hydrogen peroxide treatment regimes ranging in concentration from 300 ppm at a water temperature of 26°C. We searched 5, 10, 20-min bath in hydrogen peroxide (H_2O_2) at this dose that hatching success and embryo survival.

Keywords: Aquaculture, Izmir Bay, Bacteria, Fishes

Introduction Many researchers were investigate about the effects of various disinfectants of intensive egg incubation of marine and freshwater fish for prevent to the growth of bacteria and reduce the transfer a disease with them [1,2,3]. However, while goldfish having an important place within the ornamental fish sector, few studies on the effect and mode of application are some type of disinfectant which used during breeding time. After hatched during goldfish larvae period are seen high mortality problems caused by bacteria, such as *Flexibacter columnaris* [4], *Flavobacterium columnare [5], Aeromonas hydrophila [6]*. Hydrogen peroxide has since been investigated as an alternative treatment to control bacterial or fungal infections of eggs of several additional fish species [3,7]. Although hydrogen peroxide has long been used for external treatment of fish [8],its use for treatment of fish eggs has only recently been examined. It is considered to be a therapeutant of Low Regulatory Priority (LRP) by the U.S. Food and Drug Administration's (FDA's) Center for Veterinary Medicine (CVM) to control fungal on fish and fish eggs (R. E. Geyer, CVM, personal communication). Although hydrogen peroxide is not an approved drug, the LRP status allows hatchery personnel to administer treatments on fish and fish eggs to control or prevent fungus at 500 ppm or less with little concern for regulatory action. At the same time, evaluating the efficacy of hydrogen peroxide to treat ectoparasites of Atlantic salmon *Salmo salar*, found a linear relationship between hydrogen peroxide efficacy and temperature [9]. In the present study, goldfish eggs incubated at 26 °C were treated with increasing bath time in same concentrations of hydrogen peroxide to determine what time yielded the greatest hatching success.

Materials & Methods Hydrogen peroxide (30% active ingredient)was obtained from Sigma- Aldrich and its test solution were prepared from a stock solution of 30% hydrogen peroxide. Egg-full kakabans taken from the tank where 10 brood fish that mated randomly. The eggs were disinfected in 5 min, 10 min and 20 min with 300 ppm dose of hydrogen peroxide. Any treatment were not done in control group. Three replicates were conducted for each treatment; For each replicate, as an average 1g eggs were removed from the kakabans, and transferred to 500 mL of the test disinfectant solution in a beaker. After trial of disinfection , the solution was poured off and the eggs were rinsed three times with sterile water (about 10–20 mL).The bacteriological examination were done after disinfection treatment . Trypticase soy agar (TSA) were used to test for bacterial growth. The trypticase soy agar (TSA) medium was used to discern prevalence and abundance for all other culturable bacteria and fungi.For each treatment were inoculated per replicate to infect three agar plates.Plates were incubated at 25°C and examined 24,32 and 48 hours after inoculation.Counts were made of all colony-forming units (CFU) when possible,but many plates were classified as too numerous to count.Than the eggs were placed into 10 glass container of 5 liter volume with the same water temperature with breeding tank (which was 26 °C). An airstone was put in the middle of the each experiment container. Every day, the dead eggs were counted in their containers during hatching time. This study were made in triplicate.

Results After surface disinfection of goldfish eggs with hydrogen peroxide (30%, Sigma-Aldrich), bacterial growth in trypticase soy agar (TSA) culture media studied at 5, 10, and 20 minutes; after cultivation on the groups were counted respectively $4.94(\pm0.02)\times10^5$cfu/ml, $1.55(\pm0.34)\times10^5$cfu/ml, $9.89(\pm0.54)\times10^4$cfu/ml and $5.51(\pm0.21)\times10^5$cfu/ml were determined in the control. Accordingly, 5, 10, 20-minute disinfections and in the control group results were not found statistical important in the formation of colonies of those stored ($p> 0.05$). The survival rate of goldfish egg groups in the incubators which disinfected with 300 ppm hydrogen peroxide in 5, 10, 20 minute applications was found respectively 76 ± 17.2%, 79.11 ± 4.12% and 72.88 ± 6.99%. The survival rate was determined 84.66±3.33% in the control group.

Discussion Treatment of goldfish eggs with hydrogen peroxide (H_2O_2) result that the 300 ppm is not effective on bacteriological control and survival rate when we compared with the control group. They have not statistically importance between the time treatments.

CONTRIBUTION A L'ETUDE SYSTEMATIQUE DES FORAMINIFERES DU LITTORAL TUNISIEN

Samia Khabouchi [1]* and Atf Azzouna [1]
[1] université de Tunis El Manar: Fac. Sciences - khab.sami@yahoo.fr

Abstract
L'étude systématique préliminaire des échantillons de Foraminifères de 7 stations des côtes tunisiennes (Sidi Rayes, Borj Cedria, Radès, La Goulette et La Marsa dans le Golfe de Tunis, Mahdia et Skanès dans le Golfe de Hammamet) a permis d'identifier 60 espèces (49 + 11 non déterminées) qui appartiennent à 29 genres et 21 familles. Mots clés : Foraminifères, systématique, Golfe de Tunis, Golfe de Hammamet.

Keywords: Biodiversity, Tunisian Plateau

Introduction
Les Foraminifères sont des Eucaryotes, Protistes, essentiellement marins et benthiques. La cellule est enveloppée par le test muni de pseudopodes réticulés, la taille est comprise entre 0.1 et quelques mm, parfois moins. Le cycle de reproduction haplodiplophasique. [1], [2]. La systématique de ces protistes est basée sur : *Des critères génériques du test : nature, forme générale, nombre et arrangement des loges, microstructure de la paroi, absence ou présence de perforations, structure interne, forme et position des ouvertures. *Des critères spécifiques du test : caractère des sutures, ornementation, dimensions des loges.

Matériel et méthodes
Le choix des stations s'est basé essentiellement sur les facteurs suivant : (*) qualité des eaux: propre ou polluée, (*) température: eau froide/ eau chaude, (*) salinité. Deux types de carotte de 2cm de diamètre, de profondeur respectives 6 et 10cm ont été utilisés. Le tri s'est effectué à l'aide de pinces très fines. Les espèces sont observées directement sous la loupe biloculaire puis conservées à sec ou occasionnellement congelées.

Résultats et discussion
Le présent travail nous a permis de recenser 60 espèces appartenant à 29 genres et 21 familles ; parmi cet effectif nous avons déterminé 11 espèces signalées pour la première fois en Tunisie (*Quinqueloculina sp1, Quinqueloculina sp3, Quinqueloculina sp4, Triloculina sp, Lagena sp1, Lagena sp2, Lagena gibbera sp, Lobatula sp, Elphidium sp, Bolivina sp et Lenticulina sp*). (Figure 1)

Fig. 1. Espèces signalées pour la première fois en Tunisie

Composition taxonomique des familles (Tab 1) Les familles identifiées au cours du présent travail se divisent en trois groupes : A- Familles hautement diversifiées et qui renferment presque la moitié des espèces recensées (27 espèces parmi 60) ; trois familles qui sont : Famille des MILIOLIDAE : 14 espèces. Famille des HAUERINIDAE : 7 espèces. Famille des GLOBIGERINIDAE : 6 espèces. B- Familles à diversité moyenne : 13 espèces appartenant à 4 familles. Famille des LAGENIDAE : 3 espèces. Famille des VAGINULINIDAE : 4 espèces. Famille des UVIGERINIDAE : 3 espèces. Famille des BOLIVINIDAE : 3 espèces. C- Familles presque mono-spécifiques : 20 espèces représentées dans 14 familles. Famille des SPIROLOCULINIDAE : 2 espèces. Famille des OPHTHALMIDIIDAE : 1 espèce. Famille des PENEROPLIDAE : 1 espèce. Famille des SORITIDAE : 1 espèce. Famille des NODOSARIIDAE : 1 espèce. Famille des STILOSTOMELLIDAE : 1 espèce. Famille des AMPHISTEGINIDAE : 1 espèce. Famille des ALFREDINIDAE : 1 espèce. Famille des GAVELINELLIDAE : 1 espèce. Famille des CIBICIDIDAE : 2 espèces. Famille des ROTALIIDAE : 2 espèces. Famille des ROSALINIDAE : 2 espèces. Famille des ELPHIDIIDAE : 2 espèces. Famille des HETEROHELICIDAE : 2 espèces. Leur répartition est fonction de nombreux facteurs abiotiques, dont le stress anthropique joue un rôle primordial.

SPATIAL HETEROGENEITY OF SESSILE BENTHOS IN A SUBMERGED CAVE OF THE EASTERN MEDITERRANEAN

Vasilis Gerovasileiou [1], Dimitris Vafidis [2], Drosos Koutsoubas [3]* and Eleni Voultsiadou [1]
[1] School of Biology, Aristotle University of Thessaloniki, Thessaloniki, Greece
[2] Department of Ichthyology and Aquatic Environment, University of Thessaly, Nea Ionia, Magnesia, Greece
[3] Department of Marine Sciences, University of the Aegean, University Hill, Mytilene, Greece - drosos@aegean.gr

Abstract
Despite their scientific interest and high conservation value, marine caves of the eastern Mediterranean are poorly explored. Herein, a submerged cave from the Aegean Sea was surveyed through SCUBA diving and photoquadrats. A rich fauna of 65 taxa and 4 distinct benthic assemblages were identified. The biotic spatial heterogeneity observed was associated with the unique topography of the different cave sectors.

Keywords: Biodiversity, Rocky shores, Aegean Sea

Introduction
Marine caves constitute characteristic habitats of the Mediterranean rocky coastline. They harbour rare and protected species and have been characterized as 'biodiversity reservoirs' for particular groups of sessile animals [1]. Their topographic complexity generates abiotic gradients reflected in a marked spatial variability of their biota [2], [3]. Partially and totally submerged cave systems are protected by the EC (92/43/EEC). Recent evidence of temperature-induced alterations in Mediterranean cave-dwelling communities [4] highlights the criticality for their monitoring and conservation. However, quantitative data on the biodiversity and community structure of marine caves from the eastern basin do not practically exist.

Material and Methods
Fará cave, a submerged cave from the Aegean Sea (Lesvos Island: 38°58′11.64′ N, 26°28′39.54″ E), was mapped in detail and its benthic communities were investigated through the use of a non-destructive photographic method. The cave is 32 m long and is located at an average depth of 14 m. Fieldwork was carried out with SCUBA diving. The sampling scheme included 9 photoquadrats (3 from the ceiling, right and left walls of the cave) at 5 meters intervals, from the cave exterior to the inner dark zone. In total 72 photoquadrats were taken and the percent coverage of each species was calculated with photoQuad. Multivariate analysis was undertaken with Primer.

Results and Discussion
Sample analysis revealed a rich sessile fauna of 65 taxa belonging to 8 taxonomic groups. As previously shown [1], [3] for marine caves, Porifera were the dominant animal group in terms of species richness (45), followed by Anthozoa (8). Concerning the biotic coverage throughout the cave, Porifera had the highest percentage (41.9%), followed by Rhodophyta (12.6%), Anthozoa (11.3%), Polychaeta (9.9%), and Bryozoa (4.5%). The remaining 1.6% was covered by Chlorophyta, Foraminifera, Hydrozoa, Bivalvia, Brachiopoda, and Tunicata, while 18.6% was characterized as unidentified biogenic substrate.
Multivariate resemblance analysis revealed four distinct groups of stations (Fig. 1). The first group comprised the sciaphilic algal dominated (e.g. *Peyssonnelia rosa-marina*, *Mesophyllum* sp.) community of the exterior and entrance wall stations. The second included the two left wall stations, located 5 and 10 m from the entrance, where the locally higher sedimentation rate favored a differentiated fauna (e.g. *Axinella* spp., *Penares euastrum*). The third group constituted a typical semidark cave community dominated by sponges (e.g. *Dendroxea lenis*, *Spirastrella cunctatrix*, *Phorbas tenacior*, *Agelas oroides*). The scleractinian *Madracis pharensis* prevailed on the ceilings and overhanging walls. The last group included the inner totally dark stations, dominated by encrusting sponges (e.g. *Diplastrella bistellata* and *Hexadella pruvoti*) and serpulid polychaetes. Encrusting and cushion shaped growth forms dominated within the cave while erected forms had much lower coverage. In the middle and inner cave sectors, the encrusting bryozoans *Hippaliosina depressa* and *Onychocella marioni* formed nodules, while serpulid polychaetes formed bio-constructions.
The ceiling stations of the entrance (0C) and middle cave zones (15C) were grouped with the semidark and totally dark stations respectively, probably due to the sharper decrease of light in relation to the corresponding walls, as a result of the substrate inclination.

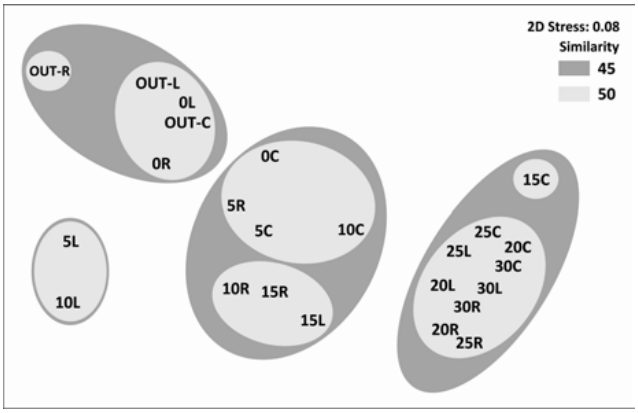

Fig. 1. Resemblance of cave assemblages demonstrated in MDS plot. C: ceiling, L: left wall; R: right wall. Numbers indicate distance from cave entrance.

The unique geomorphology of the different cave sectors can induce spatial heterogeneity of cave assemblages presumably through the modification of abiotic features [2], [3], which deserves further study in this geographic area. The creation of a digital photographic database depicting the current status of marine cave communities enables their future monitoring. This is crucial for caves frequently visited by divers and for those located in Mediterranean sub-areas which are highly subjected to alterations attributed to global climate change.

Acknowledgments
The authors thank Maria Sini for her precious help during the fieldwork. This research has been co-financed (01/2011 up to date) by the EU and Greek national funds through the Research Funding Program: Heracleitus II Investing in knowledge society through the European Social Fund. The first author also benefited from "Alexander S. Onassis Public Benefit Foundation" fellowship for postgraduate studies (10/2009-12/2010).

ACID DNASE ACTIVITY IN MUSSEL *MYTILUS GALLOPROVINCIALIS*: TEMPORAL VARIATIONS AND POLLUTION EFFECT

Ines Kovacic [1]* and Maja Fafandel [2]
[1] Juraj Dobrila University of Pula - ikovacic@unipu.hr
[2] Center for Marine Research, Ruder Boškovic Institute

Abstract
Temporal variation in the level of acid DNase activity in gills and digestive glands of the mussels *Mytilus galloprovincialis* from pristine and polluted area were determined. Acid DNase activity is tissue specific and responsive to physiological requirements and environmental conditions. Preliminary data indicated acid DNase activity in mussel gills as promising biomarker of pollution.

Keywords: Pollution, North Adriatic Sea, Enzymes, Mollusca

Introduction
New biomarkers of high sensitivity and low cost are widely investigated for marine biomonitoring purposes. Acid DNase activity has been demonstrated to be a useful biomarker for the assessment of toxic industrial pollutants in the freshwater snail [1] and in mussels from contaminated areas [2]. Our previous investigations showed that the exposure of mussels to model marine pollutants causes the increase of acid DNase activity in mussel hematocytes and hepatocytes indicating acid DNase activity as a promising biomarker [3]. In an attempt to better understand the natural and environmental changes in patterns on the acid DNase activity of *Mytilus galloprovincialis*, mussels are being collected on year basis. Preliminary results are presented.

Material and Methods
During the one year, beginning August 2012, mussels (5-6 cm in length) were collected from two sites (reference – Crveni otok and one affected by pollution – ACI marina) located in the Rovinj area, Istrian coast, Northern Adriatic. Acid DNase activity was measured in digestive gland and gills according to Fafandel et al. [3].

Results and Discussion
Acid DNase activity was detected in both tissues studied. The enzyme activity patterns in digestive glands and gills were not similar. In general, acid DNase activity was higher in gills than in digestive gland. In digestive gland maximal level occurs in October (Fig 1) while in gills maximal acid DNase activity was observed in January with no prominent peak in October (Fig 2). DNase activity increases in the period December - January in gills tissue but did not vary significantly in digestive gland where levels of enzyme activity during this period were consistently lower.

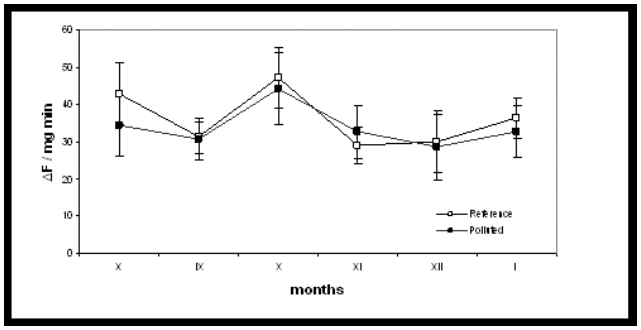

Fig. 1. Temporal variation of acid DNase activity in digestive gland of Mytilus galloprovincialis sampled from Crveni otok – reference (empty square) and ACI marina Rovinj – polluted (black square) in Adriatic sea, Croatia. (N=10)

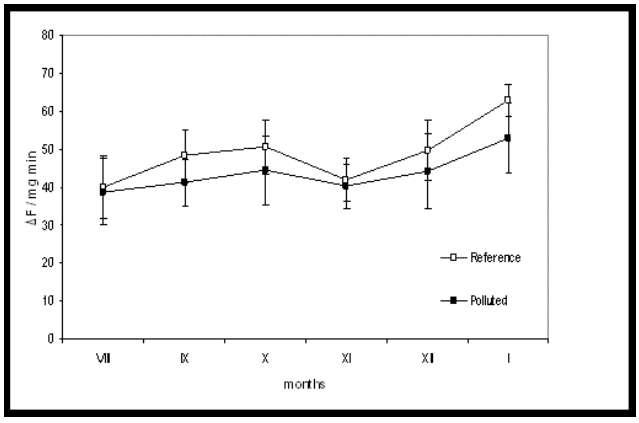

Fig. 2. Temporal variation of acid DNase activity in gill of Mytilus galloprovincialis sampled from Crveni otok – reference (empty square) and ACI marina Rovinj - polluted (black square) in Adriatic sea, Croatia. (N=10)

Difference in acid DNase activity due to the pollution impact in digestive gland was not as great as in gill tissue where enzyme activity was lower in mussels from polluted site. The highest difference in DNase activity in gills between reference and polluted site was in January.
Seasonal variations arise from a complex interaction between exogenous factors such as food availability, temperature and pollution and endogenous factors such as spawning. Spawning period was detected as significant increase of acid DNase activity in digestive gland in October due to the intense nucleic acid metabolism during gamete formation. Increase in acid DNase activity in gills during the December – January period reflects tissue-specific requirements probably due to lower temperatures during winter period. From the preliminary data presented in this work it can be concluded that DNase activity in gills can be promising biomarker of marine environmental contamination.

AQUACULTURE MÉDITERRANÉEENNE MAROCAINE : SITUATION ACTUELLE ET PERSPECTIVES DE DÉVELOPPEMENT

Abdeljaouad Lamrini [1]*
[1] Institut Agronomique et Vétérinaire Hassan II - jlamrini@gmail.com

Abstract
L'aquaculture en Méditerranée marocaine se heurte à des difficultés et ne cesse de régresser. Sa situation actuelle et ses contraintes sont passées en revue. Pour faire face à une telle situation, un réaménagement des sites actuels et la création d'autres sites sont nécessaires. Une proposition de nouveaux sites est avancée en tenant compte de leurs caractéristiques physico chimiques et des exigences aquacoles; mais l'évaluation d'une future production est complexe et nécessite une approche globale.

Keywords: Aquaculture, South-Western Mediterranean, Fishes, Bivalves

L'aquaculture a connu au niveau mondial un essor considérable passant de moins de 1 million de tonnes en 1950 à 60 millions de tonnes en 2010 (1). Elle évolue plus rapidement que les autres productions d'origine animale. Cependant, cette branche d'activité maritime n'a pas connu la même tendance au Maroc, elle a chuté de 1467 tonnes en 2005 à 332 tonnes en 2010 (2). Les sites naturels restent limités en raison des caractéristiques des côtes ; de plus, ils sont concurrencés par des projets touristiques côtiers.

La côte méditerranéenne marocaine (512 Km) est surtout rocheuse entrecoupée de baies et de fonds sédimentaires. Elle présente peu de sites protégés ; certains sont déclassés (lagunes) , d'autres sont menacés (baies).

Quant à la lagune de Nador, une des plus grandes de la rive sud de la Méditerranée (115 Km^2), elle dispose d'atouts clés liés à la richesse et à la diversité de son écosystème (3) ; elle est favorable à l'aquaculture.

MAROST, initialement installée dans cette lagune en 1985 pour élever l'huître et la palourde, a du réorganiser ses activités pour produire le bar et la daurade (4). La SAM, établie dans les années 90 sur l'estuaire de Moulouya, s'est spécialisée également dans la production de ces poissons (5).

A part ces deux sites dont les activités sont suspendues depuis 2006 pour des raisons stratégiques et de rentabilité, deux autres zones permettent l' aquaculture : baie de M'diq et baie de Ben Younech (Fig.1). Les productions ont subi une chute entre 2005 et 2010 passant de 1223 à 49 tonnes (2).

Outre les sites précités méritant d'être aménagés pour relancer des activités aquacoles, d'autres sont tout à fait indiqués pour de telles activités (Fig.1).

La lagune de Nador était dépendante du point de vue hydrodynamique d'une seule passe de 250 m de largeur (Bokhana) pour ses échanges avec la mer. Depuis 2010, un nouveau chenal de 300 m de largeur et de 6,5 m de profondeur a été établi (6). Il permet de renouveler les eaux et de restaurer la qualité du milieu. De plus, il contribue à la préservation des ressources et à la mise en place de nouvelles unités d'élevage.

Pour déterminer d'autres sites aquacoles, les conditions physicochimiques et bioécologiques du littoral méditerranéen marocains ont été examinées (7), ce qui a permis de sélectionner certains sites répondant aux exigences d'élevage. Ces sites ont été soumis à une confirmation ponctuelle de leurs caractéristiques environnementales (juillet 2009).

Quatre petites baies ont une protection partielle et des potentialités aquacoles limitées : Ras kebdana, Al Hoceima, Cala Iris et Jebha (Fig. 1)

Ras Kebdana est une réserve naturelle abritée, elle est à 6 Km à l'ouest de la Moulouya. La baie d'Al Hoceima est la partie maritime du Parc National d'Al Hoceima, elle englobe les sites côtiers les mieux préservés, l'eau y est limpide favorisant une grande biodiversité, elle offre un abri à des espèces rares. Cala Iris, située à 50 Km à l'ouest d'Al Hoceima, est une zone très abritée. La baie de Jebha survit de la pêche artisanale et de l'agriculture vivrière, une activité aquacole viendrait en complément.

Deux estuaires présentent de grands avantages du fait de leur basse situation facile à aménager : Kaa srass et Martil, mais les dangers de crues sont réels. Kaa srass, au sud de l'oued Laou, fait partie d'une aire marine protégée aux fins des pêches dont les activités peuvent être substituées par la création d'une zone aquacole. Martil, à l'embouchure de l'oued Amssa, permet aussi cette activité d'aquaculture.

Par ailleurs, étant donné les conditions climatiques clémentes du littoral méditerranéen marocain, l'aquaculture en offshore est prometteuse (8).

La production de ces sites reste à déterminer. Son évaluation est complexe et nécessite une approche globale basée sur les aspects environnementaux, technologiques, socio-économiques et stratégiques.

SULINA CASE STUDY EXPERIENCE IN PUBLIC PARTICIPATION ON ICZM PROTOCOL WITHIN PEGASO PROJECT

E. Marin [1]*, I. Nichersu [1], C. Trifanov [1], M. Mierla [1] and I. Nichersu [1]
[1] Danube Delta National Institute - jenica@indd.tim.ro

Abstract
This paper presents the experience in public participation approach carried out for Romanian case study in the frame of the PEGASO project funded by the European Union within FP7. The purpose of this research was to actively involve a wide range of stakeholders in a two day planning session, focused on issues and potentials of Sulina coastal area, with the aim to work out possible solutions for integrated coastal spatial planning within the context of ICZM protocol implementation for Black Sea. The possible solutions drawn by the participants during the session according to their point of view and interest were integrated into a final sketch and then transposed in GIS map

Keywords: Coastal management, Black Sea

INTRODUCTION
One of the objectives of PEGASO is to use the model of the existing ICZM Protocol for the Mediterranean and adjust it to the needs of the Black Sea through innovative actions. Thus, one of the tools for making sustainability assessments in the coastal zone pilots was participatory process. For the Romanian case study was selected Sulina town which is located in the South-East part of the country, on the Black Sea coast.

METHODS
For a good approach of the participatory process it was necessary to develop four thematic maps of the studied area (area location, infrastructure map, flood hazard map, map of elements vulnerable to floods) which were further used for sketching and drawing the ideas expressed by stakeholders during the session. For the public participatory approach was selected the "Sketch Match method" which is a workshop method developed by Netherlands Government Service for Land and Water Management (DLG) [1]. The interactive public participation took place in Sulina town during 2 days of work in November 2012. Participants were representatives of a wide range of stakeholders varying from local population, fishermen and NGO's to representatives of Local and County Council. The workshop consisted in forming two parallel thematic groups with following topics: spatial planning and socio-economic development.

RESULTS
The stakeholders analysed, with the help of thematic maps, the area's characteristics in two different groups. This gave them insight in the area's main problems, qualities and potentials (Fig.1):

Problems	Qualities	Potentials
• Land property issues and cadastre of Sulina coastal area	• Status of Sulina as fluvial and maritime port	• Updating the action plans and national legislation in conformity with ICZM protocol
• Lack of coastal area delineation	• Coastal biodiversity	• Potential for touristic development
• Uncontrolled development of touristic coastal activities	• Existence of wetlands and Natura 2000 sites	• Potential for public- private investments
• Decreasing fish stock and lack of a fish market Institutional conflicts	• Cultural diversity and heritage buildings	• Potential of renewable energy development
• Poor basic infrastructure in the town and coastal area	• Touristic attraction of the area	

Fig. 1. Examples of area characteristics as defined by participants

Having these starting points in mind, there were defined the main possible solutions by two categories: **(i) non structural solutions and (ii) structural solutions.**

i) it was observed that all the issues from both groups could be tackled by same **non-structural solutions**: raise public awareness which can be achieved through education, trainings, courses among population on ICZM topic as well as institutional collaboration by organizing regularly meetings at local, regional, national level.

ii) the structural possible solutions were grouped in 5 categories:

1. Infrastructure category by modernisation and enhancing accessibility. Using the "thematic maps" was identified the need of an integrated infrastructure approach and infrastructure quality improving. This refers to Garlita channel reactivation that will offer perspectives for navigation by small boats.

2. Agri-economic category which involves the necessity of reopening the canning factory and shipyard rehabilitation. Development of craft construction industry and ship repair industry were mentioned as solutions for Sulina economical revival. The reintroduction of fresh water in the southern embankment may restore opportunities for fishery in the area, enhance ecological and landscape development and offer new perspectives for local economy (developing a fish market in the area). Channel dredging was designed as a solution to improve soil quality properties of pastures for cattle breeding.

3. Within the **Social category** the main vital solution is to reopen the Hospital in Sulina in order to assure the medical care for the community. Further, creating jobs through new investments in tourism and establishment of small crafts workshops using the natural resources were other solutions sketched by the participants. Enhancement of the cultural and historical heritage and necessity of architectural building rehabilitation through legislation was also raised.

4. Tourism category which includes the delineation of camping and recreational areas as well as Sulina touristic beach in order to avoid conflicts between stakeholders. Change the functionality of a part of the deactivated shipyard for tourism purposes and job creation.

5. Environment category involves Integrated Waste Management solution in order to reduce the environment contamination hazard and waste overload.

These solutions build up the integrated final sketch for Sulina case study in which all the efforts and ideas of two days' hard work brought together (Fig.2).

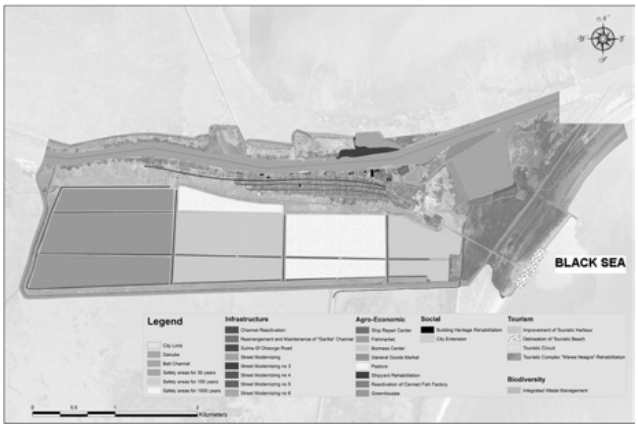

Fig. 2. The integrated final sketch with possible solutions for Sulina case study

EXPERIENCES AND LESSONS LEARNED
The results presented above emphasize a future possibility of socio-economic development of Sulina town and coastal area in accordance with ICZM protocol. The participatory session proved to be a success for Sulina case study, assuring a good cooperation process within different stakeholders, raising awareness among them.

Abstract

The Norway lobster is a burrowing decapod of elevated commercial importance for the European fishery. Understand which factors affect its diel (24-h based) catchability is of importance for its stock assessment. Here we presented preliminary results on burrow emergence modulation on lobsters exposed to water flow cycles in the laboratory simulating internal tides.

Keywords: Behaviour, North-Western Mediterranean

The Norway lobster, *Nephrops norvegicus* (L.), is a burrowing decapod distributed in the European Atlantic Ocean and in the Mediterranean Sea from 10-800 m. It is an important resource for European fishery and great attention is devoted to its stock assessment [1]. Animals can be captured only during burrow emergence and 24-h catch patterns show markedly different daily rhythms on shelves and slopes. Little is known about other ecological factors that may modulate this behavior (e.g. social interactions, hydrodynamic regimes) creating great uncertainties in stock assessment [2, 3]. Periodical sea bed currents (internal tides and inertial motion) are detected in *Nephrops* Atlantic and Mediterranean areal of distribution but their effect on burrow emergence is still unknown. Here, we presented preliminary results on the modulation of burrow emergence behavior by interplaying water currents and day-night cycles, as usually experienced by Atlantic shelf and slope populations. The burrow emergence behavior of 8 adult males of carapace length (CL; Mean ± SD) equals to 35.34±3.04 mm, was investigated in a 10-days experiment. Experiment was performed in a novel and automated multi flume actograph equipped with artificial burrows. Individual behavior was tracked by video image analysis at 10s frequency. Infrared illumination (not detectable by *Nephrops*) was always ON to track also at darkness. The trial was carried out according to the following conditions: current flow at approximately 10 $cm \cdot s^{-1}$ with a duration of 2 hours and a periodicity of 12.4-h mimicking internal tides and 15-9 monochromatic blue Light-Darkness (LD) cycles at $4 \cdot 10^{-3}$ $\mu E/m^2/s$ intensity simulating shelf conditions. Preliminary results showed that current flow have an inhibiting effect on animals' out of burrow displacement (Fig. 1), especially pronounced when occurring at darkness hours (i.e. when animals are engaged in emergence). When current started during burrow concealment (at light hours), animals retreated deeper into the burrow or scanned the outside environment with second pairs of antennae, to immediately emerge few minutes after the water flow offset.

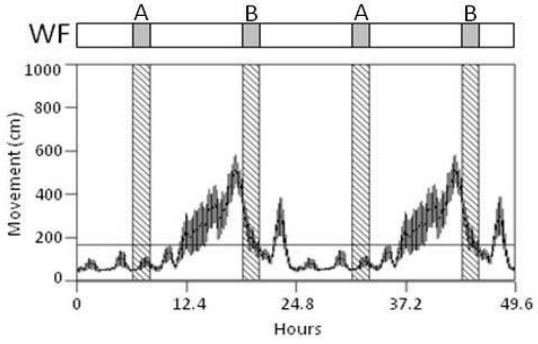

Fig. 1. Fig. 1. Double plotted waveform (24.8 h based) of one representative animal. Vertical lines represent the Standard Error of the Mean (SEM). White-grey bars represent Water Flow ON or OFF and also water flow of two hours are represented by shadowed areas. The horizontal line represents the MESOR. Water flow occurring during light hours are represented by **A** and during dark hours by **B**.

Image inspection at current flow onset showed that animals blocked themselves with a downstream orientation or immediately retired into the burrow. Blind *N. norvegicus* orientated itself downstream when exposed to water currents in laboratory [4]. Such an orientation could allow individuals to check for predators arrival, which in the case of fishes is usually performed upstream [5]. Moreover, we observed that lobsters also scanned the outside of the burrow with second antenna when current flow increases during their concealment. In this case, a speculative interpretation could relate this behavioural response to the searching for food odors bring by the current. Mechanoreceptors and chemoreceptors are present on Norway lobster's second antenna [6] and they could bring information to *Nephrops* even if it is hidden inside the burrow. No one reported before the reaction of *N. norvegicus* to water currents in presence of an important habitat feature as the burrow in presence of a LD cycle. Future research will focus on the effect of inertial motion (18h periodicity) simulating a Mediterranean scenario. These observations could be of importance when extrapolating laboratory results to the field context to obtain reliable information for fishery management of the species both in the Atlantic and in the Mediterranean.

COMMON DOLPHIN (*DELPHINUS DELPHIS*) PHOTO IDENTIFICATION IN THE REGION OF THE NE. AEGEAN SEA, GREECE

Adam King [1], Thodoris Tsimpidis [1], Anastasia Miliou [1]* and Hazel Thornton [1]
[1] Archipelagos, Institute of Marine Conservation - anastasia@archipelago.gr

Abstract
Capture-recapture analysis using photo identification was applied to the Common Dolphin *(Delphinus delphis*) population in the region of the north east Aegean Sea. The few studies which have applied photo identification techniques to this delphiniid species have used distinct pigmentation patterns and long-term natural markings on the dorsal fin to identify individuals. This study successfully identified 35 individuals from photographs obtained between 2004 and 2011, with 5 individuals sited on multiple occasions.

Keywords: Aegean Sea, Cetacea, Population Dynamics

Introduction
The Common dolphin was once one of the most common cetacean species in the Mediterranean Sea [1]. During the last decade, this species was classified as endangered based on the IUCN Red List criteria, due to a decline of 50% over the last 3 generations, the reasons behind which remain poorly understood [2], [3]. There is currently no reliable time series of abundance of common dolphins in the Mediterranean Sea, with the most recent estimate by Forcada and Hammond in 1998 [4]. For this reason, IUCN/Species Survival Commission Cetacean Specialist Group has integrated common dolphin studies among their priorities and recommended the escalation of studies focusing on common dolphin distribution abundance, population structure and factors threatening their conservation status [5], [2]. Thus with this thought in mind, we aim to estimate and photo-identify individuals of the common dolphin population frequenting in the region of the north eastern Aegean Sea, Greece.

Researchers have primarily used distinct pigmentation patterns and long-term natural markings on the dorsal fins to identify individuals [9]. Although the non-intrusive method of photo-identification of cetaceans is well established [6], only a few areas around the world, including New Zealand [7], [8], the eastern Ionian Sea [9] and the Gulf of Corinth [1], have studied common dolphins using photo-identification. Analyses of capture-recapture technique provides data on group structure, site fidelity, movement patterns [6], and yield estimates of relative and total abundance of common dolphin, essential for management and conservation planning [1].

Material and Methods
A total of 166 photographs of common dolphin obtained between September 2004 and July 2011 were examined, looking at pigmentation patterns and other markings on the dorsal fins, resulting in the identification of 35 individuals. Five individuals were frequently observed on more than one occasion (Fig. 1).

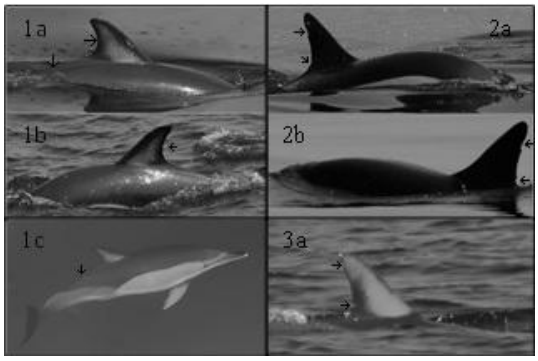

Fig. 1. Example of dorsal fin differences on three common dolphin individuals. Arrows indicate identifying features. First individual (1a,1b,1c) with distinct notch half way up the trailing edge of the dorsal fin and scar on body;, second individual (2a,2b) with two distinct notches on the trailing edge of the dorsal fin;, third individual (3a) with notch near the top and base of the trailing edge of the dorsal fin

Results and Discussion
The results of this study suggest that photo identification can be successfully applied to common dolphin population in the region of the north eastern Aegean. However, further research and photographic material are required to identify the total common dolphinpopulation in the region. As the volume of photographic material increases, the need for photographic software which can identify individuals via the analysis of pigmentation patterns is highlighted, consequently reducing potential human error.

MORPHOMETRIC SEX DIFERENCES OF THE ROUND SARDINELLA, *SARDINELLA AURITA* (VALENCIENNES, 1847), IN THE MIDDLE EASTERN ADRIATIC SEA

Bosiljka Mustac [1]* and Gorenka Sinovcic [2]
[1] University of Zadar - bmustac@unizd.hr
[2] Institute of oceanography and fisheries

Abstract
A total of 2,004 round sardinella, *Sardinella aurita* (Valenciennes, 1847) specimens were caught between November 2007 and January 2009 to analyse their nine morphometric characteristics. Monthly sampling was done from the purse seine catches in the middle eastern Adriatic Sea. The total length of males (*N*=983) varied from 11.5 to 28.0 cm (mean±*SD* =21.8 ± 3.21 cm), while it ranged from 11.0 to 32.5 cm (mean±*SD*=22.5 ± 3.67 cm) for females (*N*=1,021). A significant difference between the mean lengths of males and females was observed.

Keywords: Biometrics, Fishes, Central Adriatic Sea

Introduction : Biometry is one of the most important biological characteristics in fish population dynamics and management purposes. Since data on morphometric characteristics of round sardinella from the Adriatic Sea are sporadic, the aim of this study was to analyse its various length amounts in order to gain a better understanding of this species. Round sardinella is not an autochthonous species in the Adriatic Sea. However, nowadays due to climate change**,** round sardinella specimens are becoming more numerous and have widened their habitat (1,2,3,4).

Material and methods : Round sardinella specimens were collected from November 2007 to January 2009 by monthly random sampling of commercial purse seine catches in the middle eastern Adriatic Sea. The total length (*LT*) of the fish was measured to the nearest millimetre. Sex was determined macroscopically on the basis of the shape, appearance and structure of gonads (5). Nine morphometric (*LT, LS, LF, LA, LH, LF, H, PE, ED*; Tab. 1) characteristics were used for biometrical analysis. To analyse sex differences, variability (*V*) and two sampled *t*-test was used.

Results : Mean values of all analysed meristic characteristics for both sexes of round sardinella (*N*=2,004) are shown in Table 1. Total length of males (*N*=983) varied from 11.5 to 28.0 cm ($\bar{x} \pm SD$ =21.8 ± 3.21 cm,) while it ranged from 11.0 to 32.5 cm ($\bar{x} \pm SD$=22.5 ± 3.67 cm) for females (*N*=1,021). As presented in Table 1, females had significantly greater mean values of all analysed morphometric characteristics than males, except the eye diameter (*t*=1.59). Variability was high for all length parameters, within both sexes. The greatest variability coefficient (*V*) was observed in males length of dorsal fin base (*LA*=16.48%), while the head length of males (*LH*=13.45 %) slightly varied.

In general, mean monthly length values of females were greater than those of males, although during the February smallest total length values for both sexes were noticed (Fig.1).

Tab. 1. Morphometric characteristics of male and female round sardinella caught in the middle eastern Adriatic Sea during the period November 2007 - January 2009

Sex:	Male		Female		
Morphometric:	$\bar{x} \pm SD$	*V*(%)	$\bar{x} \pm SD$	*V*(%)	*t*
Total length (*LT*)	21.8 ± 3.2	14.71	22.5 ± 3.7	16.31	4.41
Fork length (*LF*)	19.1 ± 2.8	14.72	19.7 ± 3.1	15.76	4.38
Standard length (*LS*)	18.2 ± 2.7	14.67	18.8 ± 3.1	16.28	4.59
Anal length (*LA*)	13.3 ± 1.9	14.65	13.8 ± 2.3	16.36	4.67
Head length (*LH*)	4.09 ± 0.5	13.45	4.17 ± 0.6	14.38	3.11
Length of dorsal fin base (*DF*)	2.67 ± 0.4	16.48	2.77 ± 0.5	17.33	4.85
Maximum body height (*H*)	3.73 ± 0.6	16.08	3.87 ± 0.7	17.31	4.92
Preorbital length (*PE*)	1.29 ± 0.2	13.95	1.32 ± 0.2	15.15	3.52
Eye diameter (*ED*)	0.95 ± 0.1	14.73	0.96 ± 0.1	14.58	1.59

p<0.0001

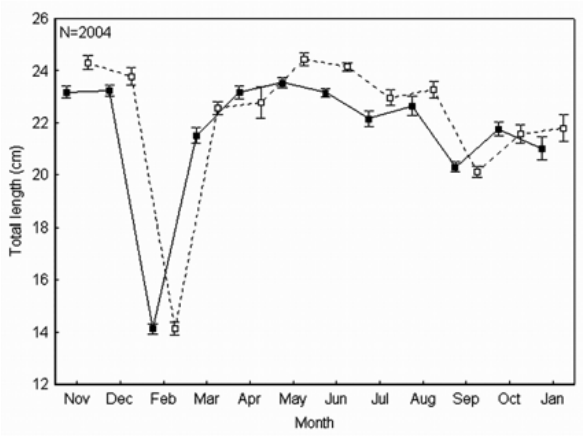

Fig. 1. Mean total length distribution (±SE) of male (plain black square : N=983) and female (empty white square : N=1,021) round sardinella from catches realized in the middle eastern Adriatic Sea during the period November 2007 - January 2009.

Discussion : The presented analyses showed that females (*N*=1,021) had significantly greater values of all analysed body lengths than males (*N*=983), except the eye diameter. Observed significant differences between sexes of the analysed mean lengths are in accordance with the results previously reported by for this species from the other seas (6). To reveal round sardinella sexual dimorphism, further and more detailed investigations, especially of genetic ones should be done.

RECENT ADDITIONS TO THE ALIEN MARINE BIOTA ALONG ITALIAN COASTS

Agnese Marchini [1], Jasmine Ferrario [1] and Anna Occhipinti-Ambrogi [1]*
[1] Department of Earth and Environmental Sciences, University of Pavia, Via S. Epifanio 14, 27100 Pavia (Italy) - occhipin@unipv.it

Abstract
New records of non-indigenous species along the Italian coasts have been reported, amounting to a total of 176, which includes suspected cryptogenic species. Many species have shown range expansion especially in the lagoon of Venice and the area surrounding Olbia (NE Sardinia).

Keywords: Tyrrhenian Sea, North Adriatic Sea, Ionian Sea, Alien species

Introduction - Target 5 of the EU Biodiversity Strategy (2011) [1] states that European countries are committed to identifying Invasive Alien Species (IAS) and their pathways by 2020, in order to develop management strategies able to control and prevent introduction and establishment of new IAS. Furthermore, in 2008 the Marine Strategy Framework Directive [2] included the presence and relative abundance of non-indigenous species (NIS) as one of the main descriptors in assessing Good Environmental Status (GES) in European marine waters. The production of validated lists of alien species and their continuous updating is therefore a crucial instrument for member states to meet the commitments towards the EU. As regards Italian coasts, a comprehensive report of multicellular NIS introduced in the period 1945-2009 was published in 2011 [3], and a focus on the hotspots of introduction and pathways was also presented [4]. Since then, new literature records have shown the presence of additional NIS or suspected cryptogenic species, as well as the range expansion of previously recorded ones. This paper offers a summary of the new records, providing an update of the presence of NIS along the Italian coast and indicating the main hotspots of introduction.

Methods - Data were extracted from AquaNIS (Information system on Aquatic non-Indigenous species)
Version: 2.0 (http://www.corpi.ku.lt/databases/index.php/aquanis).

Results - Twelve NIS, which are new to the Italian fauna, have been recorded since the publication of the list in 2011 [3] (in brackets the year of first Italian record): the macroalgae *Caulerpa taxifolia* var *distichophylla* (2008), *Gracilaria vermiculophylla* (2008), *Heterosyphonia japonica* (1999), *Hypnea flexicaulis* (2009), *Solieria filiformis* (2005), the digenean parasite *Allolepidapedon fistulariae* (2005), the polychaetes *Branchiomma bairdi* (2004), *Hesionura serrata* (2010), the crustaceans *Artemia franciscana* (2003), *Charybdis japonica* (2006), *Pseudodiaptomus marinus* (2011), and the ascidian *Didemnum vexillum* (2007). Conversely, we have not considered several recent literature records that might refer to cryptogenic species: the macroalga *Palisada maris-rubri* (1991), the deep-sea polychaete *Harmothoë vesiculosa* (2000), the ascidian *Botrylloides pizoni* n.sp., recently reported from Mar Piccolo, Taranto (2003) but likely to have originated outside the Mediterranean area. These species would require evidence from genetic analyses in order to clarify their native origin. Other species that had previously been reported in Italy have reached new regions of the Italian coastline. Most of the recent range expansions involve the lagoon of Venice (V), the Mar Piccolo of Taranto (T) and the NE coast of Sardinia, namely around Olbia (O), whereas a number of other records occurred elsewhere in Italy (E): the macroalgae *Agardhiella subulata* (V), *Aglaothamnion feldmanniae* (V), *Grateloupia turuturu* (T), the molluscs *Anadara transversa* (O), *Brachidontes pharaonis* (O), *Bursatella leachii* (O), *Crassostrea gigas* (O), *Fulvia (Fulvia) fragilis* (O), *Haminoea japonica* (E), *Polycera hedgpethi* (V), the peracarid *Caprella scaura* (T), and the bryozoans *Electra tenella* (E), *Tricellaria inopinata* (O).

Discussion & Conclusions - A former analysis of the geographical distribution of introduction events in Italy [4] had highlighted the lagoon of Venice as the main hotspot of alien species introduction, with 40 alien species introduced since 1945. The number of aliens has now increased, reaching 48, and confirms that the lagoon of Venice is an optimal site for the introduction and establishment of alien organisms. Venice also represents an important source of secondary spread of alien species by means of shipping and aquaculture activities. In particular, the transfer from Venice of live molluscs for farming has been suggested as the most likely vector, explaining the recent appearance of several alien species in the harbour of Olbia [6]. Olbia is now to be added to the list of Italian hotspots of introduction (Fig.1), displaying 12 introduced species. The updated total number of marine NIS introduced to Italy now stands at 176, but it is currently under verification as it is suspected to include a number of cryptogenic species. Eventually, the total number of NIS along the Italian coast is likely to be lower.

Acknowledgements - Support for this research was provided by the European Community's Seventh Framework Programme (FP7/2007-2013) for the project *Vectors of Change in Oceans and Seas Marine Life, Impact on Economic Sectors* (VECTORS).

Abstract
Chlorella vulgaris is a single-celled green algae with a spherical shape, about 2 to 10 μm in diameter without flagella. Ammonium (NH4+), nitrite (NO2–) and nitrate (NO3–) are the most common ionic (reactive) forms of dissolved inorganic nitrogen in aquatic ecosystems. Excessive nitrogen fertilization causes osmotic stress, in which reactive oxygen species (ROS), hydrogen peroxide (H2O2) and hydroxyl radical (•OH) are produced. reductase (NitR), rubisco large subunit (rbcL) and ascorbate peroxidase (APX) genes in Chlorella sp. were investigated in this study. There is no distinctive changes observed in chlorophyll integrity after NaNO2 treatment on the Chlorella sp. cultures. But there are variations determined on expression of APX, NitR and rbcL genes depending on nitrite stress.

Keywords: Algae, Aegean Sea

Introduction: *C. vulgaris*is a single-celled green algae with a spherical shape, about 2 to 10 μm in diameter without flagella. It contains the green photosynthetic pigments chlorophyll-a and -b in its chloroplast. Phytoplankton need nitrogen sources which are considerably important for their growth and also it is a constituent element of amino acids and thus of protein, and nucleic acids (DNA and RNA). Nitrate occurs naturally in mineral sources and animal wastes, and anthropogenically as a by product of agriculture and human wastes. Ammonium (NH_4^+), nitrite (NO_2^-) and nitrate (NO_3^-) are the most common ionic (reactive) forms of dissolved inorganic nitrogen in aquatic ecosystems. Excessive nitrogen fertilization causes osmotic stress, in which reactive oxygen species (ROS), hydrogen peroxide (H_2O_2) and hydroxyl radical (•OH) are produced. ROS are highly toxic and can cause serious damages on lipid, protein and nucleic acid metabolisms and then inhibit plant and algae growth.

Materials and Method: *C. vulgaris* was obtained from EGEMAC culture collection, University of Ege, Izmir, Turkey. Five flasks of 100 ml Chlorella sp. were used for the experiment. *C. vulgaris*culture was grown photoautotrophiclly in Bold's Basal Medium(BBM) at 27°C in under continuous illumination. Illumination provided by daylight fluorescence tubes at 20 μmol photons $m^{-2}s^{-1}$. Air was supplied to the culture. Continuous aeration was provided by bubbling air using a blower. Three different doses (0.5mM, 1mM, 2.5mM, 5 mM) of $NaNO_2$ applied to the culture flasks. Cells harvested at 24, 48, 72 and 96th hours for the analysis. For the assesment of chlorophyll integrity, DMSO added to the cell pellet and incubated at 65°C for an hour. Absorbance of the extracts was read at 665.1 nm, 649.1 nm, 435 nm and 415 nm by spectrophotometer. Chlorophyll a, chlorophyll b, and chlorophyll a/b were calculated using equations derived from specific absorption coefficients. Reverse Transcriptase-PCR was performed by using Intron he High Capacity cDNA Reverse Transcription Kit. Obtained cDNAs used for PCR analysis to determine the expression of NitR, rbcL and APX genes.

Results: The expression of *APX* encoding genes is modulated by various environmental stress including drought, salt, high light, pathogen attacks, and low temperature. In the present study, the *APX* mRNA transcript level increased after 48 h $NaNO_2$ exposure.

Fig. 1. PCR results of APX gene

Fig. 2. PCR results of NitR gene

The effects of high nitrite concentrations on alterations in chlorophll integrity and expression rates of nitrite reductase (NitR), rubisco large subunit (rbcL) and ascorbate peroxidase (APX) genes in *C. vulgaris*were investigated in this study. There is no distinctive changes observed in chlorophyll integrity after $NaNO_2$ treatment on the *C.vulgaris* cultures. But there are variations determined on expression of APX, NitR and rbcL genes depending on nitrite stress.

THE EFFECTS OF SEASON AND GENDER ON THE PROXIMATE AND FATTY ACID PROFILE OF RED MULLET (MULLUS BARBATUS) AND HORSE MACKEREL (TRACHURUS TRACHURUS)

Y. Ozogul [1]*, M. Durmus [1], M. Aydin [2], F. Ozogul [1], E. Balikci [1], S. Gokdogan [1], H. Yazgan [1] and N. Toy [1]
[1] Cukurova University Faculty of Fisheries - yozogul@cu.edu.tr
[2] Fatsa Faculty of Marine Science, Ordu

Abstract

The effects of the seasonal and gender on the proximate and fatty acid compositions in the flesh of two commercially important fish species from Black Sea were evaluated. Significant differences were found in proximate and fatty acid compositions for all seasons and gender. The major fatty acids were myristic acid (C14:0), palmitic acid (C16:0), palmitoleic acid (C16:1), stearic acid (C18:0), oleic acid (C18:1*n*9), linoleic acid (C18:2*n*6,), *cis*-5, 8, 11, 14, 17-eicosapentaenoic acid (EPA, C20:5*n*3,) and *cis*-4, 7, 10, 13, 16, 19-docosahexaenoic acid (DHA, C22:6*n*3). EPA and DHA contents were high in both fish species, increasing the value of these fish species.

Keywords: Fisheries, Black Sea

Introduction

Fish is regarded as the best source of polyunsaturated fatty acids (PUFA), especially eicosapentaenoic acid (EPA, C20:5n3) and docosahexaenoic acid (DHA, C22:6n3). Fish is one of animal protein sources as it includes amino acids, essential fatty acids, and vitamins and minerals in sufficient amounts for healthy living [1]. Fatty acids are very important nutritional elements for human health. The beneficial effect of fish consumption on human health has been related to the high content of n-3 fatty acids (PUFA). In addition, fish oil is a rich source of vitamins including vitamin A, D, E, and K, which are soluble in oil and must be taken on a regular basis because of their key roles in human health and metabolism [2]. Red mullet belonging to Mullidae family has high economic value, was widely spread in East Atlantic, Dakar, Senegal, Canary Islands, Mediterrian and Black Seas and Asor Islands [3]. Horse mackerel belonging to Carangidae family is a pelagic fish species and spread in Turkey. The total amounts of red mullet and horse mackerel caught in the Turkish coasts were 1861.4 tons per year and 18072.7 tons per year, respectively [4]. These fish species are generally consumed domestically and imported to European countries. Studies have been conducted on proximate and fatty acids content of fish species [5,6,7,8,9,10]. The aim of this research was to determine the proximate content and fatty acid compositions of two different marine water fish species from the Black Sea.

Materials and methods

Red mullet and horse mackerel were caught by a gill net for each season (autumn, winter, spring and summer) from Black Sea. Fish were then transported to the laboratory in ice for analysis. At least nine individuals from each species were gutted, filleted and minced for analyses. Lipid content was measured by the method of Bligh & Dyer [11]. Ash and moisture contents were determined as described by AOAC [12] and protein was determined by the Kjeldahl procedure using a Buchi Digestion System, Model K-424 (BÜCHI Labortechnic AG, Flawil, Switzerland) and a Kjeltec Distillation Unit B-324 (BÜCHI Labortechnic AG). Percent protein was calculated as % Nx6.25. Methyl esters were prepared by transmethylation using 2 M KOH in methanol and *n*-hexane according to the method described by Ichihara et al [13] with minor modification; 10 mg of extracted oil were dissolved in 2 ml hexane, followed by 4 ml of 2 M methanolic KOH. The tube was then vortexed for 2 min at room temperature. After centrifugation at 4000 rpm for 10 min, the hexane layer was taken for GC analyses. ***Gas chromatographic conditions*** The fatty acid composition was analysed by a GC Clarus 500 with autosampler (Perkin–Elmer, USA) equipped with a flame ionization detector and a fused silica capillary SGE column (30m×0.32mm ID×0.25µm BP20 0.25 UM, USA). The oven temperature was 140^{o}C, held 5 min, raised to 200^{o}C at the rate 4^{o}C/min and held at 220^{o}C at 1^{o}C/min, while the injector and the detector temperatures were set at 220 and 280^{o}C, respectively. The sample size was 1µl and the carrier gas was controlled at 16ps. The split used was 1:50. Fatty acids were identified by comparing the retention times of FAME with the standard 37 component FAME mixture. Two replicate GC analyses were performed and the results were expressed in GC area % as mean values±standard deviation.

Results and discussion

Determination of the effects of different fishing seasons and gender on the fatty acid composition of these species will provide valuable information on the nutrient value for both the consumers and the dieticians. In this research, significant differences ($P<0.05$) were found in proximate and fatty acid compositions among seasons and gender. The main fatty acids were myristic acid (C14:0), palmitic acid (C16:0), palmitoleic acid (C16:1), stearic acid (C18:0), oleic acid (C18:1*n*9), linoleic acid (C18:2*n*6,), *cis*-5, 8, 11, 14, 17-eicosapentaenoic acid (EPA, C20:5*n*3,) and *cis*-4, 7, 10, 13, 16, 19-docosahexaenoic acid (DHA, C22:6*n*3). EPA and DHA contents were observed to be high in both fish species, increasing the value of these fish species.

COMPARISON OF DIFFERENT WAYS TO DETERMINE AGE FOR WHOLE OTOLITH.

P. Pesci [1]*, P. Altea [1], S. Cabiddu [1], F. Palmas [1], C. Porcu [1] and S. Vittori [1]
[1] Department of Life Science and Environment, University of Cagliari, Italy. - ppesci@unica.it

Abstract
Age determination in *Mullus barbatus* Linnaeus, 1758 is generally made reading annuli in whole otoliths. They are usually seen against a black background, immersed in clear liquids. The aim of this paper is to compare the age estimation obtained with otoliths immersed in six different means (water, ethanol, glycerin, solutions of glycerin and ethanol) and dry, to understand which is the best way to read them. Coefficient of Variation (CV), Percentage of agreement (PA) and Relative Bias were calculated to evaluate the precision and accuracy. The analysis showed that age determination is more reliable when otoliths are immersed in a clear liquid (preferably a solution of glycerol and ethanol 2:1).

Keywords: North-Western Mediterranean, Growth, Teleostei, Instruments and techniques

Introduction
Age determination in *M. barbatus* is often made through the reading of otoliths. They are usually seen "*in toto*" against a black background, generally immersed in clear liquids [1, 2]. The purpose of this work is to compare and evaluate the use of different liquids, in order to indicate the more precise and accurate mean for age determination of *M. barbatus*.

Materials and Methods
40 otoliths of *M. barbatus*, collected during the MEDITS survey 2012 along the Sardinian coast (central - western Mediterranean), were selected for age reading. The individuals sampled had a total length (LT) comprised between 10 and 21.7 cm. Several pictures of each otolith have been acquired under a binocular microscope at 10 x 2 magnification with reflected light against a black background. Each otolith was firstly photographed dry, then immersed in six different liquids: water, ethanol, glycerol, 2:1 dilution with two parts of glycerol and one of ethanol (2:1 g-e), 1:1 dilution of glycerol and ethanol (1:1 g-e); 1:2 diluition with one part of glycerol and two of ethanol (1:2 g-e). At each step, otoliths were carefully rinsed in water and dried thoroughly to avoid the mixture of the different liquids and preserve the next steps. Each photo was read by three operators which did not have any information about fish length, sex and liquid used. A modal age has been estimated for each otolith, considering the average readings made by the operators with the different means. Methods were compared using the Coefficient of Variation (CV), Percentage of Agreement (PA) and Relative Bias [3]. To choose the best way of make annuli counts, we used the rank method. A rank between 1 to 7 was given to each values of CV, PA and relative bias, for each method. Then the average rank allowed to choose the most adequate method.

Results and Discussion
The age classes assigned to the sampled individuals ranged between 1 and 4 years. Each operator agreed that otoliths immersed in liquid appeared much clearer and easier to read than dry ones. The precision in the age readings has been evaluated with the CV. Water is the liquid which gave the lowest CV (6.9%) whereas the highest was obtained with dry otoliths (24.3%). High CV were also obtained using ethanol (18.5%). Accuracy has been investigated through analysis of PA. The highest values of PA were obtained immersing the otoliths in 1:1 dilution of glycerin and ethyl alcohol (PA 97.5%). The other two glycerin solutions as well gave high PA values (95% both). The less accurate reading method resulted with dry otolith (PA 60%) followed by ethanol 75%. The Relative bias analysis confirmed that the reading of dry otoliths gave the worst results (underestimation of -0.38). A certain underestimation on annuli counts came as well from the use of water (-0.10). According to this analysis, the most accurate way of reading otoliths was using glycerol (0.00) (Fig. 1). An overall average ranking was then obtained. According to it, the best way to read otoliths of *M. barbatus* was by immerging them in a solution 1:2 glycerin-ethanol. Among liquids, ethanol, which is one of the more used means, resulted the worst. However, it is clear the importance of immersing the otoliths in a clear liquid, since reading them dry always resulted the worst method.

Abstract
On March 2012, a red tide was observed in Bizerte Lagoon. The water column was characterized by a sharp pycnocline, after abundant freshwater runoff and release from dams. It was sampled at 9 depths to determine salinity, temperature, chlorophyll *a* (Chl *a*) concentration and phytoplankton abundance and composition. Water temperature (13.7 – 17.3 °C) and salinity (16 – 31.9 ° C) exhibited strong vertical gradients. Chl *a* concentration varied also vertically from 13.1 to 19.5 µg l^{-1}. Diatoms formed a pronounced bloom, which was dominated by *Chaetoceros holsaticus* (8 x 10^6 cells l^{-1}) and *C. constrictus* (7 x 10^6 cells l^{-1}). These harmful species do not produce toxins, but have long setae armed with short secondary spines and may kill fish at fairly low concentrations (<10^4 cells l^{-1}).

Keywords: Blooms, Diatoms, Lagoons, South-Western Mediterranean

Introduction
Harmful algal blooms (HABs) are increasingly reported throughout the coastal areas of all continents [1]. These events can discolour the water giving rise to red, brown, or green tides, and deplete oxygen levels through excessive respiration or decomposition. HABs negatively impact organisms in a variety of ways that can range from cell and tissue damage to organism death [1]. Increased stability of the water column due to stratification is generally favourable to HABs [1]. Here we report the incidence of a large diatom bloom which occurred after a significant winter storm event and high water stratification in Bizerte Lagoon.

Materials and Methods
Sampling was carried out on March 2012 at one station located near a shellfish farm in Bizerte Lagoon. Samples were taken from 9 depths using a HYDRO-BIOS (Kiel-Holtenau, Germany) water sampler. Water temperature and salinity were recorded *in situ* using a microprocessor conductivity meter (WTW-LF-197, Brives B.V., Germany). Chl *a* concentrations were determined using the standard spectrophotometric method of Parsons et al. [2]. Sub-samples for identification and enumeration of phytoplankton were fixed with 3 % acidLugol'ssolution and than analysed following the Utermöhl method [3].

Results and discussion
The results showed that the water column was characterised by strong vertical gradients in both temperature (13.7 – 17.3 °C) and salinity (16 – 31.9 °C) (Fig. 1) with less dense warmer surface waters floating on top of denser colder waters.

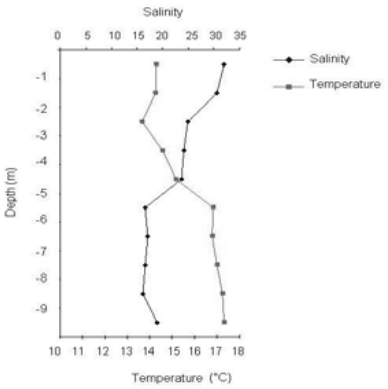

Fig. 1. Vertical profiles of water temperature and salinity in Bizerte Lagoon during the diatom bloom (17 March 2012)

Chl *a* concentration varied vertically from 13.1 to 19.5 µg l^{-1} (Fig 2), which was much higher than values generally reported for Bizerte lagoon [4].

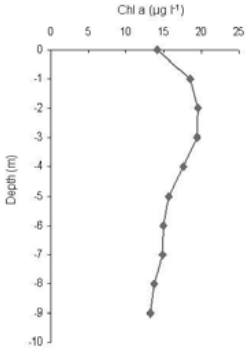

Fig. 2. Vertical profile of chlorophyll *a* in Bizerte Lagoon during the diatom bloom (17 March 2012)

Microscopic analysis of phytoplankton showed abnormally high concentrations of diatoms (Max: ~2.5 x 10^7 cells l^{-1}) dominated by *Chaetoceros holsaticus* (Max: ~8 x 10^6 cells l^{-1}) and *C. constrictus* (Max: ~7 x 10^6 cells l^{-1}). These species are non-toxic to humans, but harmful to fish and invertebrates, especially in intensive aquaculture systems, by damaging or clogging their gills [1].

Abstract
Matching exploitation to population growth rate in long lived, slow growing species is one of the more difficult tasks of conservation biology. Gorgonians are long lived species as their life-span can exceed a full century . The high valuable red coral *Corallium rubrum* is a precious Mediterranean gorgonian which populations have been subject to a selective long-lasting exploitation. Here we present our findings on colony growth rate and population age structure based on annual growth ring counts in a mesophotic population. The average colony growth rate of the basal diameter of colonies is higher in the early colony life, than decreases slowly during the following years. The aim of this research is to set out demographic models based on colony growth and transition algebraic matrixes, suitable to project population trends over time.

Keywords: Growth, Life cycles, Population Dynamics, Deep sea corals, Tyrrhenian Sea

Introduction

Age determination is a basic step in the study of population dynamics; knowing growth rates allows to estimate population age structure and to attribute a precise timing to the passage from one year to the following of each *cohort* thus setting out reliable, time explicit demographic models [1]. As red coral develops annual growth rings, an age determination method based on staining of organic matter [2] was applied to estimate the age of colonies of mesophotic "deep populations". Although our knowledge on the demographic features of red coral populations living between 10 and 50 meter depth increased considerably in recent years [3, 4 and references herein], the basic life-history traits of deep populations (the main target of harvesting nowadays), are still largely unknown (5). The aim of this study is to investigate the demography of deep *Corallium rubrum* populations [6] and to compare these findings with those obtained in the "shallow populations" of this species [7, 8, 9, 10] .

Material and Methods

To increase the demographic knowledge on deep-dwelling populations an *ad hoc* cruise was carried out during early Summer 2010 in the North and Central-East Tyrrhenian Sea (Tuscany Archipelago and Campania, between 62 and 130 m depth. [6]. A subsample of colonies from Tuscany Archipelago was sectioned and the thin-sections were stained to highlight the annual growth rings [2] . The variability in age determination between 3 different observers and that between groups of colonies of similar size (5 classes) was checked by a two factor orthogonal ANOVA which factors were: age (5 levels) and observers (3 observers). The relationship between age and basal diameter was fitted on a smaller sample of colonies, then the relation thus obtained wasapplied to estimate the age of a larger sample of colonies on the basis of their size (diameter). The growth rate and the population age structure thus obtained were compared with those previously described in shallow populations [7, 8, 9].

Results and Discussion

On the basis of a 2-way ANOVA, , no significant difference was found between the age estimated by the three independent observers. The relationship between age and basal diameter was well fitted by a power curve which was applied to share all the colonies in different size/age classes on the basis of their diameter. Thirty-height % of the overall colonies were larger than 7 mm in diameter (the minimum harvesting size in several countries), corresponding to the age of 30-35 years. The majority of colonies (97.7%) fell within the 6 – 55 years range; about half of them (51.1 %) were in the 21-25 and 26-30 age classes. Only two colonies have an estimated age of 93 and 69 years. The shallow populations previously studied at Portofino (Italy) and Cap de Creus (Spain), revealing a slightly lower average colony growth rate (0.24 vs 0,26 mm y^{-1}), less skewed age structures, shorter life-span and a several fold lower percentage of colonies below the commercial size [8].

The average colony growth rate, expressed as basal diameter of colonies, was 2-3 fold higher in the early colony life and then decreases slowly with colony age [6, 8, 10], suggesting that a larger error can be made if a linear correlation beteen the two parameters will be applied to estimate the age of larger colonies . The knowledge of these life-history descriptors, together with that of the reproductive parameters of the populations and the spatial data obtained by ROV recordings [5, 6], will greatly foster our understanding of deep dwelling red coral population structure and complex dynamics. Moreover they will allow to develop demographic models suitable to simulate population trends over time and to match harvesting to population growth rate.

Abstract
The offshore fish farming, in Italy, is rapidly expanding and becoming the most popular way the product reaches maturity. These systems use an immediately available resource, sea water, which provides the best conditions necessary to the fish growth. The mariculture coastal and offshore plants has increased almost tenfold, parallel to the increase of the production capacity of the single fish farms. These events generated a growing interest of scientific community to the alterations produced in the marine environment by these activities, mainly explicable by the placing of large quantities of wastewater with high organic content. This work shows the first results of a study aimed at the plan of the proper guidelines for mariculture siting.

Keywords: Monitoring, Aquaculture, Coastal models, Tyrrhenian Sea

Introduction and purpose of the work
The expansion of mariculture activities in the areas of interest allowed to define the 'Best Environmental Practice' to limit the impact of such activities. Within the framework of national (D.lgs152/06) and international regulations, the purpose is the environmental quality conservation related to production activities in the area that houses systems.Therefore it is necessary to provide to the administrations useful tools to assess the environmental compatibility of the sites used for mariculture. In this context the Lab. Of Experimental Oceanology and Marine Ecology (University of Tuscia) together with the Directorate for Nature Protection of the Italian Ministry of the Environment, Land and Sea, conducted a preliminary study to plan a series of guidelines for the proper siting of fishfarms in coastal areas.

Material and methods
The drafting of guidelines for mariculture plants siting has been developed through the application of a protocol for studying and monitoring a pilot area located in the Oristano Gulf in Sardinia where there is already an active mariculture plant. The review and analysis of International Standards and of the bibliography of mariculture impacts indicators and the review of offshore fishfarms in Italy (type and location) allowed to identify four groups of criteria, necessary to be assessed in order to elaborate sinoptic guidelines for the siting and to reduce the potential impacts.These criteria are: ecological/primary criteria;sanitary criteria;productive criteria; management criteria. The research activities applied to the pilot area of Oristano Gulf focused on the first criterion (ecological/primary criteria) in particular, in this first phase, the following aspects were considered: 1) development of predictive models of physical and ecological dynamics, and application of hydrodynmical models in order to simulate the diffusion of organic matter ; 2) study of integrated phytoplankton primary production in the water column; 3) water column characterization (physical-chemical-biooptical parameters) of the pilot area. The study of phytoplancton primary production and the water column characterization were carried out in two separate campaigns representative of winter and summer. The sampling plan includes 8 radial transects for a total of 29 stations, plus a further control transect composed of three 3 stations. This work shows the first results of the application of the ecological and primary criteria on a the pilot site of Oristano which allowed to verify and estimate the area of potential impacts of a fishfarm.

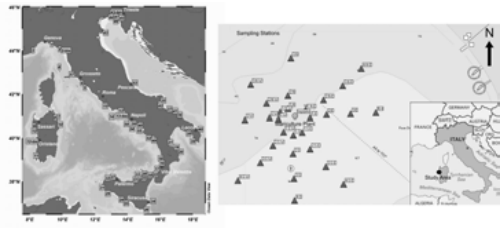

Fig. 1. Italian mariculture plants (left) and Oristano study area (right)

Results
The study area is characterized by low concentrations of the major dissolved nutrients and phytoplankton biomass. This condition of general oligotrophy is confirmed by the values of the concentration of dissolved nitrogen compounds and phosphates as well as of chlorophyll a related to the summer season and reported by IAMC-CNR of Oristano. Regarding the load of suspended solids is recognized instead an average value greater than that expected (7.54 mg/L vs 3.57 ± 1.34 mg/L). In order to acquire more information on the trophic status of the area surrounding the plant site, the concentrations of the main trophic parameters were compared with those reported by La Rosa et al. (2001) measured at a station located inside a mariculture plant in the Gaeta Gulf, and Karakassis et al. at 4 mariculture plants located in different areas of the Mediterranean Sea, respectively in Cyprus, Sicily (Italy), in Sounio (Greece) and Alicante (Spain). On the Gulf of Gaeta, in September, the concentrations of DIN (Dissolved Inorganic Nitrogen) and DIP (Dissolved Inorganic Phosphorus) are considerably higher than those reported in the present study (0.25 μmDIN / L and 0.36 μmDIP/L vs 0.08 μmDIN/L and 0.07 μmDIP/L), probably because of the different position of the monitoring stations with respect to the cages. The comparison with the data reported by Karakassis et al. showed a higher amount of phytoplankton biomass in Oristano Gulf compared to all 4 sites studied (chl a concentration is 4-5 times higher) and an average concentration of dissolved phosphates comparable to those found in Cyprus and Greece. The areas monitored in Sicily showed higher values (0.1-0.4 μm/L) whereas the areas monitored in Spain showed lower values (0.02-0.05 μm/L). The analysis of the concentrations of chlorophyll a and dissolved phosphate has also allowed to identify a spatial gradient of gradual decrease with the increasing of the distance from the cage. This gradient could be related to the enrichment of nutrients caused by mariculture activities. As for the nitrates and suspended particulate matter, instead, this decreasing trend was not detected at the distances monitored. For what concerns the modeling results, the particle size distribution of suspended particulate matter, is indicative of the hydrodynamic field of Oristano Gulf. Greater particle sizes deposited in a short time along a shorter distance from the cages, (with a minimum values measured at 245 m from the cages). The maximum values measured at 540 m form the cages shows that, at this distance, the he finer suspended component has not yet fallen on sea bottom. The increased turbidity of the water column in the stations placed at 540 m also explains the lower growth of phytoplankton organisms and dissolved inorganic nitrogen concentration.

Abstract
Le présent travail décrit les conditions du milieu et la variabilité saisonnière de la Magnoliophyte aquatique *Althenia filiformis* Petit var. *barrandonii* (Zannichelliaceae) dans la lagune de Korba. C'est le secteur Nord de la lagune qui semble présenter les conditions les plus favorables à la constitution d'herbiers pouvant être homogènes ou mixtes avec *Ruppia maritima* L. (Ruppiaceae). Dans cette zone, le développement d'*A. filiformis* s'est étendu sur 5 mois avec une biomasse variant entre 0 et 73 g MS/m^2 (Ecart-type = 17). Il s'agit d'une espèce menacée en Tunisie, comme c'est le cas dans plusieurs pays du bassin méditerranéen, étant donné sa rareté et la fragilité des écosystèmes qui l'abritent.

Keywords: Phanerogams, Gulf of Tunis, Lagoons, Phytobenthos, Hydrology

Introduction
La lagune de Korba est située dans la région du Cap-Bon au Nord-Est de la Tunisie (Fig. 1). Dans ce milieu, les peuplements phytobenthiques sont exposés aux contraintes de l'eutrophisation, au confinement et au risque d'assèchement. Les deux Magnoliophytes aquatiques *Ruppia maritima* s.s (Ruppiaceae) et *Althenia filiformis* Petit var. *barrandonii*(Zannichelliaceae) peuplant cet écosystème sont des opportunistes capables d'achever leur cycle de vie durant une courte période (un à cinq mois) avec une forte production de graines [1].

Matériel et Méthodes
Nous avons réalisé les mesures et les prélèvements durant deux cycles d'étude allant du mois de janvier 1996 au mois de décembre 1997. Nous avons mesuré la phytomasse dans trois stations réparties au Nord de la lagune, lieu de prolifération des Magnoliophytes aquatiques (Fig. 1).

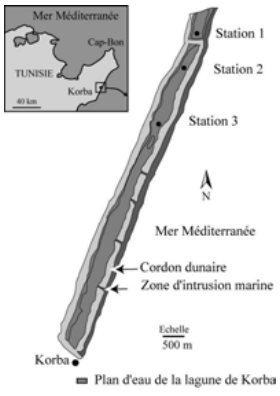

Fig. 1. Position géographique et localisation des stations d'échantillonnage dans la lagune de Korba (Nord-Est Tunisie).

Résultats et discussion
L'herbier d'*Althenia* se développe essentiellement au niveau de la station 1 du Nord de la lagune de Korba. Son extension est moins importante dans les stations 2 et 3. Les niveaux d'eau les plus faibles sont relevés à la station 1 qui passe par des périodes d'assèchement pendant la saison estivale. La hauteur de l'eau est comprise entre 0,2 à 0,4 m dans les stations 2 et 3. La salinité a varié entre 22 et 86, avec des fluctuations assez proches dans les 3 stations. L'évolution mensuelle du pH montre des valeurs comprises entre 7,5 et 9,5.
L'apparition d'*A. filiformis* s'est limitée à 5 mois/an depuis l'hiver jusqu'à la fin du printemps ou le début de l'été. La biomasse moyenne a varié de 0 à 73 g MS/m^2 (Ecart-type = 17) dans la station 1, de 0 à 15 g MS/m^2 dans la station 2 (Ecart-type = 13) et de 0 à 104 g MS/m^2 dans la station 3 (Ecart-type = 22). La production de biomasse a varié entre des valeurs <0,1 g MS/m^2/j (station 2) et 0,4 g MS/m^2/j (station 3). La production annuelle de biomasse la plus importante a été relevée à la station 3 avec 155,7 g MS/m^2 en 1996 et 69,8 g MS/m^2 en 1997 (Tab. 1)

Tab. 1. Productions de biomasses annuelles et journalières par unité de surface (g MS/m^2) de la Magnoliophyte *Althenia filiformis* dans la lagune de Korba.

Stations/Année	1996		1997	
	Production annuelle	Production journalière	Production annuelle	Production journalière
Station 1	95,49	0,26	68,66	0,19
Station 2	14,80	< 0,10	0,16	< 0,10
Station 3	155,75	0,43	69,84	0,19

A. filiformis, plante annuelle à reproduction sexuée, est inféodée aux zones humides du littoral méditerranéen [2]. Dans la lagune de Korba, elle se développe dans le secteur Nord dans des eaux relativement peu profondes (< 0,4 m) et souvent en association avec *R. maritima* comme c'est le cas dans d'autres lagunes méditerranéennes ([1] ; [3]). La salinité du milieu montre une grande variabilité, vu l'instabilité des apports en eaux douces et des échanges avec la mer. La lagune est souvent exposée à des périodes d'assèchement plus ou moins longues dans le secteur Nord. Dans ce milieu, *A. filiformis* a germé dans des conditions où les salinités sont proches de 25, dépassant largement les valeurs indiquées dans des conditions expérimentales rapportant le maximum de germination à une salinité de 13 et l'optimum de croissance à des salinités comprises entre 6 et 13 [3]. Dans notre cas, la plante arrive à supporter des salinités allant jusqu'à 78. Elle disparait suite à des changements rapides de salinité. En un mois, on a relevé la disparition de la plante suite à une baisse brusque de salinité (écart de 34,8) et le même phénomène a été observé suite à une augmentation rapide de salinité (écart de 17,7). Il est à noter que le pH est généralement alcalin durant la période de croissance d'*A. filiformis*. Dans l'ensemble, les caractéristiques hydrologiques du milieu confirment les tendances eutrophes de la lagune de Korba. Après déviation des rejets des eaux usées vers la station de traitement de Korba et déversement des eaux traitées au Nord de la lagune (depuis 2002), des transformations notables ont affecté la diversité et la répartition des Magnoliophytes, notamment l'apparition au Nord de la lagune de *Potamogeton pectinatus L.* (Potamogetonaceae), espèce à affinité d'eau douce. Plusieurs projets d'assainissement et d'aménagement des zones côtières du Cap-Bon sont en cours de réalisation et ces écosystèmes lagunaires relativement sensibles sont menacés. De ce fait, des mesures de protection sont recommandées pour la sauvegarde de ces biotopes très importants pour la survie de la Magnoliophyte *A. filiformis*, protégée dans certains pays du bassin Méditerranéen.

Abstract
L'holothurie est un animal marin qui ne fait pas partie des traditions culinaires Tunisiennes. Ce travail vise l'étude de la composition biochimique de *Holothuria polii* en vue d'une éventuelle présentation aux consommateurs. Les résultats des analyses biochimiques ont montrés que la teneur en lipides est de 10%, les protéines présentent un taux de 8%. Le profil lipidique des acides gras AG de la chair de *Holothuria polii* étudiée à l'état frais, révèle que la fraction des AG polyinsaturé AGPI est la plus dominante. Elle est représentée essentiellement par la famille des omégas 3 par le C20 :5 n-3 (EPA). Les acides gras saturés représentent la fraction intermédiaire des acides gras totaux. Les acides gras saturés représentent la fraction la plus faible des lipides totaux. <\/div>

Keywords: Biotechnologies, Chemical analysis, Echinodermata, Tunisian Plateau

Introduction
L'holothurie ou concombre de mer est un animal marin appartenant à l'embranchement des échinodermes. Parmi les 11 espèces inventoriées en Tunisie, *Holothuria polii* et *Holothuria tubulosa* sont à la fois fréquentes et abondantes le long du littoral Tunisien. Les holothuries sont des espèces de haute valeur nutritionnelle. Elles sont très appréciées par les consommateurs asiatiques. En Tunisie, ces organismes marins constituent une faune méconnue sur le plan biologique, écologique et nutritionnel. Ce travail vise l'étude de la composition biochimique et la qualité nutritionnelle de *Holothuria polii* afin de promouvoir la commercialisation de ce produit en Tunisie.

Méthodes
L'échantillonnage des Holothuries a été effectué au niveau de la baie de Bizerte. Deux méthodes analytiques d'extraction des lipides (Folch et *al*, 1957) et de méthylation des acides gras (Cecchi et *al*, 1985) ont été utilisées.

Résultats
Les résultats issus de la présente étude mettent en évidence la haute valeur nutritionnelle de cette espèce vue sa richesse en protéines et en lipides. La teneur en cendre est très importante en raison de la nature calcaire de l'endosquelette. Les teneurs en lipides et en protéines sont respectivement de 10g/100g de 8g/100g de matière fraîche (tableau 1).

Tab. 1. Composition biochimique de la chair de *Holothuria polii*

	Eau %	Protéines%	Lipides %	Cendres %
***Holothuria Polii* à l'état frais**	83.81	8	10	46.43

Selon les analyses effectuées par la chromatographie en phase gazeuse, une vingtaine d'acides gras ont été identifiés dans les lipides totaux de la chair des holothuries (tableau 2).
Le profil lipidique des AG de cette espèce, révèle que la fraction des AG saturés (A.G.P.I.) est la plus dominante avec un taux de 50,06%. Ce sont essentiellement des AG de la famille des omega 3 et omega 6. Il s'agit de l'acide docosahexaénoïque DHA C22:6 n-3, l'acide éicosapentaénoïque EPA C20:5 n-3 et l'acide linoléique C18:2 n-6. Les acides gras saturés représentent la fraction intermédiaire des acides gras totaux. Ce sont en majorité l'acide myristique C14:0, l'acide palmitique C16:0 et l'acide stéarique C18:0. Cependant, les acides gras monoinsaturés AGMI présentent les taux les plus faibles. Le taux est évalué à environ 20,98%. Ils sont représentés par les acides gras C16:1 n-7, C18:1 n-9.

RAPD ANALYSIS OF THE GENETIC VARIABILITY IN THE POPULATION OF THE SEA CUCUMBER *HOLOTHURIA POLII* AROUND THE MALTESE ISLANDS, CENTRAL MEDITERRANEAN

David Spiteri [1]* and Adriana Vella [1]
[1] University of Malta - davids@vol.net.mt

Abstract
Randomly amplified polymorphic DNA (RAPD) analysis was used to assess the genetic variation of the sea cucumber *Holothuria polii* population. A total of 33 loci were chosen from the 7 primers used. The study revealed that there is divergence between sub-populations found on the east coast and the west coast of Malta, especially at the Anchor Bay site (I = 0.7; D = 0.3). On the other hand, Delimara's sub-population showed a high homozygozity and less effective alleles (H = 0.214, N_e = 1.295), possibly due to a decline in numbers, as a result to new selection pressures. The UPGMA dendrogram obtained of the entire Maltese population shows that *H. polii* is sub-divided into two distinct populations, the north-westerly sub-populations and the south-eastern sub-populations.

Keywords: Mediterranean Ridge, Malta Trough, Malta Channel, Coastal waters

Introduction
Studies carried out on species similar to H. polii were carried out in different environments, some consisting of large geographical areas, and in protected reefs (Uthicke & Benzie, 2001). Here, "no apparent restrictions to gene flow" (Uthicke & Benzie, 2001) were noticed, meaning that no genetic differences were present. The Maltese Islands are small and situated in the middle of the Mediterranean, making the sea currents in the area highly erratic. In fact, due to the shallow bathymetry and the proximity of the two major islands in the Maltese archipelago, a complex system of mesoscale eddies and gyres forms close to the islands (Drago et al., 2003).

Material and Methods
In this study, the RAPD primers, shown in table 1 below, were selected at random from other studies carried out on other echinoderm species.

Tab. 1. RAPD primers utilised in this study

Name	Sequences 5'-3'	TA	Reference
Primer 104	GGG CAA TGA T	36°C	Karako *et al.*, 2002
Primer 148	TGT CCA CCA G	36°C	Karako *et al.*, 2002
Primer 159	GAG CCC GTA G	36°C	Karako *et al.*, 2002
Primer 2	GTT TCG CTC C	36°C	Chenuil *et al.*, 2004
Primer OPI-07	CAG CGA CAA G	41°C	Dupont *et al.*, 2000
Primer OPF-13	GGC TGC AGA A	41°C	Dupont *et al.*, 2000
Primer OPA-11	CAA TCG CCG T	41°C	Dupont *et al.*, 2000

A total of 15 primers were screened, and 7 were selected to produce 33 loci. A statistical correction in accordance with Lynch and Milligan (1994) was applied, in order to result in 6 highly polymorphic loci. Gene diversity within the three islands was found to be at an average of 43%. Overall, the Maltese Island sub-populations were found to be closely related except for the locations of Anchor Bay and Delimara.

Results
The average heterozygozity obtained in this study is higher than that found in a previous study carried out by Spiteri (2007). In this previous study the average heterozygozity was found to be 0.13. The higher value of expected heterozygozity should not be at all surprising since in this present study the population had a greater amount of alleles and a much larger distribution, than the previous study, due to the use of more loci. In fact once the grouping of closely related sites was carried out, the expected heterozygozity increased drastically, as the possibility of a small sample size was removed.

The Delimara sub-population revealed a lower effective number of alleles and therefore lower heterozygozity, which could be due to biological factors such as inbreeding, possibly due to a decline in numbers, and the Wahlund effect. The sub-population could also have passed through a recent bottleneck. In fact Freeland, 2008 describes that "allelic diversity usually decreases after a bottleneck because rare alleles are lost". A study on the same population (Spiteri, 2007) using allozymes, also resulted in an observation of a high level of inbreeding within the same site. Inbreeding can also lead to homogeneity, the effect of which can be made worse in a small population due to breeding with closely related individuals. This inbreeding can eventually lead to a reduction in genetic diversity. Although inbreeding may cause problems in future generations because of the existence of deleterious recessive alleles, there might still be a genetic advantage by preventing recombination between adaptive loci (Primack, 1998).

Once the analysis was carried out, in order for the Maltese islands to be studied as an entire population it was observed that the sub-populations at Anchor Bay (pop. 6) and Delimara Creek (pop. 1) were the most divergent from the rest of the sub-populations. A test was carried out using UPGMA (Unweighted Pair-Group Method using an Arithmetic average), which defines the "intercluster distance as the average of all the pair-wise distances for members of two clusters" (Weir, 1996). The estimated distances of the branch length refer to the likeliness ratio, meaning that the further away the branching is, the more divergent the sub-population is.

ALLOZYME GENETIC VARIABILITY IN THE SEA CUCUMBER (*HOLOTHURIA POLII)* AROUND THE MALTESE ISLANDS

David Spiteri [1]* and Adriana Vella [1]
[1] University of Malta - davids@vol.net.mt

Abstract
Allozyme electrophoresis was carried out over 7 loci that were selected from a maximum of fourteen enzymes. These 7 loci showed an average polymorphism, over the entire population, of 23%. Genetic index and distance showed that a genetic variation is present in the sub-populations surveyed, with a significant difference within the sub-populations of Delimara and Anchor Bay. 54% of the specimens sampled show that they are coming from the same population. Another 12%, mainly specimens collected from Anchor Bay, show that they are genetically different. In both these sites, different sub-populations may have been in contact with different environmental conditions allowing for changes to occur. Differences in allelic frequencies between *Holothuria polii* from different sites were also detected.

Keywords: Mediterranean Ridge, Malta Channel, Coastal waters

Introduction

Information on the biology and ecology of the sea cucumber *Holothuria polii* is sparse, since unlike most of its close relatives, it does not hold any economic value. However, being a relatively abundant species in the Mediterranean Sea, genetic studies on this species would have been expected, especially due to its unique characteristic organs' evisceration reflex on predatory-like stimulation. This allows for easy tissue collection, preventing any harm to the local population, as the organism can be put back in its natural habitat. Being filter-feeders, and relatively sedentary, holothurians are highly dependent on their environment (Ocana *et al.* 2005, Purwati & Luong-van 2003), allowing for behavioural changes to occur if any slight change in the environment occurs.

Materials and Methods

Allozyme electrophoresis

Approximately 300mg of frozen (-80^{o}C) gut tissue was mixed with the same amount of volume of extraction buffer (100mM Tris adjusted to pH 8.0 with HCl). Electrophoresis of all enzymes was carried out on 12% horizontal starch gels. In an initial screening process, 14 enzyme systems were used in order to select the best enzyme loci. The seven enzyme loci surveyed were: Phosphoglucomutase (E.C. 2.7.5.1, PGM*), Malate Dehydrogenase (E.C. 1.1.1.37, MDH*), Malate Dehydrogenase Phosphate (E.C. 1.1.1.40, MDHP*), Superoxide Dismutase (E.C. 1.15.1.1, SOD*) and Alcohol Dehydrogenase (E.C. 1.1.1.1, ADH*) as described in May 1992 These were analysed on R-Buffer (Gel Buffer: 0.03M Tris, 0.005M Citric acid, 2.5% Tray Buffer, pH 8.5; Tray Buffer: 0.06M Lithium Hydroxide, 0.3M Boric Acid, pH 8.1; electrophoresis for 7 hours at 200V and 38±2mA). Isocitrate Dehydrogenase (E.C. 1.1.1.42, IDH*) and Glucose-Phosphate Isomerase (E.C. 5.3.1.9, GPI*) as described in Murphy *et al.* 1996, were analysed on Tris-Citrate Buffer (Tray: 0.687M Tris, 0.157M Citric, pH 8.0; Gel: 1:25 Tray buffer diluted with water; electrophoresis for 5 hours at 100V and 34±4mA).

Results

Polymorphism in this investigation was found to be 23%. When compared to the value of 44% given by Bader (1998), it can be interpreted that polymorphism was low in the individuals sampled in the Maltese Islands. On the other hand in this study the mean heterozygozity was 0.13, while that reported in Bader (1998) was 0.124. These results agree with the statement that Bader made, "that the calculation of polymorphism is much more prone to statistical tests due to small sample sizes". The expected heterozygozity is not affected by this.

A statistical difference that was observed in this study was on the locus of PGM. There was no significant difference between the F_{IS} index of the other loci, and also in the mean F_{IS}. McDonald (1991) mentioned that there is evidence for temperature selection to occur at the PGM locus in certain organisms. In fact one should note that 1.3km north from Kalanka (sampling site), Hofra IZ-Zghira, the Enemalta power station is located, which releases hot water into the surrounding environment. This electricity generating plant is thus allowing for higher than average sea temperatures along the Delimara creek (Axiak and Sammut.2002; Borg, 2002). This is because the power plant, discharges its coolant water directly into the marine environment (Marsaxlokk and Delimara), at a temperature of 120°C (Borg, 2002).

Another prominent observation was at Anchor Bay sub-populations, were values for the genetic distance were found to be above 0.2. These indicate that a divergent sub-population is present. This can be related due to the fact that, one of the major outfalls is located in this area.

However to further critically assess the genetic variation around the Maltese islands, the sampling sites were grouped according to their vicinity and aspect.

The results show that although, the values, including the site for Anchor Bay, do not fit in the index range for sub-population divergence, they do not fit in the values for closely related sub-populations either. Thus the sub-populations found in the region, consisting of Anchor Bay, Ghajn Tuffieha and Ghar Lapsi (West) were still indicating divergence from the rest of the entire population.

COMPARATIVE STUDY OF SOME ENVIRONMENTAL PARAMETERS ALONG THE MEDITERRANEAN EGYPTIAN WESTERN COAST, WINTER 2009&2010

A. Tadros [1]*, A. Radwan [1], H. Hemaida [1], M. S. Guerguess [1], M. Mahmoud [1] and F. Asaad [1]
[1] National Institute of Oceanography and Fisheries - Bt_aida@yahoo.Com

Abstract
The present study aims to evaluate and compare the environmental parameters; temperature, salinity, dissolved oxygen (DO), oxidizable organic matter (OOM) and total alkalinity during winter 2009 and 2010 of the western Mediterranean coast of Alexandria, Egypt. The data revealed that, the averages of temperature (except El Mex area) and DO during winter 2009 in the studied marine sectors are higher than their corresponding values during winter 2010. Opposite trend is obtained with salinity and total alkalinity. The maximum average concentration of OOM was found at El Hammam sector and the minimum at Sidi Kerir, winter 2010. The surface distribution of both temperature and salinity decrease westwards during both winter seasons.

Keywords: Coastal waters, Hydrography, South-Eastern Mediterranean

Introduction: The northwestern coast of Egypt is extending 510 km from Alexandria to El-Saloum. The coast of this area is covered with fine and white carbonate sands [1]. The coastal zone is distinct by clear blue water; mild weather and sun prevailing most of the year which made this coast an attractive site to be developed rapidly for tourist. The previous study revealed that, during the last three decades, many touristic cities were constructed along the western coastal area exhibiting signs of stress, population pressure which cause impact to the area [2]. In this study, seawater samples were collected at sites distributed along the western coast of Alexandria, Egypt lying between longitudes 25.25ºE to 29.88ºE during winter seasons of 2009 and 2010 for studding the above mentined parameters. The distribution of the parameters was investigated and the comparison of their values during winter 2009 and 2010 were discussed.

Material and methods: Ten marine sectors during winter 2009; El Mex, Sidi Kerir, El Hammam, El Alamaen, El Dabaa, Foka, Alam El Room, Marsa Matrouh, Sidi Barani, El Saloum and six marine sectors; El Mex, Sidi Kerir, El Hammam, Marsa Matrouh, Sidi Barani and El Saloum during the winter of 2010 were studied for the above parameters (Fig1).

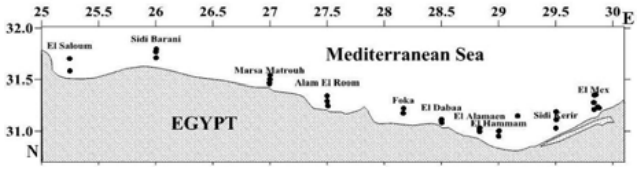

Fig. 1. Sampling locations of sectors, Med. western coast, Egypt.

The seawater samples were collected at depths ranging from 0-200m. The temperature and salinity were measured in situ using CTD. DO of seawater samples were determined according to Winkler modified method [3], oxydizable organic matter according to Calberg [4] and total alkalinity was measured according to the method described by Strickland and Parsons[5].

Results and discussion: The temperature and salinity of the studied marine sectors during 2009 lie in the ranges (16.47ºC, El Salum,-17.52ºC, El Mex) & (38.54, Sidi Barani & El Saloum- 38.79, El Almaen) respectivly. These ranges are slightly increase in their range values during 2010 (except the temperature at El Mex sector) and found to be (16.27, Sidi Barani & El Saloum-18.47ºC, El Mex) & (38.56, El Saloum-38.88,El Hammam).The surface distribution of temperature and salinity during both winter seasons decreased westwards of the Mediterranean coast, Alexandria, Egypt. The maximum temperature during 2009 and 2010 was recorded at El Mex with values (17.42ºC and 17.79ºC) and its minimum value (16.73ºC) measured at Marsa Matrouh and Sidi Barani. Also the highest surface salinity was measured at Sidi Kerir (39.9&39.93) during both winter seasons while the minimum (38.55) measured at Marsa Matrouh and Sidi Brani in winter 2009 and 38.64 measured at Sidi Barani, winter 2010. The minimum average temperature of seawater was 16.2ºC (El Dabaa, 2009) and 16.76ºC (Sidi Kerir, 2010) while El Mex sector recorded the maximum average water temperature during both winter seasons (20.05ºC and 17.89ºC) respectively.The difference in the averages of temperature measured during the winter seasons 2009 and 2010 in the marine sectors; Marsa Matrouh, Sidi Brani and El Saloum indicate the decrease in seawater temperature westward of Alexandria coast, Egypt with values 0.01, 0.03 and 0.08°C. The maximum average of salinity found at Sidi Kerir (38.902) and at El Hammam for 2009 and 2010 respectively while the minimum salinity value (38.55 and 38.65) was found at El Saloum and Sidi Barani. Dissolved oxygen concentration in the studied marine sectors; winter 2009 lie in the range (5.6ml/l, Sidi kerir) to (12.99ml/l, Sidi Barani) and decrease during winter 2010 to the range (4.9ml/l, El Saloum) to (11.5ml/l, El Hammam). During winter 2009, the average DO values are nearly similar at El Alamaen, El Dabaa, Marsa Matrouh and El Saloum sectors and found to be (11 ml/l) and the lowest average recorded at Foka sector (6.051 ml/l). It is clear that the maximum average concentration of dissolved oxygen recorded in El Alamaen sector (11 ml/l) recorded the lowest average of oxidizable organic matter concentration (1,615 $mg0_2/l$) and the highest value of OOM calculated at Foka (4.272$mg0_2/l$) met with the minimum DO concentration in comparison with its values of the rest of the marine sectors. Dissolved oxygen average values of the studied marine sectors during winter 2010 is lower than their corresponding values during 2009 and ranged between a maximum of 8.8m/l (El Mex) and a minimum of 5.8m/l (El Saloum). The previous date recorded lower DO and OOM content during winter 2006 and their average values reported in the range (4.23ml/l-5.32ml/l) and (0.17$mg0_2/l$-0.42$mg0_2/l$) in the marine sectors from El Dabaa-El Salouml[2]. The total alkalinity was measured at surface water and at selected depth of each station. Generally the total alkalinity measured in the seawater samples during winter 2009 in all marine sectors lie in the range (2.016meq/l, El Salum to2.784meq/l, El Hammam) is lower than their corresponding total alkalinity values during the winter season 2010 (2.727meq/l, Sidi Barani to 3.333meq/l ,El Saloum). The lowest average total alkalinity during 2009 and 2010 was measured at El Mex sector with value 2.66meq/l and the highest average total alkalinity values (2.72meq/l) was measured at El Hammam marine sector (2009). The maximum average of total alkalinity during 2010 (2.98meq/l) was recorded at the four marine sectors (Sidi kerir, El Hammam, Sidi Barani and El Saloum). The study of environmental parameters during winter 2009 and 2010 revealed the decrease of temperature and salinity westwards. The averages of DO and temperature during winter 2009 are higher than their corresponding values during winter 2010 and the opposite obtained with salinity and total alkalinity. The highest temperature and salinity recorded at El Mex and Sidi Kerir, while their minimum value was found at marine sectors located westwards.

FIRST DOCUMENTED REPORT OF TWO SPONGE SPECIES IN THE BLACK SEA COAST OF TURKEY

B. Topaloglu [1]*, M. Sezgin [2], L. Bat [2], M. Zengin [3] and S. Karakulak [4]
[1] Istanbul University Fisheries Faculty Istanbul; Turkish Marine Research Foundation Istanbul/ Turkey - topalbl@istanbul.edu.tr
[2] Sinop University, Fisheries Faculty
[3] Central Fisheries Research Institute Trabzon/ Turkey
[4] Istanbul University Fisheries Faculty Istanbul/ Turkey

Abstract
No sponge species has been reported from the Black Sea coast of Turkey so far. This study is the first attempt on sponges of the Black Sea coast of Turkey with two new reports: *Suberites domuncula* (Olivi, 1792) and *Dysidea fragilis* (Montagu, 1818).

Keywords: Porifera, Black Sea, Zoobenthos

Introduction
Sponges are the most primitive members of multicellular animals and play important role as habitats in the marine environment. The studies about the sponge species and especially taxonomic studies are very limited in the Turkish Coasts. According to Saritas [1] the earliest information on the sponges was reported by Forbes (1844) and first report was published by Deveciyan [2] in Turkey. Beside this, several studies were published on the sponge populations of Aegean Sea by Saritas [1; 3] and Ergüven et. al. [4]. Topaloglu studied the sponge populations of the Marmara sea [5]. Katagan reported a faunistic study about the sponge species of Turkey without any taxonomic description [6]. The latest study was realized by Evcen and Çinar [7] on the sponge species from the Mediterranean coast of Turkey and the authors gave a checklist of sponges for the coasts of Turkey and reported 115 sponge species for the sponge fauna of Turkey. Some information was given on the sponge species of the Black sea coast for Romania by Müller [8] and for Bulgaria by Konsulov [9] and Marinov and Golemansky [10]. According to the previous study [7], no sponge species have been reported from the Black Sea coast of Turkey. Therefore, this is the first report on the sponges of the Black Sea coast of Turkey.

Material and Method
Samples were compiled from several studies realized between 2008 – 2013 by trawl and SCUBA diving (see Fig.1). The samples were taken between 20-100 m depths by trawl and 5-8 m by SCUBA diving. Materials were fixed by 70 % ethanol and histological preparation for spicules and sponging skeletons were made following the Rützler method.

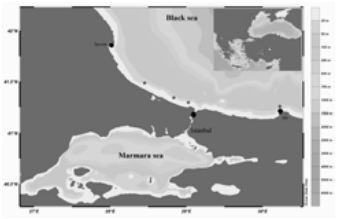

Fig. 1. Sampling Stations (* Trawl stations • SCUBA Diving stations)

Results and Discussion
Two sponge species were identified. Specimens of *Suberites domuncula* (Olivi, 1792) were collected by trawling and *Dysidea fragilis* (Montagu, 1818) by SCUBA diving. Marine species identification portal was used for identification and taxonomic description of the species (http://species-identification.org). *D. fragilis* has blue-grey color, lobate, elastic and without spicule skeleton, instead it has a network of fibres loaded with sand grains, broken spicules and other foreign material. Sometimes foreign spicules which are contaminated from other sponges can be observed in microscopic examination. The species is common in shallow waters of the Black Sea coast of Turkey. Mostly found on hard substrates, on rocks or on organisms like *Mytilus galloprovincialis* (see Fig.2.). *S. domuncula* changes from orange to brown color depending on its surrounding habitat. The collected samples in this study were mostly brown due to the muddy characteristic of the habitat. The shape is elongated globular, inhabited by a hermit crab or gastropod shell, the size up to 10 cm in diameter. The surface is smooth and velvety. Apart from the opening used by the hermit crab, there are no clearly developed oscules. Spicules are consisting tylostyles up to 250-350 x 3-5 µm. and 180-350 x 3-5 µm styles (see. Fig.2). The number of the sponge species was given as seven by Müller [8] on the Black sea coast for Romania; 22 by Konsulov [9] and 29 by Marinov and Golemansky [10] for Bulgarian coasts. There is no documented record for The Black Sea coast of Turkey. This study is the first attempt on the sponge species in the area. We actually assume that the Black Sea coasts of Turkey are more diverse. Future studies will demonstrate real numbers and the ecological roles of the sponge species in the area.

LONG TERM VARIATIONS OF NUTRIENTS AND CHLOROHYLL *A* IN THE COASTAL WATERS OF THE SEA OF MARMARA

Muhammet Turkoglu [1]* and Suleyman Tugrul [2]
[1] C.Kale Onsekiz Mart Univ., Marine Scien.&Techn.Fac. - mturkoglu@comu.edu.tr

Abstract
Temporal variations of nutrients and chlorophyll *a* (Chla) in the Sea of Marmara were investigated in relation to the eutrophication between March 2002 and December 2005. Average nutrient levels in Tekirdag were higher (NO^-_2+NO^-_3, PO^{-3}_4 and SiO_4 were 0.65±0.86, 0.19±0.37 and 3.91±5.56 mM, respectively) than the average concentrations in Çanakkale (NO^-_2+NO^-_3, PO^{-3}_4 and SiO_4 were 0.51±0.54, 0.08±0.08 and 2.41±1.69 mM, respectively). While average elemental ratios of N/P, Si/N and Si/P were 7.10±10.7, 27.7±107.6 and 62.3±110.7, respectively in Tekirdag, they were 12.3±23.1, 8.57±7.87 and 51.6±46.6 respectively in Çanakkale. In light of these ratios, the system was limited by nitrate than phosphate. Annual average chla concentration was over the 2.50 µg L^{-1} (average: 2.78±3.21 µg L^{-1}). Chla reached to 20.0 µg L^{-1} in some productive periods.

Keywords: Marmara Sea, Nutrients, Chlorophyll-A, Eutrophication, Time series

Introduction: the Sea of Marmara is located between the Aegean Sea and the Black Sea and has two flow systems reverse to each other [1]. The surface waters of the system are originated from the Black Sea surface waters. However, the surface layer waters of south west area of the Dardanelles (St. D) are largely affected by under layer waters due to the topographic upwelling [2].

To determine eutrophic situation of the surface waters in coastal stations of the Sea of Marmara, long temporal variations of nutrients and chlorophyll *a* (chla) were carried out connected with the CTD parameters in the period of March 2002 and December 2005.

Materials and Methods: the data was collected during cruises in the period of March 2002 and December 2005, in the framework of a National project of DIE (TUIK) - DPT, Turkey. It was collected 184 surface samples for each variable during the four years sampling period in the Dardanelles (Fig. 1). While CTD parameters were measured by using YSI 6600 MPS, nutrients and chla were analyzed according to the method of Strickland and Parsons (1972) [3].

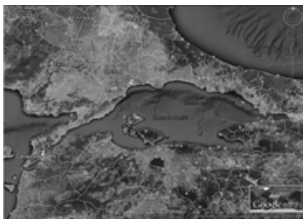

Fig. 1. The Sea of Marmara and sampling stations.

Results and Discussion: findings showed that while surface temperature varied between 5.83 and 29.80 °C (average: 17.33±6.94 °C) in the costal waters of Tekirdag (Sea of Marmara: St.M), it varied between 5.83 and 26.6 °C (average: 16.1±6.37 °C) in the costal waters of Çanakkale (Dardanelles: St.D). Due to different water layers, surface salinity values varied between 21.08 and 28.76 ppt (average: 23.83±1.79 ppt) in the Sea of Marmara, whereas the salinity varied between 21.9 and 37.1 ppt (average: 25.3±2.71 ppt) in the Dardanelles. Average level of dissolved oxygen was generally close to saturation limit (8.79±1.69 mg L^{-1}). Moreover, pH levels were in limit values and varied between 7.68 and 8.67 (average: 8.26±0.18).

Nutrient levels in the study area were dramatically higher than oligotrophic waters. On the other hand, the concentrations in the Dardanelles (St.D) were lower (NO^-_2+NO^-_3 = 0.51±0.54 µM; PO^{-3}_4 = 0.08±0.08 µM; SiO_4 = 2.41±1.69 µM) than the concentrations in the Sea of Marmara (St.M) (NO^-_2+NO^-_3 = 0.65±0.86; PO^{-3}_4 = 0.19±0.37; SiO_4 = 3.91±5.56 µM) (Fig. 2). It is known that the high nutrient concentrations in the Sea of Marmara decrease considerably as far as the Dardanelles during the Marmara surface flow due to high photosynthetic processes in the Sea of Marmara. Additionally, nutrients are partly exported to the Marmara lower layer. Ultimately, the brackish Black Sea waters reach the Dardanelles Strait with modified biochemical properties [4].

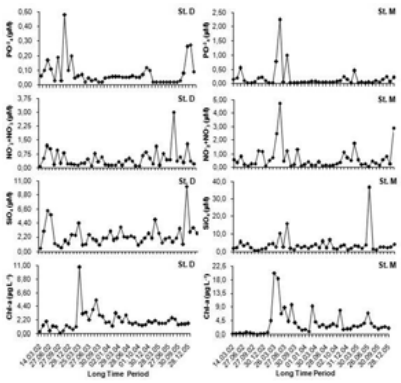

Fig. 2. Long term variations of nutrients and chlorohyll *a* in the coastal waters of the Dardanelles (St.D) and Sea of Marmara (St.M).

Average elemental ratios of N/P, Si/N and Si/P in the Sea of Marmara (St.M) were 7.10±10.7, 27.7±107.6 and 62.3±110.7, respectively, whereas average elemental ratios of N/P, Si/N and Si/P in the Dardanelles (St.D) were 12.3±23.1, 8.57±7.87 and 51.6±46.6, respectively. In light of these ratios, the system was exposed to hypereutrophication and so nitrate was more limiting nutrient than phosphate and silicate. The system was so productive that annual average phytoplankton chla level was 2.78±3.21 µg L^{-1}. On the other hand, chla levels reached to 20.0 µg L^{-1} in some spring and late summer periods (Fig. 2).

In light of the high levels of nutrients and chla, the Sea of Marmara and the Dardanelles are underneath all the heavy pollution due to the urban waste waters of Istanbul and North West Black Sea surface waters more polluted by Danube.

HETEROTROPHIC MICROBIAL ACTIVITY IN THE CILICIAN BASIN (NORTH EASTERN MEDITERRANEAN)

Nebil Yücel [1]*, Zahit Uysal [1] and Süleyman Tugrul [1]
[1] Institute of Marine Sciences Middle East Technical University - nebil@ims.metu.edu.tr

Abstract
Bacterial Carbon Production (BCP) and Heterotrophic Bacterial Abundance (HBA) were studied monthly from May 2010 to October 2011 at two stations in the Cilician basin. BCP varied between 0.002 and 0.270 mgC.m^{-3} h^{-1} in the coastal and 0.001 and 0.1 mgC.m^{-3} h^{-1} in offshore waters at the shelf break. Mean BCP rates were calculated as 0.05 and 0.015 mgC.m^{-3} h^{-1} for the coastal and offshore waters, respectively. Annual BCP was estimated as 14.6 g C.m^{-2} y^{-1} for the coastal and 12.9 g C.m^{-2} y^{-1} for the offshore zone of the Cilician basin. Our findings also support the suggestion of eastward decrease in BCP rates in the Mediterranean. BCP data provided with this study may be considered preliminary for the Cilician basin.

Keywords: Bacteria, Secondary production, Mersin Bay, North-Eastern Mediterranean, Carbon

Introduction
Eastern Med is known as one of the least productive seas in the world [1]. There exists a gradual decrease in bacterial production from west to east in the Mediterranean. Rates of BCP vary between 1 and 468 mg C m^{-2} d^{-1} for the western and between 7 and 131 mg C m^{-2} d^{-1} for the eastern Mediterranean [2].

Material and Methods
Two stations (the shallow one: 50 m deep; the offshore: 200 m), located in the Cilician basin (Fig. 1) were visited monthly from May 2010 to October 2011. BCP was measured by ^{3}H-Leucine incorporation. Samples were incubated in situ during midday for about 3 hours. HBA was measured by epifluorescence microscopy.

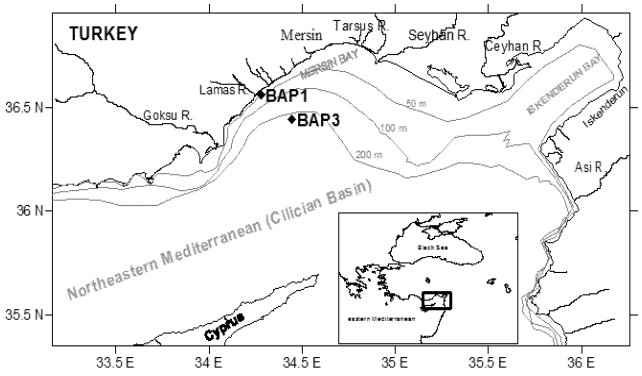

Fig. 1. Location of stations in the Cilician basin.

Results
Daily BCP rates varied between 7.4 - 39.7 at top 50 m in the shelf and 8.9 - 35.4 mg C m^{-2} d^{-1} for the 200 m water column in the offshore. BCP decreased with depth in the offshore. HBA varied in the range of 29686 and 1397129 cells ml^{-1} in the shelf and between 11989 and 886253 cells ml^{-1} in the offshore throughout the study period. Highly significant positive correlations were seen between BCP and BA (n:60, r:0.691, P<0.01) in shelf waters and similarly between BCP and temperature & salinity in the offshore ((n:60, r:0.338, P<0.01)& n:60, r:0.247, P<0.01)). Nutrient concentrations were low in the euphotic zone (nitrite+nitrate: 0.05-3.06 µM; Phosphate: 0.02-0.07 µM) in offshore waters.

RÉGIME ALIMENTAIRE D'*EPINEPHELUS COSTAE* (SERRANIDAE) DES COTES EST DE L'ALGÉRIE

Raouf Zaidi [1]*, Farid Derbal [1] and Mohamed Hichem Kara [1]
[1] Laboratoire Bioressources Marines, Université Badji Mokhtar, Annaba, Algérie. - raoufrfm@hotmail.fr

Abstract
Le régime alimentaire de la badéche *Epinephelus costae* (Heemstra, 1991) des côtes Est de l'Algérie a été analysé, qualitativement et quantitativement, entre mars 2011 et mars 2012. La vacuité digestive moyenne annuelle de 259 individus est de 18,14%. Elle ne varie pas en fonction des saisons. Cette espèce se nourrit principalement d'ostéichtyens (%IRI = 76,67) et secondairement de crustacés (%IRI = 15,46). Les autres proies (crustacés, mollusques, annélides, végétaux) sont accidentelles (% IRI < 3).

Keywords: Diet, Fishes, Algerian Sea, South-Western Mediterranean

Introduction
La badèche *Epinephelus costae* (Heemstra, 1991) a le statut d'espèce ''Data Deficient'' dans la liste rouge des poissons marins de Méditerranée [1] et très peu de recherches qui lui ont été consacrées sur les côtes nord-africaines [2]. Un travail sur son régime alimentaire a été précédemment abordé sur les côtes algériennes, mais de manière incomplète [3]. Cette étude est plus précise et donne des informations complémentaires sur la composition et les variations de l'alimentation de cette espèce au cours d'un cycle annuel.

Matériel et méthodes
Le régime alimentaire de 259 badèches *E. costae* (Lt: 20,1 – 79,9 cm; Wt: 189,32 - 5661 g) a été étudié, qualitativement et quantitativement, entre mars 2011 et mars 2012. Tous les poissons proviennent de la pêche artisanale (arbalète et palangre). Les coefficients de vacuité digestive (CV%) ont été déterminés globalement et en fonction des saisons. Le statut des proies ingérées (préférentielles, secondaires, accidentelles) a été déterminé en utilisant le pourcentage indiciaire du IRI [4].

Résultats
Le coefficient de vacuité digestive moyen est égal à 18,14%. Quelque soit la saison de pêche, la vacuité reste faible (printemps: 6,56%, été: 2,7%, automne: 7,72%, hiver: 1,16%). La figure 1 classe les principaux taxons zoologiques ingérés par *E. costae* selon les pourcentages indiciaires du IRI. Ce prédateur se nourrit principalement d'ostéichtyens (%IRI = 76,67), représentés par 11 familles et 16 espèces: 5 Sparidae, 2 Labridae, 2 Mugilidae et une seule espèce pour les autres familles (Mullidae, Atherinidae, Pomacentridae, Gobiidae, Blennidae, Trachinidae, Carangidae, Clupeidae). Les autres proies (crustacés décapodes, mollusques, annélides, végétaux) sont ingérées accidentellement (%IRI < 3). Chaque individu consomme en moyenne 1,5 proie pour un poids moyen de 3 g.

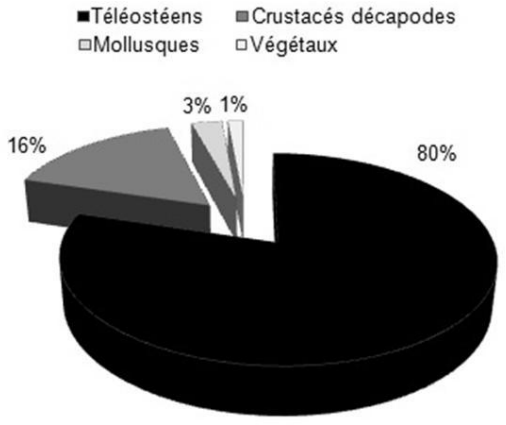

Fig. 1. Pourcentages indiciaires du IRI des principales proies ingérés par *Epinephelus costae* des côtes Est algériennes.

Discussion
Les faibles valeurs de la vacuité digestive, aussi bien chez la population globale qu'en fonction des saisons, mettent en évidence la voracité de ce prédateur. Comme la majorité des *Epinephelus* de Méditerranée, *E. costae* est un poisson carnivore, au niveau trophique élevé, comme c'est le cas d'*E. aeneus* (Troph. = 4,1), d'*E. caninus* (Troph. = 3,8) ou d'*E. marginatus* (3,7 <Troph. < 4,13) [5]. Sur les côtes de l'est de l'Algérie, la badèche se nourrit principalement de poissons téléostéens, avec une préférence pour les Sparidae, ce qui n'est pas le cas sur les côtes sénégalaises où cette espèce cible les sardinelles *Sardinella aurita* en période froide et les crevettes *Penaeus notialis* en période chaude [6]. Dans notre région, la sardinelle *S. aurita* n'est ciblée que par les petites badèches et celles de taille moyenne; les plus âgées préfèrent la sardine *S. pilchardus* [3].

THE ANALYSIS OF THE MAIN SOURCES OF VARIABILITY FOR THE ESTIMATION OF THE RED MULLET (*MULLUS SURMULETUS*, L.1758) AGE STRUCTURE AT THE STRAIT OF GIBRALTAR

Abdelaziz Zoubai [1]*, Abdeljaouad Lamrini [2] and Allal Hamouda [2]
[1] Institut National de Recherche Halieutique - a.zoubai@gmail.com
[2] Institut Agronomique et Vétérinaire Hassan II

Abstract
This paper focused on the analysis of the major sources of variability for the estimation of the red mullet age structure at the strait of Gibraltar. The results showed that the variability of the species age proportions is much higher between the landing days. Thus, for better estimates of the species demography, a further effort of sampling in number of days is required especially for the market categories composed by small fish.

Keywords: Fishes, Population Dynamics, Gibraltar Strait

Introduction

The red mullet, *Mullus surmuletus, L., 1758* (Mullidae) constitutes the main target stock of the trawl fishery and longliners at the Moroccan Mediterranean. The area of study extends from the Gibraltar Strait to Larache region over about 150 km. The present study aims to analyse the sources of variability in the estimation of red mullet age structure by sampling trawlers and longliners landings.

Material and methods

The present study was based upon monthly samples of red mullet collected in 2009 by the use of a two-stage sampling plan. A total sample of 3304 red mullet individuals, ranging in size between 10 to 30 cm, was collected. 5 specimens by length class of 1 cm and by market category were taken and measured by their fork length to the nearest centimetre then a sub-sample of 847 specimens was kept for ageing purpose. In the laboratory, scales from the shoulder between the head and the dorsal fin [5], were removed from each fish and were washed and then were illuminated with a reflected light and examined under a dissecting microscope with a dark background [1]. The age readings were done without knowledge of scales reference (length). Guidelines for pattern interpretation were based upon standardized interpretation presented in the CARE Age Reading Manual [3]. The estimate of the age proportions is done according to the principle of double sampling [8], which determines an age-length key (ALK) per month and by market category. The species ages proportions by market category and by quarter and its associated variance were then computed by the combination of the ALK's on a quarterly basis and the corresponding sample length distributions [6]. The total variance for each age and for each market category is composed by the inter-days and the intra-days variances related to the measurement and the aging of fish [7].

Results

The results showed that the red mullet age structure varies from one quarter to another ; the landings consist of fish of age varying from 0 to 9 years; the fish which are 5 years old and more are slightly represented in the landings. Moreover, for quarters 3 and 4, we noted a peak of abundance for the age groups 0, 1 and 2. Regarding the sources of variability of the species demography, we observed for all quarters that the total variance related to the estimation of the species age proportions by market category is explained to more than 80 % by the variance between the days of landings; inside each day of sampling, the ageing variance is lower (< 7 %) for fish of small and medium sizes, and higher (> 13 %), for fish of large size ; this latter increased with the fish size, as age determined for older fish is generally less precise [2].

Discussion and conclusions

The study permitted to note that the species age composition is highly variable and depends mainly on the landing days, especially for fish of age groups composing very small and small market categories. Thus, to suitably estimate the proportions of these age groups, it would be necessary to multiply further the effort of sampling in number of days for these age groups especially for the market categories composed of small fish. Previous papers [4], underlined that the age structure precision is mostly driven by the precision of the age-length-key (ALK). Similar studies recommended that prior to the estimation of the species age proportions, the ALK's should be established at each operation of sampling and be applied to the corresponding length data in order to take account of the variability of the species demography with the landing days [9].
